Notice: The authors and publisher have made every effort to ensure that the patient care recommended herein, including choice of drugs and drug dosages, is in accord with the accepted standard and practice at the time of publication. However, since research and regulation constantly change clinical standards, the reader is urged to check the product information sheet included in the package of each drug, which includes recommended doses, warnings, and contraindications. This is particularly important with new or infrequently used drugs. Any treatment regimen, particularly one involving medication, involves inherent risk that must be weighed on a case-by-case basis against the benefits anticipated. The reader is cautioned that the purpose of this book is to inform and enlighten; the information contained herein is not intended as, and should not be employed as, a substitute for individual diagnosis and treatment.

# PREFACE

The last decade has seen a remarkable improvement in clinical outcomes for most patients with cancer. The development of targeted therapies, the direct result of the sweeping discoveries of the past two decades related to the causation of cancer, has revolutionized treatment of cancer. The sweeping events of the past two decades have resulted in the mapping and sequencing of the human genome, the identification of molecular causation for many types of cancer, and the use of this information to develop targeted therapy has initiated a change, not only in the outcomes associated with cancer, but also the modes and approaches of therapy.

These changes have induced several profound changes in the medical needs of cancer patients. The first is that a larger percentage of cancer patients are living for longer periods of time. Unlike previous generations of patients treated for cancer in which survival was often poor, these “survivors” live longer and are in many cases undergoing chronic therapy for cancer. The important point is that they are surviving. Along with survivorship go many of the co-morbidities associated with cancer or short- and long-term side-effects of therapy. For example, survival in patients with myeloma was very poor as short a time ago as five years. Advances over the past two to three years using combinations of proteasome inhibitors and thalidomide derivatives have created a significant population of myeloma patients who are well controlled while they are on chronic therapy. Along with the beneficial effects of these medications, however, are a constellation of side effects that include fatigue, thromboembolism, peripheral neuropathy, and bone and cardiac abnormalities.

The goal of this textbook is to focus on existing and newly emerging internal medicine problems associated with cancer or its treatments. These problems include not only those associated with older chemotherapeutic agents, but also newer classes of drugs such as monoclonal antibodies and signaling pathway-specific small molecules. This textbook will also address emerging management issues for comorbid conditions in cancer patients.

This text is a focused attempt to systematically categorize and describe the complex and rapidly evolving field of internal medicine in cancer survivors. Although the pace of new therapies for cancer treatment is moving so rapidly that any textbook is likely to be out of date at the time of publication, we believe that the contents will provide you with a different perspective and a framework to organize rapidly accumulating new information.

“To cure the curable and make life livable for the incurable!” ‘Tis our motto.

# CONTENTS

## SECTION I: General Principles

1	<b>Introduction to the Care of the Cancer Patient</b> .....	1
	Robert F. Gagel, MD	
2	<b>Mechanisms of Complications of Malignancy</b> .....	3
	Jessica P. Hwang, MD, MPH	
	Sarah E. Cooper, BS	
	Robert F. Gagel, MD	
3	<b>Long-Term Consequences of Cancer Surgery</b> .....	10
	Isabelle Bedrosian, MD	
	Laura A. Lambert, MD	
	Raphael E. Pollock, MD, PhD	
4	<b>Collateral Damage Associated with Chemotherapy</b> .....	18
	Anne S. Tsao, MD	
	David J. Stewart, MD	
5	<b>Systemic Sequelae of Bioimmunotherapy</b> .....	33
	Auris Huen, PharmD	
	Saroj Vadhan-Raj, MD	
6	<b>Ethical and Legal Issues in the Care of a Cancer Patient</b> .....	43
	Martin L. Smith, STD	
	Anne Lederman Flamm, JD	
	Rebecca D. Pentz, PhD	

## SECTION II: Systemic Symptoms Common in Cancer Patients

7	<b>Cancer-Related Fatigue</b> .....	53
	Carmen P. Escalante, MD	
	Xin Shelley Wang, MD, MPH	
8	<b>Cancer Pain</b> .....	60
	Russel K. Portenoy, MD	
	Gaurav Mathur, MD	
9	<b>Cancer and Depression: Phenomenology and Pathophysiology</b> .....	72
	Diane S. Thompson, MD	
	Charles L. Raison, MD	
	Carolyn Jonas-Accardi, PhD	
	Andrew H. Miller, MD	
10	<b>Sleep Disorders in the Cancer Patient</b> .....	83
	Colleen G. Lance, MD	
	Karen O. Anderson, PhD, MPH	

11	<b>Nausea</b> .....	92
	John T. Patlan, MD	
12	<b>Fever</b> .....	104
	Maria E. Cabanillas, MD	
	Ricardo H. Alvarez, MD	

### SECTION III: Diagnostic Evaluations

13	<b>Imaging</b> .....	111
	William A. Murphy, Jr., MD	
	Gregory W. Gladish, MD	
	Sanjay Gupta, MD	
	Ashok J. Kumar, MD	
	Aurelio Matamoros, Jr., MD	
	Franklin C. Wong, MD, PhD, JD	
14	<b>Laboratory Investigation</b> .....	128
	Beverly C. Handy, MD, MS	

### SECTION IV: Infectious Diseases

15	<b>Risk Assessment and the Management of Neutropenia and Fever</b> .....	133
	Kenneth V. I. Rolston, MD	
16	<b>Bacterial Infectious Disease Issues: Catheter-Related Infections</b> .....	139
	Issam I. Raad, MD	
	Hend Hanna, MD, MPH	
	Dennis G. Maki, MD	
17	<b>Viral Infections</b> .....	151
	Harrys A. Torres, MD	
	Michael Boeckh, MD	
	Roy F. Chemaly, MD, MPH	
18	<b>Fungal Infections in Immunocompromised Hosts with Cancer</b> .....	162
	Dimitrios P. Kontoyiannis, MD, ScD	
	Russell E. Lewis, Pharm D	
	T. J. Walsh, MD	
19	<b>Parasitic Disease Issues in Cancer Patients</b> .....	177
	Javier A. Adachi, MD	
	Herbert L. DuPont, MD	
20	<b>Mycobacterial Infections in Patients with Cancer</b> .....	181
	Amar Safdar, MD	
	Donald Armstrong, MD	

**SECTION V: Endocrinologic and Metabolic Disorders**

21 **Hypercalcemia of Malignancy** ..... 188  
Gregory A. Clines, MD, PhD  
Theresa A. Guise, MD

22 **Endocrine Paraneoplastic Syndromes** ..... 194  
Mimi I. Hu, MD  
Sai-Ching Jim Yeung, MD, PhD  
Robert F. Gagel, MD

23 **Endocrine Neoplastic Syndromes** ..... 205  
Sai-Ching Jim Yeung, MD, PhD  
Robert F. Gagel, MD

24 **Diabetes and the Cancer Patient** ..... 209  
Pankaj Shah, MD  
Naifa L. Busaidy, MD  
Jane M. Geraci, MD, MPH  
Melissa Hamilton, RD  
Mary Ann Weiser, MD, PhD

25 **Obesity and Cancer** ..... 216  
Robert H. Lustig, MD  
H. Leon Bradlow, PhD

26 **Thyroid Disorders in Cancer Patients** ..... 226  
Steven I. Sherman, MD

27 **Pituitary and Adrenal Complications in Cancer Patients** ..... 237  
Sai-Ching Jim Yeung, MD, PhD  
Robert F. Gagel, MD

28 **Hypogonadism and Hormone Replacement in Men with Cancers** ..... 242  
Christine Lee, MD  
Shehzad Basaria, MD  
Adrian S. Dobs, MD, MHS

**SECTION VI: Disorders of the Digestive Tract and Nutrition**

29 **Gastroesophageal Issues** ..... 249  
Alexander A. Dekovich, MD

30 **Hepatobiliary and Pancreatic Disorders** ..... 258  
John T. Mullen, MD  
Eddie K. Abdalla, MD

31 **Disorders of the Digestive Tract and Nutrition: Intestinal Issues** ..... 267  
John R. Stroehlein, MD

32	<b>Graft-versus-Host Disease and the Immunologic Complications of Cancer</b> .....	278
	William A. Ross, MD, MBA	
33	<b>Interventional Gastroenterology</b> .....	285
	Jeffrey H. Lee, MD	
	William A. Ross, MD, MBA	
34	<b>Nutritional Issues in Cancer Patients</b> .....	292
	Yakir Muszkat, MD	
35	<b>Oral and Orofacial Considerations in Oncology</b> .....	307
	Mark S. Chambers, DMD, MS	
	Adam S. Garden, MD	
	Jack W. Martin, DDS, MS	
	Merrill S. Kies, MD	
	Randal S. Weber, MD	
	James C. Lemon, DDS	

**SECTION VII: Disorders of the Respiratory Tract**

36	<b>Upper Airway Problems</b> .....	320
	Rex C. Yung, MD, FCCP	
37	<b>Pneumonia in Cancer Patients</b> .....	329
	Christop Schmidt-Hieber, MD	
	Daniel N. Ginn, MPH	
	John N. Greene, MD	
38	<b>Noninfectious Pulmonary Problems in the Patient with Cancer</b> .....	342
	Shirin Shafazand, MD	
	Jeffrey Rubins, MD	
	Gene L. Colice, MD	
39	<b>Cancer-Related Issues in Mechanical Ventilation</b> .....	354
	Bruce P. Krieger, MD, FCCP	
	Mark Rumbak, MD, FCCP	
40	<b>Bronchoscopy and Lung Cancer: Diagnostic and Therapeutic Modalities</b> .....	360
	Michael J. Simoff, MD	

**SECTION VIII: Neurologic and Psychiatric Disorders**

41	<b>Direct Neurologic Complications of Cancer</b> .....	370
	Robert Cavaliere, MD	
	David Schiff, MD	
42	<b>Neurologic Toxicity of Radiotherapy</b> .....	379
	Kimberly Keene, MD	
	James Larner, MD	

43	<b>Neurologic Complications of Chemotherapy</b> .....	387
	Denise M. Damek, MD	
44	<b>Paraneoplastic Neurologic Disorders</b> .....	402
	Steven Vernino, MD, PhD	
45	<b>Neuropathic Pain</b> .....	410
	Leslie J. Blackhall, MD, MTS	
46	<b>Psychiatric Issues in Oncology</b> .....	421
	Gabrielle Marzani-Nissen, MD	
	Lora D. Baum, PhD	

**SECTION IX: Nephrologic and Urologic Disorders**

47	<b>Renal Failure and Renal Tubular Defects</b> .....	434
	John R. Foringer, MD	
	Kevin W. Finkel, MD	
48	<b>Urinary Tract Infections</b> .....	451
	Diana I. Jalal, MD	
	Bhamidipati V.R. Murthy, MD	
49	<b>Urologic Disorders</b> .....	463
	Glenn A. McDonald, MD	
	John R. Foringer, MD	

**SECTION X: Disorders of the Cardiovascular System**

50	<b>Ischemic Heart Disease in Cancer Patients</b> .....	471
	Atiar M. Rahman, MD, PhD	
51	<b>Cardiac Manifestations of Malignancy</b> .....	484
	Joseph Swafford, MD, FACC	
	S. Wamique Yusuf, MD, FACC	
52	<b>The Pericardium in the Cancer Patient</b> .....	493
	Steven M. Ewer, MD	
	Michael S. Ewer, MD, JD	
53	<b>Treatment-Induced Arrhythmia, Pacemakers, and Automatic Implantable Cardioverter Defibrillators</b> ....	508
	S. Wamique Yusuf, MD, FACC	
54	<b>Congestive Heart Failure</b> .....	518
	J. Christopher Champion, MD	
55	<b>Vascular Disease</b> .....	526
	Daniel J. Lenihan, MD	
	Atiar M. Rahman, MD, PhD	

## SECTION XI: Hematologic Disorders

- 56 **Hematologic Complications in Patients with Malignancy** ..... 535  
Graeme A. M. Fraser, MD, MSc, FRCPC  
Donald M. Arnold, MD, MSc, FRCPC  
Agnes Y. Y. Lee, MD, MSc, FRCPC

## SECTION XII: Musculoskeletal Disorders

- 57 **Rheumatologic Paraneoplastic Syndromes** ..... 550  
Megan C. MacNeil, MD  
Frank C. Arnett, MD
- 58 **Rheumatologic Issues in Cancer Patients** ..... 557  
Firas Alkassab, MD  
Frank C. Arnett, MD
- 59 **Cancer Rehabilitation** ..... 563  
Rajesh Yadav, MD  
Ki Y. Shin, MD  
Ying Guo, MD  
Benedict Konzen, MD

## SECTION XIII: Skin Disorders

- 60 **Skin Neoplasms Related to Internal Malignancy** ..... 571  
Major Michael Murphy, MC, USA, MD  
Tri H. Nguyen, MD
- 61 **Graft-versus-Host Skin Disease** ..... 578  
Sharon R. Hymes, MD  
Daniel R. Couriel, MD
- 62 **Radiation Dermatitis** ..... 590  
Sharon R. Hymes, MD  
Eric A. Strom, MD
- 63 **Alopecia** ..... 602  
Asra Ali, MD  
Sanjay Mehta, MD
- 64 **Paraneoplastic Dermatoses** ..... 610  
Jeffrey P. Callen, MD  
Bruce H. Thiers, MD
- 65 **Cutaneous Reactions to Medications** ..... 617  
Steven R. Mays, MD  
Joy Kunishige, MD

#### SECTION XIV: Ophthalmologic Issues in Cancer Patients

66	<b>Orbital Cellulitis</b> .....	628
	Dominick I. Golio, MD Dan S. Gombos, MD, FACS	
67	<b>Endogenous Endophthalmitis</b> .....	630
	Dan S. Gombos, MD, FACS	
68	<b>Ocular Side Effects Associated with Chemotherapy</b> .....	632

# Introduction to the Care of the Cancer Patient

Robert F. Gagel, MD

The beginnings of medical oncology in the middle of the twentieth century pitted the enterprising and aggressive young internist, the newly minted “oncologist,” against cancer, a terrifying disease. Other than those tumors that could be treated effectively with surgery or radiotherapy, there were few tools in the oncologist’s armamentarium to treat malignancy. The advent and rise of cytotoxic chemotherapy during the first 25 years following the Second World War resulted in a number of therapeutic successes. These included the development of successful treatment protocols for testicular cancer, Hodgkin’s lymphoma, and several other tumors. The next 20 to 25 years were characterized by the introduction of several new agents but, more importantly, by the combining of several chemotherapeutic agents and other forms of therapy. Notable among the successes were the impact of adjuvant chemotherapy in the management of breast cancer, the use of multiple chemotherapeutic agents in acute lymphoblastic leukemia, and the combined use of chemotherapy and surgery in sarcoma.

The past 10 to 15 years have been defined by molecular biology and genomics. The identification of oncogenes and tumor suppressor genes, and the insight gained from the deciphering of the genome and characterizations of signal transduction pathways important for regulation of cell growth have led to targeted therapies. Most newly developed therapeutic agents target specific signal transduction pathways. These therapies include small organic molecules, monoclonal antibodies, genetic treatments, vaccines, and other compounds. The first high-impact success of this period has been the development of imatinib, a specific tyrosine kinase inhibitor, as a highly effective oral therapy for chronic myelogenous leukemia and gastrointestinal stromal tumors. The success of these agents has led to a proliferation of activity by the biotechnology and pharmaceutical industries, leading to additional improvement in therapies for a number of malignancies and the prospect of more to come.

This recent frenetic activity occurs on a background of already improving outcomes for a wide range of malignancies. In a broad spectrum

of malignancies, there has been a significant improvement in survival over the past 30 years (Figure 1). Even more remarkably, much of the improvement, particularly during the period covered in this table, occurred during a time when relatively few new therapeutic agents were approved for use. Although the reasons for this improvement are unclear, the application of combined chemotherapy and new surgical and radiotherapy approaches are the most likely explanations.

The current pace of therapeutic discovery superimposed on the steady improvement in outcomes observed over an extended period of time, creates an expectation that this trend will continue over the next several decades. The result may be that cancer is turned into a chronic disease akin to many others, such as diabetes mellitus, immunologic disease, kidney disease, or

coronary artery disease. In each of these examples, affected individuals live with chronic disease that is controlled for years or decades, often dying from other causes.

The evolving paradigm of cancer as a chronic disease is filled with both hope and a growing sense among survivors that the long-term price, both financially and the loss of quality of life, of cancer cure or control is substantial. For many patients, this is a rollercoaster ride with terrifying periods when the cancer is diagnosed and treated, and extended periods of relief when the disease is arrested or its growth rate slowed. Unfortunately, for many, the control of the cancer is associated with a variety of medical problems caused by the malignancy, its therapy, or the stress associated with the treatment process.

The success of oncology has spawned a new discipline of internal medicine, separable from

**FIGURE 1** Trends in 5-year relative survival rates by year of diagnosis, 1974–1999. The figure shows survival rates during the 1974–1976, 1983–1985, and 1992–1999 periods for many different malignancies. The thick black line shows the improvement in 5-year survival for patients with cancer over this 25-year period. Adapted from Cancer facts and figures 2004. Atlanta (GA): American Cancer Society; 2004.

oncology, and focused on the management of the multitude of problems, acute and chronic, experienced by patients treated for cancer. Some of these problems are caused by the underlying malignancy; others result directly from the therapy; and still others evolve over years and decades caused by some combination of the natural aging process, other disease states, and long-term toxicity of the cancer treatment. Although most of these patients are joyous in their victory over a dreaded disease, they are uniformly disappointed that they have traded one problem for others they had not anticipated. I vividly recall a patient who approached me following a patient education lecture on bone loss following breast cancer who thrust a book of poetry into my hands. The book, *Reflections on Facing Cancer Fear & Loneliness*, by Lois Tschetter Hjelmstad, describes the cancer experience from a patient's perspective.<sup>1</sup> She opened the book she had authored to show me the following poem:

The test show  
I have osteoporosis  
The doctor seems surprised  
I am dismayed.  
I feel betrayed again-  
Alienated from my body-  
  
I was counting on  
My bones to hold me up  
The rest of my life

This example illustrates the anxiety felt by many and, more importantly, the uncertainty about

where patients should turn to obtain help for a variety of unanticipated problems — fatigue, sleep disorders, depression, and the more specific organ-related effects of cancer or its treatment. This confusion has only worsened in recent years as new treatment protocols have proliferated. Inevitably, each of the new therapies targets a pathway important not only for the growth of cancer but also compromises a variety of normal physiologic functions.

When patients are discharged from oncology care, they have a difficult time identifying physicians comfortable with management of disorders that occur in the context of the cancer patient. Their reintegration into the community is often challenging. Oncology patients who have been successfully treated feel, at times, like Sisyphus, the king of Corinth, who was condemned in Hades to roll a huge stone up a hill only to have it roll back down when it neared the top, necessitating that it be pushed back up again. Having defeated their malignancy, they are dismayed having to confront a new set of problems. The frustration experienced by these patients is palpable, and their increasing numbers have, in turn, spawned the development of patient advocacy programs focused on survivorship.

The good news is that the growth in this patient population has stimulated major cancer centers to develop broad-based expertise focused on these problems. There is an increasing emphasis, not only on the therapeutic benefit of a particular oncologic agent, but also its impact on

quality of life. Physicians who are not oncologists routinely work alongside oncologic investigators to assess the broader impact of therapies and to develop management strategies. Specific examples include bone loss and fractures associated with aromatase inhibitors, hypertension and bleeding disorders associated with certain tyrosine kinase inhibitors, the cardiac effects of certain monoclonal antibodies, and many others.

The goal of this textbook is to begin to identify, organize, and catalog the broad spectrum of nononcologic problems experienced by oncology patients. We see this textbook as a companion to the standard internal medicine and oncology textbooks, whose content will inevitably overlap each of these subject areas. We also recognize that as the number and complexity of therapies for cancer have increased, oncology texts have systematically shortened the discussion of the long-term side effects of therapy and other medical problems associated with cancer. We seek to fill this void.

Please join us in this inaugural edition. If you are convinced of its value and place it on your bookshelf adjacent to standard internal medicine and oncology texts, pulling it down periodically to address specific medical problems, then we will have been successful.

# Mechanisms of Complications of Malignancy

Jessica P. Hwang, MD, MPH  
Sarah E. Cooper, BS  
Robert F. Gagel, MD

What differentiates internal medicine from most other subspecialties is its focus on deciphering complex symptoms to identify and treat the underlying disease processes. In no other disease state is the internist challenged as in the management of patients with cancer. Cancer is a protean disorder in which broad and confusing symptom complexes occur with some regularity. The challenge for the internist is to sort through these symptom complexes to identify those caused by the underlying malignancy or its therapy or associated with another disorder unrelated to the malignant process. The steady improvement in cancer outcomes over the past several decades heightens the need for sharpening this skill set. Two to three decades ago, most common malignancies evolved over a period of weeks, to months, to years, making palliative care and comfort measures most important. The steady improvement in outcomes for most malignancies has changed the evolution of cancer to years, to decades, to a lifetime. In other words, most cancer patients will live with their disease for prolonged periods of time and develop the broad spectrum of health problems seen in the noncancer population. This improvement in cancer outcomes has occurred so rapidly that most general internists and family practice physicians who manage the bulk of these patients long term have insufficient experience with the management of patients in this new paradigm. Under the new paradigm of cancer care, patients may continue therapy indefinitely. The prolongation of therapy for cancer, particularly in older individuals, in whom most cancer develops, leads to a situation in which the cancer patient is likely to develop a host of other medical problems. Those of us who work in cancer centers have struggled with the appropriate management of such patients. Should the oncologist, the person most knowledgeable about the malignancy, direct general internal medicine care for these patients? Although this is logical and makes sense, the sheer

volume of patients who live with cancer has made this impractical. In most large cancer centers, departments of internal medicine have developed to provide general and subspecialty internal medicine to patients.

This chapter is an introduction to a thought process and knowledge base that, it is hoped, will enable the reader to sort through the complaints of a patient with cancer and identify clinical complexes that are unique and separable from those seen in patients without cancer. In subsequent chapters, other authors expand on each of the subspecialty areas of internal medicine with the goal of identifying medical problems in cancer patients as separable from more general medical problems.

It is important for the clinician to reject the concept that symptoms in patients with cancer (eg, weakness, fatigue, weight loss) are indecipherable. Patients with specific types of cancers and treatments develop reproducible clinical syndromes that can be understood and, in many cases, treated. Patients with cancer are also subject to the broad variety of age-related diseases seen in the general population, many of which cause symptoms that can be confused with cancer-related disorders. This text is not meant to replace the excellent general internal medicine or oncology texts but rather to fill a gap that exists between the more active treatment role of the oncologist and the broad perspective of the general or subspecialty internist or family practitioner.

In this chapter, we introduce a conceptual framework for thinking about the interplay between cancer and the broad spectrum of disorders that fall under the rubric of internal medicine. The themes that are discussed are not new: they can be outlined under several straightforward headings (Table 1). What is new is the proliferation of information about these disorders and therapeutic options that makes it worthwhile for the clinician to better understand these

mechanisms and to differentiate them from the more common mechanisms of disease in patients without cancer.

We seek to provide examples that will highlight specific mechanisms and focus on what is known rather than what is not, anticipating that we should encourage clinicians to think analytically and positively about impacting the care of a particular patient. Most importantly, it is important to complement the efforts of the oncology community, which is appropriately focused on development and application of therapies to positively impact the outcomes in patients with cancer. There is value for the patient in this complementary approach.

How does the thought process of an internist in the oncology environment differ from that of the oncologist? The most important distinction is that the oncologist is focused primarily on the therapy and management of the malignancy, whereas the internist thinks more broadly about the spectrum of disorders that might explain the symptom complex in a particular patient. Most

oncologists are far more knowledgeable about the specific patterns of cancer behavior; on the other hand, nononcology internists who work in the cancer environment are focused on the broader spectrum of medical problems. Although these two thought processes intersect at many points, there are also substantial differences.

## Fundamental Characteristics of Cancer

In the accompanying text in this series, *Cancer Medicine*, the senior editor, James Holland, defines the cardinal manifestations of cancer.<sup>1</sup> One of the primary concepts he develops is the failure of cancer cells to adhere to normal biologic principles of cellular physiology. This manifests in a number of different ways: cancer cells do not die at appropriate times, they do not conform to the normal spatial constraints of organs, and they have developed mechanisms to grow in tissues in which one would not normally expect to find them. Transformed cells also activate transcriptional pathways that are normally silenced, resulting in aberrant production of a broad spectrum of tumor products, some of which have biologic effects. These observations form the beginning of our discussion of how cancer interfaces with the broader discipline of internal medicine.

## Mechanisms of Organ Dysfunction in Cancer

To grasp the spectrum of clinical presentations that may impact oncology care, it is important to describe the multiple ways in which malignant tumors can impact normal physiology. Table 1 provides an overview of major mechanisms. Of equal importance is to consider that the symptom complex may have nothing to do with cancer. Perhaps this characteristic—the ability to blend knowledge of oncology clinical syndromes with a broad, in-depth knowledge of internal medicine—defines the nononcology internal medicine specialist.

To outline the broad spectrum of potential causes for a particular problem, it may be helpful to describe a common problem in an oncology center: a patient with lung cancer who presents with a grand mal seizure and confusion that extends beyond the postictal period. This hypothetical patient is being treated with a tyrosine kinase inhibitor that targets several tyrosine kinase receptors (vascular endothelial growth factor, epidermal growth factor, and fibroblast growth factor receptors). In the evaluation of such a patient, a broad spectrum of causes needs to be considered. It is important to recognize that neurologic problems are one of the most common reasons that cancer patients are admitted to the hospital.<sup>2,3</sup> These include spinal cord compression, brain metastases, brachial and lumbosacral

plexopathies, and leptomeningeal metastases. Although brain metastases are the most common neurologic complication in the general cancer population,<sup>4</sup> the incidence of these complications also depends on the primary cancer.

Given the frequency of brain and spinal metastasis in lung cancer, it would be appropriate to examine the patient for a mass effect or to consider the possibility of leptomeningeal metastasis of the lung cancer. It would also be important to consider other potential causes, which would include metabolic (hypo- or hyperglycemia, hyponatremia,<sup>5</sup> hypercalcemia, or severe hypothyroidism), a paraneoplastic syndrome, drug-induced (hemorrhagic effect at a site of tumor metastasis of a tyrosine kinase inhibitor that targets the vascular endothelial growth factor receptor), an infectious cause, or the broad spectrum of neurologic disorders (cerebrovascular, hemorrhagic, demyelinating) that might contribute to or cause the presenting complaint. In this particular case, the patient had no evidence of brain metastasis or hemorrhage but was found to have hyponatremia caused by excessive production of vasopressin by the malignancy. Correction of the hyponatremia quickly reversed the neurologic abnormalities. This example highlights the importance of a broad perspective. The sections that follow amplify the basic outline in Table 1.

## Compression, Obstruction, and Infiltration

### Airway Obstruction

One particularly important example is airway compression, obstruction, or infiltration. Common symptoms of airway involvement and obstruction include dyspnea, wheezing, stridor, and cough. Hemoptysis, recurrent respiratory infections, atelectasis, and hoarseness may also be associated with this complication. Obstruction of the airway can occur through several mechanisms, such as invasion through or compression of the airway by an adjacent tumor, direct invasion of the larynx, and bilateral vocal cord paralysis.<sup>6,7</sup> Invasion from a primary adjacent tumor, usually of the lung, is the most common cause of airway obstruction. This complication is also found frequently in esophageal, thyroid, and mediastinal malignancies.<sup>6</sup> Tumors involving the trachea or carina may be asymptomatic until the airway narrowing has become life threatening, whereas obstruction involving the bronchi is typically not immediately life threatening.<sup>6</sup> Airway obstruction can also be caused by tumor invasion through the bilateral vocal cords causing subsequent paralysis. Lung cancer is the most common cancer associated with bilateral vocal cord paralysis.<sup>8</sup> In this condition, the flaccid vocal cords are drawn inward during inspiration, obstructing the upper airway. A vocal cord lesion may precede,

succeed, or be concurrent with the tracheal occlusion. Bilateral vocal cord paralysis can occur concurrently with malignant tracheal stenosis and a respiratory-digestive fistula.<sup>9</sup>

Hemoptysis with life-threatening bleeding into the airway is a particularly difficult management problem. This is particularly evident in pulmonary metastasis associated with renal cell carcinoma in which there is a tendency for even small tumors to bleed. In the past, little could be done in this clinical situation, but the rapid evolution of interventional bronchoscopy, using laser techniques to cauterize a hemorrhagic tumor, has positively impacted outcomes.<sup>10</sup> Similarly, these same techniques have made it possible to clear obstructing tracheal or bronchial lesions or to place a stent that bypasses the obstructive process.

In this situation, it is also important to recognize that obstruction can mimic other disorders of the respiratory system, including pneumonia, tuberculosis or fungal infection, lung abscess, asthma, or chronic obstructive pulmonary disease. Indeed, postobstructive pneumonia or abscess is a common occurrence,<sup>11–13</sup> further clouding the differential diagnosis.

### Blood Vessel Obstruction

Obstruction can also affect other structures in the chest. A relatively well-documented complication associated with solid tumors is superior vena cava syndrome (SVCS). This syndrome often progresses slowly, although cases with acute onset have been reported. Dyspnea and swelling of the face, torso, and upper extremities are the most common symptoms. Patients may also experience chest pain, cough, dysphagia, venous distention, and, rarely, vocal cord paralysis. Headache and seizures, Horner's syndrome, changes in consciousness, and cyanosis have also been reported. If left untreated, obstruction of the superior vena cava may progress to tracheal obstruction, cerebral herniation, and even death.

The superior vena cava is particularly susceptible to occlusion owing to tumor compression, invasion, or thrombus formation because of its low pressure and thin vein wall. Its close proximity to several organs also makes it vulnerable to tumor-related complications.<sup>34</sup> Lung cancer is most commonly associated with SVCS,<sup>14–16</sup> causing 75 to 85% of cases, whereas lymphomas account for 10 to 15%.<sup>14</sup> Metastatic cancers, especially breast cancer, account for the rest of the cases of SVCS of neoplastic origin.<sup>14,15</sup> Three to 5% of lung cancer patients develop SVCS, with the small cell variant being the most common type.<sup>15,16</sup>

Neoplasms can also cause injury and stasis in other vessel walls, leading to deep venous thrombosis and pulmonary embolism.<sup>15</sup> Along

with vessel wall stasis caused by the infiltration of cancer cells, activation of thrombotic mechanisms adds to the increased risk of clot formation.

### Gastrointestinal Compression, Obstruction, or Infiltration

Assessing gastrointestinal symptoms is among the more challenging tasks facing a clinician in the context of cancer. Not only does a broad spectrum of therapeutic agents for cancer cause gastrointestinal symptoms that mimic intestinal obstruction such as abdominal distention and vomiting, but metabolic disorders may also cause ileus and other gastrointestinal symptoms. Indeed, there are no clinical signs or symptoms that differentiate malignant from benign causes, but establishing the correct etiology is important to determine treatment. Like airway obstruction, intestinal obstruction can be caused by either extrinsic pressure or tumor invasion, but, surprisingly, 26 to 38% of intestinal obstructions in patients with a cancer history are not due to recurrent or metastatic disease.<sup>17</sup> This is somewhat less true for ovarian cancer patients, who are more likely to have cancer as the cause of their obstruction than the general cancer population.<sup>18</sup> The cancers most commonly associated with obstruction are local abdominal cancers such as colorectal, ovarian, and gastric cancers.<sup>4,17</sup> Tumors from outside the abdomen associated with this complication include breast cancer, melanoma, and soft tissue sarcoma. Approximately a quarter to as many as half of patients with ovarian cancer will develop intestinal obstruction,<sup>4,17</sup> usually from extrinsic compression rather than intraluminal tumor invasion.<sup>19</sup> In addition to mechanical intestinal obstruction, motility problems may occur from the invasion of the tumor to the leaves of the mesenteries.<sup>18</sup> Gastric outlet obstruction, although uncommon, is frequently caused by malignancy. In one series, 61% of patients presenting with this disorder were found to have a causative malignancy.<sup>20</sup>

Signs and symptoms vary with the site of obstruction. Pain is the most common symptom, usually at the site of obstruction, whereas vomiting is generally common only with high small bowel obstruction. Abdominal distention is the most pronounced in patients with large bowel obstruction. Dehydration and electrolyte and acid-base imbalances are most likely to be a severe problem in patients with a low small bowel obstruction.<sup>4</sup>

As with other organ systems, it is important to consider noncancer causes of obstruction. Infection or abscess in immunosuppressed patients, adhesions from previous surgical procedures, and abscesses resulting from perforation, volvulus, or obstruction to normal blood flow in the intestine should be considered as well.

### Hepatic or Biliary Infiltration or Obstruction

The liver is the second most common metastatic site for cancer, after regional lymph nodes. Forty to 50% of patients with solid tumors develop hepatic metastasis in the course of their disease.<sup>21</sup> Neoplasms that most commonly metastasize to the liver are those of the gastrointestinal tract, followed by tumors of the lung, breast, and skin.<sup>21</sup> Many other tumors, such as renal cell carcinoma, metastasize to the liver as well. A serious complication of these metastases is liver failure. In some cases, liver metastases occur and cause liver failure rapidly after the initial primary cancer diagnosis. Diffuse liver metastases can cause liver failure without producing identifiable lesions in the liver,<sup>22</sup> and, occasionally, there is selective interference with a particular aspect of hepatic function, such as gluconeogenesis (causing fasting hypoglycemia) or production of important clotting factors.

Biliary obstruction can occur intra- or extrahepatically. Intrahepatic obstruction requires the compression or infiltration of both sides of the intrahepatic bile duct. Extrahepatic obstruction can be caused by tumor infiltration of the extrahepatic duct, a fragment from a necrotic tumor traveling to the bile duct, or hemorrhage caused by the tumor.<sup>23</sup> Primary cancers causing this complication include tumors of the bile duct, ampulla, duodenum, and pancreas.<sup>24</sup> Obstructive jaundice can also have a metastatic cause. Although this is extremely rare, gastric carcinoma is commonly the cause when metastatic biliary obstruction occurs,<sup>25</sup> although any metastatic cancer can cause this complication. Common signs and symptoms of biliary obstruction other than jaundice include nausea, pruritis, and nutritional deficiencies.<sup>26</sup> It is important to keep in mind that cholecystitis and obstructive biliary disease caused by stones occur with the same or greater frequency than is observed in the normal population. Therefore, the entire spectrum of hepatobiliary disease should be considered before concluding that the cause is related to malignancy.

### Systemic Effects

Some of the most challenging manifestations of cancer are those caused by production and secretion of proteins and other substances by malignant neoplasms. For some, we understand the underlying pathophysiology; for others, we associate the clinical syndrome with cancer but cannot identify a specific mechanism.

### Hormone Production by Malignant Tumors

Perhaps the best characterized of the paraneoplastic syndromes are those associated with hormonal production. These fall into two broad

categories: those in which the malignant cell type normally produces the causative hormone and in which the symptoms are related to excessive or unregulated hormone secretion or the “ectopic” or unexpected production of a hormonal substance by a cell type that does not normally produce this product. Specific examples of the former are carcinoid tumors (serotonin and its metabolites) that cause flushing, diarrhea, and carcinoid heart disease or islet cell malignancies in which excessive insulin, gastrin, or glucagon causes clearly defined clinical syndromes. Examples of the latter include ectopic production of adrenocorticotrophic hormone by lung carcinoma. In each of these examples and others, a clearly defined hormonal agent has been implicated in the causation of these clinical syndromes. This is an important point: in situations in which a specific hormone has been implicated, it has often been possible to develop therapeutic approaches that abrogate the effects of the hormone. The most recent example is the development of vasopressin receptor antagonists for treatment of the syndrome of inappropriate antidiuretic hormone secretion described at the beginning of this chapter.<sup>27</sup>

### Disordered Production of Clotting Factors

Coagulation disorders occur commonly in patients with malignancy. Tumor cells have been shown to produce a variety of factors that either activate the clotting system or alter the normal balance between pro- and anticoagulation.<sup>7</sup> Many of the coagulation disorders associated with cancer can be traced to over functioning of the clotting system. Tumors may secrete substances that cause the abnormal activation of the clotting system.<sup>28</sup> Neoplastic cells have been shown to generate thrombin and procoagulants.<sup>15</sup> Tissue factor, a cofactor for factor VII/VIIa that helps activate procoagulation factor X,<sup>29</sup> has been seen in solid tumors and in the macrophages of patients with cancer. Elevated levels of the coagulation factors V, VIII, IX, and XI have been seen in patients with malignancy in which vesicles shed from tumor cells bind to factor V, accelerating the coagulation pathway.<sup>29</sup> Fibrinolysis is impaired in tumors with increased levels of plasminogen activator inhibitor 1.<sup>29</sup> In addition to producing proclotting factors, tumors may also decrease the levels of proteins that inhibit thrombosis, such as protein C, protein S, and antithrombin III.

Common complications caused by increased clotting activity include deep venous thrombosis, pulmonary embolism, and inferior vena cava obstruction. There is an increased risk of pulmonary embolus in patients with mucin-producing tumors, particularly those with pancreatic, lung, stomach, colon, kidney, and ovarian cancer.<sup>14</sup> Most symptomatic cerebrovascular infarctions

are related to the tumor in cancer patients.<sup>3</sup> Whereas SVCS is usually caused by compression or invasion from a tumor, inferior vena cava obstruction is usually caused by thrombosis.<sup>28</sup>

### Nutritional Effects in Cancer

A common complaint of patients with cancer is weight loss. More importantly, there is abundant evidence that anorexia and weight loss are highly correlated with performance status and clinical outcomes in most types of metastatic cancer. Several overlapping mechanisms contribute to weight loss. The first is iatrogenic: the nausea and vomiting induced by many therapeutic agents, including radiotherapy.<sup>30</sup> In most cases, these symptoms can be managed by use of pharmacologic agents that selectively antagonize 5-hydroxytryptamine 3 receptors or by short-term enteral or parenteral feeding methods. The second is more complicated and incompletely understood at present: the complex interplay between cytokines and other substances produced or induced by cancer cells and the hypothalamic neuroendocrine system that controls orexigenic and anorexigenic signaling pathways.<sup>31</sup> There has been progress toward understanding the normal physiologic pathways that regulate appetite and satiety. These include leptin, melanocortin, orexin, neuropeptide Y, and endocannabinoid signaling pathways.<sup>32–35</sup> One hypothesis, partially supported by current information, is that cytokines (eg, interleukin [IL]-1 $\beta$ , IL-6, interferon [IFN]- $\gamma$ , tumor necrosis factor  $\alpha$  [TNF- $\alpha$ ]) produced by malignancies impact serotonergic or dopaminergic pathways that, in turn, regulate the neuroendocrine pathways that control appetite and satiety.<sup>36,37</sup> In addition, tumors produce other factors, such as proteolysis-inducing factor and lipid-mobilizing factor, that cause protein and fat degradation, leading to a cachectic state.<sup>37,38</sup> The development of competitive inhibitors for several cytokines and their application in patients with cancer will make it possible to determine whether these hypotheses are correct. The third factor that almost certainly impacts eating behavior is the development of depression. Depression is a common occurrence in patients with cancer metastasis and has been shown to have an effect on the outcome of treatment.<sup>39</sup> Although patients with metastatic cancer may have good reason to be depressed, it seems likely that a cytokine cascade that depresses serotonergic pathways is also involved in the development of depression in cancer patients.<sup>40,41</sup>

The important point for the general internist dealing with the cancer patient is to understand the complexity of weight loss in the cancer patient. In many cases, the diagnosis of cancer-related cachexia or weight loss may be complicated by other underlying treatable medical conditions. In the absence of specific diagnostic criteria or

diagnostic markers for cancer-related weight loss, it is important to search for treatable causes, including anemia, liver or renal dysfunction, endocrine deficiency or excess, cardiomyopathy, malabsorption, or pulmonary failure.

It is also important to identify and correct nutritional deficiency syndromes, a point often overlooked. All patients with cancer should be given a daily oral multivitamin. In patients who are losing weight or otherwise not faring well, studies should be performed to determine whether vitamin deficiency is a factor. If there is suspicion of malabsorption, parenteral vitamin supplementation should be considered.

### Immunologic Effects

The immune system is normally activated in response to invasion by a pathogen or to facilitate clearance of a protein recognized as foreign. Substances such as bacteria or other foreign antigens are recognized by macrophages, natural killer cells, or dendritic cells and then presented to T cells, which, in turn, activate B or antibody-producing cells or other components of the immune system. Once the offending antigen has been eliminated, the immune system returns to its basal state. In many types of cancer, there is chronic activation of the immune system by the aforementioned production or activation of cytokine pathways. Cytokines can be broadly classified as proinflammatory (IL-1 $\alpha$ , IL-1 $\beta$ , IL-2, IL-12p35, IL12p40, IL-15, TNF- $\alpha$ , and IFN- $\gamma$ ) or anti-inflammatory (IL-4, IL-8, IL-10, and IL-5), with some uncategorized. Normally, there is a balance between these two classes of cytokines; during periods of infection or inflammation, there is activation, but under normal circumstances, this system is quiescent.<sup>42</sup>

In the cancer environment, production or activation of proinflammatory cytokine pathways continues unabated, leading to chronic stimulation not only of the immune system but also of the tumor cells by cytokines. For example, in chronic hepatitis B infection, there is often a failure of the immune system to clear the virus, leading to chronic activation of cytokine production.<sup>43</sup> This, in turn, leads to recruitment of activated immune cells to the liver, resulting in chronic stimulation of hepatocytes and resultant fibrosis, cirrhosis, and hepatocellular carcinoma. In varying ways, this same type of process can affect the progression of many other tumors.

Activation of the immune system can also be used to treat cancer. There is ample evidence that cytokine treatment of several hematologic malignancies is effective and in some cases has caused long-term remission of disease. Antigenic stimulation has also been used with success in melanoma. The challenge for the future will be to identify those features of the immune system that

promote tumor regression without causing other detrimental bystander effects.

Other aspects of the immune system contribute to morbidity and mortality in the cancer patient. Therapies used to treat specific cancer types, including cytotoxic chemotherapy and corticosteroids, can have profound suppressive effects on cellular and humoral immunity, leading to an increased risk of infection. After death from cancer metastasis, infection is the leading cause of death in patients treated for cancer. There is the strongly held belief that better understanding of the immune system and the development of strategies to manipulate the immune system will improve outcomes of cancer therapy and prevent infections.

### Idiopathic or Clinical Syndromes without an Identifiable Cause

A number of protean manifestations of cancer occur with some frequency. These clinical syndromes fall into three broad categories: neurologic, systemic or hematologic, and endocrine (Table 2). The pathophysiology is understood for some; for others, there is no identifiable explanation. These clinical syndromes are discussed in greater detail in several subspecialty sections in this book. Internists caring for oncology patients should have a working knowledge of these syndromes as they can be confused with their counterparts in patients without a malignancy.

In addition, each of these syndromes challenges the skills of the internist. One example, hypoglycemia, has a multiplicity of causes, which can include increased use of glucose, such as is seen in tumors that produce insulin or insulin-like growth factor 2, decreased production of glucose when there is hepatic infiltration by tumor, or combinations of the two, such as in cortisol or growth hormone deficiency.<sup>44</sup> The neurologic presentations of myopathy and neuropathy can also be challenging.

### Treatment-Related Effects

#### Cytotoxic Chemotherapy

Cancer therapy has evolved from single-agent therapy to the current use of multiple agents that target different cellular processes. These combination chemotherapies are designed to deliver a lethal blow to the rapidly dividing cancer cell. In the evolution of chemotherapy use, at each stage, there has been the need to balance the efficacy of the therapeutic regimen with short- and long-term toxicity. The short-term effects of chemotherapy can include leukopenia, anemia, mucositis, nausea and vomiting, hepatic dysfunction, renal damage leading to decreased glomerular filtration, and cardiac and endocrine dysfunction. As one observes the progression of treatment paradigms for specific malignancies for the past several decades, a pattern emerges.

**Table 2** Categorization of Paraneoplastic Syndromes

Neurologic paraneoplastic syndromes
Autonomic and sensory neuropathy
Cord and brain lesions, including myelopathy, cerebellar degeneration, limbic encephalitis, encephalopathy
Muscle disorders, including myasthenia gravis, neuromyotonia, rippling muscle syndrome, stiff-man syndrome, and myoclonus
Gastrointestinal pseudo-obstruction
Systemic and dermatologic paraneoplastic syndromes
Hypogammaglobulinemia, acquired
Red cell aplasia
Alopecia
Pemphigus
Endocrine paraneoplastic syndromes
Hypercalcemia caused by parathyroid hormone-related protein
Carcinoid syndrome
Hyperpigmentation
Hyperthyroidism
Syndrome of inappropriate antidiuretic hormone
Hypoglycemia
Diabetes mellitus

Earlier treatment regimens applied to malignancies in which survival was poor tended to be more toxic while the oncology community searched for efficacious treatments. In tumor types in which successful combinations of chemotherapeutic agents were identified, there have been systematic efforts to identify therapies with as great or better efficacy but with lower toxicity. The example of breast cancer is illustrative. Earlier chemotherapeutic regimens used to treat breast cancer had greater side effects than those used after outcomes improved. There is a continuing trend to use less chemotherapy, particularly in early breast cancer, or to combine other treatment modalities with the use of aromatase inhibitors, whose effect on reducing the recurrence of breast cancer is related primarily to the lowering of plasma estrogen levels.

Toxicities tend to be of two types: those directly related to therapy and those whose effects are indirect. Perhaps the single best example of the former is the effect of anthracyclines (doxorubicin) on cardiac function. Anthracyclines remain an effective therapy for a broad spectrum of malignancies and remain front-line therapy in the treatment of a number of malignancies. Cardiac toxicity caused by anthracyclines is dose related and cumulative, occurring in approximately 30% of individuals who receive doses greater than 500 mg/m<sup>2</sup>,<sup>45</sup> and cardiac mortality in this group of patients is significant. The introduction of liposomal forms of anthracycline has lowered but not eliminated short-term toxicity.<sup>46</sup> Over the longer term, anthracycline toxicity contributes to overall cardiac mortality. Indeed, as coronary artery disease has receded as the most important cause of middle-age death, cardiac muscle dysfunction or cardiomyopathy has assumed greater importance. Thus, patients

who are cured of their underlying malignancy by anthracycline-based chemotherapy have a significant probability of developing later cardiac failure. Although active efforts are under way to ameliorate the effects of anthracycline toxicity on the heart or to replace this effective chemotherapeutic agent, progress has been slow.

The second type of effect from chemotherapy is one that is a secondary effect. One good example of this phenomenon is the induction of an early menopause in women with breast cancer treated with adjuvant chemotherapy. A significant percentage of these women develop an early menopause, with its attendant problems of bone loss, memory and cognitive dysfunction, and symptoms of hot flashes, vaginal dryness, and loss of libido. In recent years, these issues have been exacerbated by the further lowering of plasma estrogen levels by use of aromatase inhibitors, a class of agents that further lower breast cancer recurrence rates.<sup>47</sup> The efficacy of aromatase inhibitors has been so recently demonstrated that the long-term effects of decades of estrogen deficiency, particularly for young women, have not been clearly defined.

The general or subspecialty internist will have the greatest impact in the area of long-term effects. Most short-term effects of cancer therapy are managed skillfully by oncologists. Once a suitable period of observation (5–10 years) following treatment has passed, most patients will be returned to the care of a general physician. In-depth knowledge of potential long-term problems and their management is essential.

### Unintended Effects of Targeting Specific Signal Transduction Pathways

Another new and rapidly evolving area of interest for the internist caring for cancer patients is the

side effects of targeted therapy. These agents, many of which are small organic molecules or monoclonal antibodies that target specific signal transduction pathways, were developed with the intent of being cancer specific. As might be predicted, many of these pathways are also important in normal cells, leading to a variety of unexpected side effects. Examples of side effects are developing almost as rapidly as these agents are being introduced into clinical trials. Prominent among this group because of their success in the treatment of cancer are tyrosine kinase inhibitors that target the family of vascular endothelial growth factor receptors.<sup>48</sup> In addition to effects on vascular endothelial growth, inhibition of this class of receptors causes hypertension and through its effects on vascularity may cause tumor-related hemorrhage. In addition, this group of tyrosine kinase receptors shares considerable homology with receptors for epidermal growth factor, glial cell-derived neurotrophic factor, and fibroblast growth factor.<sup>49</sup> As a result, skin rashes (from targeting of the epidermal growth factor receptor) and nausea, vomiting, and diarrhea are common side effects. In the new paradigm of cancer treatment, patients whose tumors respond to these therapeutic agents are expected to remain on these agents for long periods of time, in some cases for life. Longevity of therapy has led to increasing concern regarding these side effects. For example, the recent observation that sunitinib, an agent with efficacy in renal cell carcinoma, causes cardiac dysfunction and failure in approximately 10% of patients treated with this agent is of concern, particularly if long-term therapy is envisioned.<sup>50</sup> The paradox presented by this rapidly evolving literature is that agents effective for treatment of malignancy as chronic (lifetime?) therapy may have to be discarded unless strategies are developed to deal effectively with these problems. As internists in cancer centers, we will have to be in the forefront of the effort to collate these side effects and develop effective preventive strategies.

### Bystander Effects Caused by the Death of Tumor Cells

Tumor lysis syndrome is characterized by the release of neoplastic cellular contents into the circulation following an exuberant response to a cancer therapeutic agent.<sup>51</sup> This clinical syndrome occurs most often within the first 48 to 72 hours after initiation of therapy for a rapidly proliferating tumor that is responsive to therapy. It occurs most commonly with leukemia or lymphoma but may be seen with any solid tumor. The major manifestations result from a failure of the kidney, liver, and other buffering mechanisms to clear or inactivate the large volume of cellular material released following a therapeutic response. Manifestations include hyperkalemia, hyperuricemia,

hyperphosphatemia, and hypocalcemia. Acute renal failure occurs with some frequency and is, most commonly, caused by precipitation of uric acid or calcium phosphate crystals. Subsequent life-threatening events include cardiac arrhythmias, metabolic acidosis, and fluid overload causing pulmonary edema and hypertension.

### Detrimental Effects of Radiation Therapy

Radiation for treatment of malignancy is a well-established and effective form of therapy for multiple forms of cancer. Its use has been incorporated into the primary management of multiple forms of cancer, and it is routinely used to treat metastasis in the central and peripheral nervous systems, skeleton, and many other sites. Older techniques for delivering radiation therapy used higher doses of radiation and were less focused, thereby resulting in a large field of exposure. Newer techniques using computerized imaging (intensity-modulated radiation therapy [IMRT] and gamma knife) to more narrowly defined fields of radiation exposure and the increasing use of proton beam therapy have reduced but not completely eliminated some of these effects. As these newer techniques have been used only during the past decade and rarely outside major cancer centers, there is still a substantial group of patients who have received radiation therapy using older technologies. It is important that the practicing internist be aware of radiation effects and include appropriate screening techniques for these effects in long-term management approaches. In the following sections, we provide some illustrative examples to highlight the concerns.

### Radiation to the Central Nervous System

Irradiation to the brain is used to treat a number of benign and malignant conditions, including primary malignancies of the brain, metastasis of many types of cancer, and benign processes, such as pituitary tumors. The long-term effects of cranial radiation may be dramatic, such as the development of a secondary primary malignancy, or subtle, as evidenced by gradual development of endocrine deficiency and associated loss of regulatory control over appetite and energy consumption. For example, more than half of patients who have received skull-based or neck radiation will develop some evidence of endocrine deficiency (growth hormone deficiency, hypothyroidism, hypogonadism, or adrenal insufficiency) over the course of a lifetime.<sup>44</sup> These effects are particularly evident in children treated for benign or malignant brain tumors in whom growth retardation, hypothalamic obesity, memory loss, fatigue, and other endocrine deficiency syndromes occur

with some regularity.<sup>44</sup> It is important to consider these possibilities, particularly those that are easily treated by hormonal replacement, in patients who develop ill- or vaguely defined symptoms in the years or decades following cranial irradiation.

### Long-Term Effects of Breast Radiation

Over the past two decades, there has been a trend to combine less aggressive surgical resection with radiotherapy to the affected breast for treatment of localized breast carcinoma with comparable or better results than earlier and more aggressive surgical approaches. Unfortunately, application of this type of radiation has had unintended effects. In a number of studies, including a large analysis of the Surveillance, Epidemiology, and End Results (SEER) database, the incidence of lung cancer and cardiac dysfunction is increased in irradiated regions.<sup>52–56</sup> Although most of these analyses were conducted on cohorts that received radiation more than a decade ago using techniques that are currently outdated, they highlight the concerns. Fortunately, radiation techniques have improved, there is clear evidence of benefit in patients with localized breast cancer with one to three positive nodes, and it can be expected that the incidence of these complications will fall in future years.<sup>57</sup> The important point is that the internist, oncologist, or cardiologist who follows these patients should incorporate cardiac and cancer screening (breast and lung) into long-term management.

### Effects of Abdominal Radiation

Radiation is applied to treat many malignancies that occur in the abdomen or adjacent structures. A broad spectrum of side effects is observed following abdominal radiation. The most serious is radiation-induced enteritis. Symptoms of this disorder include nausea, vomiting, pain, diarrhea, and rectal bleeding. Patients with severe enteritis may develop sepsis, a condition resulting from acute radiation impairment of normal cell division, micro- and macroulceration, and resultant passage of bacteria and/or endotoxin into the circulation. Radiation damage to blood vessels supplying the intestine may also contribute to this process. Cotreatment with several chemotherapeutic agents, including 5-fluorouracil, methotrexate, and doxorubicin, may increase the radiation-induced damage to normal tissues. In most patients, these acute effects will resolve within a period of 1 week, although complete recovery may take months or longer.

There are also long-term effects of radiation therapy to multiple structures within the abdomen. These may include hepatic or renal injury, ureteral strictures, narrowing of the aorta, impairment of uterine development in young patients, premature ovarian failure, and skeletal effects,

such as insufficiency fractures or failure of normal skeletal development.

Moreover, recent advances in the use of more focused radiation, such as IMRT and proton beam therapy, have already had an impact on the bystander effects of radiation. It is likely that this trend will continue, reducing the effects of abdominal radiation.

### Conclusions

There are several inescapable trends in oncology. The first is that survival in cancer patients is improving, with more than 50% of patients treated for cancer now surviving long term. Moreover, this trend is likely to continue and accelerate in the coming years as newer pathway-specific agents enter routine therapy. In this new world of oncology, long-term management of patients treated for cancer will merge with the broad spectrum of other disease processes. This will necessitate the active collaboration of oncologists and a group of general and subspecialty internists or family physicians conversant in the management of cancer, the side effects of therapeutic agents, and the broader spectrum of disorders that affect the general population. Success in oncology therapy will almost certainly lead to a new and interesting discipline of internal and general medicine that will be defined as a discrete subspecialty. We look forward to the challenges that successful therapy of cancer will bring.

# Long-Term Consequences of Cancer Surgery

Isabelle Bedrosian, MD

Laura A. Lambert, MD

Raphael E. Pollock, MD, PhD

Over the last several decades, significant improvements in outcomes have been achieved for many patients with cancer. Surgical treatment has been and remains a principal modality for cure. Technological improvements and advances in surgical management have allowed for more extensive operative interventions, and multidisciplinary approaches have expanded surgical options for previously nonoperative patients. The increase in long-term survivorship has led to an increased focus on the functional outcomes and quality of life of cancer survivors. In this chapter, we discuss the long-term management of some of the more commonly encountered consequences of cancer surgery.

## Management of Lymphedema

Regional lymph node dissection is routinely employed in the management of invasive breast cancer or malignant melanoma following a positive sentinel node biopsy or in the setting of breast cancer with known axillary metastases or stage III melanoma. Aside from disease recurrence, lymphedema is the most dreaded sequela of these procedures, with reported rates of 6 to 70% after level II axillary dissection for breast cancer<sup>1</sup> and 6 to 20% following inguinal and pelvic lymph node dissection for melanoma.<sup>2</sup> Patients who are obese and patients who undergo adjuvant radiation therapy are at an additionally increased risk of developing lymphedema.<sup>1,3</sup> Although rarely life-threatening, lymphedema is a problem of significant clinical importance. In addition to causing pain, swelling, tightness, and heaviness of the affected extremity, it places the patient at risk of recurrent skin infections, and chronic lymphedema increases the risk of developing lymphangiosarcoma (Stewart-Treves syndrome) in the affected limb. Other studies have documented a significant degree of functional impairment, psychological morbidity,

and reduced quality of life in patients suffering from lymphedema.<sup>4,5</sup> Furthermore, the psychosocial impact of lymphedema has been reported by patients to be as distressing as their initial cancer diagnosis as it serves as a reminder of the cancer and can be an overt physical disfigurement.<sup>6</sup>

The diagnosis of postoperative lymphedema is usually first considered by the clinical finding of unilateral enlargement of the operated limb. Lymphedema can occur immediately postoperatively or weeks, months, or even years later.<sup>7</sup> Other symptoms of lymphedema include a sense of fullness in the affected limb; decreased flexibility in the hand, wrist, or ankle; and difficulty fitting into clothes or jewelry.<sup>8</sup> Although a variety of methods are available for the detection of lymphedema (circumferential measurements at various points, volumetric measures using water displacement, optoelectronic scanning), there are neither established guidelines for the use of many of these methods nor consensus within the literature regarding the degree of enlargement or impairment that defines lymphedema. Currently, a circumferential measurement of selected points along the limb is the most commonly used anthropometric assessment in the clinical setting. A recent prospective study of 90 breast cancer patients evaluated the sensitivity and specificity of several different criteria for circumferential measurements and volume assessment for the detection of lymphedema. Lymphedema was identified in 43% of patients, and the authors concluded that a change in the circumference of greater than 1 cm at specific sites along the length of the arm provided reliable detection of lymphedema, with 91% sensitivity and 46% specificity.<sup>9</sup> Regardless of the method used, limb volume changes compared over time and with the contralateral limb provide the most complete objective assessment for lymphedema diagnosis and treatment. Early diagnosis and treatment help improve both the prognosis and the clinical condition.

Unfortunately, there is no cure for lymphedema. Therapeutic efforts focus on minimizing the edema to reduce the risk of chronic and recurrent infections and to restore the functional and cosmetic nature of the limb. Options for the treatment of lymphedema include compression therapy with fitted compression garments, complex decongestive therapy (CDT) (manual lymphatic drainage, bandaging, proper skin care, compression garments, and remedial exercises), or pneumatic compression pumps (chambered pumps that deliver compression distally to proximally along the limb) (Table 1). Comparison of the relative success of these methods is difficult owing to substantial variation in the definitions of lymphedema, treatment interventions, and outcome measures. Since 1989, four randomized controlled trials (RCTs) and two cohort studies of the nonpharmacologic treatment of lymphedema in patients with breast cancer have shown a significant reduction in lymphedema with the use of standard compression therapy (11–86%).<sup>10–15</sup> Similar findings were seen in three RCTs and eight cohort studies with CDT (10–79% volume reduction).<sup>12–22</sup> Three small RCTs and two cohort studies have shown a 15 to 50% volume reduction with the use of the pneumatic compression pump.<sup>10,11,15,18,23</sup>

Prior to initiating any form of therapy, it is important to identify and treat other possible sources of limb swelling, such as infection, deep venous thrombosis, or recurrent or metastatic disease. Compression therapy, CDT, and pneumatic compression pumps all require a referral to a certified physical therapist. Patients with a

**Table 1** Results of Treatment for Lymphedema

<i>Treatment Modality</i>	<i>Percent Volume Reduction</i>
Standard compression therapy	11–86
Complex decongestive therapy	10–79
Pneumatic compression pump	15–50

history of congestive heart failure may not be eligible for CDT or pneumatic compression pump therapy. Recommendations for the prevention of lymphedema include but are not limited to close surveillance for any swelling, avoiding venipuncture or blood pressure measurement on the at-risk limb, meticulous skin care, avoiding vigorous, repetitive movements and heavy lifting, avoiding tight jewelry or clothing, avoiding trauma, and wearing a well-fitted compression garment when flying.<sup>24</sup> Currently, these lifelong precautions apply to all patients until further studies better stratify an individual patient's risk of lymphedema.

### Endocrine and Exocrine Function after Pancreatectomy

Surgical treatment for pancreatic malignancy frequently requires resection of either the pancreatic head and duodenum (pancreaticoduodenectomy or Whipple procedure) or distal pancreatectomy. These procedures commonly result in intestinal disturbances and may also lead to glucose intolerance and the development of anastomotic ulcers. Patients with tumors limited to the neck or body may be treated with a segmental resection, often termed central or median pancreatectomy. Such limited resection is well tolerated and rarely leads to the development of the complications discussed below.<sup>25–27</sup>

#### Exocrine Insufficiency

The incidence of pancreatic exocrine insufficiency has been reported to range from approximately 30% to as high as 100% following pancreatic resection.<sup>28–31</sup> This wide range is due to variations across studies in how this is defined, the type of pancreatic resection, and the duration of follow-up. Reports of pancreatic insufficiency may define this biochemically (serum para-aminobenzoic acid [PABA] levels, fecal elastase 1 assay) or clinically by the presence of diarrhea or symptoms requiring pancreatic enzyme supplementation. Studies that have measured pancreatic insufficiency by fecal stool content and fecal elastase assay have shown that biochemical alterations in pancreatic exocrine dysfunction can be found in nearly 100% of patients following pancreaticoduodenectomy.<sup>28,29</sup> However, clinical determinations of pancreatic insufficiency based on the presence of steatorrhea and/or the requirement for pancreatic enzyme replacement have identified one-third to two-thirds of patients who continue to show signs of exocrine insufficiency at 1 to 2 years of follow-up after pancreatic head resection.<sup>28–30,32</sup>

A number of factors lead to the development of exocrine dysfunction after pancreatectomy. These include the extent of resection, the presence of fibrosis in the remnant pancreas,

occlusion of the pancreatic duct, inactivation of pancreatic enzymes by gastric content, and the rate of gastric emptying. Notably, although the extent of resection is clearly important, there is no linear relationship between the volume of pancreatic parenchymal loss and the development of pancreatic insufficiency.<sup>33</sup>

The clinical manifestations of pancreatic exocrine insufficiency are primarily diarrhea, abdominal pain, malabsorption, and, ultimately, weight loss (or lack of weight gain postoperatively to a preillness state).<sup>29,30</sup> Some groups have suggested that preservation of the pylorus during pancreaticoduodenectomy is associated with improved long-term nutritional status.<sup>31,34,35</sup> However, recently reported results of a prospective randomized trial of 170 patients showed no statistical differences in weight loss up to 6 months postoperatively between patients who had preservation of the pylorus and those who had standard pancreaticoduodenectomy with distal gastric resection.<sup>36</sup> van Berge Henegouwen and colleagues suggested that differences in postoperative weight gain between patients undergoing pancreatic resection have more to do with positive margins of resection rather than the type of pancreaticoduodenectomy.<sup>30</sup> Patients with distal pancreatectomy appear to be at a substantially lower risk of development of pancreatic exocrine insufficiency.<sup>27</sup>

Management of pancreatic exocrine insufficiency is usually based on clinical symptoms and is aimed at reversing the malabsorption and associated weight loss. The hallmark signs and symptoms include steatorrhea and abdominal pain. Confirmation of the diagnosis can be achieved with a number of tests, including direct measurements of fecal fat, an enzyme-linked immunosorbent assay for assessment of fecal elastase 1 levels,<sup>121</sup> and serum PABA levels.<sup>37,38</sup> Patients with clinical symptoms of pancreatic insufficiency should be treated with pancreatic enzyme supplementation. Treatment with pancreatic enzymes is titrated to relief of gastrointestinal symptoms. Significant dosage may be necessary in some patients, and high-dose preparations are available. Dietary alterations, in particular restriction of dietary fat intake, are not required. Given the sensitivity of pancreatic enzymes to degradation within the acid environment of the stomach, pancreatic enzyme preparations are frequently enteric coated and release enzyme only at nearly neutral pH levels. Acid-reducing agents such as H<sub>2</sub> blockers may sometimes be necessary to enhance the activity of oral pancreatic enzyme preparations. Subsequently, patients should closely monitor the efficacy of combining pancreatic enzymes with H<sub>2</sub> blockers because this may lead to premature dissolution of the enzyme preparation within the stomach, with a possible reduction in the efficacy of pancreatic enzyme therapy.

There has also been interest in the clinical use of agents that may ameliorate the sequelae of pancreatic exocrine insufficiency by promoting the regeneration of the remnant pancreas. Although regeneration of the pancreas is seen in animal models of pancreatic resection, in humans, atrophy of the remnant pancreas is the more common occurrence.<sup>28</sup> One hormone believed to be important in the growth of the pancreas is gastrin. Jang and colleagues used proton pump inhibitors (PPIs) in patients with pancreatic resection to increase serum gastrin levels.<sup>33</sup> Patients treated with PPIs for 3 months postoperatively had less atrophy of the remnant pancreas, were able to maintain pancreatic enzyme levels, and demonstrated improved nutritional status compared with those who did not receive PPIs. However, although such data are encouraging, longer-term data from such a strategy are required. In addition, the possible role of gastrin as a growth factor in pancreatic cancer has been raised by some groups,<sup>39,40</sup> and the use of an antigastrin antibody has been investigated therapeutically in patients with advanced pancreatic carcinoma.<sup>41</sup> Therefore, the impact of long-term PPI treatment on the survival of patients with pancreatic cancer needs to be evaluated prior to generalized use of PPIs to stimulate pancreatic regeneration following resection for carcinoma.

#### Alterations in Glucose Metabolism

Pancreatic cancer has been associated with impaired glucose metabolism,<sup>42</sup> with an improvement in diabetic status noted following resection.<sup>43</sup> These observations have led some to propose that a diabetogenic factor may be produced by pancreatic adenocarcinoma.<sup>43</sup> For those patients who do not have diabetes at presentation, the risk of developing *de novo* glucose intolerance and frank diabetes following pancreatic resection is primarily related to the extent of surgery and the duration of follow-up. The relative concentration of islets is denser in the tail of the pancreas compared with the head or body of the gland.<sup>44</sup> This would suggest that patients undergoing distal pancreatectomy may be at greatest risk of the long-term development of diabetes.

Some authors have suggested that overt diabetes is unlikely to occur in patients undergoing pancreaticoduodenectomy despite the reduced capacity to secrete insulin and glucagon in the remnant pancreas.<sup>45</sup> However, most series with longer-term follow-up demonstrate that pancreatic head resection does, in fact, increase the likelihood of new-onset diabetes, although it is difficult to ascertain the exact incidence. At 1 year of follow-up, Anderson and colleagues reported that 2 of 47 patients (4%) not previously diabetic developed diabetes after pancreaticoduodenectomy.<sup>46</sup> A similarly low incidence was reported by Lemaire and colleagues, who followed a cohort

of 19 patients after pancreaticoduodenectomy for a median of 3 years.<sup>28</sup> Of 17 patients with normal fasting blood glucose preoperatively, 3 showed impaired glucose tolerance at 42, 73, and 120 months postoperatively, although none had overt diabetes. The two remaining patients had non-insulin-dependent diabetes preoperatively, and both required insulin after pancreatic resection.

In contrast, van Berge Henegouwen and colleagues reported a 24% incidence of patients requiring oral hypoglycemics or insulin for management of endocrine insufficiency at 1 year after pancreaticoduodenectomy.<sup>30</sup> Furthermore, of patients who show early signs of abnormal glucose metabolism postoperatively, long-term follow-up studies suggest that further deterioration may occur over time. Ishikawa and colleagues followed 51 patients who were treated with pancreaticoduodenectomy and survived more than 7 years without recurrence of tumor.<sup>47</sup> At 3 months after surgery, 30 patients had a normal oral glucose tolerance test; none of these patients developed glucose intolerance or diabetes at 7 years. Of the 21 patients with abnormal glucose tolerance or diabetes at the 3-month analysis, 14 patients (67%) had further deterioration in pancreatic endocrine function at the longer-term follow-up. The incidence of diabetes in these latter studies appears to approach that seen in patients following distal pancreatectomy. From a group of 24 nondiabetic patients treated with distal pancreatectomy, Yamaguchi and colleagues found that nearly half had deterioration of glucose tolerance at 6 months of follow-up.<sup>27</sup>

The data clearly suggest that irrespective of the type of pancreatic resection, patients need to be monitored closely and consistently over time for development of alterations in glucose metabolism.

## Postgastrectomy Syndromes

Postgastrectomy syndromes have been described in approximately 20% of patients. These syndromes encompass a number of specific conditions, including dumping, postvagotomy diarrhea, alkaline reflux gastritis, atonic gastric remnant, and Roux stasis syndrome, as well as more generalized consequences, such as malnutrition and anemia. They occur as a result of loss of gastric reservoir capacity, loss of the pyloric valve mechanism, and loss of vagal innervation important for both the reservoir and emptying functions of the stomach. The likelihood of occurrence of any one of these specific conditions depends on both the type of gastric resection (total, subtotal proximal, subtotal distal) and the method used to restore gastrointestinal continuity (Billroth I, Billroth II, or Roux-en-Y gastrojejunostomy).

Management of these syndromes depends on recognizing those that are amenable to medical treatment and those for which surgery is the preferred intervention (Table 2). The clinical manifestations of postgastrectomy syndromes are described below. In general, they can be categorized as disorders secondary to rapid gastric transit (dumping, postvagotomy diarrhea), disorders secondary to functional and mechanical obstruction (Roux stasis, atonic gastric remnant), and disorders secondary to reflux of intestinal content (bile reflux gastritis). For patients with postgastrectomy syndromes, a clinical history, upper endoscopy, barium radiography, and nuclear medicine gastric emptying studies are important elements for accurate diagnosis of the specific disorder.

### Dumping

Dumping syndrome occurs in approximately 20 to 30% of patients<sup>48,49</sup> and is divided into early and late forms based on the interval between oral intake and the development of symptoms. Early dumping symptoms occur within 30 minutes of ingestion; patients experience gastrointestinal discomfort (abdominal pain, nausea, vomiting, and diarrhea) and vasomotor symptoms (diaphoresis, palpitations, hypotension, dizziness). These changes are mediated by gastrointestinal peptide hormones in response to rapid gastric emptying into the small intestine.<sup>50</sup> The sudden appearance of a large volume of hyperosmolar, high-carbohydrate load in particular tends to generate the symptoms of early dumping.

Late dumping occurs in approximately 2% of postgastrectomy patients and consists of vasomotor symptoms alone seen 2 to 4 hours after oral intake. The underlying pathophysiology is the presence of hyperosmolar food within the small intestine that triggers an exaggerated insulin response and subsequent hypoglycemia.

Management of dumping is aimed at altering the pattern of oral intake by reducing intake of concentrated carbohydrates, taking frequent, small meals, and avoiding concomitant intake of solids and liquids. In patients with late dumping,

the development of symptoms can be alleviated by intake of carbohydrates to counter the hypoglycemia. In patients with severe symptoms that cannot be managed by behavioral alterations, 50 µg of octreotide taken 15 to 30 minutes before meals appears to counter the effects of gastrointestinal hormones and alleviate dumping symptoms in many patients.<sup>51–53</sup> In general, the symptoms of dumping improve during the course of the first year with conservative measures.

### Postvagotomy Diarrhea

The pathophysiology of this disorder is likely a combination of decreased gastric relaxation secondary to vagal denervation and rapid gastrointestinal transit. Postvagotomy diarrhea is characterized primarily by watery diarrhea that occurs after eating and may be confused with dumping syndrome. However, unlike dumping syndrome, there is no clear and consistent association with the type or volume of oral intake. Postvagotomy diarrhea is also frequently episodic.

The highest incidence of postvagotomy diarrhea occurs immediately after gastric resection, and symptoms generally abate over time. Treatment is largely symptomatic with the use of antidiarrheal and antimotility agents. The use of cholestyramine, which binds bile acids, has also been described.<sup>54</sup> Dietary modifications of reducing fluid intake and avoidance of dairy products should also be attempted. In contrast to dumping syndrome, octreotide appears to be less effective in the treatment of postvagotomy diarrhea.<sup>55</sup> In addition to symptomatic treatment, it is important to rule out other causes of diarrhea, including infection and malabsorption syndromes.

### Bile Reflux Gastritis

Bile reflux gastritis occurs as a result of loss of the normal pyloric function and consequent reflux of intestinal content into the gastric remnant. Whether delayed gastric emptying is also a primary component of the pathophysiology of this disorder<sup>56</sup> or the secondary effects of bile injury to the gastric pouch remains unclear.<sup>57</sup>

Table 2 Postgastrectomy Syndromes

<i>Syndrome</i>	<i>Symptoms</i>	<i>Primary Management</i>
Dumping	Postprandial gastrointestinal distress and vasomotor symptoms	Dietary modification; octreotide in refractory cases
Postvagotomy diarrhea	Postprandial diarrhea	Dietary modification; antidiarrheal agents
Bile reflux gastritis	Epigastric pain, bilious emesis	Prokinetics/acid-reducing agents/cholestyramine Surgical revision may be required
Gastric atony	Epigastric pain, nausea, vomiting	Prokinetic agents Surgical revision may be required
Roux stasis	Epigastric pain, nausea, vomiting	Surgical revision

The incidence may be as high as 50% after some gastric operations.<sup>49</sup> Patients with bile reflux experience burning epigastric pain, nausea, and bilious vomiting. Eating exacerbates symptoms; therefore, many patients reduce their food intake with consequent weight loss.

Diagnosis is based on the clinical history and confirmation by endoscopic biopsy to distinguish bile reflux gastritis from bile staining of the gastric mucosa. Other etiologies, such as gastric outlet obstruction, gastroesophageal reflux, ulcer disease, and *Helicobacter pylori*, should be ruled out. Nuclear medicine scans may be a helpful adjunct but cannot be used as the primary diagnostic modality because transient reflux can also be seen in asymptomatic patients. Gastric emptying studies will usually demonstrate delay.

Single-agent treatments with bile-chelating agents, sucralfate, and prostaglandins have generally shown disappointing results.<sup>58-61</sup> Nonetheless, an initial trial of intensive therapy with a combination of prokinetic agents, cholestyramine, and acid-reducing agents is recommended. Patients whose symptoms persist should be referred for consideration of surgical treatment.

### Gastric Atony

Gastric atony results from loss of vagal innervation that controls gastric contractility and emptying. Symptoms include postprandial epigastric pain, nausea, and vomiting. Gastric emptying scans will show marked delay. Endoscopy and contrast radiography are important components of the workup to rule out mechanical causes of obstruction. Upper gastrointestinal series will typically demonstrate a large, flaccid gastric reservoir. Treatment with prokinetic agents is generally unsuccessful, and many patients ultimately require surgical revision.<sup>62</sup>

### Roux Stasis Syndrome

Roux stasis syndrome presents as a functional obstruction in patients who have had gastrointestinal continuity reestablished using a Roux-en-Y gastroenterostomy. The underlying pathophysiology is likely due to altered motility in the jejunal limb as a result of disruption of the intestinal pacemaker by resection of the jejunum to fashion the Roux-en-Y gastroenterostomy. Symptoms are similar to those of gastric atony and consist of abdominal pain, nausea, and vomiting after meals. Roux stasis has been described in approximately 30% of patients and appears to be related to the length of the Roux-Y limb.<sup>63</sup>

As with gastric atony, an important part of the differential that needs to be excluded is mechanical obstruction. Upper endoscopy and upper gastrointestinal series should be used to exclude this possibility. Nuclear medicine scans to document transit times through the Roux-Y limb are also helpful for making the diagnosis. The treatment is surgical revision.

### Malnutrition and Anemia

Malnutrition and weight loss are not uncommon after gastrectomy. Although in some cases, these may be due to malabsorption, in many patients, there is inadequate caloric intake to avoid adverse symptoms. For such patients, emphasis on altering eating behaviors, in particular switching from three meals daily to frequent small meals, is essential. Additionally, some patients with no preoperative history of lactose intolerance have been known to develop intolerance of dairy products after gastrectomy. The increase in intestinal pH levels with a subsequent change in the bacterial flora can lead to anaerobic bacterial overgrowth and malabsorption.<sup>64</sup>

The most frequently noted etiology for anemia after total or distal gastrectomy is loss of the intrinsic factor and subsequent malabsorption of vitamin B<sub>12</sub>. Parenteral vitamin B<sub>12</sub> replacement is therefore necessary. In addition, iron deficiency anemia and deficiency in folic acid are also described, and these sources should be sought out and treated in patients with chronic anemia following gastrectomy.

### Functional Complications of Esophageal Surgery

A number of functional consequences of esophageal surgery are recognized. These include dysphagia, vocal cord paralysis, regurgitation, delayed emptying of the neoesophagus, and dumping syndrome. Most of these complications may be seen irrespective of the surgical approach to resection (transhiatal, transthoracic) or the conduit used. Although many patients will continue to have some long-term functional complaints, studies suggest that quality of life for many returns to national norms.<sup>65,66</sup>

### Dysphagia

Some degree of dysphagia has been reported by as many as 45% of patients after esophagectomy followed for over 5 years.<sup>66</sup> Dysphagia may be a symptom of underlying mechanical obstruction, commonly from anastomotic strictures. The severity of symptoms has been shown to correlate with the probability of stricture, those patients with severe symptoms all having evidence of mechanical obstruction.<sup>67</sup> Patients with complaints of dysphagia should be evaluated with endoscopy and cine-esophagrams.

Most strictures are seen within the first 3 months of surgery, and early postoperative dilatation may be required for as many as 30 to 50% of patients after esophagectomy.<sup>68,69</sup> Most strictures can be successfully managed by dilation.<sup>68-70</sup> Multiple sessions are frequently required. By 1 year after surgery, only about 5 to 10% of patients will continue to have symptomatic strictures that require continued dilatation.<sup>69,70</sup>

These patients may be candidates for surgical intervention. In addition, stricture dilatation in patients with colonic or jejunal interpositions carries a higher risk of perforation, and surgical revision should be considered earlier in these patients.

A neurogenic etiology should be considered in patients with dysphagia who do not have radiographic or endoscopic evidence of obstruction.<sup>67</sup> Injury to branches of the recurrent laryngeal nerve is the most likely cause.<sup>67</sup> These patients are managed supportively, in particular with greater emphasis on thorough chewing. Most symptoms resolve with time.

### Vocal Cord Paralysis

The incidence of vocal cord paralysis has been reported to be 20 to 30% after esophagectomy<sup>67,71</sup> and is a result of injury to the recurrent laryngeal nerve. Paralysis may be either unilateral or bilateral. The primary symptom is that of hoarseness; however, additional difficulties with swallowing, breathing, and pulmonary complications may also be present. In the majority of patients with recurrent nerve injury, the hoarseness is transient, and many patients have resolution of symptoms within the first 4 to 6 months.<sup>67,71</sup> Patients with recurrent nerve injury have been reported to have a higher incidence of postoperative pulmonary complications,<sup>71,72</sup> and those with severe hoarseness are more likely to have problems with activity and quality of life.<sup>72</sup>

Patients with persistent hoarseness should be referred for laryngoscopy to confirm the clinical diagnosis. Patients with repeated pulmonary complications after esophagectomy should be similarly evaluated. Treatment is aimed at medialization of the vocal cord by intracordal injection with silicone or Gelfoam. The success rate in improving patient symptoms is 90%.<sup>73</sup>

### Regurgitation

Many patients will experience occasional reflux after esophagectomy, with some reports showing approximately 60% of patients with intermittent symptoms.<sup>66,74</sup>

The factors that contribute to reflux are multiple, including loss of the natural antireflux mechanism, impaired motility of the neoesophagus, and delay in gastric emptying.<sup>74</sup> In addition to typical symptoms of burning, patients may also complain of chronic cough and recurrent pneumonia.<sup>74</sup> Lying supine frequently exacerbates symptoms. Treatment is supportive. Avoidance of large meals, particularly prior to sleep, can minimize the occurrence of regurgitation. Use of prokinetics in patients with motility disorders may also be of benefit. Regurgitation that necessitates that the patient sleep upright at night is uncommon.<sup>69</sup>

## Delayed Conduit Emptying

Delayed conduit emptying may be the result of either poor motility of the neoesophagus or a delay in gastric emptying as a result of denervation of the gastric tube. Patients will frequently complain of early satiety. Contrast radiography can help elucidate the underlying etiology of delayed motility. Treatment is primarily pharmacologic, using promotility agents such as metoclopramide or erythromycin.<sup>75,76</sup> In addition, for patients who have delayed gastric emptying as a result of pyloric narrowing, upper endoscopy with balloon dilatation should be performed.

## Dumping

Postvagotomy dumping syndrome is noted in approximately 25% of patients after esophagectomy.<sup>74</sup> As with dumping after gastrectomy, the management is alteration of dietary behavior, with emphasis on frequent, small meals, separating liquids and solid intake by about 30 minutes, and the use of antidiarrheal agents.

## Pelvic Operations

The complex neuroanatomy of the pelvis, the close proximity of pelvic organs, and extended multivisceral resections for advanced disease place patients undergoing pelvic surgery for bladder, prostate, gynecologic, and rectal malignancy at risk of the development of urinary, sexual, and anorectal dysfunction after such operations. In addition, patients with stomas for fecal or urinary diversion can present with long-term complications of stenosis and prolapse and may also develop significant metabolic problems.

## Sexual Dysfunction

Injury to the parasympathetic and sympathetic nerves in the pelvis plays a primary role in the development of sexual dysfunction following pelvic operations. Additional factors that may contribute include vascular injury, psychosocial factors, and, particularly in women, pelvic scarring. Data regarding postoperative sexual function are more readily available in men than women. In part, this reflects the availability of clearly defined end points of sexual function in men, namely potency and ejaculation.

Erectile dysfunction (ED) in men is defined as an inability to achieve and maintain erections sufficient for sexual intercourse. The incidence of ED after pelvic surgery is highly variable and depends on several factors, including the type of surgery and the patient's age.<sup>77-83</sup> The relationship with the type of surgery in large part reflects the ability to preserve the parasympathetic and sympathetic innervation of the pelvis during the procedure. Preservation of neurovascular bundles bilaterally correlates with an increased likelihood of recovering sexual function; data

from prostatectomy studies indicate that, depending on age, 50 to 90% of men with full erections preoperatively can be expected to recover potency after bilateral nerve preservation compared with only approximately 25 to 50% for those with unilateral nerve preservation.<sup>77-79</sup> Importantly, for men who were potent preoperatively, recovery of sexual function after pelvic surgery can take as long as 40 months.<sup>77,84,85</sup>

Given that the primary etiology of ED in men after pelvic surgery is nerve injury, specialized testing to evaluate for the causes of ED in this setting is not warranted. However, exclusion of metabolic and endocrine conditions that impact sexual activity, such as measurement of serum testosterone, lipid profile, and thyroid function, is appropriate, particularly for men with complaints of decreased libido.<sup>86,87</sup>

Treatment of ED was substantially advanced with the introduction of sildenafil. The initial reports of the efficacy of sildenafil in ED included patients with both organic and psychogenic disorders.<sup>88</sup> More recent reports, specifically on patients with ED after pelvic operations, have similarly confirmed the effectiveness of sildenafil in this cohort.<sup>89,90</sup> Overall, approximately 80% of patients with partial or total ED after pelvic operations can be expected to respond. Doses of 100 mg will often be required to achieve satisfactory results.<sup>88-90</sup> However, the success of recovery of sexual function with sildenafil is also dependent on the preservation of pelvic neuroanatomy.<sup>90</sup> The rates of response to sildenafil according to the status of the neurovascular bundles are 72%, 50%, and 15% for bilateral, unilateral, and non-nerve-preserving operations, respectively.<sup>90</sup>

The reported side effects of sildenafil include headache, flushing, and dyspepsia, although few men discontinued the medication secondary to these side effects.<sup>88</sup> Sildenafil should be used with caution in patients with cardiovascular disease and is contraindicated for those patients on nitrates.<sup>91</sup> For patients who do not respond to sildenafil or for whom sildenafil is contraindicated, alternative treatments include implantation of a penile prosthesis, vacuum constriction devices, and intracorporeal injection or transurethral delivery of alprostadil.

Data on sexual function in women after pelvic surgery are not as readily available. Physical factors are known to be altered after pelvic operations, particularly after gynecologic and rectal operations. These include a shortened vagina, pain, vaginal dryness, and bleeding.<sup>92-94</sup> In patients who have had proctectomy, leakage of stool during intercourse is also reported.<sup>92-94</sup> Reports on sexual function and activity are more varied. Data from women following proctectomy suggest that despite some complaints of physical changes, sexual arousal, sensitivity, and frequency were unchanged postoperatively.<sup>92,94</sup> However, in a

long-term follow-up of 105 women after radical pelvic surgery, Corney and colleagues found that 66% of patients had persistent sexual difficulties, including nearly half who reported a lack of desire.<sup>93</sup> They found that psychogenic causes, in addition to organic ones, had a significant impact on postoperative sexual function. The management of sexual dysfunction in female patients is primarily supportive counseling. The role of sildenafil for treatment of sexual dysfunction in women has been investigated, with studies showing mixed results.<sup>95-97</sup> These studies have not included women experiencing deterioration of sexual function following pelvic surgery.

## Anorectal Function after Pelvic Surgery

Alterations in bowel habits are primarily seen in patients following resection of the rectum. Loss of the rectal reservoir and loss of rectal compliance contribute to an increase in stool frequency, urgency, incontinence to stool and/or flatus, and, in some instances, constipation.<sup>98-101</sup> The probability of these functional outcomes is usually inversely correlated with the level of the colorectal anastomosis.<sup>98-101</sup> As the residual rectum gains in compliance and capacitance, in many patients, these symptoms improve over the first 6 to 12 months, and in some series, functional outcomes have continued to improve 2 to 5 years after surgery.<sup>100,102,103</sup>

Treatment is directed at management of these symptoms. A rectal examination is important to confirm that rectal tone is normal and there is no impaction. Furthermore, for patients with severe symptoms that show no sign of abating over time, a barium enema or endoscopy to rule out stricture or secondary causes is important. Increasing stool bulk through the use of fiber is the mainstay of management. Intake of fiber supplements is gradually titrated upward to achieve a more formed bowel movement. Occasionally, antidiarrheal agents are necessary to control loose bowel movements, but these should be used cautiously to avoid alternating cycles of constipation and diarrhea.

In addition to pharmacologic treatments, patients should be encouraged to perform Kegel exercises daily to strengthen the muscles of the pelvic floor. Lastly, education and management of expectations are important components of care in these patients. Despite improvements in anorectal function that occur over many months postoperatively, most patients will ultimately stabilize at an average of two to three bowel movements daily,<sup>102,104</sup> and only 50 to 75% will be completely continent.<sup>98,103,104</sup>

## Urologic Dysfunction

As with sexual function, preservation of the pelvic autonomic nerves is important for maintenance

of normal bladder function postoperatively.<sup>105–108</sup> Depending on the type of nerve injury, patients may present with symptoms of urinary retention, such as urinary strain, overflow incontinence, and loss of sensation of bladder fullness. Alternatively, patients may complain of urgency and stress incontinence.

Although transient postoperative difficulties requiring intermittent catheterization are not uncommon after pelvic operations,<sup>107,109</sup> the persistence of voiding problems 6 to 8 weeks after surgery requires further evaluation. Such a workup should start with a postvoid residual as measured by catheterization or bladder ultrasonography, as well as a urinalysis and culture to rule out infection. Patients with postvoid bladder volumes exceeding 500 mL should be started on a regimen of clean intermittent catheterization. Further workup will require formal urodynamic studies to better define the etiology of urinary dysfunction and initiate appropriate pharmacologic treatment.

## Metabolic Consequences of Urinary and Bowel Diversion

### Urinary Diversion

For patients undergoing cystectomy, diversion of urine flow is generally through a segment of bowel, typically the distal ileum or a segment of colon. These urinary diversions may serve simply as a conduit to an external stoma or may be fashioned such that they form a continent urinary pouch. Among the most common complications of such urinary diversions is the development of acidosis, renal insufficiency, and renal calculi, occurring in 15 to 20% of patients (Table 3).<sup>86,87,110</sup>

The incidence of metabolic acidosis depends on the method of follow-up. Electrolyte analysis

of venous blood samples will demonstrate an incidence of approximately 15% of patients.<sup>86,87,110</sup> The incidence is much higher if patients are monitored by arterial blood gas measurements.<sup>111</sup> Whether these acid-base abnormalities impact bone metabolism is not clear.<sup>110</sup> However, alkalizing agents, such as sodium or potassium bicarbonate, should be used in children with urinary diversion as chronic acidosis may lead to bone loss and orthopedic problems.<sup>110</sup> In addition, selective use of alkalizing agents in patients with a base excess < -2.5 has been recommended.<sup>112</sup> In a series of 27 patients with urinary diversion, Stein and colleagues assessed the long-term impact of early alkalization in individuals with a base excess < -2.5.<sup>112</sup> They found no abnormalities in bone mineral density in their cohort.

Development of stones, in both the kidney and the conduit, is also not uncommon in patients with urinary diversion and likely results from a combination of stasis and bacterial colonization of the conduit. Antibiotic treatment for colonization is not warranted, and such therapy is reserved for those patients with objective evidence of infection. The presence of bacteria has also been postulated to play a role in the risk of cancer developing at the ureteroenteric anastomosis. This risk was well documented when ureterosigmoid anastomoses were performed for urinary diversion,<sup>113</sup> and sigmoidoscopy every 2 years is warranted in these patients. More recently, isolated ileal or colonic conduits for urinary diversion have replaced ureterosigmoidoscopy. Long-term data on the cancer risk in these isolated bowel conduits have not been established.

Additional complications following urinary diversion that require monitoring include renal insufficiency, deficiency of vitamin B<sub>12</sub> and malabsorption of bile salts as a result of resection of the terminal ileum for conduit formation, hyperammonemia, especially in patients with liver insufficiency, and drug intoxication with drugs that are excreted unchanged by the kidney and reabsorbed by the bowel conduit.

### Bowel Diversion

Although reestablishment of intestinal continuity after gastrointestinal surgery is the primary objective, ostomy formation, either temporary or permanent, is occasionally required in the management of the cancer patient. Long-term complications of such ostomies include prolapse, stenosis, peristomal fistula, parastomal hernia, and retraction of the stoma.<sup>114–116</sup> In addition, patients with ileostomy are prone to dehydration and electrolyte abnormalities. Control of high ileostomy output (generally > 1 L/d) is important and can be accomplished through the use of fiber and antiperistalsis agents. Alterations in uric acid levels are also seen in patients with ileostomy,

which predisposes patients toward the formation of uric acid stones.<sup>117,118</sup> Treatment of patients with aciduria has been suggested to prevent the formation of such stones.<sup>119</sup> An increased incidence of cholelithiasis has also been reported.<sup>120</sup>

# Collateral Damage Associated with Chemotherapy

Anne S. Tsao, MD  
David J. Stewart, MD

A major problem with chemotherapy is the occurrence of marked toxic effects that patients experience. Extensive research has been conducted to understand the pathogenesis of toxic effects so that they might be prevented; however, acute intratherapeutic effects of nausea, vomiting, diarrhea, and myelosuppression remain limiting factors in cancer treatment. Long-term sequelae of the chemotherapy can include infertility, carcinogenesis, and damage to the heart, kidney, lung, and nervous system. Standardized systemic symptoms are helpful for uniform management of patients on clinical trials and for initiation of appropriate dose adjustments. Several toxicity definition and grading systems are in use, largely in cooperative groups; one used frequently is the National Cancer Institute (NCI) Common Toxicity Criteria for Adverse Events (version 3) (<http://www.fda.gov/cder/cancer/toxicityframe.htm>), which grades each symptom on a scale of 0 to 4 by severity. A dose-limiting toxicity (DLT) is the clinical toxic response that determines the maximum tolerated dose.<sup>1</sup>

Additional factors to consider when evaluating toxicities of chemotherapy include determining whether they are acute or chronic and whether they are cumulative. The DLT of a single agent may differ depending on the method of administration (intravenous bolus or infusion over hours).<sup>1</sup> Treatment schedule, route of administration, other agents' used, and patient comorbidities can also affect a patient's tolerance to chemotherapy. In addition, such patient characteristics as age, renal and hepatic function, pharmacogenomic status, and previous amount of therapy are major contributors to patient tolerance of therapy.<sup>1-3</sup>

This chapter provides a general overview of both the systemic and nonsystemic toxic effects of cancer chemotherapies, along with a discussion of the various classes of chemotherapy and their mechanisms of action.

## Systemic Toxic Effects

### Myelosuppression

One of the most common DLTs of chemotherapy is hematopoietic toxicity causing myelosuppression.<sup>1</sup> The severity of any toxic effect is dependent on the drug type, dose and bioavailability, duration of exposure, and frequency of administration.<sup>4</sup> Because most cytotoxic chemotherapy agents target proliferating cells, most hematopoietic progenitor cells (mature granulocytes, erythrocytes, and thrombocytes) that are in the peripheral circulation are affected by the therapy. Pluripotent hematopoietic stem cells do not divide frequently, and in normal cases, stem cells will produce one daughter cell that differentiates and another daughter cell that becomes another stem cell.<sup>5</sup> Bone marrow stem cells may also be affected, especially by alkylating agents, which can result in an even longer period of myelosuppression.<sup>1,4</sup> High doses of chemotherapy will prolong the bone marrow recovery period, and studies have found that a decrease in granulocyte-macrophage colony-forming unit cells can be seen for up to 3 years after therapy.<sup>4</sup>

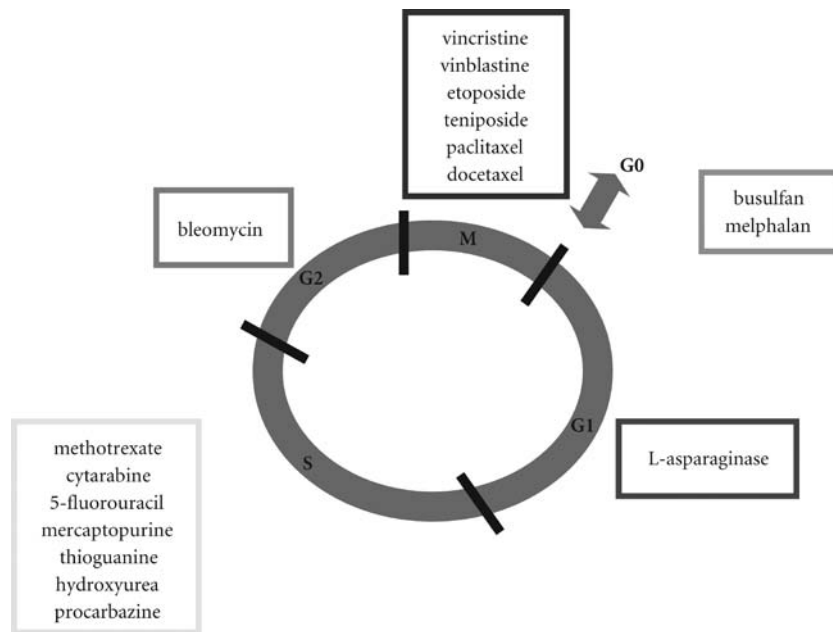

Different chemotherapy agents will affect a patient's bone marrow reserve differently. These agents target different phases of the cell cycle (Figure 1). For example, alkylating agents cause 1 to 4 weeks of myelosuppression, with recovery within 4 weeks, whereas antimetabolite agents will nadir granulocyte counts within 1 week, with recovery approximately 3 weeks later. Myelosuppression can also be delayed by agents such as mitomycin-C, nitrosoureas, and procarbazine, which depress granulocyte counts 3 to 4 weeks after treatment.<sup>4</sup>

Anemia is reported in up to 90% of patients receiving chemotherapy. Clinical symptoms include fatigue, lethargy, weakness, irritability, dyspnea, and reduced performance status.<sup>6</sup> The severity of chemotherapy-induced anemia depends on the dose of the agent, the duration of treatment, and the patient's bone marrow

reserve.<sup>6,7</sup> Younger patients with more cellular bone marrow are likely to tolerate chemotherapy better than older patients. Patients with iron deficiency anemia or marked bone marrow infiltration by tumor will have more complicated cases of chemotherapy-induced anemia.<sup>7</sup> Chemotherapy may also complicate preexisting anemia; anemia owing to chronic disease is associated with erythroid hypoplasia of the bone marrow, and chemotherapy agents compound the problem by delaying the maturation of the erythroid lineage cells.<sup>8</sup> Treatment for anemia consists of red blood cell transfusions, administration of recombinant erythropoietin, and vitamin supplementation and should be initiated based on the clinical presentation.<sup>9,10</sup> In general, patients who are symptomatic and have hemoglobin levels below 10 g/dL should receive intervention.<sup>11</sup> Patients with a cardiac history of angina may require more aggressive therapy. Iron supplementation should be initiated if the ferritin level drops below 100 ng/mL.<sup>7</sup> Cisplatin may cause anemia through reduced erythropoietin production resulting from the agent's nephrotoxicity.

Thrombocytopenia occurs 8 to 14 days after chemotherapy and can occur concomitantly with neutropenia.<sup>7</sup> As a general rule, chemotherapy should be delayed if platelets are below 100,000/mm<sup>3</sup>. Thrombocytopenia places patients at increased risk of bleeding, but spontaneous bleeding rarely occurs when the platelet level is above 20,000/ $\mu$ L.<sup>7</sup> Patients who are not bleeding should still receive platelet transfusions when their platelet counts drop below 10,000/mm<sup>3</sup>. Other factors that complicate thrombocytopenia include hypersplenism, concomitant use of antiplatelet and anticoagulant medications, and sepsis. Thrombocytopenia has been reported as a DLT for gemcitabine, carboplatin, dacarbazine, 5-fluorouracil (5-FU), lomustine, mitomycin, and thiotepa. Cumulative effects from carmustine, fludarabine, lomustine, mitomycin-C, streptozocin, and thiotepa have also been reported,

**FIGURE 1** Schematic showing chemotherapy agents that act during specific phases of the cell cycle phase.

and agents that have cumulative bone marrow toxicity are also more likely to cause thrombocytopenia than are agents with relatively little cumulative effect.

Neutropenia is a common DLT chemotherapy. Neutrophils have life spans of 6 to 8 hours after their release from the bone marrow and are the initial responders to infection and development of a host reaction to infectious agents. Neutropenia occurs within 5 to 14 days after chemotherapy, with recovery of counts in 721 days.<sup>7</sup> Neutropenia is defined as an absolute neutrophil count (ANC) less than 1,500/mm<sup>3</sup> by some authors, whereas others define it as a count less than 1,000 or 500/mm<sup>3</sup>. The risk of infection rises as the neutrophil count falls below 1,000/mm<sup>3</sup> and is inversely related to the neutrophil count during neutropenia. As a general guideline, chemotherapy should be withheld if the ANC drops below 1,000 to 1,500/mm<sup>3</sup>. The NCI toxicity grading scale quantifies neutropenic toxic responses on a scale of 1 to 4. A grade 4 or life-threatening, toxic response is defined as an ANC less than 500/mm<sup>3</sup>.

Patients with hematologic malignancies are at higher risk of neutropenic complications owing to the underlying disease.<sup>12</sup> Febrile neutropenia is considered a life-threatening oncologic emergency and requires immediate intervention with antibiotics and evaluation for sepsis.<sup>12</sup> Febrile neutropenia has been defined in several ways. For example, some authors have defined it as a temperature greater than 38.2°C (101°F) with a granulocyte count of less than 1,000/mm<sup>3</sup>, whereas others have defined it as fever greater than 38.2°C for over 1 hour associated with a grade 4 ANC.<sup>1</sup> Neutropenia can be treated using human granulocyte colony-stimulating factor (CSFs).<sup>12</sup> The current American Society of

Clinical Oncology (ASCO) guidelines recommend primary prophylactic use of CSFs when the anticipated risk of febrile neutropenia exceeds 40% in patients who are at high risk of febrile neutropenia or infection. Patients who have had one episode of febrile neutropenia after chemotherapy are considered high risk and should receive CSF support during subsequent cycles of chemotherapy unless the chemotherapy dose is reduced. However, CSFs have not shown any benefit in disease-free or overall survival, and their use in febrile patients receiving chemotherapy is not recommended except in a high-risk situation.<sup>13</sup>

### Gastrointestinal Symptoms

The gastrointestinal toxic effects of chemotherapy include nausea, vomiting, diarrhea, and mucositis. Chemotherapy-induced nausea and vomiting (CINV) may markedly affect a patient's quality of life during chemotherapy and can be a factor in determining a patient's ability to tolerate further treatment. The risk factors for CINV include a high level of chemotherapy emetogenicity (Table 1), young patient age, female gender, history of pregnancy-related or motion sickness, nausea, patient anxiety, history of CINV with previous chemotherapy, and low social functioning. Patients with a history of heavy alcohol use appear to have a reduced risk of CINV.<sup>14-16</sup>

Acute CINV (defined as CINV occurring within the first 24 hours after chemotherapy administration) arises when chemotherapy damages enterochromaffin cells in the gastrointestinal tract, resulting in the release of serotonin. The serotonin binds to 5-hydroxytryptamine<sub>3</sub> (5-HT<sub>3</sub>) receptors in vagal afferent nerves and the chemoreceptor trigger zone, activating the vomiting

**Table 1** Emetogenicity of Commonly Used Chemotherapy Agents

High

center in the medulla lateral reticular formation.<sup>15</sup> The release of dopamine and its interaction with dopamine receptors play a lesser role than the serotonin pathway. CINV may also be “delayed” or “anticipatory.”<sup>15</sup> Delayed emesis is defined as emesis occurring after 24 hours and maintained for several hours (sometimes 120 hours or more) afterward and is thought to be mediated by substance P neurokinin-1 (NK-1) receptor pathways.<sup>15,17</sup> NK-1 receptors line the intestinal tract and the nucleus tractus solitarius of the brain. Substance P, a tachykinin, binds to the NK-1 receptors at the nucleus tractus solitarius and induces vomiting.<sup>16</sup> Substance P is released in two phases, first from the direct cytotoxic effect of chemotherapy on the chemoreceptor zone and then from the damaged enterochromaffin cells in the gastrointestinal tract. CINV is also regulated by dopamine 2 receptors. Dopamine receptors are located in the chemoreceptor trigger zone, and blockade enables some control over emesis.

Anticipatory nausea is nausea that occurs prior to chemotherapy administration and is a conditioned response to chemotherapy. In this setting, antiemetic prophylaxis is less effective and behavioral modification is recommended.<sup>15</sup> Two additional minor categories of CINV are reported: breakthrough CINV and refractory

CINV.<sup>16</sup> Breakthrough CINV occurs in patients who are receiving preventive antiemetic therapy. Patients with refractory CINV develop adverse symptoms after initially responding to antiemetic therapy during the first few cycles of chemotherapy.

If effective antiemetics are not given, acute CINV can occur in up to 98% of patients receiving highly emetogenic agents, such as cisplatin. Delayed CINV has been reported in up to 61% of patients. The incidence is lower for less emetogenic agents.<sup>15</sup> Antiemetic regimens for acute CINV include 5-HT<sub>3</sub> receptor antagonists in combination with corticosteroids. Corticosteroids are thought to prevent emesis by prostaglandin antagonism, although the exact mechanism is unclear. Delayed CINV requires additional therapy with steroids, possibly 5-HT<sub>3</sub> antagonists, dopamine 2 receptor antagonists such as (metoclopramide), and NK-1 receptor antagonists. Control of acute CINV may decrease the incidence of delayed CINV.<sup>15,16</sup>

Diarrhea, if prolonged and severe, can lead to dehydration and malabsorption. Chemotherapy-induced diarrhea is graded by the number of additional bowel movements above a normal baseline. The pathophysiology of chemotherapy-induced diarrhea is not clear but is partly due to chemotherapy-induced damage to intestinal crypt cells, which divide rapidly, and a delay in regeneration of the intestinal villi and intestinal absorptive surface. Changes in absorptive capability lead to diarrhea by altering the osmotic gradient in the intestine. Inflammatory cytokines, which promote secretion of intestinal fluids and electrolytes from the crypt cells, are also secreted.<sup>18</sup> Chemotherapy itself will occasionally lead to the development of *Clostridium difficile*-induced diarrhea.

Agents that commonly cause diarrhea include 5-FU, irinotecan, methotrexate, docetaxel, and doxorubicin. Diarrhea is dose limiting in irinotecan and 5-FU combinations. Patients who develop chemotherapy-induced diarrhea should modify their diet to avoid greasy, spicy, or fried foods and any milk products. The BRAT diet (bananas, rice, applesauce, and toast) with clear liquids is recommended until the diarrhea lessens.<sup>18</sup> Maintaining fluid intake is critical to replace the volume lost and can require up to 3 to 4 L of fluid per day. Antidiarrheal agents such as loperamide, diphenoxylate or atropine, and, in severe cases, octreotide can be used.<sup>18</sup>

Mucositis can occur at any mucosal surface between the mouth and the rectum or vagina and is characterized by inflammation of the mucosa. The patients most likely to develop mucositis include those undergoing high-dose chemotherapy with hematopoietic stem cell transplantation or patients with head and neck cancer receiving concomitant radiotherapy. The agents most likely to cause mucositis are methotrexate, etoposide, 5-FU, and irinotecan.<sup>19</sup>

Chemotherapy likely induces mucosal injury through direct toxicity or indirectly by stimulating reactive oxygen species, causing destruction of the stem cells in the basal layer of the epithelium. This injury, in turn, leads to epithelial thinning, ulceration, and secondary colonization by infectious pathogens. In addition to causing epithelial injury, the generation of reactive oxygen species leads to activation of nuclear factor κB, which leads to the production of proinflammatory cytokines, tumor necrosis factor, interleukin-6, and platelet-activating factor. Additional transcription factors lead to apoptosis of submucosal endothelial cells and fibroblasts, which leads to changes in capillary permeability and the submucosal supportive layer. Mucosal injury with ulceration then occurs, with development of a pseudomembrane and colonization by bacteria.<sup>20</sup>

Stomatitis or oral mucositis can be acute (with mucosal inflammation, ulceration, or bleeding) or chronic (with xerostomia, taste alterations, trismus, or soft tissue and bone necrosis).<sup>20</sup> With chemotherapy-induced stomatitis, the injury occurs within 1 to 2 weeks of treatment. The risk factors for development of stomatitis include poor nutritional status, alterations in oral flora, poor salivary function, old age, male gender, and the presence of inflammation.<sup>20,21</sup> Symptoms will generally improve with the restoration of bone marrow products. Several agents are under investigation to prevent oral mucositis, among them amifostine, benzydamine, and *N*-acetylcysteine.<sup>20</sup> Taste alterations can occur, with more perception of bitterness, a metallic taste, or increased perception of sweetness. The agents that most commonly affect taste perception are cyclophosphamide, dacarbazine, doxorubicin, 5-FU, levamisole, methotrexate, nitrogen mustard, cisplatin, and vincristine. Esophagitis may have symptoms of dysphagia, odynophagia, and epigastric pain. Substernal symptoms indicate worsening esophagitis. Previous or concurrent radiation will worsen the effects of chemotherapy. Dactinomycin, doxorubicin, and gemcitabine may markedly potentiate radiation injury to the esophagus, whereas 5-FU, hydroxyurea, procarbazine, and vinblastine have a lesser potentiation effect.<sup>22</sup> Severe esophagitis may require placement of a feeding tube. Vaginitis is uncommon but can occur 3 to 5 days after therapy and resolve within 7 to 10 days. Superimposed *Candida* infections may complicate esophagitis and vaginitis.

### Skin Changes

Chemotherapy can induce skin hyperpigmentation, hypersensitivity, acral erythema, pruritus, photosensitivity, alopecia, nail pigmentation or Beau's lines, and onycholysis. Hyperpigmentation can be seen in the skin, nails, and mucous membranes and tends to be more prominent

in patients with darker skin. Bleomycin can cause a typical flagellate hyperpigmentation.<sup>23</sup> Other agents that cause hyperpigmentation are busulfan, cyclophosphamide, carmustine, irinotecan, 5-FU, doxorubicin, and etoposide. Skin hypersensitivity reactions can include urticaria and angioedema and can be accompanied by anaphylaxis. L-Asparaginase causes hypersensitivity in 10 to 20% of patients.<sup>23</sup> Paclitaxel or the Cremophor EL vehicle within which it is formulated can cause rapid onset of hypotension, rash, dyspnea, and bronchospasm. Docetaxel causes skin hypersensitivity, rash, anaphylaxis, and fluid retention. Cisplatin, carboplatin, etoposide, procarbazine, cytarabine, levamisole, topotecan, trimetrexate, melphalan, methotrexate, all-*trans* retinoic acid, and nitrogen mustard can also cause hypersensitivity. Single-agent busulfan, etoposide, procarbazine, hydroxyurea, bleomycin, methotrexate, and cytarabine or high-dose combination chemotherapy can lead to erythema multiforme. Skin desquamation, "hand-foot" syndrome, acral erythema, or erythrodysesthesia is typically associated with cytarabine, doxorubicin, 5-FU, paclitaxel, or docetaxel.<sup>23</sup> This reaction may increase with subsequent therapy, and the cause is unknown. Photosensitivity to ultraviolet light may be caused by 5-FU, dacarbazine, all-*trans* retinoic acid, vinblastine, and high-dose methotrexate.

Alopecia, or hair loss, is a common toxic effect and is often seen with trimetrexate, cyclophosphamide, doxorubicin, dactinomycin, daunorubicin, etoposide, idarubicin, ifosfamide, irinotecan, mechlorethamine, paclitaxel, topotecan, and vincristine. Milder hair loss is seen with bleomycin, carmustine, epirubicin, 5-FU, methotrexate, melphalan, mitomycin, mitoxantrone, teniposide, and vinorelbine. Hair is the most rapidly proliferating cell population in the body and is therefore susceptible to the effects of chemotherapy. Chemotherapy can also cause mitotic arrest and atrophy of the root bulb. Alopecia has been reported to be more severe when more highly lipophilic metabolites are used as these agents can penetrate the hair follicles more easily.<sup>24</sup> Chemotherapy also may decrease nail-bed growth in a similar manner and manifest as Beau's lines or onycholysis.

### Cardiotoxic Effects

Cardiotoxicity may have immediate or delayed effects. Toxic effects can occur during or immediately after the chemotherapy infusion or within a few days or weeks. Acute toxicity can manifest as pericarditis, arrhythmias, electrocardiographic changes, and pump dysfunction and is likely to resolve once therapy is stopped. Chronic cardiotoxic effects occur months or years after therapy and can consist of nonreversible cardiomyopathy and congestive heart failure.<sup>25,26</sup>

Anthracyclines are the agents most often associated with acute and chronic cardiotoxic effects. Several risk factors are associated with a greater likelihood of cardiotoxic response: a higher cumulative dose, preexisting heart disease, older patient age, mediastinal irradiation, female gender, hypertension, high rate of administration, bolus administration, and combination chemotherapy (doxorubicin with trastuzumab or cyclophosphamide).<sup>25,26</sup> The exact mechanism of action is not proven, but the cardiotoxic effects of anthracyclines are suspected to result from the generation of free oxygen radicals and oxidative stress.<sup>26</sup> These free oxygen radicals are directly toxic to myocytes and lead to the loss of myocardial fibrils, mitochondrial changes, and apoptosis.<sup>26–28</sup> Unfortunately, anthracycline-induced cardiomyopathy is irreversible and carries a poor prognosis. Current recommendations for anthracycline use include limiting the cumulative dose (eg, to less than 550 mg/m<sup>2</sup> in the case of doxorubicin), prolonging the drug infusion time, and considering the use of liposomal formulations in high-risk patients. Dexrazoxane, an iron-chelating cardioprotectant, may sometimes be used during chemotherapy. However, this agent should be used only on selected patients as its effect on the antitumor efficacy of the anthracycline is unknown.<sup>25</sup>

High-dose cyclophosphamide has been associated with acute pericarditis, myocarditis, and congestive heart failure. Although rare, these side effects can be fatal.<sup>26</sup> The cardiotoxic effects are not cumulative, and the risk factors include concurrent doxorubicin use, a higher dose (> 1.5 g/m<sup>2</sup>/d), and previous irradiation.<sup>26</sup> The toxic effect can be reversed once the agent is stopped. Patients treated with ifosfamide have similar findings, but up to 17% of them may experience cardiotoxicity.<sup>25</sup>

5-FU is cardiotoxic in 8% of patients. The effects generally occur within the first 72 hours of infusion and include angina, acute ischemia, arrhythmia, myocardial infarction, and even cardiac arrest.<sup>25</sup> Risk factors include concurrent radiation, preexisting heart disease, and the continuous infusion route of administration. Patients who have experienced cardiotoxicity should cease therapy immediately and should not be rechallenged.<sup>25,26</sup>

Paclitaxel can cause asymptomatic bradycardia, hypotension during infusion, and myocardial infarction or other arrhythmias (including atrioventricular conduction blocks, left bundle branch blocks, ventricular tachycardia, and atrial fibrillation).<sup>25</sup> Approximately 30% of patients develop asymptomatic bradycardia. Symptoms can be exacerbated with concomitant cisplatin administration.<sup>26</sup>

### Neurotoxic Effects

The neurotoxic effects of chemotherapy can occur in the central nervous system (CNS) or peripheral

nervous system (PNS). Cerebellar toxicity causing ataxia may be caused by 5-FU and by high-dose cytarabine. Potentially serious metabolic encephalopathy may occur with ifosfamide (particularly at high doses or in the presence of hypoalbuminemia) and is also seen occasionally with high-dose paclitaxel, cisplatin, nitrosoureas, and (rarely) cytarabine.<sup>29</sup> The encephalopathy is usually reversible after the cessation of therapy. In rare situations, carboplatin can cause cortical blindness, and cisplatin can lead to headaches, strokes, and seizures.<sup>29</sup>

High-dose systemic methotrexate given intravenously can cause a transient leukoencephalopathy, and intrathecal methotrexate can cause aseptic meningitis, with onset 2 to 4 hours after methotrexate injection and a duration of up to 3 days. In some cases, transverse myelopathy can develop,<sup>29</sup> but the risk may be reduced by ensuring that the saline used as a diluent is preservative free. A combination of delayed neurotoxic effects and leukoencephalopathy has been seen in patients who received high-dose methotrexate with brain irradiation. This condition carries a poor prognosis and is characterized by progressive dementia, gait disturbances, aphasia, hemiparesis, and death. The etiology is unclear.<sup>29</sup>

PNS toxic effects most frequently consist of a pure sensory neuropathy (possibly owing to the lack of a blood-nerve barrier in the dorsal root ganglion), with motor neuropathies being seen less frequently and cranial neuropathies rarely. With the vinca alkaloids and taxanes, the neuropathy is often acute, with symptoms coming on soon after drug exposure and frequently accompanied by neuralgic pain. Conversely, with cisplatin, the peripheral neuropathy is often delayed in onset and may not first appear until several weeks after the completion of therapy. The more severe the neuropathic symptoms, the lower the probability that they will resolve, although very gradual improvement may occur in some patients, even in the face of severe symptoms. In some cases, the neuropathy can be disabling, either owing to neuropathic pain or to the patient's inability to feel his or her feet (making it very difficult to maintain balance and walk in the dark).<sup>29,30</sup> Motor neuropathy, with weakness and loss of ankle reflexes, can be seen in patients with severe neuropathy, particularly those who received vinca alkaloids. Patients at higher risk of chemotherapy-related peripheral neuropathy include diabetics, patients with preexisting peripheral neuropathy, patients with hepatic insufficiency, and those receiving large cumulative doses of neurotoxic agents (eg, cisplatin doses > 400 mg/m<sup>2</sup>).<sup>29</sup> The degree of neurotoxicity varies within families of drugs, with vincristine being the most neurotoxic of the currently used vinca alkaloids and vinorelbine being the least neurotoxic, paclitaxel being more neurotoxic than docetaxel, and oxaliplatin being more

neurotoxic than cisplatin, which, in turn, is more neurotoxic than carboplatin.<sup>31</sup> Cytarabine is rarely associated with painful sensory neuropathy, brachial plexopathy, and lateral rectus muscle palsy.<sup>29</sup> Neuropathic pain can occur in the PNS as axons regenerate. As the axons repair damaged endings, the threshold for stimuli is lowered and patients have an increased perception of sensitivity and pain. Another mechanism that has been suggested is abnormal sensitivity of the afferent neurons to the sympathetic nervous system response and noradrenergic agonist receptor binding. Also, tumor necrosis factor  $\alpha$  is reported to activate nociceptors.<sup>30</sup>

In addition to causing sensory and motor neuropathies, vincristine (and, to a lesser extent, other neurotoxic agents) may cause autonomic neuropathy, manifesting as constipation, bladder atony, impotence, orthostatic hypotension, and an altered cardiac rate. Ototoxic effects consisting of tinnitus and high-frequency hearing loss owing to the loss of hairs in the organ of Corti may be caused by cisplatin and, to a lesser extent, by carboplatin. This condition is permanent, cumulative, and dose related and is more likely to occur in pediatric patients, in older patients with preexisting hearing loss, and in patients receiving cranial irradiation. Nitrogen mustard, vincristine, and vinblastine also have been reported to be ototoxic.<sup>31</sup> Nitrogen mustard causes loss of the outer hair cells in the cochlea and leads to irreversible sensorineural hearing loss and tinnitus. Vincristine and vinblastine are suspected to affect the organ of Corti sensory cells, and vincristine also affects the spiral ganglion cells and fibers.<sup>31</sup>

### Pulmonary Toxic Effects

Pulmonary toxic effects may be irreversible and serious. Presenting clinical symptoms can include a nonproductive cough and dyspnea. Symptoms of progression are heralded by basilar rales, hypoxia, and cyanosis. Eventually, pulmonary insufficiency may become irreversible and death can occur.<sup>32</sup> Generally, destruction of endothelial cells is followed by pneumocyte necrosis, with altered pulmonary parenchyma and connective tissue, and obliteration of alveoli, manifested as restrictive lung disease and decreased diffusion capacity. Toxicity can manifest as diffuse alveolar damage (DAD), nonspecific interstitial pneumonia (NSIP), bronchiolitis obliterans organizing pneumonia (BOOP), or pulmonary hemorrhage.<sup>33</sup>

DAD can result from bleomycin, busulfan, carmustine, cyclophosphamide, mitomycin, or melphalan exposure. The acute phase of DAD occurs 1 week after exposure and manifests as alveolar and interstitial edema. Type II pneumocytes then proliferate, and pulmonary fibrosis develops a few weeks later. This can progress to a honeycomb lung. A drop in diffusing capacity

is seen in severe cases.<sup>33</sup> NSIP is characterized by inflammation and hyperplastic type II pneumocytes. NSIP can occur in isolated patches of the lung and is associated with methotrexate, carmustine, and chlorambucil.<sup>33</sup>

BOOP is characterized by the proliferation of immature fibroblastic plugs located in the respiratory bronchioles, alveolar ducts, and spaces. Radiographs show bilateral peripheral opacities that are distributed equally throughout the lungs.<sup>33</sup> BOOP is associated with bleomycin, cyclophosphamide, and methotrexate. Pulmonary hemorrhage is uncommon but can result from high-dose cyclophosphamide, mitomycin, and cytarabine.<sup>33</sup>

Bleomycin causes lung toxicity in 3 to 5% of the patients who receive it.<sup>34</sup> Bleomycin is inactivated by hydrolase enzyme, which is not present in lung tissue; hence, bleomycin can accumulate in the lung. Endothelial cell type I pneumocytes are damaged early on, resulting in type II pneumocyte migration into alveolar spaces and interstitial changes. Fibroblasts then proliferate, causing pulmonary fibrosis.<sup>33</sup>

Cytarabine is directly toxic to pneumocytes and endothelial cells. Both cytarabine and mitomycin-C can cause capillary leak syndrome. This leads to pulmonary edema and respiratory failure. Cyclophosphamide can lead to alveolar hemorrhage and fibrin deposition. Carmustine inhibits lung glutathione disulfide reductase and can cause pulmonary toxic effects 6 weeks to 3 years after therapy. Among all patients exposed to carmustine, 20 to 30% will experience pulmonary toxicity. This percentage can increase to 50% when a cumulative dose above 1,500 mg/m<sup>2</sup> is given.<sup>35</sup> Methotrexate can damage type I pneumocytes and stimulate the formation of hyaline membranes.

### Hepatotoxic Effects

Hepatotoxic agents can act by damaging the parenchymal cells. Also, obstruction of hepatic blood flow leads to hepatocellular necrosis, cholestasis, hepatitis, and veno-occlusive disease. Hepatotoxic effects range from elevation of hepatic enzymes to cirrhosis.<sup>36</sup> High-dose methotrexate, high-dose cytarabine, 5-FU, gemcitabine, irinotecan, and trimetrexate can all lead to elevated hepatic enzymes.<sup>37</sup> Fluorodeoxyuridine given intra-arterially causes chemical hepatitis and stricture of intra- and extrahepatic bile ducts. Irreversible biliary sclerosis also can develop.<sup>36</sup> Most chemotherapy agents are not hepatotoxic, however. Dose modifications of certain chemotherapy agents are recommended in some patients with hepatic compromise (see the Appendix).

### Genitourinary Toxic Effects

Hemorrhagic cystitis can result from cyclophosphamide or ifosfamide therapy and can manifest as microscopic hematuria or frank bleeding. It is

caused by binding of the metabolite acrolein to the bladder mucosa, resulting in inflammation and ulceration.<sup>38,39</sup> Cyclophosphamide induces microscopic hematuria in 10% of patients. Mesna, a uroprotectant, contains sulfhydryl, which binds and inactivates acrolein. Chronic complications, such as long-term cystitis, bladder fibrosis, contraction, and bladder cancer, can occur.<sup>40–42</sup> Ifosfamide is also metabolized to acrolein and requires mesna administration. Gemcitabine can cause microscopic hematuria and proteinuria.

Chemotherapy can cause both acute and chronic nephrotoxic effects, ranging from direct renal cell damage to obstructive nephropathy caused by metabolite precipitate formation.<sup>43</sup> Renal tubules are highly vulnerable to chemotherapy-induced damage because of their generous blood supply and their resorption of drugs, which prolongs exposure time. Tumor lysis syndrome can also lead to urate nephropathy and renal failure. A list of chemotherapy agents that require dose modification with renal compromise is found in the Appendix.

Cisplatin damages both proximal and distal tubules, with acute focal tubular necrosis of the distal convoluted tubules and collecting ducts. Casts can also form, with dilatation of the convoluted tubules.<sup>42,44</sup> Acute damage often occurs 3 to 21 hours after cisplatin administration and may be irreversible. Patients can have permanent decreases of 20 to 30% in glomerular filtration rates.<sup>44</sup> The histologic changes seen in chronic renal damage include thickening of the tubular basement membrane, interstitial fibrosis, and degeneration of the renal tubule epithelium. Magnesium wasting caused by changes in renal tubular function is a common chronic problem.<sup>44</sup> When tubular damage occurs, urinary excretion of endothelin 1 and Tamm-Horsfall protein may occur.

Ifosfamide can also cause widespread damage throughout the nephron. Often glomerular, proximal, and distal tubule damage is seen, along with renal tubular acidosis. Risk factors include a high cumulative dose, young patient age, concurrent use with cisplatin, and preexisting renal abnormalities.<sup>43</sup> The exact pathogenesis is not certain but is suspected to be related to the metabolite chloroacetaldehyde. Other agents that can cause renal dysfunction are lomustine and carmustine, which cause delayed renal failure; mitomycin-C, which causes microangiopathic hemolytic anemia; and gemcitabine, which causes hemolytic-uremic syndrome (HUS).

Thrombotic thrombocytopenic purpura-hemolytic-uremic syndrome (TTP-HUS) has been associated with mitomycin-C and gemcitabine. To a lesser degree, cisplatin, 5-FU, cytarabine, and daunorubicin have also been reported to cause TTP-HUS.<sup>45</sup> This condition is characterized by thrombocytopenia, anemia, neurologic deficits, renal failure, and fever. Although rare,

it is a serious complication of chemotherapy. Mitomycin-C is thought to cause a decrease in prostacyclin, which leads to direct damage to the renal endothelium and platelet aggregation.<sup>45</sup>

### Rheumatologic Toxic Effects

Arthralgias and myalgias commonly occur after chemotherapy. In general, the symptoms begin 1 to 2 days after therapy and last for 3 to 5 days. Taxanes have been reported to induce moderate to severe arthralgia and myalgia.<sup>46,47</sup> The mechanism of action is unclear, and supportive analgesia is the recommended treatment. Treatment should begin with nonsteroidal or codeine-containing agents and can be advanced to short courses of glucocorticoids, if needed, in more severe cases.<sup>47</sup>

## Agents and Mechanisms of Action

### Antimetabolite Toxic Effects

Antimetabolites are weakly acidic molecules that inhibit cellular metabolism. These agents are all cell cycle phase specific and act as false substrates for deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) synthesis.<sup>48</sup> Methotrexate is an antifolate with activity against leukemia, lymphoma, breast cancer, head and neck cancer, osteogenic sarcoma, colon cancer, bladder cancer, and choriocarcinoma. This agent inhibits de novo purine and pyrimidine biosynthesis and demonstrates the majority of its activity during the S phase of the cell cycle. Methotrexate is a highly specific inhibitor of dihydrofolate reductase that regulates the intracellular tetrahydrofolate pool. When methotrexate becomes polyglutamated, inhibition of thymidylate synthase also occurs.<sup>49</sup>

The primary route of elimination for methotrexate is renal.<sup>49</sup> The methotrexate half-life may be prolonged and toxicity increased in patients with third-space fluid collections (ascites or pleural effusions, which ideally should be drained prior to methotrexate administration) and in bladder cancer with ileal conduits. Intrathecal administration of methotrexate to treat meningeal cancer can also result in myelosuppression or mucositis because therapeutic blood levels may be reached. If high-dose methotrexate with leucovorin rescue is used, patients must receive aggressive intravenous hydration and the urine should be kept at a pH > 7 for 24 to 48 hours by intravenous sodium bicarbonate to ensure that the methotrexate does not precipitate in renal tubules. Blood levels should be monitored every 24 hours starting 24 hours after high-dose methotrexate administration. Leucovorin must be given 24 hours after infusion and continued until the methotrexate blood level is < 50 nM.<sup>49</sup>

The DLT of intravenous methotrexate is myelosuppression. Another common toxic effect is mucositis, which occurs 3 to 7 days after systemic administration.<sup>49</sup> Renal toxic effects

result from intratubular precipitation of methotrexate. Pneumonitis and hepatotoxicity may be seen with chronic daily oral administration.<sup>49</sup> High-dose methotrexate may cause acute encephalopathy (starting within 6 days and resolving 48 to 72 hours later), with paresis, aphasia, behavioral abnormalities, and seizures.<sup>29,50</sup> Chronic encephalopathy may develop 2 to 3 months after high-dose therapy, with dementia and paralysis.<sup>29</sup>

Intrathecal methotrexate may cause acute chemical arachnoiditis, subacute arachnoiditis, and chronic encephalopathy. Acute chemical arachnoiditis occurs immediately after intrathecal therapy. Patients present with nuchal rigidity, vomiting, fever, and inflammatory cell infiltrate in the cerebrospinal fluid. Subacute arachnoiditis occurs in 10% of patients after the third or fourth course of intrathecal therapy and causes cranial nerve palsies, seizures, motor paralysis, or coma.<sup>29,51</sup> Chronic encephalopathy occurs months to years after intrathecal therapy and presents as dementia, limb spasticity, and, in advanced cases, coma.<sup>29</sup>

5-FU is most commonly used in colorectal, breast, head and neck, pancreatic, gastric, anal, and esophageal cancers and hepatocellular carcinoma. Within the cell, 5-FU is converted into active metabolites that are incorporated into DNA or RNA or that inhibit DNA synthesis. 5-FU is eliminated by metabolic conversion by dihydropyrimidine dehydrogenase (DPD). Patients who are DPD deficient because of an inborn error of metabolism experience greater myelosuppression, gastrointestinal toxicity, and neurotoxicity and should not be rechallenged with 5-FU.<sup>49,52</sup> 5-FU is not usually markedly neurotoxic unless administered in the setting of DPD deficiency.<sup>29</sup>

5-FU has a short plasma half-life of 7 to 20 minutes and is generally administered by bolus injection daily for  $\geq 5$  consecutive days or as a multiday continuous intravenous infusion.<sup>49</sup> The main DLT is myelosuppression, which occurs more often with a bolus administration route. Mucositis, diarrhea, and hand-foot syndrome occur more often with continuous drug infusion. 5-FU occasionally causes angina, coronary vasospasm, electrocardiographic changes, cerebellar ataxia, or encephalopathy with somnolence, confusion, seizures, and, rarely, coma.<sup>49,53</sup> Ocular toxic effects include blepharitis, tear duct stenosis, and acute and chronic conjunctivitis.<sup>54</sup> With hepatic artery infusion, cholestatic jaundice with biliary sclerosis can occur.

5-FU interacts with several drugs, which increase its toxicity.<sup>49</sup> When methotrexate is given before 5-FU, 5-FU metabolite formation increases, as does toxicity. When 5-FU is combined with allopurinol, acute or subacute cerebellar dysfunction, visual disturbances, or seizures can occur.<sup>29</sup> Leucovorin enhances 5-FU's effect by forming a ternary complex with thymidylate synthase

and the 5-FU metabolite 5-fluorodeoxyuridine monophosphate.

Capecitabine (Xeloda) is a third-generation oral fluoropyrimidine that is absorbed intact by the gastrointestinal mucosa and is activated by three successive enzymatic steps in the intestine, liver, and tumor (by thymidine phosphorylase). Thymidine phosphorylase is expressed at higher levels in tumor than in normal tissue.<sup>49</sup> Capecitabine is used in breast cancer and in cancers in which 5-FU has clinical activity. Capecitabine is contraindicated in patients with  $\text{CrCl} < 30$  m/min and requires dose reductions in patients with moderate renal impairment. The most common toxic effects include hand-foot syndrome and diarrhea.<sup>49,55</sup> Infrequently, mucositis, myelosuppression, alopecia, and hyperbilirubinemia can be seen.<sup>56</sup> Drug interactions can occur with warfarin and phenytoin.

Cytarabine (Ara-C) is an arabinose nucleoside isolated from the *Cryptotethya crypta* sponge. It is commonly used in leukemias, non-Hodgkin's lymphoma, and meningeal carcinomatosis. Intracellular activation to the triphosphate ara-CTP is required for therapeutic activity. Cytarabine inhibits DNA synthesis and repair. Cytarabine has a short plasma half-life (7–20 minutes) and is excreted in the urine as an inactive metabolite.<sup>49</sup> Intrathecal cytarabine rarely causes encephalopathy, seizures, aseptic meningitis, and myelopathy.<sup>29</sup> The pathophysiology of action of intrathecal cytarabine neurotoxicity is unknown, but the risk appears to be reduced by using preservative-free saline as a diluent. Standard-dose intravenous cytarabine can lead to myelosuppression (neutropenia and thrombocytopenia), nausea, vomiting, diarrhea, intrahepatic cholestasis, and, rarely, pancreatitis. In rare cases, "Ara-C syndrome" can occur, characterized by an allergic reaction presenting as fever, myalgia, bone pain, skin rash, and conjunctivitis. High-dose cytarabine can cause severe myelosuppression, mucositis, cerebral and cerebellar dysfunction, noncardiogenic pulmonary edema, pneumonia, conjunctivitis, and hand-foot syndrome.<sup>49</sup>

Gemcitabine is a fluorine-substituted analogue of deoxycytidine and requires intracellular activation by deoxycytidine kinase. This agent has activity in cancers of the pancreas, lung, ovary, bladder, breast, and colon. Gemcitabine inhibits DNA synthesis and repair and alters RNA processing and messenger RNA translation. Gemcitabine also targets ribonucleotide reductase. Gemcitabine is metabolized in the liver, plasma, and peripheral tissues; most of the drug is excreted in the urine within 24 hours of administration. Common toxic effects of gemcitabine include myelosuppression (neutropenia and thrombocytopenia), flu-like syndrome, mild nausea and vomiting, mild proteinuria or hematuria, and transient elevations in liver function test values. An infusion reaction, characterized by acute onset of dyspnea, flushing, facial swelling, headache, or

hypotension, occurs in a small proportion of patients. In addition, HUS has been reported.<sup>49,57</sup>

## Purine Analogues

6-Thiopurines are used to treat acute leukemia. They inhibit de novo purine synthesis in the cell after conversion by hypoxanthine-guanine phosphoribosyltransferase to ribonucleoside monophosphates. At high doses, most of the agents are eliminated renally. The main toxic effects include myelosuppression (neutropenia and thrombocytopenia), nausea and vomiting, diarrhea, mucositis, cholestatic jaundice, and altered cell-mediated immunity.<sup>49</sup> Drug interactions can occur with allopurinol, which inhibits xanthine oxidase, an enzyme that regulates the thiopurine 6-mercaptopurine. A 6-mercaptopurine dose reduction of 50 to 75% from the standard single-agent dose is needed when this agent is used in conjunction with allopurinol. No dose reductions are needed, however, when using the related agent 6-thioguanine.

The fluorinated antimetabolite fludarabine enters cells and undergoes phosphorylation by deoxycytidine kinase to the triphosphate metabolite fludarabine triphosphate (F-Ara-ATP), which competes with deoxyadenosine triphosphate for incorporation into DNA. This process leads to the inhibition of DNA synthesis and repair and RNA processing. Fludarabine is used primarily in the lymphoid malignancies chronic lymphocytic leukemia and non-Hodgkin's lymphoma. The main route of elimination is renal. The main toxic effects include myelosuppression (neutropenia and thrombocytopenia), nausea and vomiting, diarrhea, fatigue, mild elevation in liver function test values, and fever. In addition, immune system abnormalities can occur.<sup>49</sup> Fludarabine can suppress  $\text{CD4}^+$  and  $\text{CD8}^+$  T cells, leaving patients with an increased risk of opportunistic infections.<sup>58,59</sup> It may be more than a year after treatment before  $\text{CD4}$  counts normalize, and patients should receive trimethoprim-sulfamethoxazole prophylaxis against *Pneumocystis* pneumonia. In rare situations, autoimmune hemolytic anemia and thrombocytopenia can occur.<sup>60</sup>

Cladribine is a purine nucleoside analogue primarily used in the treatment of hairy cell leukemia. This agent can also be used in indolent lymphoid malignancies, such as chronic lymphocytic leukemia, low-grade non-Hodgkin's lymphoma, and some T-cell leukemias. Cladribine enters cells, becomes metabolized to cladribine triphosphate, and accumulates until reaching lymphotoxic levels. This agent also inhibits ribonucleotide reductase and DNA synthesis and repair and can initiate apoptosis of quiescent lymphocytes. A single course of therapy can induce complete remission in 65 to 91% of patients with hairy cell leukemia.<sup>49</sup> Cladribine is eliminated renally, with 25% of the drug excreted unchanged. The most common toxic effects include myelosuppression (neutropenia and

thrombocytopenia), nausea and vomiting, and fever.<sup>61</sup> Approximately 40 to 50% of patients with hairy cell leukemia receiving cladribine develop a fever,<sup>49</sup> which may be related to tumor cell apoptosis and release of cytokines or pyrogens.<sup>62</sup> Cladribine also induces marked immunosuppression, with both T and B cells being affected. Some patients require up to 1 year after cladribine therapy to recover their T-cell counts and up to 2 to 3 years for the B cells to normalize.<sup>63</sup>

### Alkylating Agents

The alkylating agents consist of a wide spectrum of drugs, including cyclophosphamide, ifosfamide, nitrogen mustard, melphalan, chlorambucil, carmustine, procarbazine, dacarbazine, busulfan, and thiotepa. Alkylating agents attack negatively charged, electron-rich nucleophilic sites on DNA, most commonly the N7 of guanine, the N3 of cytosine, and the O6 of guanine. This action alters DNA structure and function and interferes with DNA base pairing, replication, and transcription. Alkylating agents can react with one or two strands of DNA to form a covalent “cross-link.”<sup>32</sup> The main toxic effects of alkylating agents include myelosuppression (which is the DLT), nausea and vomiting, mucositis, diarrhea, oligospermia, amenorrhea, and infertility with prolonged use<sup>32</sup>; teratogenicity with fetal malformations in the first trimester of pregnancy; and carcinogenesis (which is more likely with melphalan than cyclophosphamide). Infrequently, pulmonary interstitial pneumonitis and fibrosis can be seen after treatment with busulfan, melphalan, chlorambucil, cyclophosphamide (particularly with prolonged daily, low-dose oral administration), mitomycin-C, and carmustine.<sup>32</sup> Melphalan, an amino acid analogue, is used in multiple myelomas, high-dose myeloablative therapy, and isolated limb perfusion for melanoma and sarcoma.<sup>32</sup>

Cyclophosphamide is activated by liver P-450 microsomal enzymes into cytotoxic metabolites that cross-link DNA and inhibit DNA synthesis and function at all phases of the cell cycle.<sup>32</sup> Although cyclophosphamide is metabolized extensively in the liver, it is eliminated in the urine. The toxic metabolite acrolein causes hemorrhagic cystitis in 5 to 10% of patients.<sup>64,65</sup> Cyclophosphamide doses must be reduced in patients with renal dysfunction. The major toxic effects associated with cyclophosphamide include myelosuppression (nadir at 1.5 to 2.5 weeks and recovery within 3 weeks for granulocytes), nausea and vomiting, syndrome of inappropriate secretion of antidiuretic hormone (SIADH) with hyponatremia, and hypersensitivity. High-doses may be cardiotoxic. Cyclophosphamide has marked immunosuppressive effects and is often used in the treatment of autoimmune diseases and as part of the preparative regimen for

bone marrow transplantation.<sup>32</sup> Rare cases of neurotoxicity have occurred, causing vision changes, confusion, and dizziness.<sup>29</sup> An uncommon late sequela of cyclophosphamide use is bladder contracture or fibrosis with bladder cancer.<sup>40,64</sup> An increased risk of treatment-related acute myelogenous leukemia is also reported.<sup>66</sup>

Ifosfamide is an isomer of cyclophosphamide and has a similar mechanism of action. Ifosfamide is activated at a slower rate than cyclophosphamide but is more likely to cause hematuria and therefore must be administered with mesna and hydration to provide uroprotection.<sup>32</sup> Ifosfamide is metabolized to chloroacetaldehyde, which is thought to contribute to both its neurotoxicity and renal toxicity.<sup>67</sup> Ifosfamide can cause acute encephalopathy characterized by cerebellar and extrapyramidal symptoms, seizures, and sometimes coma. The clinical findings begin within 1 day of drug infusion and resolve within 3 to 4 days. The risk factors associated with encephalopathy include hypocalcemia, low serum albumin, high dose of the drug, rapid infusion, renal or hepatic impairment, and previous cisplatin exposure.<sup>29</sup> Marked drug interactions can occur, with precipitation of the anticoagulant effect of warfarin and an increased risk of neurotoxicity when given with phenobarbital.<sup>29</sup>

Carmustine, a nitrosourea, can cross the blood-brain barrier and enter the CNS,<sup>32,68,69</sup> where concentrations can reach more than 50% of plasma drug levels. Carmustine is mainly used to treat brain tumors either in an adjuvant setting or for advanced disease.<sup>70</sup> Carmustine spontaneously decomposes into chloromethylisocyanate, which is a known pulmonary toxin.<sup>32,71</sup> Higher cumulative doses of the drug are associated with greater pulmonary toxicity, and pulmonary function tests may be considered at baseline and periodically during treatment. An increased risk of pulmonary toxic effects is seen in patients with a baseline carbon monoxide diffusing capacity < 70%. Nitrosoureas often produce two granulocyte nadirs, with an early drop during the first 3 weeks of treatment, apparent recovery, and then a subsequent drop at 5 to 6 weeks after treatment.<sup>32</sup> Nausea and vomiting are also prominent with carmustine. Carmustine is formulated in ethanol at concentrations that are high enough to cause symptoms in some patients.

Hydrazine and triazine derivatives are agents that methylate the O6 position of the guanylic acid in DNA.<sup>32</sup> Procarbazine, a phenylhydrazine derivative, has clinical activity against brain tumors, Hodgkin’s disease, and non-Hodgkin’s lymphoma.<sup>32</sup> It was originally developed as a monoamine oxidase inhibitor and can potentiate other CNS agents (eg, barbiturates, opiates, antihistamines, and phenothiazines). Hypertensive reactions can occur when using procarbazine with other sympathomimetics, tricyclic antidepressants, or tyramine-rich foods (eg, wine, dark

beer, bananas, yogurt, and ripe cheese). Alcohol use can precipitate a disulfiram (Antabuse) effect, with symptoms of sweating, flushing, and headache. Procarbazine also causes nausea, vomiting and myelosuppression. Procarbazine is activated by the P-450 system; the interaction leads to the formation of a metabolite that methylates DNA. Procarbazine is rapidly and completely absorbed after oral dosing, with peak plasma levels achieved within 1 hour.

Dacarbazine is a triazine derivative that is used in the treatment of melanoma and Hodgkin’s disease.<sup>32</sup> After intravenous administration, dacarbazine is metabolized into a methyl diazonium that methylates DNA.<sup>72,73</sup> It is highly emetogenic and somewhat myelosuppressive. Temozolamide, another triazine analogue that decomposes into a methyl diazonium ion,<sup>32</sup> is administered orally and is much less emetogenic than dacarbazine. It is currently used in the treatment of CNS tumors and melanoma.

### Anthracyclines

The anthracyclines include doxorubicin, daunorubicin, idarubicin, and epirubicin; they are related to the anthracenediones, such as mitoxantrone. Doxorubicin is used in cancers of the breast, lung, ovary, stomach, and bladder and in soft tissue sarcoma, hepatoma, Hodgkin’s disease, and non-Hodgkin’s lymphoma. Daunomycin is used in acute lymphoblastic leukemia and acute myelogenous leukemia. Mitoxantrone has activity in prostate cancer, lymphoma, leukemia, and breast cancer. Anthracyclines and anthracenediones form complexes with topoisomerase II and DNA strands, preventing rejoining of the DNA strands after topoisomerase II temporarily breaks it to enable DNA unwinding for replication. This leads to topoisomerase II–dependent DNA double-stranded breaks. In the presence of iron, these agents can also form free oxygen radicals and cause peroxidation of membrane lipids. These agents are primarily metabolized in the liver, with 40 to 50% excretion in the stool.<sup>74</sup> Dose reductions are required in patients with liver dysfunction.

The main toxic effects associated with anthracyclines are dose-limiting myelosuppression and mucositis, diarrhea, alopecia, skin radiation recall, severe local tissue damage if the drug extravasates into subcutaneous tissues, and red-orange discoloration of the urine for 1 to 2 days after therapy.<sup>74</sup> Cardiotoxicity may be experienced and can be severe. Acute pump failure within the first 2 to 3 days of treatment can occur, with arrhythmias or conduction problems, pericarditis, or myocarditis. Chronic cardiotoxic effects (eg, dilated cardiomyopathy) are associated with a high cumulative dose and are thought to arise from membrane lipid peroxidation related to the

heart's decreased ability to detoxify oxygen free radicals.<sup>28</sup> Associated risk factors include age > 70 years, a history of hypertension or other cardiac disease, previous irradiation of the mediastinal region, and a high cumulative drug dose (eg, above 450 to 500 mg/m<sup>2</sup> for doxorubicin).<sup>25,25</sup> Giving the drug by prolonged administration reduces both the peak drug concentration and the risk of cardiomyopathy but increases the risk of both mucositis and extravasation. Epirubicin is somewhat less cardiotoxic than doxorubicin. Mitoxantrone, which is somewhat less likely to cause nausea and vomiting, alopecia, and cardiotoxic effects than anthracyclines, may cause bluish discoloration of the fingernails, sclera, and urine for 1 to 2 days.

Several drug interactions can occur between P-450 active drugs and the anthracyclines. Phenobarbital and phenytoin may enhance the metabolic clearance of doxorubicin. Cyclophosphamide, mitomycin-C, and trastuzumab can increase the risk of cardiotoxic effects.<sup>25,28</sup> Dexrazoxane, an iron chelator, can reduce the cardiotoxicity of doxorubicin but may also decrease its efficacy.<sup>25</sup>

## Platinum Analogues

Commonly used platinum agents include cisplatin, carboplatin, and oxaliplatin. The platinum agents are among the most useful of all chemotherapy agents, with a very wide range of activity. Cisplatin has activity in breast, lung, head and neck, ovarian, bladder, testicular, esophageal, and gastric cancers.<sup>76</sup> The only common malignancies that are generally unresponsive to platinum are cancers of the colon and kidney. Cisplatin binds covalently to DNA, with preferential binding to the N7 of guanine and adenine, and forms intra- and interstrand DNA cross-links. DNA adduct formation leads to inhibition of DNA synthesis, transcription, and function and induction of apoptosis. The platinum compounds also form complexes with nuclear and cytoplasmic proteins, which contributes to their antitumor activity and toxicity.

Whereas cisplatin is excreted in the urine via glomerular filtration and tubular secretion, the major method by which cisplatin is detoxified is by rapid, irreversible binding to albumin. The active, toxic free drug has a plasma half-life of only about 30 minutes, whereas the half-life of protein-bound drug in the plasma is several days. The main DLT is nephrotoxicity, which affects 30 to 40% of patients.<sup>76,77</sup> Renal damage is cumulative and mainly involves the proximal and distal convoluted tubules. The risk of serious nephrotoxicity is decreased by ensuring adequate hydration during and after drug administration and by use of mannitol to induce diuresis. The risk increases with increasing doses and may be peak concentration related in that it may be more

common in the case of rapid drug administration. Patients often have an asymptomatic, acute rise in serum creatinine in the first few days after cisplatin administration, followed by gradual improvement over the subsequent 2 to 3 weeks. Hypomagnesemia owing to renal wasting is very common and often requires magnesium replacement. In most patients, this condition gradually improves after discontinuation of therapy. Salt wasting, metabolic acidosis, hypocalcemia, hypokalemia, and SIADH caused by tubule damage occur occasionally.<sup>76</sup>

Neurotoxicity can also be dose limiting, with development of an irreversible sensory peripheral neuropathy.<sup>76</sup> Cumulative doses above 400 mg/m<sup>2</sup> will often cause paresthesias and numbness. Peripheral neuropathy may begin several weeks after the completion of therapy, very gradually worsen over time, and then very gradually improve. Cisplatin occasionally causes autonomic neuropathy. Rare cases of encephalopathy, stroke, and seizures have been reported.<sup>29</sup> Impairment of color vision can be detected by sensitive retinal test, but often the impairment is not clinically detectable.

Cisplatin is highly emetogenic. As in other emetogenic chemotherapies, acute nausea is due to damage to gastrointestinal enterochromaffin cells, which causes release of the neurotransmitter serotonin. As serotonin becomes elevated, it triggers nausea and vomiting by interacting with 5-HT<sub>3</sub> receptors in vagal nerve endings and in the chemoreceptor trigger zone. Typically, the nausea and vomiting begin 5 to 6 hours after therapy, although patients who become severely nauseated after one course of therapy may develop anticipatory nausea that occurs much earlier (potentially even while thinking about an upcoming appointment for treatment).

The acute nausea and vomiting generally last for 8 to 12 hours, and delayed nausea (thought to be due to the release of substance P) can last for 3 to 5 days. In addition, foods may taste metallic and the patient may experience a loss of appetite. Ototoxicity causing high-frequency hearing loss (4,000–8,000 Hz) or tinnitus by damaging the cochlear hair cells is very common. Although it is usually very mild, it is severe in some patients and irreversible.<sup>77</sup> The risk of ototoxic effects increases with an increase in the cisplatin dose per course, with an increase in the rate of drug administration (ie, with a high peak concentration) if cranial radiation is also given and with a preexisting hearing impairment. Ototoxic effects typically manifest within 24 hours of drug administration.

Myelosuppression is relatively uncommon with normal doses of cisplatin, and part of this agent's usefulness derives from the fact that full doses of it can be given with full doses of other myelosuppressive agents. Reduced erythropoietin

production is a common consequence of cisplatin nephrotoxicity and causes anemia that is amenable to treatment by recombinant erythropoietin analogues. Anemia may also be caused by a direct effect of cisplatin on bone marrow. Rarely, hemolytic anemia arises.

In rare cases, side effects include arrhythmias, acute ischemic vascular events, Raynaud's syndrome, pulmonary fibrosis, glucose intolerance, and pancreatitis.<sup>44,77</sup> Although cisplatin is not generally regarded as a vesicant, intra-arterial administration may occasionally result in severe local tissue damage.

Several drug interactions do occur with cisplatin administration. Caution is particularly important when cisplatin is given with other nephrotoxic agents (eg, aminoglycosides and amphotericin B). Cisplatin reduces the renal clearance of etoposide, ifosfamide, methotrexate, and bleomycin, and systemic thiol-containing proteins (eg, amifostine and mesna) may inactivate cisplatin. In addition, cisplatin administered before paclitaxel will lower paclitaxel clearance rates, which may lead to increased myelosuppression. Cisplatin's toxicity is also increased if it is administered before topotecan instead of after it. The efficacy of the cisplatin-etoposide combination in small cell lung cancer is schedule dependent, with greater activity if cisplatin is given before etoposide.

Carboplatin is a second-generation compound; its mechanism of action is identical to that of cisplatin, and it has an identical spectrum of antitumor activity, although in some malignancies, it is felt to be somewhat less effective than cisplatin. Its spectrum of toxicity is substantially different from that of cisplatin; however, this is thought to be due to a reduced rate of conversion to the reactive aquated species that bind to DNA and proteins. The major toxic effect is induced by carboplatin myelosuppression, which is dose limiting, with other toxic effects being much less pronounced than with cisplatin.<sup>76,78</sup> Myelosuppression manifests mainly as thrombocytopenia, with a nadir at 17 to 21 days after therapy and recovery by day 28. Additional toxic effects include acute and delayed nausea and vomiting, alopecia, peripheral neuropathy, mild renal pathology, and, in some cases, an allergic reaction that arises after seven or eight courses of therapy.<sup>76</sup> The primary route of carboplatin excretion is renal; the rate of renal excretion is directly proportional to the glomerular filtration rate, permitting accurate prediction of drug pharmacology and toxicity (and adjustment of dose) based on renal function.

Oxaliplatin is a third-generation compound with the same mechanism of action as cisplatin and carboplatin. For reasons that are unclear, however, it has a markedly different spectrum of activity than cisplatin or carboplatin and is most

effective against cancers of the colon, pancreas, and stomach. With oxaliplatin, neurotoxic effects are dose limiting and can present in two forms: acute (< 14 days) or persistent (> 14 days).<sup>76</sup> Acute neurotoxic effects include reversible paresthesias, hypersensitivity to cold, jaw and eye pain, ptosis, muscle cramping, and motor nerve hyperexcitability. Neurotoxicity can manifest a few minutes after drug infusion and resolve within a few days; it recurs after each cycle of treatment. The mechanism of action is suspected to involve axon conductance and neuronal excitability.<sup>29</sup> Neurotoxic effects can be triggered or enhanced by cold temperatures. Laryngopharyngeal dysesthesia, which may present with choking, difficulty breathing, or swallowing, is a dose-dependent effect and is seen in patients receiving more than 850 mg/m<sup>2</sup> oxaliplatin. This dysesthesia is reversible and may last 3 to 4 months. The persistent form of toxic effects occurs after a high cumulative dose of oxaliplatin and is similar to cisplatin-induced neuropathy.<sup>29</sup> This condition is reversible within 4 to 6 months after the cessation of therapy.<sup>76</sup> Oxaliplatin-induced myelosuppression is uncommon, but gastrointestinal toxic effects, such as nausea, vomiting, and diarrhea, may be seen.

### Taxanes

Taxanes target the N-terminal of the  $\beta$  subunit of microtubules and prevent tubulin depolymerization, thereby stabilizing the mitotic spindle complex and preventing tumor cell proliferation.<sup>79</sup> Taxanes are administered intravenously and are primarily metabolized by the liver and excreted in the stool. The main DLT of paclitaxel is myelosuppression, specifically neutropenia.<sup>79</sup> Patients may also experience an acute hypersensitivity reaction to the Cremophor EL vehicle, with dyspnea, bronchospasm, skin flushing, urticaria, and hypotension; the reaction often occurs within the first 2 to 3 minutes of the initiation of infusion and almost always happens within the first 10 minutes.<sup>80</sup> Paclitaxel infusions require premedication with dexamethasone, diphenhydramine hydrochloride (Benadryl), and antihistamine agents. Additional toxic effects include a dose-dependent peripheral neuropathy (mainly sensory but motor or autonomic in some cases), bradycardia, ventricular arrhythmias, rarely mucositis, diarrhea, nausea and vomiting, alopecia, transient elevations of liver function test values, and onycholysis.<sup>79</sup> Paclitaxel has several drug interactions. Concomitant administration of cisplatin will lower paclitaxel clearance rates and increase myelosuppression. Cyclophosphamide can also increase symptoms of myelosuppression when administered before paclitaxel. Paclitaxel reduces the clearance of doxorubicin by 30 to 35%, and P-450 enzyme inducers (eg, phenytoin and phenobarbital) may accelerate the metabolism of paclitaxel and decrease drug levels.

Docetaxel is a semisynthetic derivative that stabilizes tubulin polymerization and has activity in breast, lung, head and neck, ovarian, bladder, testicular, and gastroesophageal cancers. The main toxic effect is myelosuppression, with dose-limiting neutropenia. Up to 25% of patients experience major or minor hypersensitivity reactions if they are not premedicated. Docetaxel can induce a fluid-retention syndrome, with edema, weight gain, pleural effusion, and ascites. The risk of fluid accumulation increases at cumulative doses > 400 mg/m<sup>2</sup>. In 50% of patients, a rash develops on forearms and hands. Additional toxic effects include mild to moderate peripheral neuropathy, mucositis, general malaise, asthenia in up to 70% of patients, and alopecia.<sup>79,81</sup>

### Topoisomerase I Inhibitors

Camptothecins act by binding topoisomerase I, a nuclear enzyme that temporarily breaks DNA and permits it to unwind for replication. Topoisomerase inhibitors permit the topoisomerase to break the DNA but do not permit it to subsequently rejoin the DNA strands, thereby giving rise to single-stranded DNA breaks for agents that inhibit topoisomerase I and double-stranded DNA breaks for agents that inhibit topoisomerase II. The camptothecin derivative irinotecan is active against colorectal, lung, cervical, ovarian, gastric, and esophageal cancers and lymphoma. This agent requires hepatic activation by a carboxylesterase enzyme to form the SN-38 metabolite.<sup>74</sup> The major toxic effects include a dose-limiting diarrhea (acute and delayed), nausea and vomiting, transient elevations in liver function test values, fatigue, and alopecia. In addition, myelosuppression can be dose limiting with an every 3-week schedule and is significantly more likely to arise after the third and fourth cycles of therapy. Less frequently, pneumonitis, arrhythmias, and paralytic ileus can occur.<sup>82,83</sup>

Topotecan is used in small cell lung and ovarian cancers. It can be administered intravenously or orally. Topotecan is eliminated by the kidney and requires a dose reduction in the setting of renal dysfunction. The major toxic effects are dose-limiting neutropenia and myelosuppression; flu-like symptoms with headache, fever, chills, malaise, mild nausea, and vomiting; transient elevation in liver function test values; diarrhea; generalized fatigue; and skin rash.<sup>74,84</sup>

### Topoisomerase II Inhibitors

Topoisomerase II inhibitors include the anthracyclines, the anthracenediones, and etoposide; as noted, these inhibitors cause double-stranded DNA breaks by inhibiting the DNA-rejoining portion of the enzyme's activity. The anthracyclines have been described previously. Etoposide is an epipodophyllotoxin that is active in lung

cancer, germ cell tumors, and non-Hodgkin's lymphoma; etoposide is also used in high-dose therapy with bone marrow or stem cell transplantation. Etoposide is metabolized in the liver by the cytochrome P-450 microsomal system by means of glucuronidation, with about 30 to 50% of the drug excreted in the urine.<sup>74</sup> Patients with renal dysfunction require dose reductions. The main toxic effects owing to etoposide include dose-limiting myelosuppression, nausea and vomiting, mucositis, alopecia, and, rarely, headache, seizures, and somnolence.<sup>29</sup> Patients are also at risk of a hypersensitivity reaction to the polysorbate 80 vehicles, which can manifest as chills, fever, bronchospasm, tachycardia, facial and tongue swelling, and hypotension. Hypersensitivity primarily occurs when the drug is administered rapidly intravenously, whereas it is rarely seen if the drug is given over an hour or more, and it is not seen with oral administration. Etoposide is also carcinogenic and associated with the t(11;23) translocation in acute myelogenous leukemia.<sup>74</sup>

### Vinca Alkaloids

The vinca alkaloids include vincristine, vinblastine, vindesine, and vinorelbine. These agents bind to specific sites on tubulin, prevent tubulin dimer polymerization, and inhibit mitotic spindle apparatus formation. These effects result in mitotic arrest and tumor cell apoptosis. Vinca alkaloids are metabolized in the liver by the cytochrome P-450 system and are excreted in stool.<sup>79</sup> As a class, the vinca alkaloids are potent vesicants. Vincristine is used in pediatric and adult acute leukemias, Hodgkin's and non-Hodgkin's lymphoma, Wilms' tumor, Ewing's sarcoma, neuroblastoma, and rhabdomyosarcoma. The DLT is peripheral neuropathy. As with most other neurotoxic chemotherapy agents, peripheral neurotoxicity is dose dependent and primarily sensory, but it can also involve motor, autonomic, and cranial nerves. Additional toxic effects are paralytic ileus and intestinal obstruction, urinary retention, postural hypotension, and SIADH. Vinblastine is used in germ cell tumors, Hodgkin's lymphoma, and breast cancer. Myelosuppression is dose limiting, and mucositis, alopecia, peripheral neuropathy, and SIADH can also occur. Vindesine causes both myelosuppression and severe peripheral neuropathy. It is occasionally used in the treatment of non-small cell lung cancer.

Vinorelbine is a semisynthetic analogue of vinblastine and is active against non-small cell lung, breast, and head and neck cancers and against Hodgkin's lymphoma; it appears to be more effective than other vinca alkaloids. Vinorelbine is metabolized by the P-450 system, with excretion via the biliary tract and in stool.

Myelosuppression is dose limiting, with neutropenia being most prominent. In addition, nausea and vomiting, diarrhea, constipation, elevated liver function test values, alopecia, peripheral neuropathy, and SIADH can occur. Vinorelbine can cause severe phlebitis in the vein into which it is infused, but the risk of phlebitis is reduced by rapid administration and by postadministration flushing of the vein. Vinorelbine has several drug interactions and can reduce effective blood levels of phenytoin.<sup>79</sup>

### Miscellaneous Agents

Bleomycin is extracted from the fungus *Streptomyces verticillus* and contains DNA-binding and iron-binding regions at opposite ends of the peptide. This agent requires activation by oxidized iron to form oxygen free radicals, which then cause single- and double-stranded DNA breaks and cell death. Up to 70% of bleomycin is excreted in the urine, and dose modification is required in the case of renal dysfunction.<sup>85</sup> The major concern when using bleomycin is its pulmonary toxicity. Patients may develop a reversible acute inflammatory reaction in the lungs, with pulmonary infiltrates evident on chest radiographs; rales may arise after exposure to even low cumulative doses, with a risk of much more serious chronic pulmonary pneumonitis and fibrosis occurring at higher cumulative doses. Approximately 3 to 5% of patients receiving a total of 400 to 450 units develop a subacute or chronic pneumonitis. The proportion increases to 10% in patients treated with higher doses. Presenting clinical symptoms include cough, bibasilar infiltrates, and pulmonary nodules. Additional predisposing factors include age > 70 years, underlying lung disease, previous pulmonary or mediastinal irradiation, and use of high-concentration oxygen.<sup>33</sup> Extreme caution is required to limit the fraction of inspired oxygen during surgery in patients previously treated with bleomycin. Additional toxic effects of bleomycin include hyperpigmentation of skin, thickening of nail beds, ulceration or desquamation in severe cases, vascular events (eg, Raynaud's syndrome, myocardial infarction, and stroke),<sup>86</sup> and hypersensitivity reactions in 25% of patients.<sup>34,85</sup> Cisplatin can decrease the renal clearance of bleomycin and may enhance its toxicity.

### Chemotherapy-Induced Secondary Malignancies

Secondary malignancies induced by chemotherapy were first described in 1947 by Haddow.<sup>87</sup> Chemotherapy interacts with DNA and can cause irreversible genetic mutations that accumulate and progress to frank carcinogenesis. Most carcinogenic agents have long latency periods, and a multistep process involving initiators and

promoters is required. Both the toxic agent and the host immune system and environment play a role in initiating a second malignancy. Combined exposure to chemotherapy and radiation will increase the risk of carcinogenesis (Table 2). Patients with preexisting germline mutations are especially at risk of second malignancies because of both their genetic makeup and the toxicity of the chemotherapy. Included in this category of patients are those who have microsatellite instability or impaired DNA repair mechanisms (eg, hereditary nonpolyposis colorectal cancer and retinoblastoma).<sup>88</sup>

Patients who have loss of heterozygosity in the *TP53* gene are more prone to therapy-related acute myelogenous leukemia after exposure to alkylating agents.<sup>89</sup> In addition, chemotherapy for certain disease types has an above-average risk of secondary malignancies. High-risk diseases (and the chemotherapy regimen or agent causing the secondary malignancy) include Hodgkin's disease (treated with the doxorubicin, bleomycin, vinblastine, and dacarbazine or the mechlorethamine hydrochloride, procarbazine, vincristine, and prednisone regimen), non-Hodgkin's lymphoma (cyclophosphamide, doxorubicin, vincristine, and prednisone), multiple myeloma (melphalan), acute lymphoblastic leukemia (etoposide), testicular cancer (bleomycin, etoposide, and cisplatin), ovarian cancer (cyclophosphamide, doxorubicin, and cisplatin), bone marrow transplantation (alkylator combination

therapy), and breast cancer (high-dose cyclophosphamide-doxorubicin combinations).<sup>90,91</sup> The Surveillance, Epidemiology, and End Results (SEER) database review of 21,708 patients with breast cancer reported an 11.5-fold relative risk of developing a secondary leukemia at 4.2 years.<sup>66</sup> Further studies in 82,700 women with breast cancer reported a 10-fold increase in the relative risk of leukemia with chemotherapy alone and a 17.4-fold higher relative risk after chemotherapy and radiation.<sup>92</sup>

The exact carcinogenic mechanisms of action differ between the classes of chemotherapy drugs. Chemical carcinogens often require metabolic activation to an electrophilic intermediate, which reacts with DNA bases, particularly the negatively charged or nucleophilic N7 of guanine.<sup>93</sup> Cyclophosphamide and mitomycin-C also cause secondary tumors by means of this mechanism, whereas L-phenylalanine mustard and nitrogen mustard do not require metabolism to form alkylating species. Doxorubicin and mithramycin form reactive oxygen intermediates, which can cause DNA strand breaks and lead to carcinogenicity.

### Therapy-Related Acute Myelogenous Leukemia

Therapy-related acute myelogenous leukemia accounts for 10 to 20% of all cases of this cancer.<sup>88</sup> There is no gender or ethnic predisposition, but older age at drug exposure appears to increase the risk.<sup>91</sup> Patients have developed therapy-related acute myelogenous leukemia in response to alkylating agents, topoisomerase II inhibitors, and combination regimens. Unfortunately, most therapy-related acute myelogenous leukemia carries a poor prognosis, with a median survival of 9 months. The exceptions to this general rule include patients with favorable cytogenetics (t(8;21), inv (16), and t(8;16)) who respond to therapy and patients with de novo disease who have the same translocations.<sup>89</sup>

There are two main groups of therapy-related leukemia. The first is acute myelogenous leukemia that results from exposure to topoisomerase II inhibitors and the second from exposure to alkylators.<sup>94</sup> Topoisomerase II inhibitor-related acute myelogenous leukemia occurs 2 to 3 years after treatment and typically has an M4 or M5 phenotype by the French-American-British (FAB) classification system. Alkylator therapy-related acute myelogenous leukemia occurs 5 to 7 years after treatment and is associated with myelodysplasia and loss of chromosomes 5 and 7.<sup>94</sup>

Etoposide, a topoisomerase II inhibitor, has been associated with secondary acute non-lymphocytic leukemia (ANLL), with a risk of 5.9% at 4 years in children.<sup>95</sup> At 6 years, the risk was reported as 3.8%.<sup>96</sup> Pui and colleagues noted that a schedule of twice-weekly or weekly

**Table 2** Carcinogenic Risk of Chemotherapy Agents

etoposide or teniposide increased the risk of ANLL at 6 years to 12.3%.<sup>96</sup> Etoposide causes dose-dependent chromosomal damage that can be perpetuated in cells of the hematopoietic system. It is suspected that cytogenetic abnormalities are due to topoisomerase-induced abnormal sister chromatid exchanges.<sup>97</sup> In vitro studies of etoposide-treated cells have found frequent breaks in chromosomes 1, 11, and 17.<sup>98</sup> Translocations in the *MLL* gene at chromosome 11q23 have been reported.<sup>99,100</sup> Also associated with etoposide-induced ANLL is the lack of a preleukemic phase.<sup>98</sup> A meta-analysis conducted by the NCI Cancer Therapy Evaluation Program on 12 cooperative group trials (11 in the pediatric population) reported a cumulative dose-dependent increase in the risk of secondary leukemias at 6 years after treatment.<sup>101</sup> Patients with germ cell tumors treated with cisplatin, etoposide, and bleomycin have been reported to have a 1 to 4.7% cumulative risk of developing leukemia by 5.7 years after treatment.<sup>98</sup>

Alkylating agent-induced acute myelogenous leukemia has a peak incidence at 4 to 6 years after treatment and a range of onset of 1 to 20 years.<sup>97</sup> A cumulative dose-response effect is associated with an increased risk of myelodysplastic syndrome or acute myelogenous leukemia. Carcinogenesis is caused by direct alkylator therapy-induced stem cell damage. Alkylating agents form covalent bonds with the DNA bases and cause intra- and interstrand DNA cross-linking and breaks. Aberrant DNA coding then occurs, with the potential for malignant transformation.

Studies of multiple myeloma patients report a high incidence of ANLL attributed to previous alkylator-based therapy.<sup>102,103</sup> In an international collaborative group evaluation of cancer registries, alkylator-based chemotherapy had a relative risk of 12, was at greatest risk 4 to 5 years after treatment, and persisted for at least 8 years.<sup>104</sup> The conclusion of this study was that chlorambucil and melphalan were more leukemogenic than cyclophosphamide.<sup>105</sup> Several alkylating agents have been reported to cause therapy-related acute myelogenous leukemia. This list includes cyclophosphamide, ifosfamide, procarbazine, chlorambucil, melphalan, and busulfan.<sup>88</sup> Single-agent melphalan and busulfan reportedly confer the highest acute myelogenous leukemia risk, and combination therapies such as mechlorethamine, Oncovin (vincristine), procarbazine, and prednisone (MOPP) carry a higher risk than single agents.<sup>97</sup> Melphalan has been used in ovarian cancer and is associated with a marked increase in the risk of secondary acute leukemia in some reports, showing a 93- to 174.4-fold increase in risk.<sup>102,105–108</sup> The NCI and Connecticut Tumor Registry reported a relative risk of 4.1 for acute leukemia in 32,251 women treated for ovarian cancer.<sup>109</sup> In breast cancer patients, melphalan

carried a 5-fold higher risk of secondary leukemia.<sup>110</sup>

Anthracycline therapy does not appear to significantly increase the risk of leukemia. The University of Texas M.D. Anderson Cancer Center reported a 0.5% higher risk of secondary leukemia at 10 years in 1,474 patients treated with six cycles of 5-FU, doxorubicin, and cyclophosphamide.<sup>111</sup> Radiation increased the risk to 2.5% at 10 years. However, combination regimens for hematologic malignancies, such as Hodgkin's disease, have been reported to have a significantly greater risk of secondary leukemia. A case-control study conducted in the Netherlands reported that 1,939 patients with Hodgkin's disease had as much as a 40-fold increase in the risk of leukemia owing to treatment with (MOPP).<sup>112–114</sup>

### Solid Tumors

Second primary solid tumors can arise from previous field defects in the aerodigestive tract or previously irradiated areas. In general, single-agent chemotherapy is infrequently associated with second primary solid tumor formation. However, the treatment of certain diseases is associated with higher rates of second primary solid tumors. Up to 20% of patients with Hodgkin's disease can develop second malignancies within 15 years of the primary therapy.<sup>115–117</sup> A German review of 1,500 Hodgkin's disease patients showed a 20-year cumulative risk of 19% for second primary solid tumors.<sup>118</sup> This statistic may be high as a significant proportion of the solid tumors arose from a previously irradiated field.

Cyclophosphamide is associated with bladder toxicity and the development of bladder cancer.<sup>119,120</sup> The risk appears to increase with the cumulative dose, with an overall 4.5-fold increase in risk.<sup>120</sup> The carcinogenic pathway is activated by the acrolein metabolite, which is toxic to bladder mucosa; bladder fibrosis and dysplasia can transform into a malignant phenotype.

### Fertility and Mutagenicity

Cancer occurs in pregnant women at a rate of 1 per 1,000.<sup>121,122</sup> The most common malignancies encountered are breast cancer, melanoma, cervical cancer, lymphoma, and leukemia.<sup>123,124</sup> Chemotherapy agents have known teratogenicity, with the extent of the effect dependent on exposure time, dose, lipid solubility, molecular weight, and the stability of binding to plasma proteins.<sup>122,125</sup> As cytotoxic agents target rapidly dividing cells, the effects on a growing fetus are a major concern when considering the use of chemotherapy in pregnant patients. During pregnancy, the volume of distribution, protein binding, and renal clearance of drugs are typically increased. Other pharmacokinetic factors, such as drug

absorption, are also affected.<sup>126</sup> The timing of delivery is also a concern when pregnant patients undergo chemotherapy as thrombocytopenia can complicate labor.

First-trimester use of chemotherapy should be avoided if possible. Use of chemotherapy during this time will significantly increase the risk of major fetal malformations or spontaneous abortion.<sup>122,125,127</sup> If chemotherapy is necessary during the first trimester of pregnancy, doxorubicin and the vinca alkaloids have the lowest rates of teratogenic effects.<sup>127</sup> The gestational age of the fetus at the time of chemotherapy exposure is the most likely predictor of what type of malformation will occur.<sup>122</sup> The first 2 weeks of pregnancy are highly susceptible to fetal death and spontaneous abortion. This is when the zygote implants and develops amnion. During weeks 2 to 8 after conception, teratogenesis of major organs, such as the heart, neural tube, and limbs, can occur. Limb buds appear between the fourth and sixth weeks of gestation.<sup>127</sup> Even after embryonic organogenesis is completed, the hematopoietic system, CNS (visual), and genitalia remain vulnerable.<sup>122</sup> CNS congenital defects include neural tube defects and mental retardation. Cardiac abnormalities include truncus arteriosus, atrial septal defects, and ventricular septal defects. Amelia, meromelia, cleft lip, low-set malformed ears and deafness, microphthalmia, cataracts, and glaucoma can occur. Also, masculinization of female genitalia and enamel hypoplasia and staining may be seen.

Second- and third-trimester exposure to chemotherapy increases the risk of intrauterine growth retardation (IUGR) and low birth weight.<sup>128</sup> In addition, minor congenital anomalies and functional defects can occur. Some studies report that children exposed to chemotherapy in utero can have normal learning behavior and intact immune and hematologic systems.<sup>129</sup>

### Fetal Effects owing to Specific Chemotherapies

#### Alkylating Agents

In 1968, a review of the literature on alkylating agents found that women treated during the first trimester of pregnancy had a 16% chance of giving birth to children with fetal malformation.<sup>130</sup> First-trimester treatment, but not second- or third-trimester exposure, with cyclophosphamide was associated with marked malformations.<sup>126,131,132</sup> Fetal malformations associated with cyclophosphamide include low-set ears, eye abnormalities, loss of toes, cleft palate, blepharophimosis, a flat nasal bridge, and microcephaly.<sup>122,126</sup> Although safe alkylator agent use in the second and third trimesters has been reported, the risks of fetal death and IUGR are increased, regardless of the timing of exposure.<sup>122</sup> The dacarbazine used in the ABVD regimen for Hodgkin's disease is

associated with intrauterine growth retardation (IUGR) and minor malformations.<sup>122</sup> Busulfan in the second trimester can lead to malformations.<sup>133</sup>

#### Antimetabolites

Methotrexate given at doses greater than 10 mg per week is associated with fetal malformations, such as oxycephaly, low-set ears, skin folds, absence of toes, growth retardation, and rib abnormalities.<sup>127,134</sup> First-trimester exposure to methotrexate has been associated with fetal death.<sup>122,122</sup> 5-FU is very teratogenic and should be avoided in pregnancy, especially in the first trimester.<sup>127</sup> 5-FU in combination with other agents can lead to intrauterine fetal growth malformation and fetal death. Cytarabine exposure, even after the first trimester, leads to limb malformation, intrauterine fetal death (IUFD), fetal growth retardation, and neonatal death.<sup>122</sup> Cytarabine is highly teratogenic in animals and is recommended only in the second and third trimesters of pregnancy.<sup>127</sup> However, chromosome abnormalities have been reported with cytarabine exposure throughout all trimesters.<sup>127</sup> Cytarabine also causes low birth weight, perinatal seizures, cytopenias, and preterm labor.<sup>127</sup> 6-Mercaptopurine crosses the human placenta, but only a 1 to 2% fetal blood concentration is seen.<sup>126</sup> Mercaptopurine has been reported to cause IUGR and IUFD but has a lower degree of association with congenital abnormalities.<sup>122</sup> First-trimester use of 6-mercaptopurine has been associated with chromosomal, hematologic, and immunologic abnormalities in the fetus.<sup>126</sup> Second-trimester use of 6-mercaptopurine has also led to chromosomal changes.<sup>126</sup>

#### Anthracyclines

Anthracycline use during pregnancy has been associated with transient marrow hypoplasia, fetal limb malformations (after first-trimester exposure), IUGR, IUFD, and transient myelosuppression. Although cardiotoxicity is a concern in patients receiving anthracyclines, it is unclear whether fetal exposure leads to cardiotoxicity. Idarubicin, a more lipophilic agent, has been associated with IUFD and cardiomyopathy. In one study of a small number of cases, 23% of fetuses and neonates exposed to epirubicin-based combination chemotherapy died. Doxorubicin, with its higher protein binding, is recommended instead of epirubicin or idarubicin in pregnant women but only in the second or third trimester.<sup>122,126</sup>

#### Vinca Alkaloids

Vinca alkaloids are less teratogenic than the antimetabolite agents.<sup>122,125,135</sup> Fetal malformations can occur with first-trimester use, especially when

vinca alkaloids are used in combination therapy. However, single-agent vinblastine has been used in all trimesters without evidence of teratogenicity.<sup>127</sup>

#### Taxanes

Taxanes have been reported to be lethal in animal models. Only a small number of case reports involving taxane exposure have been published, and although no malformations were seen, taxanes are not recommended in pregnancy because of the paucity of information.<sup>122</sup>

#### Platinum Agents

Platinum agents have been associated with fetal sensorineural hearing loss, cardiomegaly, CNS abnormalities, IUGR, and IUFD.<sup>122</sup> Cisplatin is preferred over carboplatin for use in pregnancy because carboplatin is more likely to cause thrombocytopenia and has the potential for higher placental transfer because it is less protein bound than cisplatin.<sup>122</sup> Published case reports suggest that use of cisplatin is safe in the second and third trimesters of pregnancy.<sup>127</sup>

#### Topoisomerase II Inhibitors

There is limited information about the use of etoposide in pregnancy. The agent has been associated with neonatal alopecia and ventriculomegaly.<sup>136,137</sup>

#### Male Fertility

In men, the seminiferous tubules are lined by spermatogenic and Sertoli's cells. Sertoli's cells regulate the release of spermatozoa from the germinal epithelium and maintain the blood-testis barrier.<sup>138</sup> Chemotherapy can be directly toxic to immature spermatozoa in the germinal epithelium or to Sertoli's and Leydig's cells. Cytotoxic agents can block maturation of spermatozoa and lead to incompetency.<sup>138</sup> Once the seminiferous tubules are damaged, testicular atrophy becomes clinically evident. Increased serum follicle-stimulating hormone is seen when spermatogenesis is impaired.

In animal models, Sertoli cell damage and abolition of sperm release from the germinal epithelium occur after doxorubicin, cisplatin, 5-FU, and methotrexate administration.<sup>138,139</sup> Doxorubicin has been shown to cause an absence of primary spermatocytes.<sup>138,140</sup> Cisplatin affects intermediate- and late-stage spermatids with Sertoli cell damage.<sup>141</sup> 5-FU leads to arrest in spermatid development.<sup>139</sup> Carmustine and procarbazine affect stem cells and early and intermediate spermatogonia.<sup>141</sup>

Alkylating agents are the chemotherapy agents most likely to cause male infertility.<sup>138</sup> Cyclophosphamide affects early and late spermatogonia and spermatocytes, resulting in decreased sperm counts.<sup>138</sup> Alkylator therapy has

been shown to cause Leydig cell dysfunction in up to 30% of men.<sup>142</sup> In multiple-agent therapy, chromosome abnormalities in human sperm have been reported.<sup>142</sup>

In general, spermatogenesis can recover, even after high-dose chemotherapy is given. Standard or conventional doses of vinblastine, etoposide, bleomycin, and ifosfamide do not appear to impact long-term fertility.<sup>143,144</sup> However, cyclophosphamide at a cumulative dose higher than 7.5 g/m<sup>2</sup> can cause irreversible infertility.<sup>145</sup> Patients with testicular cancer who receive more than four cycles of chemotherapy also are at greater risk of infertility.<sup>143</sup> Fertility recovery depends on the amount of chemotherapy and its duration of administration. Treatment with multiple agents causes longer-lasting azoospermia than single-agent therapy and increases the risk of long-term infertility.

#### Female Fertility

During oogenesis, a primitive female germ cell gives rise to a mature ovum. Oocytes are coated by granulosa cells and remain in prophase until they become a mature or graafian follicle prior to ovulation. Oocytes that are not ovulated become atresic and are resorbed.

Chemotherapy affects follicular growth and maturation. Ovarian fibrosis and follicle destruction may occur, followed by amenorrhea and elevation of serum follicle-stimulating hormone and luteinizing hormone.<sup>146,147</sup> Vaginal atrophy and endometrial hypoplasia then occur. Younger patients appear to recover from amenorrhea more quickly than older ones, although age and the amount of chemotherapy taken together will better predict the timing of ovarian function recovery.<sup>47,148</sup> Alkylating agents (particularly busulfan) are the most likely to cause ovarian dysfunction.<sup>138</sup>

In animal models, cyclophosphamide is directly toxic to ovarian follicles and decreases serum estradiol and progesterone.<sup>149</sup> Doxorubicin also causes apoptotic changes in oocytes, with bax protein up-regulation. In humans, busulfan at a dose of 0.5 to 14 mg daily for 3 months can cause permanent amenorrhea.<sup>138,150</sup> Antimetabolites such as methotrexate, conversely, do not appear to have ovarian toxicity.<sup>151</sup> Etoposide at doses up to 5 g causes oligo- or amenorrhea in 41% of women.<sup>152</sup> Despite the animal model data, doxorubicin is less toxic to ovaries than are alkylating agents.<sup>138</sup> Combination regimens have a higher risk of amenorrhea and ovarian failure.<sup>47,138</sup> Among women receiving 6 months of adjuvant chemotherapy (cyclophosphamide, methotrexate, and 5-FU) for breast cancer, those over 40 years old had a 70% ovarian failure rate and those younger than 40 years had a 40% failure rate.<sup>47,153</sup>

## Effects on the Immune System: Autoimmunity

Postchemotherapy rheumatism is a disease characterized by noninflammatory musculoskeletal pain that is symmetric and associated with stiffness and mild swelling in both large and small upper and lower extremity joints.<sup>154</sup> This condition occurs in the absence of metastatic cancer or laboratory findings of rheumatologic disease. It has most often been reported in patients who received adjuvant chemotherapy for breast cancer (cyclophosphamide combined with methotrexate and 5-FU or doxorubicin and 5-FU). Many of the patients reported developed rheumatic complaints 2 to 6 months after completing chemotherapy.<sup>155–157</sup> Symptoms include myalgia, arthralgia, arthritis, periarticular swelling, and tenosynovitis. Postchemotherapy rheumatism has also been reported in patients with ovarian cancer who received cyclophosphamide-based therapy.<sup>158</sup> In addition, chemotherapy has been reported to worsen rheumatic complaints in patients with preexisting disease.<sup>159</sup> The biologic mechanism of postchemotherapy rheumatism is not known.<sup>159</sup>

Autoimmune vascular abnormalities have been associated with cytotoxic chemotherapy. It is well known that 5-FU induces a cardiotoxic effect, which can range from anginal symptoms to myocardial infarction and death. The exact mechanism of action is unknown but is suspected to involve either an autoimmune reaction to 5-FU or 5-FU-induced cell death that leads to an inflammatory response.<sup>53</sup> 5-FU may also induce acute coronary artery spasm while the drug is being administered. 5-FU has also been reported to induce Raynaud's syndrome, with digital ischemia and necrosis.<sup>160</sup> Raynaud's syndrome has also been reported in combination regimens using bleomycin, vinblastine, and cisplatin as measured by hand arteriography.<sup>86</sup>

Autoimmune reactions have been reported in patients receiving purine analogues, such as fludarabine and 2-chloro-2'-deoxyadenosine.<sup>161</sup> The proposed mechanism of action includes an allergic reaction to agents, cytokine release, or T-cell imbalance, leading to release of autoantibodies. The most common conditions that can result include hemolytic anemia, thrombocytopenia, bicytopenia (Evans's syndrome), and neutropenia.<sup>161</sup> In some instances, vasculitis, urticaria, pemphigus, interstitial pneumonia, and glomerulonephritis may also arise.

HUS is a serious condition characterized by renal failure, microangiopathic hemolytic anemia, and thrombocytopenia.<sup>162</sup> Mitomycin-C and gemcitabine have been associated with HUS.<sup>163,164</sup> Up to 10 to 15% of patients receiving mitomycin-C develop HUS,<sup>164,165</sup> and gemcitabine is reported to induce HUS in 0.015 to 0.25% of patients.<sup>57,162,163</sup> Chemotherapy-induced HUS carries a poor prognosis, with high mortality rates.<sup>163</sup>

Mitomycin-C-induced renal failure can develop 8 to 10 months after therapy and is associated with direct damage to renal endothelial cells.<sup>164</sup> Gemcitabine-induced HUS is associated with high cumulative doses of gemcitabine (2.5–40.3 g<sup>2</sup>) and has a delayed presentation of 3.8 to 13.1 months.<sup>163</sup> Plasma exchange has been reported to benefit HUS therapy.

## Appendix

### Dose Reductions Required in Cases of Organ Dysfunction

#### Chemotherapy agents requiring dose reduction in patients with liver dysfunction

Amsacrine  
Daunorubicin  
Doxorubicin  
Epirubicin  
Idarubicin  
Mitoxantrone  
Paclitaxel  
Docetaxel  
Vinblastine  
Vincristine  
Thiotepa  
Irinotecan

#### Chemotherapy agents requiring dose reduction in patients with renal dysfunction

Methotrexate  
Capecitabine  
Fludarabine  
Cisplatin  
Carboplatin  
Oxaliplatin  
Bleomycin  
Cyclophosphamide  
Ifosfamide  
Etoposide  
Hydroxyurea  
Topotecan

# Systemic Sequelae of Bioimmunotherapy

Auris Huen, PharmD  
Saroj Vadhan-Raj, MD

In the last two decades, bioimmunotherapy has achieved great strides in establishing its role in medical treatment. Agents previously investigated for salvage or palliative purposes are considered part of standard treatment for untreated patients. Since the introduction of the first recombinant protein, human insulin, into the market, many biologic drugs have been approved by the Food and Drug Administration (FDA) for clinical use in the United States.

Bioimmunotherapy encompasses all therapy related to the modification of the immune system's response to infection or malignancy.<sup>1</sup> The roots of biotherapeutics trace back to before the nineteenth century, when manipulation of the immune response was used to treat cancer, but the inability to produce adequate quantities limited their broad clinical application. Advancements in production techniques in the 1970s to 1980s allowed for large quantities of purified product to be readily available for investigation. In the past two decades, many new biologic compounds have been identified with the use of powerful molecular biology tools.

Several classes of agents fall under the umbrella of bioimmunotherapy, including monoclonal antibodies (MoAbs), interferons, interleukins (ILs), cytokine antagonists, and growth factors. Although grouped together, agents in this category are vastly different in character and treatment indications. These agents generally differ from traditional chemotherapy in both side-effect profiles and dose-toxicity relationships.<sup>2</sup> This chapter will focus on only the biologic agents that have been FDA approved or investigated for therapeutic applications in oncology or as supportive care agents. The goal is to provide an overview of their systemic effects.

## Bioimmunotherapy Agents and Systemic Effects

### Monoclonal Antibodies

The discovery of antibody-based therapy began in 1890 when transferable immunity was first described by von Behring and Kitasato in the

animal model.<sup>3</sup> However, it was not until the discovery of hybridoma technology<sup>4</sup> by Kohler and Milstein in 1975 that the large-scale production of therapeutic monoclonal antibodies (MoAbs) became possible.

The MoAbs bind to specific antigens on the surface of the targeted cell and, once bound, incite an immune response to the antigen and consequently the cell bound to the antigen. Some antibodies may also directly induce apoptosis via other pathways.<sup>5</sup>

Early murine MoAb carried 100% murine protein sequences and incited severe hypersensitivity reactions owing to the development of human antimouse antibodies (HAMAs).<sup>6,7</sup> The HAMA response impairs targeting and accelerates MoAb clearance, subsequently decreasing its potency. Development of partly human (chimeric) and humanized (complementary determining region grafted) MoAb via recombinant deoxyribonucleic acid (DNA) technology significantly decreased this immunogenic response.<sup>8</sup> A chimeric molecule is still detectable in human circulation for 2 weeks compared with 2 days for a murine molecule.<sup>6</sup> Most therapeutic antibodies are chimeric (30–35% murine) or humanized (< 10% murine), but murine antibodies are also in use. Although occurring at a lower rate, human antichimeric antibody and human antihuman antibody have also been reported.<sup>2</sup>

MoAbs can be classified into three groups: unconjugated (naked), conjugated with immunotoxins, and radioimmunotherapy. Table 1 summarizes the currently approved MoAbs, their biologic targets, and FDA-approved indications.<sup>9–24</sup>

### Unconjugated Antibodies

Unconjugated antibodies independently mediate cell death via recruitment of an immune response via antibody-dependent cell-mediated cytotoxicity (ADCC) and complement-dependent cytotoxicity. In ADCC, the Fc constant region of the antibody engages effector cells such as natural killer (NK) cells, monocytes, and macrophages. These effector cells function to illicit phagocytosis and cytotoxicity. The Fc region additionally activates complement.<sup>5</sup> This mechanism requires

high tumor expression of the antigen and tight antibody-antigen binding. Antibody-mediated calcium channel inhibition may also directly induce apoptosis independently of an immune response, such as with rituximab.<sup>25</sup> Examples of unconjugated MoAb include rituximab, alemtuzumab, trastuzumab, cetuximab, and bevacizumab, each specific to a spectrum of antigenic targets.

Unconjugated antibodies are used clinically for treatment of hematologic and solid tumor malignancies, as well as for management of infections. Single-agent response rates in hematologic malignancies range from 20 to 48%.<sup>26–28</sup> Given that the biologic targets of antibodies differ from those of traditional cytotoxic chemotherapy, MoAbs may also enhance the chemotherapy response without increasing toxicity and overlapping patterns of resistance.<sup>29</sup>

Adverse events of unconjugated MoAb predominantly involve hypersensitivity or infusion-related reactions. These symptoms can vary from rash, fevers, chills, and rigors to severe urticaria, hypotension, bronchospasm, dyspnea, and anaphylaxis. These reactions can occur in up to 77% of patients receiving MoAb infusion. Infusion reactions generally improve with subsequent doses and are managed successfully with supportive medications.<sup>12</sup> Other less common adverse effects reported with unconjugated MoAb include cardiotoxicity associated with trastuzumab; severe and prolonged immunosuppression and infections with alemtuzumab; hypertension, coagulopathy, and decreased wound healing with bevacizumab; and acneiform rash with cetuximab.

Cardiotoxicity is not uncommon among cancer agents.<sup>30</sup> The risk of development of cardiotoxicity with trastuzumab is 4% with monotherapy and 27% when used concurrently with anthracyclines and cyclophosphamide.<sup>31</sup> But unlike anthracycline-induced cardiotoxicity, the cardiac effects associated with trastuzumab are generally asymptomatic or mild and responsive to medical management. Cardiomyopathy with trastuzumab did not appear to be dose dependent, and some patients are able to continue with trastuzumab therapy with proper management

Table 1 Monoclonal Antibodies and Their Treatment Indications<sup>9-24</sup>

Drug	Target	Indication(s)
<b>Unconjugated MoAb for oncology indication</b>		
Alemtuzumab (Campath)	Anti-CD52 antibody	B-cell chronic lymphocytic leukemia in patients who have been treated with alkylating agents and who have failed fludarabine therapy
Bevacizumab (Avastin)	Anti-VEGF antibody	For use in combination with intravenous 5-fluorouracil-based chemotherapy as a first-line treatment for metastatic colorectal cancer
Cetuximab (Erbix)	Anti-HER1 antibody	(1) In combination with radiation therapy, is indicated for the treatment of early stages of most types of head and neck cancer (2) Patients with head and neck cancer whose tumor has grown larger or has spread to other parts of the body after receiving treatment containing a platinum-based chemotherapy (3) EGFR-expressing metastatic colorectal carcinoma ± irinotecan-based chemotherapy
Rituximab (Rituxan)	Anti-CD20 antibody	(1) For relapsed or refractory low-grade or follicular, CD20-positive, B-cell NHL (2) For the first-line treatment of diffuse large B-cell, CD20-positive, NHL (a type of NHL) in combination with CHOP or other anthracycline-based chemotherapy regimens (3) For use in combination with methotrexate for reducing signs and symptoms in adult patients with moderately to severely active rheumatoid arthritis who have had an inadequate response to one or more TNF antagonist therapies
Trastuzumab (Herceptin)	Anti-HER2 antibody	For metastatic breast cancer in HER2-overexpressed tumors
<b>Unconjugated MoAb for autoimmune diseases and other indications</b>		
Adalimumab (Humira)	Anti-TNF antibody	(1) Reducing signs and symptoms, inducing major clinical response, inhibiting the progression of structural damage, and improving physical function in adult patients with moderately to severely active rheumatoid arthritis (2) Reducing signs and symptoms of active arthritis in patients with psoriatic arthritis
Basiliximab (Simulect)	Anti-IL-2 receptor antibody	Prophylaxis of acute organ rejection in patients receiving renal transplants
Daclizumab (Zenapax)	Anti-IL-2 receptor antibody	Prophylaxis of acute organ rejection in patients receiving renal transplants
Efalizumab (Raptiva)	Anti-CD11a antibody	For chronic moderate to severe plaque psoriasis in adults age 18 yr or older
Infliximab (Remicade)	Anti-TNF- $\alpha$ antibody	(1) Reducing signs and symptoms, achieving clinical remission and mucosal healing, and eliminating corticosteroid use in patients with moderately to severely active ulcerative colitis who have had an inadequate response to conventional therapy (2) Reducing signs and symptoms and inducing and maintaining clinical remission in patients with moderately to severely active Crohn's disease who have had an inadequate response to conventional therapy (3) Reducing the number of draining enterocutaneous and rectovaginal fistulae and maintaining fistula closure in patients with fistulizing Crohn's disease (4) Reducing signs and symptoms in patients with active ankylosing spondylitis (5) Reducing signs and symptoms of active arthritis in patients with psoriatic arthritis (6) In combination with methotrexate for reducing signs and symptoms, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis
Muromonab CD3 (Orthoclone OKT3)	Anti-CD3 antibody	Treat rejection of transplanted organs, including the heart, kidneys, and liver
Omalizumab (Xolair)	Anti-IgE antibody	For moderate to severe persistent asthma in adults and adolescents
<b>Unconjugated MoAb for infectious disease</b>		
Palivizumab (Synagis)	Antibody directed at the epitope of the A antigenic site of the F protein of RSV	Prevention of serious lower respiratory tract disease caused by RSV in pediatric patients at high risk of RSV disease
<b>Radioimmunotherapy</b>		
Ibritumomab Tiuxetan (Zevalin)	Anti-CD20 antibody attached to <sup>90</sup> yttrium	Relapsed or refractory low-grade, follicular, or transformed B-cell NHL, including patients with rituximab (Rituxan) refractory follicular NHL
Tositumomab <sup>131</sup> iodine (Bexxar)	Anti-CD20 antibody attached to <sup>131</sup> iodine	Relapse or refractory low-grade follicular lymphoma or transformed NHL, including patients with rituximab refractory NHL
<b>Immunoconjugate</b>		
Gemtuzumab Ozogamicin (Mylotarg)	Anti-CD33 antibody attached to calicheamicin derivative	Relapsed acute myeloid leukemia in first relapse patients who are 60 yr of age or older and who are not considered candidates for cytotoxic chemotherapy

CHOP = cyclophosphamide, doxorubicin, Oncovin (vincristine), and prednisone; EGFR = epidermal growth factor receptor; IgE = immunoglobulin E; IL = interleukin; MoAb = monoclonal antibody; NHL = non-Hodgkin's lymphoma; RSV = respiratory syncytial virus; TNF = tumor necrosis factor; VEGF = vascular endothelial growth factor.

and monitoring.<sup>32</sup> The mechanism of trastuzumab-associated cardiotoxicity is still being investigated. It has been postulated that trastuzumab may have direct cardiotoxic effects on the heart mediated by the presence of HER2 receptors on cardiac tissue.<sup>33</sup>

Alemtuzumab targets the CD52 antigen expressed on B and T lymphocytes. Most treated patients will experience significant and prolonged lymphopenia by 2 to 4 weeks that may persist up to 1 year.<sup>34,35</sup> Concurrently, patients may also experience neutropenia between 2 and 12 weeks, with extreme cases lasting several months.<sup>36</sup> A combination of these factors leads to increased risk of infection and infection-related mortality. In addition to bacterial infections, atypical infections with *Pneumocystis jiroveci* (formerly *P. carinii*), viral reactivation, and invasive fungal infections are common.<sup>37</sup>

The use of bevacizumab to block angiogenesis by vascular endothelial growth factor (VEGF) is associated with cardiovascular adverse effects, coagulopathy, and decreased wound healing. Hypertension is a common adverse effect associated with bevacizumab. VEGF antagonism has been linked to inhibition of nitric oxide, leading to vasoconstriction. The reported incidence is 15 to 30%, with only 2% graded as severe.<sup>10,38</sup> Hemorrhage and thrombosis have been reported with bevacizumab. The risk of severe hemorrhage or thrombosis is low. VEGF inhibition has been proposed to decrease the ability of endothelial cells to respond to injury, thereby increasing the risk of bleeding. A prothrombotic state has been attributed to inhibition of nitric oxide-mediated platelet aggregation.<sup>10,39,40</sup> Wound complications and dehiscence have been associated with bevacizumab.<sup>10</sup>

Dermatologic toxicity has been reported in clinical trials with cetuximab. Up to 89% of treated patients reported dermatologic side effects, but only 11% were severe.<sup>41</sup> The most common presentation is a follicular rash, usually in an acneiform distribution. Although the precise mechanism of development of rash has not been elucidated, inhibition of the epidermal growth factor receptor pathway by cetuximab may interfere with development of hair follicles, leading to an inflammatory response.<sup>42,43</sup>

Unconjugated MoAbs are also indicated in the treatment of various autoimmune indications. Most of these agents are targeted at cytokines and are discussed in the cytokine antagonist section of this chapter.

### Conjugated Antibodies

Therapeutic MoAbs may be used as delivery vehicles for toxins and cytotoxic therapy, theoretically targeting only specific diseased cells and sparing normal ones. Immunotoxins are conjugated antibodies with protein toxin bound to the MoAb.

Protein toxins disrupt protein synthesis and ultimately lead to cell death. This mechanism requires the antibody- (with toxin) antigen complex to undergo endocytosis once binding occurs at the cell surface, thereby delivering the toxin directly into the targeted cells.<sup>5</sup>

Gemtuzumab ozogamicin is a conjugated MoAb with activity in acute myeloid leukemia (AML) targeting CD33-positive cells. The antibody portion is attached to a derivative of the highly potent natural toxin calicheamicin via a carboxylic acid linker. An overall remission rate of 26% (defined as less than 5% bone marrow blasts, a normal white blood cell count without blasts, and transfusion independence) has been reported for elderly patients with relapsed AML (based on three multicenter phase II trials).<sup>24</sup> In addition to hypersensitivity reactions, gemtuzumab ozogamicin has also been associated with myelosuppression and hepatotoxicity. Venooclusive disease (incidence up to 17% of treated patients) has been attributed to the calicheamicin derivative.<sup>44</sup>

### Radioimmunotherapy

Historically, one of the drawbacks of radiotherapy had been the inability to target tumor cells while sparing normal tissue. Using the same principle as antibody-conjugated chemotherapy, radioimmunotherapies also use MoAb as a delivery mechanism to provide targeted therapy. MoAb conjugates are labeled with a  $\beta$ -emitting isotope, such as <sup>90</sup>yttrium and <sup>131</sup>iodine, and can deliver localized radiation therapy by binding to antigens on tumor cells. Additionally, radiation is emitted to surrounding tumor cells. This effect on neighboring cells is sometimes referred to as the “bystander effect.”<sup>25</sup> Cytotoxicity occurs independently from receptor internalization and an immune-mediated response. For the treatment of relapsed non-Hodgkin’s lymphoma, radioimmunconjugates <sup>90</sup>yttrium ibritumomab tiuxetan and <sup>131</sup>iodine tositumomab <sup>131</sup>iodine have approximate overall response rates of 39 to 92%.<sup>45</sup> <sup>90</sup>Yttrium ibritumomab tiuxetan has demonstrated superior activity over the naked MoAb rituximab.<sup>46</sup> Both radioimmunotherapy agents are murine antibodies and target the CD20 antigen on B lymphocytes. The murine antibody was chosen in this class of agents to increase clearance and decrease prolonged radiation exposure. Adverse reactions are generally mild but primarily include prolonged myelosuppression, with nadirs occurring 5 to 8 weeks from therapy. Small fractions of patients receiving tositumomab <sup>131</sup>iodine may develop hypothyroidism despite thyroid protection during treatment.<sup>45</sup>

The MoAbs have been used successfully in the treatment of various diseases outside the oncology arena. Palivizumab is the first MoAb indicated for treatment of infection. It is directed

against the epitope of the A antigenic site on the F protein of respiratory syncytial virus (RSV), thereby inhibiting RSV replication. The agent is indicated for the prevention of RSV infections in high-risk pediatric patients.<sup>21</sup>

Research is ongoing uncovering new antigenic targets for which MoAbs may be used as part of a treatment modality. New routes of administration, such as intraperitoneal and intrathecal, are also currently being investigated, increasing the utility of these agents.<sup>47,48</sup>

### Interferons

Over 40 years ago, Isaacs and Lindenmann described a protein that “interfered” with viral growth.<sup>49</sup> This substance, called interferon (IFN), has been investigated extensively for treatment of oncologic and nonmalignant diseases. Various mechanisms of action and biologic activity have been reported, but the details have only been partially elucidated.<sup>50</sup> IFNs impair viral replication by synthesis of a number of enzymes that interfere with cellular and viral processes. They also possess antitumor activity, which seems to be related to both modulation of the immune response to the tumor cells and direct antiproliferative effects.<sup>49</sup>

IFNs are divided into two major groups based on binding to either the type I or type II IFN receptor. The type I IFNs are IFN- $\alpha$ , IFN- $\beta$ , IFN- $\omega$ , and IFN-tau. IFN- $\gamma$  is the only type II IFN. On viral stimulation, almost all cells will produce type I IFNs, but the primary sites of production are leukocytes and fibroblasts. In contrast, type II IFNs are produced by T cells and NK cells following immunologic stimuli, such as with T cell-specific antigens and staphylococcal enterotoxin A.<sup>49</sup> IFNs are species specific and receptor dependent. Binding of IFNs to receptors outside the cell membrane leads to the phosphorylation of Janus-activated kinase (Jak) molecules intracellularly. Signal transducers and activators of transcription in the cytoplasm are activated by Jak, which translocates to the nucleus to activate transcription of IFN-stimulated genes.<sup>49,50</sup> Biologic activities of IFNs include inhibition of cell proliferation, enhanced phagocytic activity of macrophages, increased cytotoxic activity of NK cells, enhanced major histocompatibility complex (MHC) class I and II antigen presentation pathways, and antiangiogenic effects.<sup>49–51</sup>

The development of DNA technology for the sequencing and cloning of genes led to the ability to produce and purify large quantities of IFN for clinical application.<sup>49</sup> Table 2 lists the IFNs approved for treatment of various malignant and nonmalignant diseases.<sup>52–60</sup>

#### Interferon- $\alpha$

The primary production sites for IFN- $\alpha$  are the leukocytes. This subgroup of IFNs possesses a multitude of modulatory activity in immune and

Table 2 Types of Interferon and Treatment Indications<sup>52–60</sup>

IFN	FDA Indication(s)
IFN- $\alpha$ 2a, recombinant (Roferon-A)	AIDS-related Kaposi's sarcoma CML, chronic phase Hairy cell leukemia Chronic hepatitis C
Pegylated IFN- $\alpha$ 2a (Pegasys)	Chronic hepatitis B and C
IFN- $\alpha$ 2b, recombinant (Intron A)	AIDS-related Kaposi's sarcoma Condyloma acuminatum Follicular lymphoma Hairy cell leukemia Chronic hepatitis B and C Malignant melanoma
Pegylated IFN- $\alpha$ 2b (Peg-Intron)	Chronic hepatitis C
IFN- $\alpha$ n3 (Alferon N)	Refractory or recurring condylomata acuminata
IFN alfacon-1 (Infergen)	Chronic hepatitis C
IFN- $\beta$ 1a (Avonex, Rebif)	Multiple sclerosis
IFN- $\beta$ 1b (Betaseron)	Multiple sclerosis
IFN- $\gamma$ 1b (Actimmune)	Chronic granulomatous disease Malignant osteopetrosis

AIDS = acquired immune deficiency syndrome; CML = chronic myeloid leukemia; FDA = US Food and Drug Administration; IFN = interferon.

tumor cells. In tumor cells, IFN- $\alpha$  has been observed to directly inhibit tumor proliferation, as well as up-regulation of tumor-specific antigens, MHC I, and adhesion molecules. Stimulatory effects are also reported in NK cells and macrophages. IFN- $\alpha$  can also lead to both stimulatory and inhibitory effects on T lymphocytes.<sup>49</sup> Currently, four forms of IFN- $\alpha$  are available in the United States. IFN- $\alpha$ 2a and IFN- $\alpha$ 2b are both recombinant proteins derived from *Escherichia coli*. The two agents differ by a single amino acid at position 23. IFN- $\alpha$ n3 is produced from pooled units of human leukocytes stimulated by the Sendai murine virus.<sup>56</sup> In contrast, IFN alfacon-1 is a recombinantly produced non-naturally occurring IFN. Its polypeptide sequence was derived by scanning sequences of several naturally occurring IFN- $\alpha$  subtypes.<sup>57</sup> Pegylated formulations of IFN- $\alpha$  combine the IFN molecule to a polyethylene glycol moiety. This slows the metabolism of the molecule and provides increased sustained exposure and increased efficacy.<sup>61,62</sup>

IFN- $\alpha$  has been used in both oncology and nononcologic diseases. IFNs exhibit antitumor activity in solid tumors and hematologic malignancies. IFN- $\alpha$  is indicated for the front-line treatment of chronic myeloid leukemia in the chronic phase. The median survival for patients with some evidence of cytogenetic response has been approximately 6 years, and over 90% of patients with a complete cytogenetic response are in remission at 10 years.<sup>50</sup> It has also been shown to prolong disease-free survival in chronic myeloid leukemia patients after allogeneic stem cell transplantation. Response rates of 40 to 50% as a single agent have been demonstrated in non-Hodgkin's lymphoma.<sup>63</sup> In addition, IFN- $\alpha$

also has shown activity in multiple myeloma, melanoma, and renal cell carcinoma.<sup>50</sup>

#### Interferon- $\beta$

Many mechanisms of action of IFN- $\beta$  have been proposed. IFN- $\beta$  may exert antiproliferative effects through suppression of *c-myc* gene expression in tumor cells.<sup>64</sup> The two recombinant formulations IFN- $\beta$ 1a and IFN- $\beta$ 1b are currently available for the treatment of multiple sclerosis. IFN- $\beta$  slows the frequency of neurologic disturbances and progression of physical debilitation in patients with multiple sclerosis.<sup>62</sup> The once-weekly injection of IFN- $\beta$ 1a may be preferred over IFN- $\beta$ 1b owing to decreased injection-site reactions and a lower incidence of neutralizing antibodies.

#### Interferon- $\gamma$

This IFN is also known as the immune IFN since it is derived from immune stimulation of T cells. It is an activator of T cells and macrophages in synergy with IL-2. It up-regulates both MHC classes I and II and possesses higher antiproliferative properties compared with IFN- $\alpha$  or IFN- $\beta$ .<sup>49,64</sup> The recombinant protein is used in prevention of infection in patients with chronic granulomatous disease. In these patients, the risk of infection was decreased by 67% compared with placebo. IFN- $\gamma$  has also been shown to delay time to progression in malignant osteopetrosis.<sup>60</sup>

#### Adverse Effects

IFNs have been associated with multiple systemic adverse effects. The incidence and severity of these effects are dependent on the dose, route,

and duration of therapy.<sup>50</sup> In general, short infusions and bolus administration are associated with decreased incidence of adverse effects compared with continuous infusion. IFN-mediated release of other cytokines, such as tumor necrosis factor (TNF)- $\alpha$ , IL-1, IL-2, and IL-6, may be responsible for the adverse effects observed with IFN.<sup>65</sup>

The most common acute toxicity associated with IFN is flu-like or constitutional symptoms (eg, fatigue, fever, chills, malaise, headache, rigors, anorexia). The cellular and inflammatory immune response incited by IFN and induced cytokines may result in these constitutional symptoms. Up to 96% of patients receiving systemic administration of IFN have reported this adverse effect.<sup>54</sup> Symptoms usually occur on initiation of therapy and subside within a few months with continued use.

Chronic side effects include fatigue, anorexia, weight loss, and alteration in mood. Fatigue may persist throughout therapy and may worsen over the length of treatment altering quality of life. It may also contribute to the reasons for discontinuation of therapy.<sup>49,65</sup>

Depression is a serious and dose-limiting adverse effect associated with IFN therapy.<sup>49</sup> Suicide ideation and attempts have been attributed to IFN therapy.<sup>66</sup> The incidence tends to be greater among the type I IFN (IFN- $\alpha$  6–26% and IFN- $\beta$  25–34%). The etiology is unclear but may stem from the direct and indirect effects of IFN on the hypothalamus and alterations in neurotransmitter levels.<sup>65</sup> Additionally, other neurologic and psychiatric disorders, such as mood instability (manic-depressive), psychosis, neuropathy, somnolence, and impairment of cognitive function, have been reported.<sup>49</sup> The incidence and severity of neurologic disorders are dose and duration dependent.

Thyroid dysfunction has also been associated with IFN therapy, manifesting as hypo- or hyperthyroidism.<sup>67,68</sup> The thyroid autoantibodies can develop in up to 40% of patients treated with IFN.<sup>69</sup> IFN's toxicity on the thyroid may be due to direct and indirect effects on the thyroid gland.<sup>49</sup> Direct mechanisms for IFN-induced thyroid disease include inhibition of thyroid-stimulating hormone-induced gene expression, decreased iodine organification, and decreased thyroxine release. Indirect effects relate to activation of secondary cytokines.<sup>69</sup> Hyperglycemia and hypertriglyceridemia have also been reported with IFN therapy.<sup>50</sup>

High-dose IFN therapy may result in the development of myelosuppression. Neutropenia (more common), thrombocytopenia, and anemia occurred in patients receiving IFN therapy. Other laboratory abnormalities include liver function test elevations, which are usually mild and reversible, and have been reported in up to 63% of patients receiving IFN- $\alpha$ .<sup>62</sup>

IFNs are a potent class of cytokines that modulate the immune response. These effects are harnessed for the treatment of various autoimmune, infectious, and oncologic conditions. Various challenges remain for this class of agents: better definition of the mechanism of action and the limitation of adverse effects associated with IFNs. Better understanding of these factors will further broaden the therapeutic application of these agents.

## Interleukins

The ILs are a diverse group of cytokine proteins that are produced primarily from activated T lymphocytes and monocytes. These substances function primarily to enhance the immune response but have been reported to also stimulate cellular differentiation (as hematopoietic growth factors).<sup>64</sup> The ILs and their resultant signal proteins orchestrate the complex balance between cellular activation and immunomodulation. Interactions with ILs may be redundant, stimulatory, or inhibitory.<sup>70,71</sup> ILs display both inhibition of tumor growth, as seen in patients treated with IL-2 for renal cell carcinoma, and stimulation of tumor proliferation, demonstrated by IL-6 in multiple myeloma. Two ILs are approved by the FDA to date for clinical indications: IL-2 and IL-11. IL-11 is a platelet growth factor and is discussed under the section on growth factors.

### Interleukin-2

In 1976, a T-cell growth factor was isolated in cultures of mitogen-stimulated human peripheral blood mononuclear cells. This protein, later termed IL-2, was also found to induce proliferation of B cells, NK cells, and lymphokine-activated killer cells. IL-2 was produced by activated T lymphocytes and by some T-cell leukemias.<sup>72</sup> There are two recombinant forms of IL-2: aldesleukin and teceleukin derived from *E. coli*. Only aldesleukin is FDA approved.<sup>73</sup> IL-2 binds to the specific cell surface receptor IL-2 receptor, expressed on both T and B lymphocytes. Recombinant IL-2 binds to IL-2 receptor, inducing tyrosine phosphorylation of multiple cellular proteins, resulting in the synthesis of a multitude of secondary cytokines, such as IL-1, TNF, and IFN- $\gamma$ .<sup>72</sup> IL-2 has also demonstrated activation of both humoral and cell-mediated immunity.<sup>71</sup>

Aldesleukin is indicated for the treatment of adults with metastatic renal cell carcinoma and melanoma.<sup>73</sup> In metastatic renal cell carcinoma in which treatment options are limited, high-dose intravenous IL-2 therapy demonstrated response rates ranging from 0 to 40%, with a median of 15% in all trials.<sup>70</sup> In patients with a complete response, IL-2 improved the quality and durability of tumor response. Lower subcutaneous doses of IL-2 and combination therapy with IFN- $\alpha$  and

5-fluorouracil have been evaluated in renal cell carcinoma. Continuous infusion IL-2 is used in combination with chemotherapy and IFN- $\alpha$  (biotherapy) in the treatment of metastatic melanoma. IL-2 has shown activity in non-Hodgkin's lymphoma and leukemia and in lymphoma following stem cell transplantation.<sup>72</sup>

Toxicities associated with IL-2 therapy are dose and schedule dependent.<sup>74</sup> Higher doses and continuous infusion of IL-2 correlate with more adverse effects, such as constitutional symptoms and capillary leak syndrome, compared with lower doses and bolus intermittent administration. Toxicities can be severe and life-threatening if not properly managed but usually resolve 2 to 3 days on discontinuation of IL-2 therapy.<sup>72,75</sup> In clinical trials for metastatic renal cell carcinoma and melanoma, the majority of patients were not able to receive all planned doses of IL-2 owing to toxicity.<sup>73</sup>

Capillary leak syndrome is a toxicity resulting from increased capillary permeability and decreased vascular resistance caused by secondary cytokines induced by IL-2.<sup>72</sup> Cytokines lead to generation of complement-activating products, endothelial cell antigens, and neutrophil activation. The result is fluid shifting to an extravascular space and consequently hypovolemia (oliguria, ischemia, confusion) and fluid retention (edema, weight gain, pulmonary congestion, pleural effusion, ascites).<sup>71,72</sup>

Cardiovascular adverse effects are a dose-limiting toxicity associated with IL-2 therapy, the majority of which manifests as hypotension (70% of patients with a 20 to 30 mm Hg decrease in systolic pressure). Tachycardia and other cardiac symptoms, such as arrhythmia, have been reported. Neurologic changes have also been reported in patients receiving IL-2 therapy. This toxicity can be dose limiting, with confusion and somnolence being the most common, at a reported incidence of 34 and 22%, respectively, in patients treated for renal cell carcinoma and melanoma.<sup>71,72</sup>

Constitutional symptoms are also common with IL-2 therapy, developing in more than 50% of patients.<sup>73</sup> Symptoms include chills, fever, and fatigue. Increased TNF- $\alpha$  serum levels stimulated by IL-2 have been implicated with the development of fever.<sup>76</sup> These symptoms appear to have an increased frequency in the high-dose regimens.<sup>77</sup> Other adverse effects associated with IL-2 therapy include gastrointestinal symptoms (nausea and vomiting), prerenal azotemia, hyperbilirubinemia, increased infection risk, and endocrine dysfunction (hypo- and hyperthyroidism).<sup>72</sup> Hypothyroidism is more common, with a reported incidence of 35% of patients receiving IL-2.<sup>78</sup> Proposed mechanisms include suppression of thyroid-stimulating hormone secretion and development of antithyroid antibodies.<sup>79</sup>

Although treatment with IL-2 is associated with significant toxicity and often requires close monitoring, with the prophylactic measures to prevent toxicity, the incidence of drug-related mortality is reported to be 2% (in single-agent studies).<sup>73</sup> Patient selection and determination of the optimal dose are the primary challenges with this treatment modality.

### Denileukin Diftitox

Denileukin diftitox is a fusion protein consisting of a fragment of diphtheria toxin genetically fused to IL-2. Denileukin diftitox targets IL-2 receptors on the surface of malignant cells and some normal lymphocytes. Once bound, the fusion protein is internalized, cleaving the toxin moiety into the cytoplasm, leading to the death of these cells.<sup>80</sup> Denileukin diftitox was FDA approved in 1999 for the treatment of patients with persistent or recurrent cutaneous T-cell lymphoma (CTCL) whose malignant cells express the CD25 component of the IL-2 receptor.<sup>81</sup> Approximately 30% (21 of 71) of patients with CTCL demonstrated a reduction in tumor burden of 50% or greater.<sup>82</sup>

Significant adverse events included flu-like symptoms (91%), acute hypersensitivity-type reactions (69%), nausea and vomiting (64%), infections (48%), and vascular leak syndrome (27%), consistent with some of the IL-2-related toxicities.<sup>82</sup> CTCL patients are particularly susceptible to infections because of the compromised condition of their skin. It is unknown if increased infection may be related to denileukin diftitox therapy targeting some normal lymphocytes.

## Growth Factors

Myelosuppression is a common dose-limiting factor of chemotherapy and increases the need for hospitalization, intravenous antibiotic administration, transfusion of blood products, dose reduction, and treatment delays. These factors may lead to significant negative effects on patient quality of life or even response to treatment. Recently, significant progress has been made in understanding the process of hematopoiesis by which mature cellular elements of blood are formed.<sup>83</sup> Hematopoietic growth factors are regulatory molecules that function by activating the mature blood cells and promoting the growth, survival, and differentiation of progenitor cells. Several growth factors are marketed for the minimization of chemotherapy-induced hematologic toxicity. The FDA-approved recombinant human hematopoietic growth factors are listed in Table 3.<sup>84-90</sup> Palifermin is the only growth factor not targeting hematopoiesis. The second-generation growth factors pegfilgrastim and darbepoetin alfa have long serum half-lives and have been approved by the FDA for use in the oncology setting.

Table 3 Hematopoietic Growth Factors and Their Indications

Growth Factor	Target	FDA-Approved Indication
Filgrastim (G-CSF, Neupogen)	Committed granulocytes	Decrease the incidence of infection, febrile neutropenia, in patients with nonmyeloid malignancies receiving myelosuppressive anticancer drugs associated with a significant incidence of severe neutropenia with fever
Sargramostim (Leukine)	Committed and noncommitted cells	(1) Use following induction chemotherapy in older patients with acute myelogenous leukemia (2) Use in myeloid reconstitution after autologous and allogeneic BMT (3) Use in BMT failure or engraftment delay (4) Use in mobilization and following autologous BMT
Pegfilgrastim (pegylated G-CSF, Neulasta)	Committed granulocytes	To decrease the incidence of infection, as manifested by febrile neutropenia, in patients with nonmyeloid malignancies receiving myelosuppressive anticancer drugs associated with a clinically significant incidence of febrile neutropenia
Epoetin alfa (Procrit, Epogen)	Committed erythroid progenitor cells	(1) For the treatment of anemia in patients with nonmyeloid malignancies in whom anemia is due to the effect of concomitantly administered chemotherapy; to decrease the need for transfusions in patients who will be receiving concomitant chemotherapy for a minimum of 2 mo (2) For the treatment of anemia in chronic kidney disease patients not on dialysis; to elevate or maintain the red blood cell level and to decrease the need for transfusions (3) For the treatment of anemia related to therapy with zidovudine in HIV-infected patients (4) For the treatment of anemic patients (Hb >10 to ≤ 13 g/dL) scheduled to undergo elective, noncardiac, nonvascular surgery to reduce the need for allogeneic blood transfusions
Darbepoetin (Aranesp)	Committed erythroid progenitor cells	(1) For the treatment of anemia associated with chronic renal failure, including patients on dialysis and patients not on dialysis (2) For the treatment of anemia in patients with nonmyeloid malignancies in whom anemia is due to the effect of concomitantly administered chemotherapy
IL-11 (Oprelvekin, Neumega)	Committed megakaryocyte progenitor cells	For the prevention of severe thrombocytopenia and the reduction of the need for platelet transfusions following myelosuppressive chemotherapy in adult patients with nonmyeloid malignancies who are at high risk of severe thrombocytopenia
Palifermin (Kepivance)	Epidermal cells	To decrease the incidence and duration of severe oral mucositis in patients with hematologic malignancies receiving myelotoxic therapy requiring hematopoietic stem cell support

BMT = bone marrow transplantation; G-CSF = granulocyte colony-stimulating factor; Hb = hemoglobin; HIV = human immunodeficiency virus.

Anemia in cancer patients can be multifactorial, including nutritional deficiencies, hemolysis, blood loss, bone marrow involvement, anemia of chronic disease, a blunted endogenous erythropoietin (EPO) response, and cytotoxic treatment causing a damaging effect on bone marrow precursor cells, which is usually proportional to the intensity of the chemotherapy dose. Additionally, this anemia may be related to the renal toxicity of some chemotherapy agents, such as platinum agents.

EPO was the first hematopoietic growth factor to become commercially available in the United States. Several randomized and non-randomized trials have demonstrated that EPO can significantly reduce transfusion requirements and improve quality of life.<sup>91,92</sup> Approximately 60% of all cancer patients receiving chemotherapy will respond to EPO treatment. Darbepoetin has an efficacy similar to that of EPO for the management of chemotherapy-induced anemia.<sup>93</sup> Darbepoetin contains two additional N-glycosylation sites over EPO, giving it a longer half-life.<sup>87</sup> This allows for the drug to be given up to every 3 weeks compared with traditional weekly dosing with EPO.

Treatment with erythropoietic agents has been well tolerated in cancer patients. Rarely,

hypertension associated with a dramatic rise in hemoglobin has been observed.<sup>94</sup> Occasionally, patients with underlying central nervous system disease may have increased seizure activity in the context of the aforementioned hypertension. The incidence of venous thrombosis has been reported to be somewhat higher with the use of these agents, with the incidence reported around 6% in patients receiving the active treatment compared with 4% with patients receiving the placebo in randomized trials for correction of anemia. However, the risk is significantly increased in the recent studies targeting higher hemoglobin values for reducing tumor hypoxia and for prevention of anemia. Two of these studies have also reported an adverse outcome on survival.<sup>95,96</sup> Although EPO has been widely used, with an excellent safety profile in the management of anemia in oncology and nephrology, these findings have raised concerns and caution against targeting higher hemoglobin levels.

Granulocyte colony-stimulating factor (G-CSF) is a myeloid lineage growth factor that stimulates the production and functions of mature neutrophils. G-CSF was first approved in 1991 for its ability to reduce the incidence of febrile neutropenia in cancer patients receiving myelosuppressive chemotherapy. This indication

has been further expanded to include other areas of utility within the practice of oncology, including the mobilization of progenitor stem cells for use in blood and marrow transplantation and the stimulation of neutrophil recovery following high-dose chemotherapy with stem cell support. Additionally, G-CSF is indicated to increase neutrophil production in congenital neutropenic states and other endogenous myeloid disorders.<sup>97</sup>

Granulocyte-macrophage colony-stimulating factor (GM-CSF) stimulates the production of neutrophils, monocytes, and eosinophils and has been FDA approved since 1991 for use in patients with nonmyeloid malignancies undergoing autologous bone marrow transplantation. Since then, GM-CSF has received approval for other indications, such as the reduction of myelotoxicity for leukemia patients following induction chemotherapy. More recently, GM-CSF has been reportedly effective as an immune stimulant for management of infectious disease and in the oncology setting when used concurrently with other biologic agents.<sup>98,99</sup>

Myeloid growth factors are generally well tolerated. Mild to moderate bone pain, which usually manifests at the onset of therapy or at the time of neutrophil recovery, is the predominant side effect observed with the use of G-CSF. On

occasion, the pain may be severe enough to require analgesics for control.<sup>100</sup> Other rare side effects include cutaneous vasculitis, activation of preexisting psoriasis, and Sweet's syndrome.<sup>97</sup> The most common side effects reported with the use of GM-CSF have included constitutional symptoms, such as fever, bone pain, myalgia, headaches, and chills. These side effects are more frequent when GM-CSF is administered at higher doses or by continuous intravenous infusion than with traditional subcutaneous dosing. In the transplant setting, no excessive toxicity has been reported with the use of GM-CSF compared with controls. Other rare side effects, such as first-dose phenomenon and capillary leak syndrome, are reported with *E. coli*-derived GM-CSF (not approved in the United States), and not with sargramostim (Leukine).<sup>97</sup>

Following standard-dose chemotherapy, severe thrombocytopenia requiring platelet transfusions is uncommon. However, it can be cumulative in patients treated with multiple chemotherapeutic regimens and represents a significant problem in patients receiving dose-intensive or myeloablative chemotherapy. Several hematopoietic cytokines with thrombopoietic activity have been evaluated in clinical trials, including IL-1, IL-3, IL-6, IL-11, thrombopoietin (TPO), megakaryocyte growth and development factor (MGDF) and granulocyte colony stimulating factor/IL-3 fusion molecule (PIXY 321). Most of these cytokines have shown modest thrombopoietic activity and mediate a number of biologic effects, including some untoward effects. At this time, IL-11 is the only thrombopoietic cytokine approved by the FDA for clinical use.<sup>89</sup>

IL-11 is a pleiotropic cytokine with hematopoietic, anti-inflammatory, and mucosaprotective activities. Based on its thrombopoietic activity, IL-11 was FDA approved in 1997 for the prevention of severe thrombocytopenia and the reduction of platelet transfusion following myelosuppressive chemotherapy in patients with non-myeloid malignancies.<sup>101</sup> However, the systemic adverse effects have limited its wide clinical utility. The most common side effects experienced with IL-11 are injection-site reactions and mild to moderate fluid retention, which may be manifested by either peripheral edema or pulmonary edema with dyspnea. IL-11 administration has increased the size of preexisting pleural effusions in some patients.<sup>97</sup>

Additionally, reports of decreased hemoglobin values are thought to be related to the dilutional effect of fluid retention. In addition, palpitations, tachycardia, and atrial arrhythmias have also been reported with this agent, making it difficult to use in patients with a history of cardiac disease.<sup>89</sup>

## Immunoglobulins

The immunoglobulins (Igs) are polyclonal antibodies collected from pooled human plasma.

These antibodies are collected from 3,000 to 100,000 healthy blood donors, representing a diverse mixture of various antibodies present in normal serum.<sup>102</sup> These antibodies provide passive immunity directed against foreign pathogens and natural autoantibodies. These autoantibodies react against self-antigens, which are responsible for the immunomodulatory activity of Ig. Igs have been used for decades in the treatment of multiple diseases, ranging from antibody-mediated autoimmune states to infections. Controlled trials have demonstrated the efficacy of intravenous Ig in idiopathic thrombocytopenic purpura, dermatomyositis, Guillain-Barré syndrome, myasthenia gravis, graft-versus-host disease, Kawasaki disease, prevention of infection in leukemia patients, and others.<sup>102,103</sup> More recently, more specific forms of Ig are available with higher antibody titers specific to infectious pathogens, such as cytomegalovirus, hepatitis, or varicella zoster.

Adverse effects associated with Ig are generally mild and uncommon. Similar to administration of any allogeneic blood product, the most common adverse reaction is hypersensitivity or infusion-related reactions, which are infusion rate dependent. The symptoms may include fevers, chills, bronchospasms, skin rash or hives, and anaphylaxis. A rapid rate of antibody infusion may precipitate renal dysfunction in patients unable to tolerate the large protein load administered. Preparations of intravenous immunoglobulin (IVIG) stabilized with sucrose may be more prone to cause renal dysfunction owing to hyperosmolality.<sup>62</sup> Although often used interchangeably, various different commercial preparations of IVIG may have differences in adverse reaction profile owing to differences in the manufacturing process, Fc receptor function, and complement fixation.<sup>104</sup>

## Cytokine Antagonists

Cytokines have varied cellular effects in the human body. Some of these effects are beneficial and are used to treat diseases. In some cases, cytokine activity is part of the pathogenesis of disease. Cytokines have also been identified as major mediators of systemic manifestations of several disease processes. Cytokine antagonists have been developed to block their effects and improve patient outcome. Several cytokine antagonists, such as TNF- $\alpha$  and IL-1 antagonists, have been evaluated for treatment of autoimmune states. IL-2 MoAbs have also been developed for use as immunosuppressants in the transplant setting.

### TNF- $\alpha$ Antagonists

TNF is a proinflammatory cytokine produced by macrophages and T cells. Exposure to TNF at sites of inflammation leads to activation of proinflammatory cytokines and production of destructive enzymes, resulting in tissue damage.<sup>105</sup>

Currently, there are three TNF- $\alpha$  inhibitors (adalimumab, infliximab, etanercept) on the US market. These agents block the activity of TNF via different mechanisms and are indicated for the treatment of inflammatory conditions. Adalimumab (human antibody) and infliximab (chimeric mouse-human IgG1) are MoAbs directed at TNF- $\alpha$  and inhibit its binding to TNF receptors. A major clinical response has been observed in patients receiving these agents in combination with methotrexate chemotherapy compared with placebo and methotrexate in patients with rheumatoid arthritis. Infliximab has activity in multiple other diseases, such as Crohn's disease, ulcerative colitis, and ankylosing spondylitis.<sup>18</sup> Infliximab has also been investigated for the treatment of steroid-refractory graft-versus-host disease in bone marrow transplant recipients.<sup>106</sup> Adalimumab is indicated for psoriatic arthritis.<sup>14</sup>

Infliximab is associated with infusion-related adverse effects, observed in approximately 20% of patients.<sup>18</sup> The infusion reactions with infliximab may be related to development of antibodies against the drug. The incidence of antibody is lower in patients who receive a concurrent immunosuppressant (10–43%) versus those who did not (18–75%).<sup>107</sup> Treatment with infliximab is also associated with antibodies to double-stranded DNA and antinuclear antibodies.<sup>107</sup> The scheduled administration of infliximab is associated with a lower risk of immunogenicity compared with episodic treatment. Patients treated with adalimumab may also have infusion-related effects.<sup>14,108</sup>

Patients receiving these agents are at higher risk of infections associated with atypical organisms and opportunistic infections, such as cytomegalovirus, histoplasmosis, aspergillosis, and nocardiosis.<sup>109,110</sup> The microbial organisms responsible for these infections are generally intracellular pathogens or pathogens kept in check by cell-mediated immunity. This finding may be supported by experimental studies establishing the role of TNF in protective immunity.<sup>111</sup> Several cases of tuberculosis have been reported in patients receiving infliximab and adalimumab. The infections seem to be more reported with infliximab, presumably because of its potent TNF inhibitory activity. Therefore, it is recommended that patients are appropriately evaluated for latent infections prior to initiation of such treatment, and a high index of suspicion and appropriate surveillance cultures, with prompt empiric treatment, may be required to prevent morbidity and mortality.

More patients treated with anti-TNF- $\alpha$  antibodies developed malignancies compared with patients receiving placebo, although the direct causal relationship remains controversial. All TNF- $\alpha$  inhibitors were associated with an increased incidence of non-Hodgkin's and

Hodgkin's lymphoma in treated patients.<sup>112</sup> Up to a fourfold higher risk has been reported in patients receiving adalimumab. Other solid tumor malignancies have also been observed.<sup>14</sup>

Etanercept is a genetically engineered fusion protein with two identical chains of TNF receptor p75 monomer fused with the Fc domain of IgG1, binding to TNF and inhibiting its activity. Similar to infliximab, it is indicated for treatment of various autoimmune diseases, such as rheumatoid arthritis, ankylosing spondylitis, and plaque psoriasis. It is being investigated for treatment of graft-versus-host disease in stem cell transplant recipients and various hematologic malignancies.<sup>113,114</sup> Infections, injection-site reactions, flu-like symptoms, and headache have been reported in clinical trials with etanercept.<sup>107</sup> An increased incidence of lymphoma (three times the expected rate) has been observed in patients receiving etanercept for rheumatoid arthritis.<sup>115</sup>

#### IL-1 Antagonists

IL-1 is a proinflammatory cytokine produced in response to inflammation.<sup>116</sup> The activity of IL-1 includes stimulation of osteoclast activity, leading to increased inflammation and in synovial tissue possibly increasing bone and cartilage attrition in addition to other diverse activities, such as hematopoietic stimulation and augmentation of the T-cell response.<sup>117</sup>

Anakinra is a IL-1 antagonist indicated for the treatment of rheumatoid arthritis. It is a recombinant form of the human IL-1 receptor antagonist. In combination with methotrexate, anakinra improves response compared with methotrexate alone. Adverse reactions are generally mild but may include an increased risk of infections. The risk of infection with anakinra is lower compared with TNF inhibitors.<sup>116</sup> Neutropenia has also been associated with the use of this agent.<sup>117</sup>

#### IL-2 Antagonist

The stimulation of a T cell–mediated cellular immune response to allogeneic organ transplant is mediated by IL-2. Binding of IL-2 to high-affinity IL-2 receptors on activated T lymphocytes leads to activation of cell-mediated immunity associated with allograft rejection. MoAb targeting the IL-2 receptor blocks the activation pathway for T-cell activation and mutes its response to antigenic stimulation.<sup>62</sup> Basiliximab and daclizumab are both recombinant antibodies targeting the IL-2 receptor used to prevent acute organ rejection in the renal transplantation setting in combination with other immunosuppressants. Both agents are being investigated in oncology patients for the treatment of graft-versus-host disease following bone marrow transplantation.<sup>118,119</sup> Adverse effects attributable to the IL-2 receptor antagonists (compared with placebo)

were not found in these studies.<sup>15,16</sup> However, in other settings, such as ulcerative colitis, fever, and lethargy, upper respiratory infections with basiliximab and headache and skin rash with daclizumab have been reported.<sup>107</sup>

#### Thalidomide

Thalidomide, an immunomodulatory agent with multiple biologic activities, has been shown to have efficacy in the treatment of patients with refractory, relapsed myeloma. Although the precise mechanism of action responsible for this activity is unknown, the inhibitory effects of thalidomide on the various cytokines that stimulate angiogenesis (VEGF, basic fibroblast growth factor) and cytokines (IL-6, IL-1 $\beta$ , and IL-10 and TNF- $\alpha$ ) secreted into the microenvironment of the marrow and modulating the growth and survival of myeloma cells may play an important role in its antitumor activity.<sup>120</sup> The clinical side effects of thalidomide include drowsiness or sedation, fatigue, constipation, dizziness, and peripheral neuropathy.<sup>81</sup> The efforts are directed at developing more potent analogues (lenalidomide) with fewer side effects.

### Conclusions

Recent advances in biotechnology have accelerated the development of biologic agents, leading to novel therapeutic options and diagnostic tools. The number of biologic response modifiers will increase as understanding of cellular signaling processes improves. Manipulation of cell signaling and subsequent modulation of the immune system will continue to play an integral part in the management of immune-related diseases and malignancies. Research also continues with adoptive cellular therapy, a strategy intended to eliminate tumor either by a direct antitumor effect or by indirect effects on the immune system, although no form of cellular therapy has as yet been FDA approved.

Although the arsenal of biologic agents is growing, it is also important to understand the mechanisms responsible for the systemic effects of these agents to optimize their clinical utility and to develop more potent analogues with fewer side effects. Many of these side effects, although they may not be serious, nevertheless can have a significant impact on patients' quality of life. Furthermore, some systemic sequelae, such as opportunistic infections, can lead to life-threatening complications. Therefore, it is important to remain cognizant about the full spectrum of biologic effects and prevention or management of adverse events.

Significant advances are also being made in the area of supportive care for the prevention and attenuation of toxicity as the biology of the

underlying process is better understood and new tools are available to intervene and improve the tolerance of cytotoxic treatment. The targeting of various receptors, such as 5-hydroxytryptamine<sub>3</sub> and neurokinin-1, with novel antiemetics has significantly ameliorated nausea and vomiting. Recent progress in the understanding of biology of the bone disease has identified the role of RANK/RANKL pathways and other novel targets and opened up new possibilities for the treatment of malignant bone disease and the prevention of skeleton-related complications. The enhanced understanding of biologic effects and how to improve the therapeutic index by minimizing untoward systemic effects and enhancing clinical benefits will likely broaden the therapeutic applications of cytokines and other biologic response modifiers in the future.

# Ethical and Legal Issues in the Care of a Cancer Patient

Martin L. Smith, S.T.D.  
Anne Lederman Flamm, J.D.  
Rebecca D. Pentz, Ph.D.

## The Shift from Paternalism to Partnership

Clinical decision making and the physician-patient relationship have undergone major revolutionary changes, starting in the last quarter of the twentieth century. Prior to the 1970s, the prevailing model for decision making was paternalism. This model was founded on physicians' commitment to patients' well-being and the ethical principles of beneficence and nonmaleficence and was dominated by physicians' expertise and authority. In this model, patients played a passive, almost child-like role of obediently and unquestioningly following doctors' orders. But paternalism has been replaced by an expectation of partnership between physicians and patients. The partnership model continues to affirm medical expertise but recognizes patients' expertise as well, that is, that patients are most knowledgeable about their own values, goals, and preferences, all of which should be incorporated into clinical decisions for a particular patient. A partnership model emphasizes mutuality and shared decisions between physicians and patients. The emergence and significance, as a standard of care, of engaging patients in an informed consent process are symbolic of the shift from paternalism to partnership.

Multiple forces and factors contributed to the changes noted above. The Civil Rights Movement in the United States during the 1950s and the 1960s, with its emphasis on individual freedom, rights, and liberties, provided a cultural basis and backdrop for similar emphases taking root in health care delivery. Revelations in the 1960s and 1970s of significant abuse and misuse of research subjects, in which the medical researchers failed to respect research participants as persons by ignoring their right to receive information about the research and to consent voluntarily to participate, produced public horror and shock. The US government responded by

enacting federal regulations for protecting research subjects. Similar protections for clinical practice developed subsequently. Court cases also provided greater legal clarity regarding disclosure of information and patients' rights regarding consent or refusal of treatment. In *Canterbury v. Spence* (1972), the court affirmed that

The patient's right of self-decision can be effectively exercised only if the patient possesses enough information to enable an intelligent choice. The patient should make his own determination on treatment.... Social policy does not accept the paternalistic view that the physician may remain silent because divulgence might prompt the patient to forego needed therapy. Rational, informed patients should not be expected to act uniformly, even under similar circumstances, in agreeing to or refusing treatment.<sup>1</sup>

The *Canterbury* court also attempted to set forth an objective standard for the disclosure of information to a patient: "what a prudent person in the patient's position would have decided if suitably informed of all perils bearing significance."<sup>1</sup> Applying informed consent standards to life-sustaining treatment, the New Jersey Supreme Court in *In re Quinlan* (1976) found the implied right to privacy under the US Constitution to be sufficiently broad to include a patient's right to refuse medical treatment.<sup>2</sup> Specifically, the court permitted Karen Quinlan's parents to authorize the discontinuation of a life-sustaining ventilator from their incompetent 21-year-old daughter, who had suffered a severe anoxic event 10 months before. In 1981, the Judicial Council of the American Medical Association (AMA), echoing *Canterbury v. Spence*, recognized informed consent and patients' participation in their own health care decisions, even if the physician disagrees, as "a basic social policy."<sup>3</sup>

The content of this chapter is framed by the ethical and legal changes to clinical decision

making that were summarized above. Within this framework of the changed and changing physician-patient relationship—which we view as a positive development—we describe informed consent and the ethical and legal standards for decision making, the importance of assessing a patient's decisional capacity, the initiation of advance care planning and discussions about cardiopulmonary resuscitation (CPR), and the challenges arising when the physician-internist assumes the role of patient-confidant and coordinator of overall care.

## Informed Consent: Process and Transparency

The shift from paternalism to partnership has not been without accompanying ambiguities. For example, how do physicians respect the autonomy and freedom of patients to make their own health care choices while at the same time not abandoning traditional duties of providing medical recommendations, advice, and counsel? Where is the line of demarcation between educating, advising, recommending, and persuading patients about particular courses of treatment judged by physicians to be best for their patients and the extremes of being coercive and manipulative or totally nondirective? In their discussion on the ethical and legal myths about informed consent, Meisel and Kuczewski noted that some physicians believe that respect for patient autonomy requires them to operate a medical cafeteria "in which they must set out all therapeutic options and let patients choose, each according to his or her own appetite."<sup>4</sup> These authors label medical practice in accordance with this myth as "a serious sin of omission" that abdicates a central part of the physician-patient partnership, namely, the physician's role as medical advisor, a professional with expert knowledge crucial for the patient's health. To actualize this role, physicians should

see informed consent as a shared, collaborative, educative process that includes human interaction, conversation, questions, and answers. To avoid operating a medical cafeteria, Meisel and Kuczewski suggested that physicians distinguish between particular treatment options (eg, chemotherapy, radiation) and the goals of those treatments (eg, cure, remission, palliation). In their view, treatments are often discussed in detail, but patients are not really sure what the treatments are ultimately meant to do. Further, as disease responds or progresses, treatments and the goals of treatment can change. They noted the relevance of the distinction between treatments and goals in the following way: “Patients are not experts at treatments; physicians are. However, patients’ preferences are central to the choice of treatment goals. Thus, in selecting and revising treatment goals, physicians and patients need to form a partnership.”<sup>4</sup> This partnership is particularly important as treatment goals shift from curative to palliative; if forged, the partnership supports communication during difficult end-of-life discussions.

Another ambiguity arising from the partnership model of the physician-patient relationship is how much information to disclose to patients so that they can make good and informed decisions. Ethics, law, and regulatory bodies (such as the Joint Commission for Accrediting Health Care Organizations) have clarified the general categories of information to be disclosed. These elements include the proposed treatment’s (or diagnostic procedure’s) nature, purpose, risks, and benefits; reasonable alternatives and their risks and benefits; and the likelihood of achieving treatment goals. Although helpful for structuring the kinds of information to be disclosed, this list of categories still does not identify how much information physicians need to disclose, and patients need to understand, to satisfy each element. State laws in the United States typically require physicians to meet either the “reasonable professional” or the “reasonable patient” standard. The former requires physicians to follow customary professional practice, that is, to disclose to patients the amount and kinds of information that a reasonable professional would customarily disclose. Beauchamp and Childress explained the rationale for this standard:

Disclosure, like treatment, is a task that belongs to physicians because of their professional expertise and commitment to the patient’s welfare. As a result, only expert testimony from members of this profession could count as evidence that a physician has violated a patient’s right to information.<sup>5</sup>

The “reasonable patient” standard requires physicians to provide the amount and kind of information that a hypothetical reasonable patient would find material or pertinent to making a

decision about a treatment or diagnostic procedure. This standard has gained increasing acceptance both in practice and in law because it is more compatible with the partnership model of the physician-patient relationship. Regarding this standard, Beauchamp and Childress provided a note of caution:

Whatever its merits, the reasonable person standard encounters conceptual, moral, and practical difficulties. First, the concepts of “material information” and “reasonable person” have never been carefully defined. Second, questions arise about whether and how the reasonable person standard can be employed in practice. Its abstract and hypothetical character makes it difficult for physicians to use, because they have to project what a reasonable patient would need to know.<sup>5</sup>

Brody proposed “the transparency standard” as an alternative and as a “means to operationalize the best features of the conversation model in medical practice.”<sup>6</sup> Contrasting his proposal with the reasonable professional and the reasonable patient standards, he stated:

According to the transparency model, the key to reasonable disclosure is not adherence to existing standards of other practitioners, nor is it adherence to a list of risks that a hypothetical reasonable patient would want to know. Instead, disclosure is adequate when the physician’s basic thinking has been rendered transparent to the patient.<sup>6</sup>

For example, if a physician determines which treatment to recommend based on the published literature on the risk and benefits of this treatment compared with alternative ones, the physician should explain those risks and benefits. If, on the other hand, the physician was convinced that the least risky treatment was unreasonably inconvenient for the patient (eg, it involved a lengthy hospital stay), the physician should explain that trade-off to the patient.

In summarizing this approach, Brody stated: “Essentially, the transparency standard requires the physician to engage in the typical patient-management thought process, only to *do it out loud in language understandable to the patient*.”<sup>6</sup> To fulfill their partnership obligations, patients need to participate in medical decisions, to the extent that they wish, by asking questions prompted by the disclosure of the physician’s reasoning. Such questions, of course, need to be answered by the physician to the patient’s satisfaction. Given that patients sometimes do not even know which questions to ask, encouraging the presence of family members or anyone whom the patient views as a trusted advisor or advocate is important when crucial decisions must be made.

A transparency model of informed consent might also respond to the concerns raised by

Cassell and colleagues regarding the potentially impaired thinking in sick patients.<sup>7</sup> The core of their concern is that sick patients, especially if they are hospitalized, may too easily or quickly consent to treatments and procedures, not because these are judged by patients to be in their best interests but because of the authoritative influence of their physicians. Cassell opined: “The biggest thief of autonomy is sickness.”<sup>8</sup> The transparency model of informed consent, because it does not rely on authority but allows the patient to discern the thinking process underlying the physician’s recommendation, may allow patients to determine if their physician’s reasoning agrees with their own.

Informed consent as a conversational, educational, transparent process contrasts with an event-based model. According to Lidz and colleagues,

The event model of informed consent treats medical decision making as a discrete act that takes place in a circumscribed period of time, usually shortly before the administration of treatment, and emphasizes the provision of information at that time.... The consent form, with its detailed recital of risks and benefits, can be seen as the central symbol of the event model.<sup>9</sup>

A view of informed consent as an event is the product of a reductionism, that is, a rich and multifaceted concept and process is reduced to a patient’s signature on an informed consent form. Nothing could be farther from the truth. Although documenting consent via a printed form or a notation in the patient’s medical record is important for a variety of practical and legal reasons, the patient’s signature on a form is the least important element of informed consent. The human interaction, the respectful exchange of information, the dialogue that includes questions and satisfactory answers, and the establishment of mutual trust that occur before the event of signing all promote the core values and legally required elements of informed consent, as well as the physician-patient partnership. Moreover, these core values extend beyond the moment of a document’s execution and continue throughout treatment so that a patient is free to withdraw consent or change treatment goals at any time during the treatment process. Informed consent neither starts nor ends with signing a document.

### Assessing Decisional Capacity

The partnership model of the physician-patient relationship and the informed consent process presume that the patient has the cognitive skills to participate adequately in health care decision making. For various reasons (eg, sedating medication, cerebrovascular accident, head trauma), patients experience temporary or permanent loss

or diminution of cognitive abilities. When doubts arise about a patient's cognition, the primary physician has the responsibility to assess the patient's decisional capacity. Seeking the assistance and input of mental health professionals (eg, a psychiatrist, a psychologist, or a social worker) can be helpful and appropriate. Whether or not assistance is sought, the patient should be assessed for specific cognitive skills or abilities to (1) express a choice, (2) understand relevant information, (3) appreciate the medical situation and its consequences, and (4) reason with relevant information.<sup>10</sup> This clinical assessment should be focused on the specific decision to be made and occur after a process of information disclosure about that specific decision. In other words, the question is not whether the patient has cognitive abilities to manage all spheres of his or her life but to make a specific medical decision after having received relevant and transparent information about the proposed therapeutic or diagnostic treatment and its goals. The assessment is not dependent on whether the patient is able to communicate orally. For example, a patient who is in an intensive care unit, intubated and supported by a ventilator, might still retain decisional capacity as long as the patient has some method of communicating his or her wishes.

Related to the four cognitive skills listed above, Grisso and Appelbaum recommended that the clinician performing the assessment (ie, the primary physician or the mental health professional) structure a set of questions around each skill being assessed.<sup>10</sup> For example, for the ability to express a choice, the patient could be asked: "Have you decided whether to go along with your doctor's suggestions for treatment? Can you tell me what your decision is?" For the ability to understand relevant information, the patient could be instructed as follows: "Tell me in your own words what your doctor told you about the nature of your condition, the recommended treatment (or diagnostic test, or research protocol), the possible benefits from the treatment or test or research, the possible risks or discomforts of the treatment or test or research, the possible risks and benefits of alternative treatments, and the possible risks and benefits of no treatment at all." Alternatively, for the second skill, the patient could be told and asked: "Your doctor gave you a percentage chance that [a named risk] might occur with treatment. In your own words, how likely do you think the occurrence of [the named risk] might be? Why is your doctor giving you all this information? What will happen if you decide not to go along with your doctor's recommendation?" For the ability to appreciate the situation and its consequences, the patient could be instructed as follows: "Tell me what you really believe is wrong with your health now." Then the patient could be asked: "Do you believe that you

need some kind of treatment? What is the treatment likely to do for you? Why do you think it will have that effect? What do you think will happen if you are not treated? Why do you think your doctor has recommended [a specific treatment] for you?" Finally, pertaining to the ability to reason with relevant information, the physician or other professional performing the assessment might inquire: "Tell me how you reached the decision to accept [or reject] the recommended treatment? What were the factors that were important to you in reaching the decision? How did you balance those factors?"

### Standards for Decision Making

The gold standard for clinical decision making involves a patient who currently has decisional capacity and is able to engage presently in the process of informed consent. Most adult patients in the outpatient setting and many hospitalized patients meet this gold standard. Also, as some pediatricians and others have argued, some mature adolescents are able to meet this standard as well.<sup>11–13</sup>

But when a patient's decisional capacity is judged to be insufficient, the silver standard needs to be invoked and used, that is, turning to and using proxy or surrogate decision makers, when available. The ethical and legal expectations of the surrogate decision maker are to provide a substituted judgment, that is, voicing the values, preferences, and wishes of the patient and, based on those, making the decision that the patient would have made. In the words of Beauchamp and Childress:

Accordingly, if the surrogate can reliably answer the question, 'What would *the patient* want in this circumstance?' substituted judgment is an appropriate standard. But if the surrogate can only answer the question, 'What do *you* want for the patient?' then this standard is inappropriate.<sup>5</sup>

Occasionally, patients express their wishes or preferences to their physicians, other health care professionals, or family and friends (see Advance Care Planning below). When this has occurred, and especially when a patient's wishes and statements have been documented in the patient's medical record, such indicators of a patient's directives can extend patient autonomy into the time period when the patient lacks decisional capacity. When the previously expressed wishes of the patient exist and have been well documented, the silver standard of substituted judgment is more confidently actualized.

When proxy or surrogate decision makers are unable to formulate a substituted judgment because of a lack of knowledge about the patient, a third or bronze standard for decision making should be used, the standard of best interests.

Strictly speaking, this standard is neither connected to nor an extension of patient autonomy and preferences. Rather, the best interest standard attempts objectively to weigh the benefits and burdens of the proposed treatment or diagnostic procedure, with the goal of maximizing benefit and minimizing risks and harms. This standard for decision making, which mirrors the paternalism of a former era, is useful not only when an available proxy or surrogate lacks specific knowledge about patient preferences but also for pediatric decision making for young patients<sup>12</sup> and when the medical team must make health care decisions for a patient because no patient surrogate has been found, designated, or identified.

### Advance Care Planning

As noted above, a substituted judgment is only as good as the knowledge that the surrogate has about the patient's wishes, preferences, and values. Some patients will have had very specific and concrete discussions with family, friends, physicians, or other health care professionals about their wishes and treatment preferences related to particular clinical situations. But most adult patients have not engaged in such conversations or in what has been called "advance care planning."

Emanuel and colleagues described advance care planning as a multistage process by which individuals indicate their preferences for future medical care in the event of decisional incapacity.<sup>14</sup> This patient-centered process can be subdivided into three stages: (1) thinking about preferences and proxies, (2) communicating preferences to others, and (3) documenting preferences and designated proxies. The goals and benefits of advance care planning include extending patient self-determination and control into situations when decisional capacity has been lost; facilitating communication and minimizing future conflict; decreasing family anxiety, stress, and burden when significant decisions must be made for the patient; reducing overtreatment or undertreatment; saving health care resources and dollars because the treatments the patient would not have wanted are not initiated or continued; and providing legal protections for those with ultimate decision-making authority, especially when decisions lead to a patient's death.

Multiple barriers have been identified to explain why most patients seem to avoid thinking about their preferences and communicating them to others and why many physicians fail to initiate advance care planning discussions with their patients. An overarching cultural barrier is a general societal difficulty with thinking and talking about dying and death, whether one's own or someone else's. Metaphorically, death is "the elephant in the room"—present and obvious,

especially in situations of serious illness, yet calling attention to it or conversation about it is to be avoided almost at all costs. A narrower but similar cultural barrier exists within US hospitals, ambulatory clinics, and other health care facilities, where the dying and death of patients (and talk of such) may be viewed as medical or patient failure. The military metaphors often associated with cancer (eg, the *war* or *battle* against cancer, the therapeutic *armamentarium* used to *counterattack* cancer, *defend* the body, and *defeat* disease) reinforce the expectation that patients and their physicians are to wage a courageous fight, subtly conveying that they have more control over illness than they actually do. Physicians sometimes fear that death talk or death preparation, especially early in an illness, can be interpreted as a sign that the battlefield is being surrendered prematurely. However, studies have shown that patients prefer a realistic approach, particularly if it is individualized to the patient's situation, and the physician projects confidence and competence during the discussion.<sup>15,16</sup>

Practical barriers to advance care planning, and the substantive conversations between patients and physicians they require, include time constraints and compensation concerns.<sup>17</sup> Advance care planning, by the very nature of its cognitive content and emotional evocations, can be time-intensive and psychologically difficult and draining. Physicians who experience constant pressures to see more patients in the course of a day to generate more revenue could easily relegate advance care planning to the bottom of a priority list of issues to be addressed during a 10- to 20-minute office visit.

Some studies report that patients and physicians have diverse views about who should initiate advance care planning.<sup>18</sup> Patients wait for physicians to initiate such discussions, and physicians wait for patients to initiate such discussions, resulting in mutual misunderstandings and silence. A physician's reluctance to initiate the discussion may be due to discomfort with talking about dying and death, fear of causing the patient distress, a desire to protect patients and maintain their hope, a belief that only older and seriously ill or terminal patients should be concerned about such issues, and a lack of training, skills, or knowledge about advance directives. Patients' reluctance to initiate advance care planning discussions may be due to fear of their own death, an overly optimistic view of medical prognosis, the absence of a trusting relationship with the physician, a perception that such issues and decisions should remain private, and cultural beliefs and practices that emphasize communal or familial decision making over the individualism, self-determination, and independence that characterize patient autonomy.

Overcoming this multitude of barriers is a significant challenge. But physicians committed to empowering patients to be partners in their own health care decisions are not without practical resources<sup>19</sup> and strategies. Back and colleagues addressed the common concern that frank conversation will destroy hope.<sup>20</sup> These authors recommended that physicians engage patients in a conversation that has a dual agenda of "hoping for the best while preparing for the worst." They asserted:

Hoping for a cure and preparing for potential death need not be mutually exclusive. Both patients and physicians want to hope for the best. At the same time, some patients also want to discuss their concerns about dying, and others probably should prepare because they are likely to die sooner rather than later. Although it may seem contradictory, hoping for the best while *at the same time* preparing for the worst is a useful strategy for approaching patients with life-limiting illness. By acknowledging all the possible outcomes, patients and their physicians can expand their medical focus to include disease-modifying and symptomatic treatments and attend to underlying psychological, spiritual, and existential issues.<sup>20</sup>

Within this framework of a dual agenda, these authors offer five practical recommendations: (1) give equal time to hoping and preparing; (2) align patient and physician hopes, with a first step of directly inquiring from patients what they are hoping for; (3) encourage but do not impose the dual agenda of hoping and preparing; (4) support the evolution of hope and preparation over time; and (5) respect hopes and fears, responding to the patient's emotions.

Where, when, and with whom should physicians initiate discussions about advance care planning? We recommend ambulatory clinics as the preferred site because outpatients are often less stressed and anxious and are more likely to be able to focus on the issues, information, and recommendations associated with advance care planning. Further, if a physician incorporates advance care planning into routine clinical appointments with many or most patients, some of the patient's immediate worries and questions (such as "Why is my doctor bringing this up now? What does she know about my medical condition that I don't know?") may be quickly dispelled when the physician is able to say "I'm not singling you out and I'm not holding back medical information about you. I have these conversations with all my patients." Intending the process of advance care planning to occur over time during multiple outpatient visits allows the physician to introduce the topic, encourage the patient to think about preferences and discuss them with close family and friends, and provide the patient with take-home materials (eg, pamphlets, copies

of advance directives, videotapes) aimed at reinforcing basic information. Using this kind of a strategy increases the likelihood that advance care planning will extend appointments only by a few minutes.

Not all physicians will routinely initiate advance care planning with patients. Nevertheless, there can be specific clinical indicators that signal a degree of urgency for physicians to initiate end-of-life discussions. Quill opined that the following situations are more urgent indicators for meaningful end-of-life discussions: patients facing imminent death, patients who talk about wanting to die, patients or families inquiring about a hospice, patients recently hospitalized for severe progressive illness, and patients suffering out of proportion to the prognosis.<sup>21</sup> In oncology, a relapsed patient or one found to have metastatic disease is a priority candidate for advance care planning. At a minimum, physicians need to be attentive to patients manifesting clinical "triggers" and to respond quickly by initiating advance care planning discussions with them.

Physicians should remember that they play a key but not an all-encompassing role in the advance care planning process. In addition to raising issues, helping patients understand their diagnoses and prognoses, and encouraging patients to reflect on their preferences and values, physicians can and should direct patients and their families to appropriate support persons and resources, such as social workers, chaplains, and midlevel practitioners (eg, physician assistants, advance practice nurses) who may be knowledgeable and skilled in this area.

The third stage for advance care planning is documenting preferences and designated proxies. One caution about this third stage is the tendency to reduce what should be a quality conversational and educational process to the signing of documents—similar to the tendency to reduce the informed consent process to the event of getting a patient's signature on an informed consent form. All states in the United States now have legislatively approved advance directive forms, which may provide instructions regarding medical treatment in the event of a terminal or irreversible condition (usually called a living will) or designate a surrogate or proxy decision maker when a person loses decisional capacity (a medical power of attorney or durable power of attorney for health care). Traditionally, a living will directs the limitation or cessation of treatment for specified medical conditions, but some states (eg, Texas) allow patients to request being kept alive in a terminal or irreversible condition using available life-sustaining treatment. In either case, physicians should be open and honest with patients about their willingness and ability to honor the advance directive. Most living will instructions are very general (eg, do not specify or distinguish

which life-sustaining treatments a patient is declining) and apply narrowly in explicitly stated medical conditions (eg, terminal illness or irreversible conditions, such as a permanent vegetative state). Most commentators acknowledge that documents designating proxy decision makers are more flexible and more useful because instructional documents such as a living will could not practically list or anticipate all or most of the medical situations that could befall a patient. But the more flexible medical power of attorney is useful only if a patient designates a proxy decision maker who knows the patient well and his or her values and preferences or who has had substantive conversations with the patient about his or her wishes for various anticipated medical circumstances.

Since 1991, US federal law has required hospitals, health maintenance organizations, and hospices to inquire of patients, on admission, whether they have an advance directive.<sup>22</sup> A patient's response to this inquiry is to be recorded in the patient's medical record, and many health care organizations encourage patients to provide copies to be placed in their medical records. Federal law also states that access to care cannot be conditioned on whether a patient has completed an advance directive. Many patients will complete advance directive documents without the participation or knowledge of their primary care physician or oncologist. In an outpatient setting, routinely asking patients whether they have completed advance directives can be an excellent entry into a discussion about advance care planning.

Although the execution of legislatively approved forms is probably the most common manner for patients to document preferences and proxies, completion of these forms is not the only way to document patient wishes. When physicians engage patients in advance care planning, written summaries should be documented in the progress notes of a patient's medical record.

### CPR and Do Not Resuscitate

Discussing patients' desires regarding CPR in the event of a cardiac or respiratory arrest can also be a part of advance care planning. Since the 1980s, discussions with patients about resuscitation status have become more commonplace. Most, if not all, hospitals have policies addressing CPR and "code status." Although most hospitals have chosen to designate decisions and corresponding medical orders to not provide CPR as do not resuscitate (DNR) orders, there is no uniform designation for such orders. For example, some hospitals and health care facilities have chosen instead to designate such orders as do not attempt resuscitation orders, as no CPR orders, or as allow natural death orders. Significantly, when patients

are in transit from one care setting to another (eg, via ground or air ambulance) or are able to be cared for in a private home, many states have passed legislation allowing emergency medical personnel to honor out-of-hospital DNR orders.<sup>23</sup>

Addressing resuscitation status in a proactive, timely way is crucial for many oncology patients, especially for those who have incurable or metastatic disease, comorbidities, or major organ failures. Within a context of "hoping for the best, preparing for the worst" (as discussed above), physicians should first help patients understand the realities of CPR and the resuscitative modalities that are entailed (ie, chest compressions, electric shock, intubation, pharmacologic agents). Further, physicians should include in such conversations empiric data that demonstrate relatively low rates of survival to discharge for all inpatient CPR attempts (approximately 17%)<sup>24</sup> and the even lower outcomes for inpatients who experience anticipated cardiac arrests as a result of their metastatic disease, comorbidities, or multiple organ failures.<sup>25</sup> Patients should also be informed that a DNR order does not mean that they will be abandoned by their physicians or health care teams (ie, a DNR order is not equivalent to a do not treat order) and that a DNR order is not incompatible with continuing other aggressive treatments. Discussions of treatments with a patient for whom a DNR order has been written should include the goals of particular treatments and the likelihood of achieving those goals. Continued chemotherapy, antibiotic administration, and blood transfusions may be appropriate when an acute condition is reversible, when a patient's quality of life can be enhanced, or when continued treatments or procedures can serve palliative purposes. A DNR order need not be rescinded during aggressive treatments, including surgery and anesthesia,<sup>26-28</sup> as long as the patient understands the risks involved and possible benefits of resuscitation during a specific procedure.

Discussions with patients about resuscitation status can be excellent opportunities to review and revise explicitly the goals of treatment. Initially, treatment goals may realistically include cure or remission. But over time, depending on whether a patient responds to treatment, the goals may need to incorporate palliation or eventually shift to comfort care only.

### Confidant and Coordinator of Overall Care

Although emphasis on patient autonomy and individual choice has transformed the physician-patient relationship into one characterized by partnership rather than paternalism, physician-internists often retain the role, once held by the beloved "family doctor" or "general practitioner,"

as a patient's confidant and coordinator of overall care. These responsibilities can generate numerous ethical dilemmas in which internists must weigh their obligations to patients against compelling family and public interests. Managing patients' overall care also results in heightened obligations and challenges related to communication, information management, allocation of medical resources, and conflict resolution. This segment of the chapter identifies and analyzes specific conflicts arising in internists' roles as confidants and coordinators of overall care, reviews existing guidelines for managing these dilemmas, and proposes ethically justifiable responses.

### Physician-Internist as Confidant

Since the implementation of the Health Insurance Portability and Accountability Act of 1996 (HIPAA),<sup>29</sup> physicians are more attuned than ever to the ethical obligation to maintain the confidentiality and privacy of patients' medical information. However, ethical dilemmas related to possessing sensitive information about patients' conditions and lives predate HIPAA by thousands of years. Ethical standards, as reflected in the ancient Hippocratic Oath and current professional guidelines, emphasize confidentiality as fundamental to the physician-patient relationship.<sup>30</sup> Physicians' duty of confidentiality is a corollary of the patients' right of individual autonomy, which encompasses the right to control the use of their own health care information. The legal relationship of physicians to patients is a fiduciary one; loyalty and the duty to act in patients' best interests obligate physicians to maintain the confidentiality of information entrusted to them by patients. An individual's right to privacy in personal matters is also constitutionally based.<sup>31</sup> Additionally, respect for confidentiality has practical advantages; patients will be more forthcoming with the information physicians need to provide effective medical care if they trust that the information will remain confidential.

Although the HIPAA clarifies the legal consequences of unauthorized disclosures, it also articulates circumstances that might justify disclosure of confidential information, for example, threats of violence to others or mandatory reporting of abuse. Other statutory requirements, societal norms, and ethical values can also guide internists when they feel some ethical compulsion to disclose patient information obtained in confidence by patients. In general, exceptions to the general rule of confidentiality require strong ethical justification. Yet the duty to maintain confidentiality can be outweighed, in some circumstances, by internists' competing duties of beneficence and nonmaleficence to patients themselves and broader obligations to patients' family members and the public. Existing legal and professional

authorities' standards may offer guidance. We discuss these with several examples that occur with relative frequency.

### Family Secrets

Internists frequently learn sensitive information about a patient that the patient wishes to maintain as a secret even from close family, such as the sexual activity of a teenager, a spouse's drug abuse problem, or a surprise finding of nonpaternity. The internist might anticipate benefit to the patient accruing from disclosure to family members yet fear potential harm as well. Exacerbated when an internist has more than one physician-patient relationship within a single family, these situations can pose grave ethical challenges and need to be evaluated on a case-by-case basis. Generally, if the physician judges disclosure to family members to be beneficial, persuading the patient to disclose is the best course of action.

### HIV and Communicable Diseases and the Duty to Warn

Although human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS) is far from the first communicable disease to trouble physicians and public policy makers with whether to disclose the patient's condition to others, the epidemic nature of the disease and the absence of an effective cure generated controversy about how to balance the patient's privacy interest against the risks to others.<sup>32,33</sup> When a physician knows that a patient has a communicable disease, such as HIV/AIDS, and knows that the patient has not disclosed the condition to sexual partners or caregivers who will likely be exposed to the patient's bodily fluids, physicians' ethical and legal duties of confidentiality conflict with obligations to warn those who might be harmed by nondisclosure.

The duty to warn third parties to the physician-patient relationship derives in part from a 1976 court case decided by the Supreme Court of California. In *Tarasoff v. Regents of the University of California*,<sup>34</sup> the defendant-psychotherapist's patient, who had stated his intentions in therapy, killed the plaintiffs' daughter. In response to the plaintiffs' claim that the therapist should be liable for a duty to warn, the court ruled that a health care professional is required to take reasonable actions, breaching confidentiality as necessary, to warn an identifiable third party when the patient poses a serious and imminent threat to that party.

Statutory<sup>35</sup> and ethical<sup>36</sup> guidelines that attempt to define when a breach of confidentiality is justified by a duty to warn continue to recognize the factors emphasized by the *Tarasoff* court, specifically, the identifiability of the third party and the likelihood and magnitude of harm if the

third party is not warned. Additional factors include the preventability or treatability of the communicable disease. The case for disclosure diminishes when it is not possible to prevent, treat, or minimize the severity of the illness.

Individual autonomy is not an absolute right. If an individual's choice endangers innocent others or threatens the public health, restrictions may be ethically justified. Thus, whereas a patient might abdicate his or her duty to disclose information to their partners or intimates, physicians have an independent obligation to weigh their duty of confidentiality against the interests of others. At a minimum, physicians' disclosure of the HIV diagnosis or a communicable disease directly to patients should include counseling about implications for intimate partners. When counseling patients with communicable diseases, physicians should inform patients about the limitations of the physician's protection of privacy. For example, if a patient asks his physician not to tell his wife that he tested positive for HIV/AIDS, the physician could agree to maintain confidentiality while the patient was admitted to hospital but might inform the patient that the physician would not discharge him to his wife's care at home, where she might be exposed to his bodily fluids, as long as she remained unaware of his positive status.

Applicable laws may permit or mandate disclosure to sexual partners or other persons potentially exposed to a communicable disease, so physicians should be familiar with and obtain legal advice regarding legal parameters. However, legal guidance may not address all situations and will likely provide little practical advice regarding the methods of disclosure. Recommendations for breaking bad news to patients, which include ensuring privacy, empathic delivery, and adequate time for questions and emotional reactions, also apply to disclosure to partners. In cases in which disclosure is permitted but not mandated, physicians need to weigh the social and interpersonal implications of informing others, acknowledging the potential negative consequences of the information, societal stigma, employment and housing discrimination, and the impact on insurability.

### Genetic Risks and the Results of Testing

Internists are increasingly likely to have patients who undergo genetic testing. Particularly if they were the referring physicians, internists may incur responsibility to participate in disclosure of results directly to patients. Positive results for an individual patient may imply an increased risk to that patient's relatives, potentially generating tension between an internist's obligations to respect the privacy of a patient's genetic information and a

duty to inform third parties about the heightened risk.

The availability of effective interventions that reduce the risk of developing a related disease or lessen the ensuing harm from a particular genetic susceptibility strengthens the ethical justification for breaching patient confidentiality. When a medical intervention, such as screening in hereditary breast, colon, or other cancers, or other means of prevention (eg, dietary restrictions for phenylketonuric patients), clearly reduces harm from a particular genetic disorder, the beneficial consequences more compellingly favor disclosure. In contrast, the impact of not informing relatives of their hereditary risks is less forceful when the genetic risks are indeterminate or when no effective medical intervention exists to prevent harm.

Existing case law recognizes that physicians' duties of beneficence can extend beyond an individual patient and has imposed obligations to disclose genetic information when the disclosure has the potential to prevent harm to third parties. However, courts have differed on whether the physician's duty to warn at-risk relatives is discharged by informing the patient of relatives' increased health risks. In *Pate v. Threlkel*, the Florida Supreme Court recognized that privacy limitations often prohibit physicians from disclosing the patient's medical condition to others, that patients can ordinarily be expected to pass on a warning, and that requiring a physician to seek out family members would place too heavy a burden on the physician.<sup>37</sup> Thus, the court said, "in any circumstances in which the physician has a duty to warn of a genetically transferable disease, that duty will be satisfied by warning the patient."<sup>37</sup>

A New Jersey court explicitly disagreed with *Pate v. Threlkel*, requiring instead that "reasonable steps be taken to assure that the information reaches those likely to be affected or is made available for their benefit."<sup>38</sup> Finally, in *Molloy v. Meier*, a Minnesota Supreme Court opinion held that "a physician's duty regarding genetic testing and diagnosis extends beyond the patient to biological parents who foreseeably may be harmed by a breach of that duty."<sup>39</sup> The facts of *Molloy v. Meier* involve primarily a failure to test for genetic traits and not specifically the failure to breach confidentiality to warn. However, *Molloy v. Meier* is significant because by allowing the lawsuit to continue, the court agreed that failure to warn in the context of genetic information can result in harm, in this case a conception that allegedly would not have occurred if the mother had been warned about fragile X syndrome.

The HIPAA also provides some guidance. Its stringent privacy rule requires that disclosure of protected information must be "necessary to prevent or lessen a serious and imminent threat

to the health or safety of a person or the public; and [be] to a person or persons reasonably able to prevent or lessen the threat, including the target of the threat....<sup>35</sup> Although this exception suggests that disclosure directly to the at-risk third party might be supportable, the internist would have to consider whether the specific threat met the substantive components of this exemption. Consider the case of a person with a genetic mutation predisposition to hereditary nonpolyposis colorectal cancer (HNPCC). Monitoring and early detection can prevent and lessen a serious threat to the person's health, with surveillance reducing the incidence of colorectal cancer by more than 50% and overall mortality by 65%.<sup>40</sup> Yet it is difficult to argue that the threat is imminent because the average age at onset of colorectal cancer in HNPCC families is 44 years. The HIPAA exception appears not to apply.

Several professional organizations recommend that the informed consent process prior to genetic testing include discussions of the patient's responsibility to warn at-risk relatives. The Council on Ethical and Judicial Affairs of the AMA asserts that, at the time of testing, physicians should discuss with patients "circumstances under which they would expect patients to notify biological relatives of the availability of information related to the risk of disease,"<sup>41</sup> with the responsibility for notification lying with the patient. Similarly, the American Society of Clinical Oncology concludes that "the cancer care provider's obligations (if any) to at-risk relatives are best fulfilled by communication of familial risk to the person undergoing testing."<sup>42</sup>

These guidelines notably do not recommend that physicians notify relatives directly in breach of patient confidentiality. The AMA's advice also acknowledges that some relatives may not want the genetic information, even though the patient's knowledge makes it available to them. Genetic counselors can contribute valuable expertise, insight, and guidance when physicians consider whether potential harm to third parties justifies a breach of patient confidentiality.

### Risks to the Public

Internists encounter myriad situations in which they are aware that a patient's condition poses risks to the general public. In such circumstances, the *Tarasoff*-based duty to warn may be inapplicable because those at risk are not specifically identified. However, ethical and legal obligations to breach patient confidentiality may still be compelling.

Some examples involving breach of confidentiality for public safety have reached sufficient scope and threat so as to justify virtually national policies, such as state notification of tuberculosis patients. Other public health risks threatened by

nondisclosure are more ambiguous yet likely are far more common. Internists must weigh when an elderly patient's vision problems or dementia results in an inability to drive a car safely. A patient who is a commercial truck driver, pilot, or physician may disclose to his internist that he regularly abuses alcohol or drugs.

Although each patient's situation deserves its own evaluation, existing law may provide guidance. Some state laws impose a legal duty to report dangerous conduct to an appropriate authority. For example, a physician may be legally obligated to report to the state department of transportation a truck driver's medical condition that poses a danger to the driver or others, although most states allow for physicians to report on a permissive basis.<sup>43</sup> Some states require physicians in specific circumstances to report to the state medical board their awareness of an impaired colleague.<sup>44</sup>

Ethical justification for disclosure of conditions that threaten the general public reflects the fact that an individual's right to self-determination, with its corollary right to control personal and medical information, does not encompass the right to harm others. Thus, when a patient's medical condition puts others at risk, the physician need not maintain confidentiality to respect autonomy. Autonomy is not a consequential benefit to be weighed against potential societal harms; rather, harm to others limits the autonomy of an individual member of a democratic society.

Legal reporting requirements, if they exist, may provide immunity against liability for the resulting breach of patient confidentiality, but they may not absolutely mitigate the negative consequences and ethical implications. If a physician elects disclosure, the physician should attempt to mitigate adverse consequences. Elderly patients may have been unaware of or in denial about their disabilities, and a physician's decision to disclose the risks they pose to others may threaten not only their independence but perhaps their self-image and psychological well-being. A better course would be to help the patient recognize disabilities and work with him or her toward alternative ways of meeting the goals of independence.

Limited disclosure to family caregivers or social supports, who may already have explicitly or implicitly authorized access to the patient's information, may constitute an alternative to legal or official mechanisms for protecting the public. The circumstances of the patient's communication may suggest other alternatives to disclosure. If the impaired patient disclosed the condition as a first step toward rehabilitation, the physician may be able to ascertain the patient's commitment to terms that sufficiently reduce the public threat. Some states have programs, authorized by licensing boards or unions, to permit

impaired professionals to avoid disclosure as long as they participate in a treatment program. Specifically for physicians, the Federation of State Physician Health Programs offers programs in every state in the United States that address physician impairment.<sup>45</sup> Seeking the advice of mentors or legal and ethics consultants may also be helpful in hard cases. In all situations, however, physicians should avoid making explicit promises of confidentiality they cannot legally or ethically keep.

### Coordinator of Overall Care

Increased specialization in health care contributes to the array of professionals who provide care for patients. Internists, as primary or central care providers, will encounter ethical challenges in their roles as frequent "gatekeepers"<sup>46</sup> to medical services and as mediators among consultants with divergent opinions. These roles illuminate the often competing interests internists must balance. Although patient best interest remains paramount, alliances with consultants, affiliations with institutions, and legitimate self-interest can create pressures running counter to this fundamental obligation.

As a backdrop to the specific ethical issues that arise, strong interpersonal and communication skills facilitate the fulfillment of the internist's obligations as coordinator. A physician's empathic manner<sup>47</sup> and effective style of communication support the provision of quality medical care.<sup>48</sup> Physicians' communication shortcomings have been shown to limit the collection of significant information from patients.<sup>49</sup> Studies done with oncology patients show that a substantial segment of the lay public does not understand the terms and medical jargon doctors used to describe diagnosis, prognosis, screening, and treatment procedures and that doctors overestimate patients' levels of understanding.<sup>50</sup> Such misunderstandings may affect patients' decision making, treatment preferences, and satisfaction with care.<sup>51</sup> Moreover, multiple studies have shown that poor physician-patient or physician-family communication and a perceived lack of caring correlate with increased exposure to litigation.<sup>52,53</sup>

Internists are no more or less likely than other physicians to have greater or fewer skills in communicating with and communicating caring to patients. However, the centrality of an internist's role as a coordinator of overall care increases the likelihood of the internist's responsibility for summarizing complex medical judgments and options, producing a single medical recommendation from multiple sources of information and possibly divergent opinions, and securing the patient's trust and affiliation amid numerous specialty consultants. These responsibilities heighten internists' need for empathy, competence, and expertise in communication.

Evidence that internal medicine trainees grow more cynical and less compassionate and that empathy as a trait is not easy to inculcate<sup>54</sup> suggests that cultivating communication skills and empathy is difficult. Moreover, the literature contains a litany of reasons why exhibiting these skills is so challenging in the modern medical setting, including inadequate<sup>55</sup> and potentially counterproductive<sup>56</sup> training, time and resource constraints,<sup>57</sup> and competitive pressures.<sup>58</sup>

Despite these obstacles, extensive resources exist to cultivate these characteristics and skills in medical professionals. The medical literature contains both empirically and experience-based guidance.<sup>59–62</sup> Commentaries written or contributed by patients poignantly offer insights and suggestions based on their positive and negative experiences.<sup>63–66</sup> Training courses that offer interactive techniques and role playing offer opportunities to practice and are a promising modality for increasing interpersonal skills.<sup>67</sup> The Internet is also a valuable resource for information about training opportunities to increase these skills.

### Internist as Gatekeeper

Although the cost-saving strategies of managed care differ from the medical field's traditional fee-for-service practice, both systems raise ethical concerns related to physicians' financial interests. Physicians can just as easily overuse resources in the fee-for-service setting as underuse them in the context of managed care. Both inappropriate uses of health care resources pose a direct risk to patients. Moreover, individual physicians' primary duties to patients coexist with the profession's collective responsibility to advocate for the health and well-being of the public.<sup>68</sup> Adherence to the principle of justice, defined as the just distribution of health resources within the community, impels all physicians to practice responsible stewardship of resources they control.

Thus, whatever the organization of health care delivery, the principles for resource allocation remain consistent. The American College of Physicians (ACP) *Ethics Manual* posits two guiding principles: (1) all health-related resources should be used in a technically appropriate and efficient manner, avoiding unnecessary testing, interventions, and consultations, and (2) resource allocation decisions, such as rationing medical care among recipients, are most appropriately made at the level of policy, not at the bedside. In light of physicians' parallel obligations to patients and society, they are ethically bound to object to policies that undermine the fundamental ethical commitment of physicians to care appropriately for their patients.<sup>68</sup> The ACP has also published a more detailed statement of ethical principles, developed by a working group that included patients, clinicians, ethicists, and managed care leaders, to guide allocation of resources in the current health care environment.<sup>69</sup>

### Relationships with Consultants

The breadth and scope of medical knowledge necessitate internists' frequent use of specialized consultants, but consultants' participation magnifies the communication and interpersonal challenges already present in the physician-patient relationship. The ACP *Ethics Manual* encourages primary physicians to obtain competent consultation but recommends explicit clarification among professionals in advance of the consultation about its scope and durational authority for patient care.<sup>68</sup>

When disagreements arise, candid discussion between the internist and consultant about the medical bases for their divergent judgments not only creates reciprocal learning opportunities but also enhances the internist's ability, requisite for informed consent, to depict the patient's options accurately.<sup>70</sup> Patients ultimately need to elect the option that best meets their goals and risk orientation, but trust in a particular physician critically influences patients' choices.<sup>71,72</sup> Internists' medical recommendations are optimally informed by respectful discussion with consultants, thereby warranting patients' trust. Further, internists are often in the best position to understand the patient's entire medical and personal situation, key ingredients for formulating the best medical recommendations.

Ensuring adequate communication among the numerous diagnostic and treatment providers also poses potential ethical hazards. The relative insecurity of electronic communication methods such as transmission via facsimile, electronic mail, and cellular telephones has made the duty of confidentiality, now federally mandated by the HIPAA, harder to uphold. Simultaneously, concern about genetic discrimination and revelation of misuses of medical information have heightened the public's attention to the privacy of their information. Internists should clarify security mechanisms and policies within their organizations and should inform patients choosing to communicate by electronic means about security limitations. When communicating with consultants, brief electronic mail interchanges may not adequately capture the subtleties of the patient's condition; the internist must take care that the consultant's advice is based on adequate information.

### Alternative Medicine

Coordinating overall care obligates internists to ascertain patients' use of complementary or alternative medical (CAM) therapies. The results of a US survey indicate that total visits to CAM providers (629 million) exceeded total visits to all primary care physicians (386 million) in 1997 and that total out-of-pocket expenditures for CAM therapies, including both products and

professional services, were estimated to be \$27 billion, an amount comparable to projected out-of-pocket expenditures for all physician services.<sup>73</sup> Often these nontraditional interventions are complementary to and not exclusive of conventional medicine.<sup>74</sup>

Advising patients on CAM therapy represents a fundamental challenge. Although formal studies of some CAM therapies are under way, evidence for many types simply does not exist. Both their effectiveness and potential hazards, whether inherent in or in conjunction with conventional interventions, remain unknown. Many CAM practitioners are unregulated by any oversight body; thus, physicians and patients are ill-equipped to judge the quality of their services. Physicians interested in or willing to incorporate patients' use of CAM therapies into the care plan are disadvantaged in ensuring patient best interest. Finally, patients' refusals of or delays in conventional treatment owing to reliance on CAM therapies can complicate the provision of quality medical care and may even threaten the physician-patient relationship.

The routine balancing of risks and benefits in physician-patient decision making about CAM therapies versus conventional medical treatment must accommodate for the absence of evidence. Factors to consider include the severity and acuteness of the illness; curability with conventional treatment; degree of invasiveness, associated toxicities, and side effects of conventional treatment; quality of evidence of safety and efficacy of the desired CAM treatment; degree of understanding of the risks and benefits of CAM treatment; knowledge and voluntary acceptance of those risks by the patient; and persistence of the patient's intention to use CAM treatment.<sup>75</sup>

Physicians should clarify and attempt to incorporate the values and beliefs patients express by seeking CAM therapies, including patients' views of their own best interests. A helpful step-by-step strategy for advising and comanaging a patient who uses CAM therapy begins with an emphasis on patient safety, with continued monitoring, and includes clear documentation of clinical activity of both CAM and traditional medical interventions with ongoing conversations and advice related to the patient's treatment decisions.<sup>76</sup>

### Terminating the Physician-Patient Relationship

Traditionally, physicians have been free to choose whom they will serve. Once the physician-patient relationship is established, however, physicians incur a legal and ethical duty to treat. Termination of the relationship can be justified, but improper termination constitutes abandonment, an act of negligence, and violates the fiduciary

responsibility to act in the patient's best interest. The prospect of terminating the physician-patient relationship usually arises in the context of patients who exhibit extreme or repeated nonadherence to the physician's advice.

Recommendations for a proper termination process reflect a combination of ethical principles and legal guidance from common and statutory law.<sup>77</sup> Organizations may have internal policies or protocols as well. Generally, the physician must notify the patient in writing, preferably in a manner that establishes receipt, such as certified mail. The document should unequivocally state that the physician intends to discontinue providing medical care for the patient and may describe the reasons for, as well as previous efforts to avoid, termination. The letter should state that the physician will continue to treat the patient for a reasonable time period, the duration of which should reflect the patient's condition and how long it should reasonably take the patient to find another treating physician. The letter should also state clearly the date that termination becomes effective (eg, "March 30," not "10 days from receipt of this letter").

Liability concerns related to negligent referrals favor recommending or referring the patient to a local medical society or physician referral service rather than to a specific practitioner. The letter should also indicate agreement to transfer records to the new physician on receipt of the patient's signed authorization to do so. Finally, the letter should acknowledge that the physician will see the patient if a medical emergency arises within a stated period of time after termination.

Practical realities may prevent a provider from completely severing the relationship. Specialists may not have replacements available who can provide comparable care. Emergency centers cannot turn away patients if they need to be stabilized, even if the hospital notified the patient of termination. Physicians participating in managed care group plans may not be able to sever the patient's relationship with the entire group and thus may have to care for the patient as part of his or her group responsibility.

Moreover, the ethical and professional obligations of physicians to patients suggest that termination should be considered as a last resort. Physicians can inform patients directly at the outset of a relationship of patients' own obligations, such as arriving for scheduled appointments, paying for services, and participating in treatment, and can remind patients about these stipulations as problems arise. Written "care contracts" may be introduced to emphasize the need for the patient's participation in treatment and can state termination of the relationship as a consequence of nonadherence to a described treatment plan.

Reviewing some of the theories and empiric data that attempt to explain the reasons for patients' nonadherence suggests some considerations and approaches that might enable a physician to continue managing the patient.<sup>78,79</sup> A patient's decision not to adhere to medical recommendations may reflect the need to retain some measure of control, a serious denial of the reality of illness, or a more extreme personality disorder. These considerations might be worth exploring directly with the patient or, with the patient's permission, with family members, friends, or a therapist to inquire into the patient's motivations and characteristics. A formal assessment of decision-making capacity may determine whether compulsory treatment might be justified.

A patient's social circumstances should also be considered. Illiteracy, the inability to arrange for child care or transportation, or the inability to pay for treatment may be contributing to nonadherence. Problems deriving from the physician's own relationship with the patient may be a factor; for example, failures of communication and of trust or discordance between expectations may be yielding a dissatisfaction that leads to nonadherence.<sup>80,81</sup> Volitional disability, a patient's inability to prevent self-destructive nonadherence that might be compared to compulsive or addictive behavior, might also be the source of the problem.<sup>82</sup> Engaging patient advocates, social workers, behavioral therapists, addiction experts, or other allied health professionals may generate additional ideas for redressing the patient's nonadherence.<sup>83,84</sup>

Finally, physicians should consider whether the patient's nonadherence reflects the patient's individual rationality in the face of chronic illness.<sup>85,86</sup> A patient may not be willing to sacrifice a way of life that he or she singularly values, leaving the physician forced to accept the patient's life-threatening choices. When best efforts to understand and modify patients' nonadherent choices fail, terminating the physician-patient relationship may be necessary.

## Conclusion

The goal of this chapter has been to create an ethical and legal framework that supports quality care of cancer patients in a variety of clinical settings. Significant elements of our framework include a partnership model for the physician-patient relationship; an informed consent process that emphasizes communication, education, and transparency; end-of-life care that helps patients retain hope while preparing for the reality of death when appropriate; and the physician's role of confidant and coordinator of patients' overall care.

Throughout the chapter, we have explicitly addressed a selected set of ethical and legal issues. In doing so, we hope that we have also created a framework for identifying, analyzing, and addressing other ethical and legal issues that time and space have prevented us from including.

# Cancer-Related Fatigue

Carmen P. Escalante, MD  
Xin Shelley Wang, MD, MPH

Cancer-related fatigue (CRF) is a significant problem that increases the stress and anxiety of both patients and caregivers. Because of successes over the last several years of being able to stabilize and even cure some patients, cancer has now been relegated to the status of a “chronic condition,” similar to comorbidities such as hypertension, cardiac disease, congestive heart failure, and diabetes mellitus.

Fatigue is a common symptom of many serious illnesses, including cancer. Its presence adds little to the diagnosis,<sup>1</sup> and so far, it has no objective physiologic or behavioral markers. Often neglected and undertreated,<sup>2,3</sup> fatigue is commonly associated with other physical and psychological disorders and may decrease a patient’s quality of life and functioning. Because more precise screening tools are available for some cancers, management of comorbidities has improved, and lives have been extended, we expect new cancer diagnoses to continue to increase. Most of these newly diagnosed cancer patients will receive treatment, and fatigue will continue to top the list of symptoms associated with cancer.

CRF must be addressed early in the patient’s evaluation. The symptom must be acknowledged, and an attempt must be made to reverse the contributing conditions, given the fact that there is currently no gold standard regarding fatigue therapy. Multiple conditions that contribute to fatigue, such as pain, depression, anemia, and hypothyroidism, are treatable.

CRF may occur before, during, or after cancer treatment and as a result of any type of cancer treatment. Some patients experience fatigue before the cancer is diagnosed, and fatigue may seem to be one of the most severe symptoms, partly because of the type and extent of the malignancy at the initial diagnosis. Patients with a hematologic malignancy, for example, are more likely to exhibit significant anemia and have a high risk of infections because of low neutrophil counts. For these patients especially, collection of baseline data to establish the presence and intensity of CRF is often helpful in understanding the effect of cancer treatment.

Most patients experience fluctuations in fatigue during high-dose chemotherapy, with fatigue increasing as the patients’ blood counts approach their nadir and improvement as the counts recover.<sup>4</sup> Patients who receive radiotherapy may experience a gradual deepening of fatigue as the treatment goes on.<sup>5</sup> Sometimes patients experience more fatigue during treatment than before it began but do not describe it as increasing.<sup>6</sup> They may hesitate to complain of growing fatigue because they believe it is an expected part of treatment, they do not wish to be a “complainer,” or they may fear that the treatment will be modified or stopped as a result of the complaint. Many patients experience persistent fatigue between chemotherapy treatments. A relevant issue for patients cured of malignancy, CRF may continue for years following treatment and cure.<sup>7,8</sup>

Some cancer patients may need to maintain sufficient function either at work or at home after their diagnosis, and persistent fatigue may prevent them from doing so. Fatigue may affect both physical and cognitive functions. Many patients have trouble with short-term memory or concentration. Neurocognitive dysfunction may lead to loss of livelihood and increased dependence on caregivers for assistance in daily activities. Patients may feel increased anxiety and frustration from a loss of pleasurable activities, such as reading or solving puzzles. Increasing dependence on others and an assortment of associated negative emotions may cause patients to experience depression, which often compounds the fatigue.

Because of CRF’s increased incidence, its complexity, and the profound effects it has on cancer patients, health care providers should be encouraged to evaluate and treat this symptom. The uncertainties of assessment and treatment can be cleared up only by a continuing focus on the symptom, with encouragement of further research to define its pathophysiologic mechanisms, development of targeted pharmaceutical agents, and well-designed clinical trials that will strengthen the armamentarium of treatment choices.

Here we examine the current state of knowledge of CRF, including frequently seen clinical manifestations and associated symptoms, proposed hypotheses related to pathophysiologic mechanisms, related etiologies, diagnostic tools available for measurement, and current treatments.

## Clinical Manifestations

Several definitions of CRF are found in the literature. The National Comprehensive Cancer Network (NCCN) describes CRF as a persistent, subjective sense of tiredness related to cancer or cancer treatment that interferes with usual functioning.<sup>9</sup> Other words and phrases to describe fatigue include a lack of energy, weakness, tiredness, an increased effort in regard to a given task, increased sleepiness, and lassitude. It is important to have the patient describe the fatigue and how it affects her or him. Some patients may feel the effect only on physical stamina, whereas for others, cognitive aspects may be an issue as well.

## Prevalence

The prevalence of CRF ranges from 60 to 90% of cancer patients, the variance depending on the CRF definition used and the presence of other factors in the population studied (cancer type, extent of disease, presence of comorbidities or treatment complications, cancer treatment received, medications, physical condition, and presence of other symptoms). Compared with other cancer-related symptoms, fatigue was the most severe symptom reported by a large outpatient sample who had various cancers and were receiving differing treatments in a comprehensive cancer center.<sup>10</sup> More than 30% of cancer patients reported severe fatigue, feeling weak, or not getting things done, whereas fewer than 30% reported other symptoms. Severe levels of fatigue are more common in cancer patients than in the general population. Half of the patients with hematologic malignancies described severe fatigue (defined as 7 or higher on a 0- to 10-point scale).<sup>11</sup> Approximately one-third of patients with solid tumors reported severe fatigue when asked, whereas only 17% of a community-dwelling sample reported

this level of fatigue.<sup>12</sup> Newly diagnosed non–small cell lung cancer patients experienced significantly more fatigue than did patients with newly diagnosed breast or prostate cancer.<sup>13</sup>

### Associations with Treatment

Surgery, chemotherapy, radiotherapy, biologic response modifiers, and hormonal treatment have been associated with fatigue, although more consistent data support the association of fatigue with chemotherapy, radiotherapy, and biologic response modifiers. The literature concerning the effects of surgery on fatigue is limited. Forsberg and colleagues asked patients with colon, rectal, or stomach cancer to complete surveys prior to surgery and 6 weeks postoperatively.<sup>14</sup> Similar fatigue levels were noted at each time point: 43% preoperatively and 49% postoperatively, with minimal variation in symptom patterns. Galloway and Graydon studied colon cancer patients postoperatively and noted the presence of fatigue before the patients' discharge.<sup>15</sup>

Haylock and Hart's first demonstration of the association between radiotherapy and fatigue was followed by numerous studies that examined fatigue incidence and symptom pattern during radiotherapy regimens.<sup>16–30</sup> These studies make known that fatigue commonly begins at the start of radiotherapy, usually increases, and then plateaus between the second and fourth week of treatment. On treatment completion, fatigue gradually decreases and usually resolves by 3 months post-treatment. The cause of fatigue owing to radiotherapy is unclear.

The association of fatigue and chemotherapy has been noted for about 20 years and has been studied in a variety of cancer types, although the association of fatigue and chemotherapy has been most thoroughly studied in breast cancer patients.<sup>6,22,31–34</sup> The symptom pattern of fatigue in patients undergoing chemotherapy is not consistent, probably because of the variation in disease and treatment characteristics (ie, chemotherapy regimen, stage and extent of disease, measurement method, and time). As the complexity of a chemotherapy regimen increases, fatigue levels increase apace. Greene and colleagues reported fatigue onset within 24 to 48 hours after treatment with pulsed therapy,<sup>35</sup> whereas Richardson and colleagues demonstrated that the least fatigue occurred directly before the next treatment course began.<sup>34</sup> Breast cancer patients receiving adjuvant chemotherapy have greater fatigue than matched controls without cancer.<sup>6,35</sup>

Patients on biologic response modifiers experience such intense and intolerable fatigue that this often limits their ability to continue treatment with these agents.<sup>36–39</sup> Extremely limited data about this treatment modality make symptom patterns difficult to describe. Similarly, the side effects of hormonal treatment have not

been well assessed and are frequently underestimated.<sup>40</sup> Leonard reported lethargy and lack of energy related to hormonal treatment.<sup>41</sup>

### Pathophysiology of CRF

The pathophysiology of CRF has not been elucidated; however, several mechanisms are proposed in the literature. According to the muscle metabolism hypothesis, cancer or cancer treatment results in a defect in adenosine triphosphate regeneration in skeletal muscle, decreasing the ability to perform mechanical work and producing the symptom of fatigue.<sup>42,43</sup>

The vagal afferent hypothesis suggests that cancer or cancer treatment causes release of neuroactive agents that activate vagal afferents, thereby decreasing somatic motor output and causing sustained changes in particular regions of the brain associated with fatigue.<sup>44–46</sup> The theory of serotonin dysregulation is based on an increase in brain serotonin (5-hydroxytryptamine [5-HT]) levels in localized regions of the brain and an up-regulation of certain 5-HT receptors, leading to decreases in somatomotor drive, modified hypothalamic-pituitary axis (HPA) function, and a sensation of decreased capacity to perform physical work.<sup>47,48</sup> The HPA dysfunction hypothesis proposes that cancer or its treatment either directly or indirectly causes change in the HPA function, leading to endocrine changes that either cause or contribute to fatigue.<sup>49,50</sup>

Many laboratory studies have identified cytokines as central mediators of “sickness behavior” owing to infections.<sup>51</sup> Sickness behavior includes decreased locomotor activity, decreased feeding, decreased exploration of the environment, less sexual activity and other social interactions, and increased sleep (specifically slow-wave sleep). CRF in humans may be similar to sickness behavior, with its characteristics of general malaise, lack of motivation to eat, and decreased interest in activities. Cytokines were linked recently to mental and physical functioning of cancer patients and were associated with pain, depression, sleep disturbances, and cachexia.<sup>52–54</sup>

### Fatigue-Associated Symptoms

Rarely occurring alone, fatigue is frequently associated with a cluster of symptoms related to either cancer or cancer treatment.<sup>55–58</sup> The symptoms most often coupled with fatigue include pain, nausea, depression, sleep disturbances, and dyspnea.

Fatigue and depression were shown associated in several studies. Visser and Smets demonstrated, in a cohort of 308 adult outpatients treated with radiation therapy, that fatigue was not predictive of depression and vice versa.<sup>59–63</sup> Sleep disturbances have been less studied, yet fatigued cancer patients receiving treatment show severely disrupted sleep patterns.<sup>63,64</sup> Berger and

Farr conducted a prospective repeated-measures study of 72 women free of unstable chronic illnesses during the first three chemotherapy cycles after surgery for stage I or II breast cancer.<sup>64</sup> The authors noted that women whose sleep is disrupted at chemotherapy cycle midpoints are at risk of CRF. The overall effects of less daytime activity, more daytime sleepiness, and night awakenings were associated with higher CRF levels. To manage fatigue, Visser and Smets suggested that CRF and night awakenings be assessed at the midpoint of chemotherapy cycles and that appropriate treatment interventions be developed to promote daytime activity and nighttime rest.<sup>63</sup>

Many cancer patients are anemic. Several large community-based studies demonstrated that treatment with erythropoietin alfa increased the patients' hemoglobin levels, decreased their red blood cell transfusion requirements, and showed an association between patient's quality of life and hemoglobin level.<sup>33,65–68</sup> Recently, treatment with darbepoetin alfa produced similar outcomes.<sup>69,70</sup>

### CRF Assessment Tools

The first step of measuring fatigue is severity level currently and over time. The selection of fatigue assessment tool (with or without company of other measurements) depends on the specifics of the intervention or research. Specifically, it depends on the need for rapid screening versus a more comprehensive appraisal and consideration of psychometric qualities (standardization, reliability, validity).

Successful treatment and management of CRF depend on reliable and valid assessment tools. Patient self-report has become a standard method in clinical practice for assessing fatigue dimensions, including fatigue severity and interference with daily activities. A good assessment tool for measuring CRF is characterized by a small number of valid, simple items; patient-friendly scaling; understandable terms; standard administration and scoring methods; and demonstrated reliability and validity. Another characteristic should be easy translatability to other languages for comparisons in different populations.

Several CRF assessment tools offer variability in coverage, structure, standardization of administration and scoring, and high levels of reliability and validity. In Table 1, they are categorized as to whether they are unidimensional or multidimensional tools.

### Evaluating the Patient with CRF

Whatever tool is chosen, it must be reproducible and practical. Patients with significant fatigue often feel overwhelmed, and when measurement requires much time, they may be unable to complete it. In clinical practice, a simple

Table 1 Selected Fatigue Assessment Tools

Tool	Total Items	Time Window
Unidimensional		
Cancer-Related Fatigue Distress Scale <sup>110</sup>	20	Past 7 d
Brief Fatigue Inventory <sup>12</sup>	9	Past 24 hs

Hormonal treatment

one-question screening tool may be sufficient; for example, “What was your worst level of fatigue during the last 24 hours, on a scale of 1 to 10, with 10 being worst fatigue?” The NCCN Cancer-Related Fatigue Guideline screens are based on a patient’s response to a single tool. If the patient has moderate to severe fatigue, completion of a more comprehensive fatigue assessment tool should be performed.<sup>58</sup>

The *International Classification of Diseases*, tenth revision (ICD-10), describes the CRF diagnostic criteria as follows<sup>71–73</sup>:

1. Six or more of 11 possible fatigue symptoms, with one being “significant fatigue,” have been present every day or nearly every day during the same 2-week period in the past month.
2. The symptoms cause clinically significant distress or impairment in important aspects of functioning.
3. The symptoms are the result of cancer or cancer treatment.
4. The symptoms are not primarily due to a comorbid psychiatric disorder.

Use of consistent diagnostic criteria will improve consistency in condition- and treatment-related CRF epidemiologic estimates.

Patients with moderate to severe fatigue require a thorough medical evaluation, including a careful history that focuses on fatigue onset; duration, intensity, and changes over time; associated symptoms; and factors that may alleviate or worsen fatigue. The assessment should include the patient’s current disease status, type and length of cancer treatment and its ability to cause fatigue, and the patient’s response to treatment. For patients who are disease free, the evaluation should include the question of whether recurrence is a cause of fatigue, and for those with underlying malignancy, whether fatigue is related to disease progression. These questions often provoke extreme anxiety in the disease-free patient and family members, and reassurance that the fatigue is unrelated to the disease may reduce their fears. Other factors that may affect fatigue

and should be considered include medications used (both prescribed and over-the-counter, including herbal and vitamin and mineral supplements), nutritional aspects (weight changes, variations in caloric intake, fluid and electrolyte imbalances); decreases in activity and physical deconditioning; and the presence of comorbidities (infection, hypothyroidism, or cardiac, pulmonary, renal, hepatic, neurologic, or endocrine dysfunction). Table 2 summarizes potential contributing factors to CRF.

CRF is an important outcome measure and should be considered when conducting trials of new pharmacologic agents to combat cancer. Decreases in CRF may be represented by a reduction in treatment toxicity, improved palliation for patients with progressive or advanced disease, or better functional and health status in cancer survivors. Fatigue may affect other aspects of care, such as morbidity and mortality, cost of care, and patient satisfaction with care. It may also serve as an indicator of quality of life.

### Intervention in CRF

Given that the pathophysiologic mechanisms of CRF are still poorly understood, the root cause cannot be targeted. However, contributing and potentially reversible conditions are anemia, depression, and pain, all of which can be managed.

All patients should be provided with education concerning the side effects of specific tumors and cancer treatment regimens. This will often alleviate the anxiety and stress patients and caregivers feel if they assume that when fatigue is present, the malignancy is worsening or recurring. Patients and caregivers may also be able to make better lifestyle adjustments if they understand and expect certain symptoms. For example, patients on some chemotherapy regimens may expect decreasing blood counts beginning approximately on day 7, with a nadir usually between days 10 through 14; these will bring higher levels of fatigue, and patients should prioritize activities during this time period.

Treatment of CRF may be categorized into nonpharmacologic and pharmacologic treatments. Nonpharmacologic treatments include exercise, energy conservation, sleep enhancement, nutritional therapy, and cognitive and behavioral treatment strategies. Pharmacologic treatments include erythropoietin and darbepoetin; stimulants such as methylphenidate, pemoline, and modafinil; selective serotonin reuptake inhibitors; and corticosteroids.

### Nonpharmacologic Treatments

#### Exercise

Graded aerobic exercise has been shown in randomized controlled trials to have a beneficial effect on fatigue,<sup>74–80</sup> and several trials demonstrated improvements in both fatigue and function.<sup>74,76,80</sup> The exercise types used in these trials included bed-cycle ergometer, home-based walking programs, and resistance exercise. Most studies included only patients with breast cancer.

Three studies showed reductions in fatigue and improvement in quality of life.<sup>77-79</sup>

Because patients with bone metastases, neutropenia, thrombocytopenia, and fever need to be cautious in pursuing an exercise program, the patient and health care provider should discuss the type of exercise, frequency, intensity, and duration. Exercise programs should be tailored to the patient's needs, considering her or his overall medical status, including significant comorbidities in addition to cancer, the status of physical conditioning, the extent of neoplastic disease, and the cancer treatment modality in which the patient is currently engaged. Age and gender may be less important but should be considered. Patients with significant comorbidities or deconditioning should have a medical evaluation before beginning an exercise program; they may benefit from being referred to a physical medicine and rehabilitation program.

#### Psychosocial Interventions

Randomized clinical trials of various psychosocial interventions have demonstrated significant improvements in fatigue levels.<sup>81-87</sup> The interventions included weekly support groups, individual psychotherapy, support groups providing education and stress management, coping strategy programs, tailored behavioral interventions, and professionally or self-administered stress management training. All resulted in decreased fatigue and improvement in various other symptoms. Recently, patients in a randomized clinical trial by Given and colleagues, in which a cognitive behavioral intervention was used, demonstrated significant improvement in both fatigue and pain after 10 weeks, and this was maintained at 20 weeks by patients who started the trial with moderate to severe symptoms.<sup>86</sup>

#### Restorative Therapy

Cimprich described the concept of attentional fatigue in cancer patients as decreased capacity to concentrate or focus attention during stressful or challenging situations.<sup>88</sup> Studies of attention-restoring interventions demonstrated improvement in concentration and problem-solving abilities, with earlier return to work by patients who used the intervention.<sup>89,90</sup> These studies also focused primarily on breast cancer patients.

#### Sleep Therapy

The sleep disturbances of cancer patients are often more of quality than quantity of sleep.<sup>63</sup> Research on this issue and its relationship to fatigue is limited. In two studies using actigraphy to measure sleep and activity, cancer patients were found to spend more time sleeping or resting than healthy individuals, and the sleep pattern of cancer patients was shown to be severely

disrupted.<sup>33,91</sup> Berger and colleagues performed a prospective pilot study to test the feasibility of a sleep promotion plan, including aspects of sleep hygiene, relaxation therapy, stimulus control, and sleep restriction techniques, in 25 stage I and II breast cancer patients.<sup>92</sup> The intervention resulted in improved treatment adherence rates over time, and in most patients, sleep and wake patterns returned to normal values.

Patients with sleep disturbances may benefit from a consistent bedtime and wake-up regimen. They should avoid caffeine and stimulating activities such as an exercise regimen in the evening, avoid late or long afternoon naps, and limit bedtime to normal sleep time. Comforting activities before bed (warm bath, reading, tranquil music) and a favorable sleep environment (quiet, cool, dark, comfortable room) may be helpful.

#### Energy Conservation

Little research has been done on this issue, although patients commonly will prioritize activities if they have significant levels of fatigue. Barsevick and colleagues recently completed a randomized clinical trial that compared energy conservation and activity management (ECAM) by 200 patients with a control intervention including 196 patients focused on nutrition.<sup>85</sup> Patients in the ECAM group experienced a modest but significant improvement in fatigue, although the intervention was not associated with changes in overall functional performance.

### Pharmacologic Treatments

#### Stimulants

No randomized controlled trials have been done to assess the use of stimulants in managing CRF, but some of the drugs have been studied in other conditions, such as fatigue related to human immunodeficiency virus (HIV) disease<sup>93</sup> and multiple sclerosis.<sup>94,95</sup>

Use of pemoline to treat fatigue related to multiple sclerosis produced inconsistent beneficial effects. It has not been used in patients with CRF, and its association with severe liver dysfunction in some patients resulted in its disfavor.<sup>96</sup>

Methylphenidate and modafinil have been used in most attempts to manage CRF. Methylphenidate is a central nervous system stimulant similar to amphetamine. It has a peak plasma concentration of 1 to 3 hours, a plasma half-life of 2 hours, and a duration of action of 3 to 6 hours.<sup>97,98</sup> Baseline doses generally are 5 mg in the morning and 5 mg at noon, with titration as necessary. The maximum recommended dosage is 1 mg/kg/d. The side effects of hypertension, tachycardia, nervousness, insomnia, and anorexia in children preclude its use in patient populations susceptible to these conditions. Three studies of methylphenidate, with fatigue as an end point,

are summarized in Table 3. Sarhill and colleagues demonstrated a beneficial effect of methylphenidate in a small group of patients with advanced cancer.<sup>99</sup> The primary outcome variable was fatigue. Bruera and colleagues used a prospective open study of 31 patients with advanced cancer and fatigue.<sup>100</sup> Fatigue was the primary end point, although multiple symptoms were assessed. Patients took 5 mg methylphenidate by mouth every 2 hours as needed for 7 days (maximum 20 mg/d). They had significant improvement in fatigue using this treatment schedule without sleep disruption.

Modafinil is another central nervous system stimulant approved by the US Food and Drug Administration for treatment of narcolepsy. It has been studied in patients with fatigue induced by multiple sclerosis and has produced improvement in levels of fatigue at 200 mg per day.<sup>101</sup> The usual dose of modafinil is 100 to 200 mg in the morning, with another dose at noon or shortly thereafter. The maximum dosage used is 400 mg per day. No randomized clinical trials of the use of this agent have been done with cancer patients.

#### Antidepressants

In most patients, but particularly cancer patients, fatigue and depression are related, although if there is a shared pathophysiology, it is unknown. Because of the close association, questions have been raised whether treating patients with antidepressants will lower levels of fatigue. Morrow and Hickok conducted a double-blind, randomized, placebo-controlled study with 738 patients undergoing chemotherapy who received either 20 mg of paroxetine or placebo.<sup>102</sup> Patients who received paroxetine experienced significantly fewer depressive symptoms but no significant change in levels of fatigue. Other studies of particular classes of antidepressant and different modes of cancer therapy are necessary to determine whether fatigue can improve in these circumstances. Currently, antidepressants are reasonable medications to prescribe to patients with fatigue if patients are depressed. Patients with sleeping difficulties and depression may benefit from antidepressants such as nortriptyline and amitriptyline because of the drugs' sedative qualities. Bupropion may benefit patients with CRF because it has stimulant pharmacologic properties.

#### Steroids

Most trials concerning steroids and fatigue use end-point measures other than fatigue, such as strength, weakness, or activity level. There is no consensus that use of these end points demonstrates the benefits of steroids in fatigue management. In addition, the adverse side effects related to steroid administration must be taken into account.

Table 3 Pharmacologic Treatment of Cancer-Related Fatigue with Methylphenidate

Investigators	Type of Study	Number/Features of Patients	Fatigue Outcome
Sarhill et al <sup>99</sup>	Prospective open-label pilot	11/advanced cancer	Improved
Bruera et al <sup>100</sup>	Prospective open study	30/advanced cancer	Improved
Schwartz et al <sup>118</sup>	Prospective pilot/methylphenidate + aerobic exercise	12/melanoma patients on interferon	Improved

Moertel and colleagues studied 116 patients with advanced gastrointestinal cancer in a double-blind randomized trial, administering dexamethasone 0.75 mg/d, dexamethasone 1.5 mg 4 times a day, or placebo.<sup>103</sup> After 4 weeks of treatment, 34% of patients in the two dexamethasone groups showed improved “strength” compared with the placebo group. Bruera and colleagues, in a randomized, double-blind, placebo-controlled, crossover study including 40 patients with advanced cancer, used methylprednisolone 16 mg orally twice a day.<sup>104</sup> After 2 weeks of treatment, the activity levels of 61% of patients increased, but the changes became nonsignificant 2 weeks later. Della Cuna and colleagues, who enrolled 403 patients with advanced cancer in a blinded, randomized, parallel-group study, administered either intravenous methylprednisolone 125 mg/d or placebo.<sup>105</sup> Self-reported “weakness” scores did not improve.

In a similar study by Popiela and colleagues with 173 women with advanced cancer, an improvement in “weakness” was noted by the women in the steroid group after 2 weeks of treatment, but the improvement did not last past the first 2 weeks.<sup>106</sup>

#### Complementary Alternative Therapy

Although no well-designed trials have been done to test these therapies for CRF, there is much interest in herbal treatments, massage therapy, and acupuncture. Patients should be cautious in their use of herbal treatments because there may be profound drug interactions. Given that they are easily acquired at health food stores, patients may not think of them as medications, but patients should be asked about the use of herbal agents during their clinic visits.

Acupuncture, used to treat pain, nausea, and vomiting,<sup>107</sup> has not been well studied in patients with CRF. In a pilot study of 31 patients who had completed cytotoxic chemotherapy, Vickers and colleagues used acupuncture to determine whether this intervention might improve fatigue.<sup>108</sup> Randomized into two treatment arms, patients underwent acupuncture twice a week for 4 weeks or once a week for 6 weeks. The mean improvement following acupuncture, 31.1%, indicated that the question of whether this intervention is effective for CRF deserves further study.

#### Summary

CRF is the most common complaint of cancer patients and is frequently the most distressing symptom because it interferes with multiple aspects of daily life. Awareness and study of this symptom have grown tremendously in recent years, although much about the mechanism is still unknown.<sup>109</sup> In clinical evaluations of patients with CRF, health care professionals should focus attention on reversible causes for which therapies are readily available to ameliorate the symptom. Chemotherapy-induced anemia, for example, is easily treated with erythropoietin or darbepoetin, with significant improvement in or resolution of fatigue. CRF education should be made available to all patients and their family supporters. Such education often alleviates the stress and anxiety provoked by misinformation. Exercise interventions, which have been shown to lower fatigue levels, should be tailored to individual patients, taking into account such factors as comorbidities, extent of disease, and level of deconditioning. There is a great need for well-designed clinical trials to evaluate pharmacologic agents to treat fatigue in cancer populations. There is also a need for better understanding of the pathophysiologic mechanisms attributed to CRF so that interventions targeting these mechanisms may be designed and evaluated.

# Cancer Pain

Russell K. Portenoy, MD  
Gaurav Mathur, MD

Approximately 30 to 50% of patients undergoing antineoplastic therapy and 75 to 90% of patients with advanced disease have chronic pain severe enough to warrant opioid therapy.<sup>1-3</sup> There are numerous obstacles to effective pain management, and inadequately treated pain is commonly encountered in practice. These obstacles relate to deficiencies in clinician knowledge and skills, health care systems that limit access to care, and the tendency to underreport pain on the part of patients. To improve patient outcomes, strategies are needed to address all of these obstacles. Clinician education based on well-accepted guidelines for treatment is central to this effort. Education must focus on both the assessment of pain and the many approaches that now exist to manage it.

## Definitions

According to the International Association for the Study of Pain, pain is “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.”<sup>4</sup> To clarify the approach to pain assessment, it is useful to distinguish pain from both nociception and suffering.

Nociception is the activity produced in the afferent nervous system by potentially tissue-damaging stimuli. Nociception is clinically inferred whenever tissue damage is identified. Pain is the perception of nociception and can be sustained in the absence of ongoing tissue injury by any of a variety of factors. Neuropathic pain syndromes are presumably sustained through plastic changes in the nervous system; so-called psychogenic pains are attributed to psychological disturbances. Targeting only the nociceptive component without addressing these other factors can lead to a poor outcome, in which the focus of tissue damage is ameliorated but the pain continues.

Suffering has been described as a perceived threat to the integrity of the person, as a type of “total pain”<sup>5</sup> or overall impairment in the quality of life. Suffering may be driven by unrelieved symptoms (including pain), psychological or psychosocial disturbances, or spiritual distress.

Other factors, such as financial concerns, also may be prominent. Patients vary in psychosocial and spiritual strengths and weaknesses and consequently suffer in different ways when dealing with symptoms such as pain.

## Models of Care

The assessment and management of pain must be positioned within a broader effort to preserve quality of life and address the nature of the suffering experienced by the patient and family. An understanding of the physical, psychosocial, and spiritual issues that may undermine quality of life or worsen suffering is fundamental to this process. The therapeutic approach that addresses these issues is known as palliative care. Palliative care is a therapeutic approach to the care of patients with any type of life-threatening illness and their families.<sup>6</sup> It is focused on maintaining quality of life throughout the course of the illness and must intensify as the end of life approaches. The goals of this model include symptom control; effective communication among patient, family, the treatment team, and others; management of psychological distress and comorbid psychiatric disorders; and support for efforts to address family stress, social isolation, and spiritual distress. Palliative care recognizes the need to provide practical support in the home and to manage caregiver distress and burden. If the disease progresses and the end of life is anticipated, palliative care strives to provide opportunities for a comfortable and dignified death and bereavement support for families.

Palliative care is now considered an approach that should be implemented at a generalist level by all physicians who care for patients with serious medical illnesses. It should also be available at a specialist level for those patients and families who have more complex needs. In the United States, specialist-level palliative care is now provided through a growing number of institution-based palliative care programs and through hospice programs. Physicians and nurses may now pursue subspecialty training and certification in palliative care. There is consensus about the elements that should be provided in institution-based programs.<sup>6</sup>

The United States established hospice as a government entitlement program in the early 1980s. Treatment by a hospice program is supported by a benefit available to eligible patients insured by Medicare or Medicaid; comparable benefits are available through most other insurances. When optimally delivered, hospice can provide specialist-level palliative care to patients with advanced illness. Eligibility is determined by patient election of the benefit and physician certification of a prognosis of 6 months or less should the disease run its expected course. It is a capitated health care system that provides most care at home but can also offer access to hospital beds if needed. By regulation, the care must include management by a hospice physician, nurse, social worker, and chaplain; access to medicines, supplies, and durable medical equipment related to the terminal illness at no cost to the patient; access to aides and other services as needed; and 13 months of bereavement support for the family after the death of the patient. This robust benefit now is provided through more than 3,300 hospice programs nationwide. About half of the more than 900,000 patients who are now served annually by these programs have cancer.

Despite the large population served, the hospice benefit is underused. The median length of stay in these programs is less than 20 days, reflecting the tendency to refer patients very late in the course of the illness. This tendency most likely results from a combination of factors, including the linkage of hospice with death and the misconception that the primary physician must relinquish care of a patient once admitted to the program.

Hospice programs vary in size and quality of the services provided. Many have little physician involvement and cope with the financial constraints of a capitated system by limiting the types of treatments that may be offered to patients. These factors also drive late referrals. The hospice industry in the United States now is attempting to address these limitations and is exploring a modern concept of hospice care, known as “open access.” The future will likely bring expanded use of hospice services, with earlier referrals and better integration of hospice with ongoing

oncologic care. This integration will also be supported by the continued development of institution-based palliative care programs, which lack the resources available to hospice but are well situated to assist with earlier treatment of the many concerns that may adversely affect quality of life during the course of the disease.

## Evaluation of the Patient with Cancer Pain

### Pain Characteristics

The pain complaint should be characterized in terms of clinically relevant descriptors. This information, combined with ancillary medical data, may allow the identification of the etiology for the pain, including its relationship to the underlying disease, and the development of inferences about pain pathophysiology.

### Temporal Features

Acute pain usually has a well-defined onset and a readily identifiable cause (eg, surgical incision). If it is associated with other features, these usually are anxiety, overt pain behaviors (moaning or grimacing), and signs of sympathetic hyperactivity (including tachycardia, hypertension, and diaphoresis).

In contrast, chronic pain is characterized by an ill-defined onset and a prolonged, fluctuating course. Overt pain behaviors and sympathetic hyperactivity typically are absent, and vegetative signs, including lassitude, sleep disturbance, and anorexia, may be present. A clinical depression evolves in some patients.

Most patients with chronic cancer pain also experience periodic flares of pain, or “breakthrough pain.”<sup>7</sup> An important subtype of breakthrough pain is “incident pain,” which is precipitated by voluntary activity. A recent international study demonstrated an association between breakthrough pain and higher ratings on worst and average pain scales and higher pain interference with function.<sup>8</sup> The recognition of breakthrough pain as a significant problem has supported the use of so-called “rescue” doses—a short-acting opioid administered on an as-needed basis—during long-term opioid therapy.

### Topographic Features

Focal pain is experienced at or near the causative lesion. Referred pains are experienced at a site distant from the lesion. Pain may be referred from any structure, including nerve, bone, muscle, soft tissue, and viscera.<sup>9,10</sup> Various subtypes can be distinguished. Pain may be referred along the course of an injured peripheral nerve (such as pain in the thigh or knee from a lumbar plexus lesion) or nerve root (radicular pain). Pain also may be referred to a site remote from the

nociceptive lesion and outside the dermatome affected by the lesion (eg, shoulder pain from diaphragmatic irritation).

Knowledge of pain referral patterns is needed to guide the evaluation. For example, a patient with recurrent cervical cancer who reports progressive pain in the inguinal region may require evaluation of numerous structures to identify the underlying lesion, including the subadjacent pelvic bones and hip joint, pelvic sidewall, paraspinal gutter at an upper lumbar spinal level, and intraspinal region at the upper lumbar level.

### Intensity

Measurement of pain intensity may be accomplished using a numeric scale (0–10), a verbal rating scale (none, mild, moderate, severe), or a visual analogue scale. Pictorial scales are particularly useful for the very young and patients with mild to moderate cognitive impairment. The particular scale is less important than its consistent use to monitor and document the status of pain over time.

Pain measurement is best performed by providing a framework for the patient. A specific question about the experience of pain “on average during the past day” or “at its worst during the past week” will be most informative. Patients can usually provide a detailed response to such a question.

In assessing pain intensity, it is important to obtain information about factors that increase or decrease the pain. In some cases, this information highlights the need for additional evaluation or specific interventions.

### Quality

The variation in pain phenomenology, including descriptors of quality (eg, aching, sharp, burning, stabbing), suggests the existence of multiple types of pain mechanisms. Research into pain mechanisms is proceeding rapidly, and there is reason to hope that the future may bring an opportunity to diagnose pain disorders according to the predominating mechanism and use this information to select a mechanism-based treatment. Unfortunately, clinicians presently are far from this level of sophistication.

Information about the quality of the pain, when combined with other elements in the pain assessment, may provide clues about the etiology of the pain and allow classification according to broad pathophysiologic categories (see below). Although these categories represent a gross simplification of complex mechanisms, they have clinical utility, potentially suggesting specific types of interventions.

## Etiology and Inferred Pathophysiology

To the extent that credible conclusions can be drawn, an important goal of the pain evaluation

is to determine etiology. In most patients with cancer, pain can be related to an underlying nociceptive lesion, usually direct invasion of pain-sensitive structures by the neoplasm.<sup>11</sup> The structures most often involved are bone and neural tissue, but pain also can occur when there is an obstruction of hollow viscus, distention of organ capsules, distortion or occlusion of blood vessels, and infiltration of soft tissues. The etiology of pain relates to an antineoplastic treatment in about one-quarter of patients, and fewer than 10% have pain unrelated to the neoplasm or its treatment.<sup>11</sup>

Identification of the etiology of the pain can provide an opportunity for a primary therapy, such as radiotherapy. A survey of patients referred to a pain service in a major cancer hospital noted that previously unsuspected lesions were identified in 63% of patients.<sup>12</sup> This outcome altered the known extent of disease in virtually all patients, changed the prognosis for some, and provided an opportunity for antineoplastic therapy in approximately 15%.

Information from the history, examination, and imaging studies also may identify a specific pain syndrome and allow inferences about underlying pathophysiology. Pathophysiology may be categorized as nociceptive, neuropathic, psychogenic, idiopathic, or mixed. Although these labels represent constructs that presumably reflect complex interactions among multiple processes, they are clinically relevant, in many cases suggesting the use of specific therapies.

Nociceptive pain indicates that an inference has been made that pain is sustained predominantly by ongoing tissue injury. Nociceptive pain can involve either somatic or visceral structures. Somatic pain is often described as aching, stabbing, throbbing, or pressure-like. Visceral pain is usually gnawing or crampy when arising from obstruction of a hollow viscus and aching or stabbing when arising from other visceral structures. Visceral pain is often referred to cutaneous sites or may be poorly localizable.

Pain is labeled neuropathic if the evaluation suggests that it is sustained by abnormal somatosensory processing in the peripheral or central nervous system. Neuropathic mechanisms are involved in approximately 40% of cancer pain syndromes and can be caused by disease or by treatment.<sup>13</sup> Dysesthesia, or abnormal uncomfortable sensations that may be described using words such as “burning,” “shock-like,” and “electrical,” is suggestive of neuropathic mechanisms. On physical examination, the presence of allodynia (pain induced by nonpainful stimuli) and hyperalgesia (increased perception of painful stimuli) further suggests this diagnosis. Patients may or may not develop motor or autonomic dysfunction in the distribution of the involved nerve.

The term *psychogenic pain* refers to pain that is believed to be sustained predominantly by psychological factors. These pains may be more precisely characterized by applying the widely accepted taxonomy of somatoform disorders proposed by the American Psychiatric Association.<sup>14</sup> These pains share an assessment that reveals positive evidence for the psychopathology that is believed to be causally related to the pain. This is uncommon in the cancer population, notwithstanding the importance of psychological influences in the presentation of the pain complaint and the patient's adaptation. Given the complexity of these pains, the inability to identify a structural cause for the pain should not lead to the assumption that the pain is psychogenic. Similarly, the identification of a structural etiology should not be taken as the complete explanation if psychological factors are evident.

In the absence of a lesion capable of explaining the pain and positive evidence of a somatoform disorder, it is appropriate to label the pain idiopathic. In the cancer population, this label usually suggests the need to reassess etiology and pathophysiology at a later time.

## Cancer Pain Syndromes

Efforts to improve the assessment of cancer pain have been greatly encouraged by the description of numerous pain syndromes, each of which is defined by a cluster of symptoms and signs.<sup>11,13</sup> Syndrome identification can help direct the diagnostic evaluation, clarify the prognosis, and target therapeutic interventions.

Acute pain syndromes are commonly caused by diagnostic or therapeutic interventions, including surgery (Table 1). Chronic pain syndromes may be directly related to the neoplasm or to antineoplastic therapy (Tables 2 and 3).

## Chronic Pain Syndromes Related to Direct Tumor Invasion

The most common pain syndromes are nociceptive and result from metastatic injury to bone. Only a small proportion of bone metastases become painful, and the factors that result in pain are only beginning to be elucidated.<sup>15</sup> Multifocal bone pain is usually caused by widespread metastases. The spine is the most common site of bone metastasis, and back or neck pain is associated with varied discrete syndromes. For example, tumor invasion of the C1 or C2 vertebra can cause progressive neck or posterior occipital pain, which is exacerbated by flexion of the neck. Metastasis to the C7 or T1 vertebral bodies may cause pain that refers inferiorly to the interscapular region, and a lesion of the T12 or L1 vertebral bodies can refer pain to the ipsilateral sacroiliac joint or iliac crest. Without recognition of pain referral patterns, imaging can be directed to the wrong location.

**Table 1** Acute Pain Syndromes in Cancer Patients

Acute pain associated with diagnostic procedures
Lumbar puncture headache
Bone marrow biopsy
Lumbar puncture
Venipuncture
Paracentesis
Thoracentesis
Acute pain associated with analgesic techniques
Spinal opioid hyperalgesia syndrome
Acute pain after radiopharmaceutical therapy of metastatic bone pain
Acute postoperative pain
Acute pain associated with other therapeutic procedures
Pleurodesis
Tumor embolization
Nephrostomy insertion
Pain associated with bone marrow transplantation
Acute pain associated with chemotherapy
Pain from intravenous or intra-arterial infusion
Intraperitoneal chemotherapy
Headache owing to intrathecal chemotherapy
Painful oropharyngeal mucositis
Painful peripheral neuropathy
Bone or muscle pain from colony-stimulating factors or chemotherapies
5-Fluorouracil-induced angina
Acute pain associated with hormonal therapy
Painful gynecomastia
Luteinizing hormone–releasing factor tumor flare in prostate cancer
Hormone-induced acute pain flare in breast cancer
Acute pain associated with immunotherapy
Arthralgia and myalgia from interferon and interleukin
Acute pain associated with radiation therapy
Painful oropharyngeal mucositis
Acute radiation enteritis or proctitis
Early-onset brachial plexopathy following radiation for breast cancer
Acute tumor-related pain
Vertebral collapse and other pathologic fractures
Acute obstruction of hollow viscus (eg, bowel, ureter, bladder outlet)
Headache from intracranial hypertension
Hemorrhage from tumor
Acute pain associated with infection
Myalgia and arthralgia associated with sepsis
Pain associated with superficial wounds or abscesses

**Table 2** Chronic Pain Syndromes in Patients with Cancer: Tumor-Related Pain Syndromes

Nociceptive pain syndromes
Bone, joint, and soft tissue pain syndromes
Multifocal or generalized pain (focal metastases or marrow expansion)
Base of skull metastases
Vertebral syndromes
Pain syndromes of the bony pelvis and hip
Tumor invasion of joint, soft tissue, or both
Paraneoplastic pain syndromes
Hypertrophic osteoarthropathy
Tumor-related gynecomastia
Neoplastic involvement of viscera
Hepatic distention syndrome
Rostral retroperitoneal syndrome
Chronic intestinal obstruction and peritoneal carcinomatosis
Malignant pelvic and perineal pain
Chronic ureteral obstruction
Neuropathic pain syndromes
Painful peripheral mononeuropathies
Painful polyneuropathies
Plexopathy
Cervical
Brachial
Lumbosacral
Sacral
Radiculopathy
Epidural spinal cord compression

Adapted from Portenoy RK, Lesage P. Management of cancer pain. *Lancet* 1999;353:1696–7.

Other nociceptive syndromes are caused by obstruction, infiltration, and compression of visceral structures. Patients with liver metastases may experience focal pain, which usually is sharp or pressure-like, in the right upper quadrant of the abdomen. Intrahepatic disease may refer pain to the right scapula. Diaphragmatic irritation may refer pain to the shoulder, and any lesion in the rostral retroperitoneum can produce pain that mimics the pain of pancreatic cancer, with referral to the midback. Chronic partial bowel obstruction is a common complication of many tumors, particularly ovarian and colorectal, and may produce frequent abdominal cramping or sharp and aching pains that may be worsened by eating, activity, and constipation.

Cancer-related neuropathic pain syndromes are usually caused by tumor infiltration or compression of peripheral nerves or nerve roots.<sup>11,13</sup> The resultant pain syndromes are highly variable and often challenging to treat. Painful mononeuropathies can occur after injury to any nerve that carries afferent fibers. A painful polyneuropathy may be paraneoplastic but more often has an etiology unrelated to the cancer, such as multiple vitamin deficiencies, metabolic derangements, or neurotoxic drugs. The paraneoplastic polyneuropathies include a dorsal root ganglionopathy

and a painful sensorimotor neuropathy. Painful radiculopathy usually is caused by a metastatic tumor arising from the vertebral body. Other possible causes include leptomeningeal metastases, primary epidural metastases, and primary tumors that arise from the root.

### Chronic Pain Syndromes Related to Cancer Therapy

Chronic noiceptive pain syndromes also may be related to cancer therapy. For example, radiation to bone and systemic corticosteroid therapy can cause focal painful osteonecrosis. Interruption of lymphatic channels by surgical manipulation or radiation can result in painful lymphedema.

Neuropathic pain following cancer treatment may be associated with mononeuropathy or polyneuropathy. Chemotherapy-induced polyneuropathy is common and may be a consequence of treatment with any number of agents, including vinca alkaloids, cisplatin, carboplatin, oxaliplatin, or paclitaxel. Most patients improve once chemotherapy is stopped, but some develop persistent pain.

Surgical incisions at any site can precipitate a neuropathic pain syndrome. The best described examples are associated with amputation at any site. Neuropathic pain at the site of the incision may be related to painful neuromas (stump pain

in amputation) or to other processes in the peripheral nerve; injury also can initiate changes that are presumably central and result in a deafferentation pain syndrome (phantom limb when associated with amputation).

Radiation-induced fibrosis can injure peripheral nerves and cause neuropathic pain that may begin months to years following treatment. This pain is generally less prominent than nerve injury caused by neoplasm. Slowly progressive weakness, sensory disturbances, radiation changes of the skin, and lymphedema are often associated.

### Overcoming Obstacles in Cancer Pain Treatment

Cancer pain is frequently undertreated, and the evaluation should attempt to identify the barriers that may compromise treatment efforts. Positive strategies may be needed to overcome these barriers and increase the likelihood of a favorable outcome.

#### Patient Education and Attitudes

Patients can hinder their own pain control. They may believe that pain is a “normal” part of cancer and that little can be (or should be) done to relieve it. A few believe that pain has redemptive power. Patients also may object to the use of an opioid for any of a variety of reasons: fear of becoming “addicted,” fear of continually escalating the dose, or fear of side effects. Some of these concerns may arise from having witnessed destructive drug abuse in the family or having a personal history of abuse.

Most of these fears can be alleviated by careful listening and explanation by the clinician. A recent study demonstrated an improvement in cancer pain outcomes after a focused educational session with a trained nurse, which included self-assessment of pain, information about opioid use and side effects, and pointers on communication with the physician.<sup>16</sup> The clinician must explain that opioids can treat pain effectively and that side effects usually can be managed. Patients should be advised that physical dependence, the capacity to experience abstinence if the drug is stopped abruptly or an antagonist is administered, is a biologic phenomenon and poses no clinical problem as long as simple steps are followed to avoid abstinence. Patients also should be disabused of the concern that tolerance to analgesic effects commonly compromises long-term opioid efficacy. In the absence of worsening pain related to progressive disease, opioid doses typically remain stable.

Patients must be told specifically that physical dependence is not the same as addiction, a term that is commonly misused by both physicians and patients. Addiction is a biopsychosocial disorder with a strong hereditary component and

behavioral manifestations characterized by compulsive drug use, loss of control over use, drug craving, and use despite harm.<sup>17</sup> Patients with no history of drug abuse or addiction must be reassured that addiction is a rare problem during treatment for pain; patients with a history of substance use disorder must be informed that pain usually can be managed concurrently with the addictive disease.

#### Biomedical Barriers

Patients may be unable to swallow, absorb, or metabolize the opioid because of comorbid disease. Mental status changes may prevent patients from expressing their symptoms or from understanding how and when to take pain medication. These barriers must be addressed by the clinician to ensure effective pain control. Alternative routes of opioid delivery are available if enteral intake is difficult (see below). Communication difficulties can be addressed, and caregivers, when properly educated about pain assessment and treatment, can be of invaluable assistance.

#### Physician Barriers

Concern about the risks associated with opioid use, including the risk of side effects and the risk of addiction, can lead a clinician to be unnecessarily wary and therefore undertreat pain.<sup>18</sup> Physicians, like patients, may stigmatize the use of opioids, despite the wide acceptance of their use for cancer pain treatment. Physicians treating cancer pain should be comfortable with opioid therapy and possess strategies to address side effects or problematic drug use. Physicians also must become familiar with the laws and regulations governing opioid use, including the elements of documentation that are required by those in the law enforcement and regulatory communities.

#### Other Barriers

Involved family members and caregivers can sometimes become unintentional barriers to effective pain control. Family members may fear the use of opioids in a loved one, especially in the context of cultural or community stigma. The physician should make every effort to include family members and educate them to alleviate such fears.

In the United States, a fragmented health care system continues to impose unnecessary burdens on patients, families, and health care providers. These difficulties can be particularly challenging for patients who are seriously ill. Home visits by professionals and home delivery of medicines can be invaluable services to the ailing cancer patient but are largely unavailable. A recent study found the use of morphine in home-care hospice patients to be safe and effective, even at very high doses.<sup>19</sup>

Other barriers are also important. For example, an increasing amount of literature suggests that access to optimal care may be compromised by minority status.<sup>20</sup> These barriers deserve further study.

## Management of Chronic Cancer Pain

The evaluation of the patient with cancer pain should provide the information necessary to characterize the pain complaint, determine its etiology and presumed pathophysiology, understand its impact, and clarify relevant comorbidities. This understanding is the basis for therapeutic decision making.

### Role of Primary Therapy

Primary treatments for the pain include antineoplastic therapies and interventions directed at other pathologies. Although the palliative role of chemotherapy is widely accepted,<sup>21–23</sup> the specifics have received limited study. Nonetheless, it is a common observation that patients who attain a partial or complete tumor response also experience symptom improvement. Two chemotherapies, mitoxantrone for prostate cancer and gemcitabine for pancreatic cancer, received regulatory approval largely on the basis of symptom palliation.

Radiation therapy has been reported to provide effective palliation of pain in up to 50% of patients treated for bone metastases,<sup>24,25</sup> and pain control is the reason for treatment in the majority of patients who receive this intervention. Analgesia also commonly results when radiation is used to treat other disorders, including epidural disease, tumor ulceration, cerebral metastases, superior vena cava obstruction, and bronchial obstruction. Patients with a limited prognosis (ie, months) may benefit from single doses or a shortened fractionation schedule, thereby decreasing treatment burden.<sup>26</sup>

### Pharmacotherapy of Chronic Cancer Pain

Although primary therapies can be very helpful in selected patients, most patients require symptomatic analgesic therapy. Prospective trials indicate that 70 to 90% of patients can achieve adequate relief of cancer pain using a pharmacologic approach.<sup>3,27,28</sup> Effective pain management requires expertise in the use of nonsteroidal anti-inflammatory drugs (NSAIDs), opioid analgesics, and adjuvant analgesics. The term *adjuvant analgesic* is applied to a diverse group of drugs that have primary indications other than pain but can be effective analgesics in specific circumstances, such as the treatment of neuropathic pain.

A model approach to the selection of analgesic drugs for cancer pain, known as the “analgesic ladder,” was developed in the 1980s by an expert

panel for the World Health Organization (WHO).<sup>3</sup> Although the analgesic ladder approach has evolved since it was created and rigid adherence to its guidelines is no longer justified, key elements are still accepted. Most important, the approach reinforces the consensus view that persistent moderate to severe cancer pain should be treated with an opioid-based drug regimen. From this perspective, the analgesic ladder has been very useful as a tool to educate policy makers and others about the need for access to opioids.

According to the analgesic ladder approach, mild to moderate cancer pain is first treated with acetaminophen or an NSAID. This often is combined with an adjuvant drug to provide additional analgesia (ie, an adjuvant analgesic), treat a side effect of the analgesic, or help manage a coexisting symptom.

Patients who present with moderate to severe pain or who do not achieve adequate relief after a trial of an NSAID should be treated with a so-called “weak” opioid (see below). This is typically combined with an NSAID and may also be administered with an adjuvant drug. Those who present with severe pain or who do not achieve adequate relief following appropriate administration of drugs on the second rung of the ladder should receive a so-called “strong” opioid, which may be combined with an NSAID or an adjuvant drug as indicated.

### Nonsteroidal Anti-inflammatory Drugs

The nonopioid analgesics include acetaminophen (also known as paracetamol), dipyron, and the diverse NSAIDs. These drugs have a well-established role in the treatment of cancer pain.<sup>29–31</sup> Dipyron is not available in the United States, and practice usually focuses on the use of the NSAIDs. These drugs may be the sole analgesics required by patients with generally mild pain and should be considered as adjunct therapy for opioid-based treatment of moderate or severe pain. NSAIDs appear to be especially useful in patients with nociceptive pain, particularly bone pain and pain related to grossly inflammatory lesions, and relatively less useful in patients with neuropathic pain.<sup>32–34</sup> In addition, NSAIDs have an opioid-sparing effect that may be helpful to prevent the occurrence of dose-related side effects.<sup>33</sup>

All NSAIDs have the potential for nephrotoxicity, with effects that range from peripheral edema to acute or chronic renal failure. Clinical effects and serum creatinine must be monitored periodically in the medically frail cancer patient who receives an NSAID for ongoing treatment of pain.

NSAIDs all increase the risk of gastrointestinal ulcers and bleeding. The selective cyclooxygenase (COX)-2 inhibitors appear to have a relatively reduced risk of these outcomes, and many clinicians recommend these drugs as

first-line therapy for all patients at a relatively high risk of ulcer, including the elderly, those concurrently receiving a corticosteroid, and those with a history of peptic ulcer disease or NSAID-induced gastroduodenopathy, and medically frail patients who are less able to tolerate a gastrointestinal hemorrhage.

This approach is reasonable, notwithstanding recent data that have raised concerns about an increased risk of cardiovascular events in populations treated with the selective COX-2 inhibitors. Recently, rofecoxib was withdrawn from the US market by the manufacturer after a study revealed a doubling of cardiovascular risk after 18 months of use. Similar effects were suggested for high-dose celecoxib in a cancer prevention trial, valdecoxib in a trial of patient who underwent coronary bypass surgery, and naproxen in a dementia prevention trial. Other large studies of celecoxib have not shown this effect.<sup>35</sup>

At present, the extent to which cardiovascular toxicity may be an effect of specific drugs, a class effect of the COX-2 selective inhibitors, or possible with any NSAID is uncertain. Given the current evidence, it is appropriate to continue the preferential use of COX-2 selective inhibitors in populations with a relatively high risk of gastrointestinal toxicity. Many with cancer pain would be in this category.

### Adjuvant Analgesics

The adjuvant analgesics comprise numerous drugs in diverse classes, most of which are commercially available for indications other than pain but may be analgesic in selected circumstances (Table 4).<sup>36</sup> Treatment with one of these drugs is generally considered if an optimally administered opioid regimen fails to provide a satisfactory balance between pain relief and side effects. These drugs are particularly useful in the treatment of neuropathic pain, bone pain, and pain related to bowel obstruction.

Corticosteroids are multipurpose adjuvant analgesics. In addition to their use in neuropathic pain, these drugs may improve anorexia, nausea, and fatigue and are often used in open-ended therapy when cancer is relatively advanced. They are empirically used to treat the pain associated with lymphedema, bowel obstruction, metastatic bone pain, headache associated with intracranial mass lesions, and superior vena cava syndrome. Dexamethasone and prednisone are typical choices, and long-term administration is common in advanced illness. Doses are typically modest, such as dexamethasone 1 to 4 mg or prednisone 5 to 10 mg daily. Higher doses are sometimes used when pain is severe and rapid control of pain cannot be obtained with an opioid.

Anticonvulsants, antidepressants, and sodium channel blockers have analgesic effects in neuropathic pain.<sup>36</sup> The safety and efficacy of

Table 4 Adjuvant Analgesics

Indication	Class	Examples		
Neuropathic pain	Steroids	Dexamethasone Prednisone		
	Antidepressants	Tricyclics	Amitriptyline Desipramine Nortriptyline	
		SSRIs/SNRIs	Paroxetine Citalopram Venlafaxine Duloxetine Bupropion	
	Anticonvulsants		Gabapentin Carbamazepine Valproate Clonazepam Lamotrigine Topiramate Oxcarbazepine Zonisamide Levetiracetam Tiagabine	
		Sodium channel blockers	Mexilitine Tocainide	
		$\alpha_2$ -Adrenergic agonists	Tizanidine Clonidine	
		NMDA receptor antagonists		Ketamine Dextromethorphan Amantadine Memantine
			GABA agonists	Baclofen
			Topical agents	5% Lidocaine patch Local anesthetic creams Capsaicin
		Bone pain	Bisphosphonates	Pamidronate
			Other osteoclast inhibitor	Calcitonin
	Radiopharmaceuticals		Strontium <sup>89</sup> Samarium <sup>153</sup>	
	Bowel obstruction	Steroid	Dexamethasone	
Anticholinergic drugs		Scopolamine Glycopyrrolate		
Somatostatin analogue		Octreotide		

GABA =  $\gamma$ -aminobutyric acid; NMDA = *N*-methyl-D-aspartate; SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

A trial with an oral sodium channel blocker, such as mexilitine, usually is considered after antidepressant and anticonvulsant drugs have been tried.<sup>42</sup> Intravenous or subcutaneous lidocaine may be useful in the treatment of severe, rapidly increasing neuropathic pain.

Other drugs are also used for neuropathic pain.<sup>36</sup> There is extensive experience with the  $\gamma$ -aminobutyric acid (GABA) agonist baclofen and limited experience with the  $\alpha_2$ -adrenergic drugs tizanidine and clonidine. Recently, interest has focused on the use of the *N*-methyl-D-aspartate inhibitors. Dextromethorphan, memantine, amantadine, and ketamine are all considered among the agents that may be tried for neuropathic pain. Small studies have suggested benefit from ketamine in cancer patients with difficult neuropathic pain,<sup>43,44</sup> but this drug carries the risk of psychomimetic effects and must be used cautiously.

Topical agents represent another adjuvant analgesic strategy. A lidocaine patch (Lidoderm)<sup>45,46</sup> is now available and has been shown to be effective in postherpetic neuralgia. In a study in cancer patients with surgical neuropathic pain (eg, postmastectomy syndrome), topical capsaicin, a peptide that depletes substance P in small primary afferent neurons, was found to significantly decrease pain.<sup>47</sup>

Opioid-refractory malignant bone pain is another syndrome for which adjuvant analgesics often are considered. The preferred drugs include bisphosphonates, radiopharmaceuticals, and calcitonin. The bisphosphonates, including pamidronate, clodronate (not available in the United States), and zoledronate, are usually considered first. There has been increasing evidence that these drugs improve the overall morbidity associated with bone metastases.<sup>48</sup>

Adjuvant analgesics also are commonly employed in the setting of advanced bowel obstruction. Aggressive pharmacotherapy, particularly in those with advanced disease, may control symptoms and obviate the need for drainage procedures. Treatment usually involves the combination of anticholinergic drugs (eg, scopolamine or glycopyrrolate), octreotide, corticosteroids, and opioids.<sup>49</sup>

### Opioid Analgesics

Expertise in the administration of opioid analgesics is the foundation of cancer pain management. The clinician should have knowledge of opioid pharmacology and a clear grasp of practical guidelines for dosing.

#### Opioid Selection

The distinction between so-called “weak” and “strong” opioids, which was originally incorporated into the WHO analgesic ladder approach, is

gabapentin are well established,<sup>37–40</sup> and this drug is typically tried first. Of the newer drugs, the evidence of analgesic efficacy is strongest for pregabalin, lamotrigine, topiramate, and levetiracetam. Pregabalin is now available in the United States, approved for the treatment of two types of neuropathic pain. Other anticonvulsants, including zonisamide, oxcarbazepine, tiagabine, and the older drug valproate, also may be tried for neuropathic pain. The benzodiazepine

clonazepam also is commonly tried, particularly if anxiety is prominent.

Although there is substantial evidence for the analgesic efficacy of the tricyclic antidepressants, particularly amitriptyline,<sup>41</sup> the use of these drugs is often limited by the high likelihood of side effects. Newer antidepressants, such as duloxetine, venlafaxine, paroxetine, citalopram, and bupropion, are also analgesic and are better tolerated in the cancer population.

more operational than pharmacologic. The weak opioids are conventionally administered orally for moderate pain in those patients with limited previous opioid exposure. The strong opioids are conventionally used to treat severe pain and pain in those already receiving opioid therapy. In the United States, the former group includes codeine, hydrocodone (only with acetaminophen or ibuprofen), dihydrocodeine (only with aspirin), oxycodone (combined with aspirin, acetaminophen, or ibuprofen), propoxyphene, and, occasionally, meperidine. Tramadol, a unique centrally acting analgesic with a mechanism that is partly opioid, is also generally included in this group. Oxycodone is included only in terms of the formulation that combines this opioid with acetaminophen or an NSAID.

The designation of these medications as “weak” is inappropriate because none are characterized by a ceiling effect. Nonetheless, these drugs are used at doses that are potentially effective only in those patients with limited opioid exposure and often only with moderate pain. The opioids that are combined with acetaminophen or ibuprofen in a single tablet may be escalated until the dose of the coanalgesic reaches a level associated with toxicity. In the case of acetaminophen, this is usually a maximum of 4 g/d (and less in patients with known hepatic disease or a history of heavy alcohol consumption). Propoxyphene and meperidine usually are avoided because toxic metabolites may lead to neuroexcitatory effects, including seizures.

Opioids used conventionally for severe pain include morphine, fentanyl, oxycodone, (without acetaminophen or aspirin), hydromorphone, oxymorphone, levorphanol, and methadone. Historically, morphine was considered the preferred first-line drug, based on worldwide experience, ease of dosing, and the availability of numerous formulations. In recent years, however, recognition of large variation in the response to different opioids has reinforced the understanding that an alternative opioid may be preferable for individual patients. There is no one preferred opioid, and the decision to choose one over another is usually based on the available formulation, cost, and previous experience. Therapeutic failure with one drug may be followed by remarkable success with another.<sup>50</sup>

Morphine is metabolized to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G). Accumulation of these metabolites can result in side effects.<sup>51–53</sup> Liver dysfunction has only a small effect on morphine kinetics,<sup>54</sup> but renal insufficiency results in accumulation of M3G and M6G. For this reason, morphine should be administered cautiously to patients with renal insufficiency. An opioid with no known active metabolites, such as fentanyl, may be preferred.

The role of methadone is expanding in pain management. This drug is available as a racemic mixture of the L-isomer (an opioid compound) and the D-isomer (an *N*-methyl-D-aspartate receptor blocker). The D-isomer may yield independent analgesic effects and partially reverse opioid tolerance; these effects may be responsible for a greater than expected potency when methadone is administered. Methadone has reliable absorption and a low cost. Given its long half-life, consistent pain control usually is possible with dosing three to four times per day. The use of methadone presents challenges, however, because its half-life varies widely across patients and its potency in those with previous opioid exposure is difficult to predict accurately. To ensure safety, a switch to methadone from another drug should be accompanied by a large reduction in the equianalgesic dose and a prolonged observation period to judge the full effect. Recent reports also indicate a potential for Q–T prolongation from high doses of methadone, but the clinical significance of this effect is not clear.<sup>55,56</sup> Nonetheless, methadone should be used cautiously in patients at risk of arrhythmia or receiving other drugs that could prolong the Q–T interval.

#### *Routes of Administration*

Long-term administration of an opioid is best accomplished by the oral or transdermal route. Numerous oral formulations are available, including modified-release forms of morphine (with dosing intervals of 12 or 24 hours), oxycodone (12-hour dosing interval), and hydromorphone (24-hour interval). A modified-release oxymorphone is now available. The transdermal route is available for fentanyl and offers a 48- to 72-hour interval; this formulation is preferred by some patients and may be associated with less constipation.<sup>57</sup> A recent study supported the effectiveness of transdermal fentanyl even in both opioid-naïve patients and patients converting from a “weak” opioid.<sup>58</sup>

Long-term parenteral dosing can be used for patients who are poor candidates for oral or transdermal formulations. Continuous intravenous infusion is most feasible for patients with an indwelling central venous port. This approach eliminates fluctuations in plasma concentration. Any opioid available in an injectable formulation may be administered in this manner. Ambulatory infusion via the subcutaneous route has been made possible with the development of small infusion pumps. Typically, a 25-gauge “butterfly” needle is inserted subcutaneously and can be left under the skin for as long as a week. High-concentration, low-volume infusions must be used to accommodate limited fluid volumes (eg, less than 5 mL/h).<sup>59</sup>

Opioids and other drugs may also be delivered into the epidural or intrathecal spaces.

Neuraxial infusion can provide opioid analgesia at doses far lower than those required systemically and can therefore provide equivalent or better analgesia with fewer side effects. The strongest indication for neuraxial analgesia is the presence of intolerable somnolence or confusion in patients who experience some degree of analgesia from systemic therapy. In a recent controlled trial, continuous intrathecal infusion of morphine via an implanted drug delivery system yielded better pain control, less fatigue, and improved survival than comprehensive medical management alone.<sup>60</sup> Other drugs can be combined with the opioid to further enhance analgesia. The preferred opioid drugs for chronic intraspinal infusion are morphine and hydromorphone, and the most common admixture drugs include bupivacaine, a local anesthetic, and clonidine, an  $\alpha_2$ -agonist. A novel analgesic, ziconotide, was recently released in the United States for intrathecal therapy.

Many methods for neuraxial infusion are now in use.<sup>61</sup> They include a percutaneous epidural catheter, which is usually tunneled to the anterior abdominal wall and connected to an ambulatory infusion pump; a totally implanted epidural catheter connected to a subcutaneous portal, which, in turn, is connected to an ambulatory pump; and an intrathecal catheter connected to a totally implanted continuous infusion device. Patients with life expectancies exceeding 3 months usually are considered for intrathecal infusion via an implanted pump.

The oral transmucosal form of fentanyl has been shown to be safe and efficacious when used to treat breakthrough pain in cancer patients receiving a fixed-dose opioid regimen for persistent pain.<sup>7,62</sup> Absorption through the oral cavity is theoretically possible with any opioid, particularly those that are, like fentanyl, highly lipophilic.<sup>63</sup> Although injectable formulations of any opioid therefore could be tried, practical considerations and the variable absorption of most drugs do not support wider use of this approach.

Rectal formulations of hydromorphone, and morphine are available in the United States and have potencies that are believed to approximate oral dosing. This route is generally used in opioid-naïve patients who are transiently unable to take oral drugs.

#### *Dosing*

Following initiation of opioid therapy, dose adjustment usually is required. As the dose is titrated, most patients experience a favorable balance between analgesia and side effects, which generally persists unless there is progression in the pain-producing pathology. Recurrent pain necessitates another period of dose titration. In all cases, the dose of an opioid should be increased until acceptable analgesia is produced or unmanageable side effects supervene. The absolute dose of the opioid is immaterial as long as the balance

between analgesia and side effects remains acceptable to the patient. Conventionally, the size of the increment at each dose escalation is between 30 and 100% of the total daily dose on the previous day. The lower end of this range is used if the pain is not severe or the patient is medically frail; the upper part of the range is appropriate for severe pain in the patient who is more robust.

For persistent or frequently recurring pain, the best outcome is achieved by administering an opioid according to a fixed, around-the-clock schedule. Long-acting opioids are preferred because of convenience and the likelihood that treatment adherence will be better than with frequent daily doses. Some clinicians prefer to start therapy with an “as-needed” regimen in the hope of facilitating dose finding. A recent study suggests, however, that dosing also can be initiated with a long-acting drug, without sacrificing effectiveness or increasing risk.<sup>64</sup>

Given the high prevalence of breakthrough pain, the coadministration of a short-acting drug along with a long-acting baseline regimen—a technique called “rescue” dosing—is common practice.<sup>7</sup> An oral rescue dose can be prescribed every 2 hours “as needed” at a dose equal to 5 to 15% of the total daily opioid consumption.

There is large variation in the response of an individual to each opioid. Some patients develop side effects rather than satisfactory analgesia, a scenario now termed “poor responsiveness.” The development of poor responsiveness during an opioid trial should be considered specific to the drug, route, and clinical setting. The occurrence of poor responsiveness necessitates a change in the therapeutic strategy.

Among the approaches that may be used to manage the patient with a poor response to an opioid trial is a switch of the opioid, or so-called “opioid rotation.” When patients are switched from one opioid to another, the dose of the new drug is calculated based on well-accepted equianalgesic doses (Table 5).<sup>65</sup> The calculated dose of the new drug is reduced to account for incomplete cross-tolerance and individual variation. A reduction in dose by 25 to 50% is typical practice. There are two exceptions, however: a safety factor has already been built into the conversion to transdermal fentanyl, and the dose of this formulation usually is not reduced. When converting to methadone, the dose should be reduced by 75 to 90% because of the possibility of a greater-than-expected potency from this drug.

#### Management of Side Effects

Effective side-effect management is a fundamental aspect of opioid therapy (Table 6).<sup>66</sup> Side-effect management may improve the quality of analgesia and the likelihood of treatment adherence. Patients who experience poor responsiveness during titration of an opioid may also become

**Table 5** Opioid Analgesics Used for the Treatment of Persistent Cancer Pain

Drug	Dose (mg) Equianalgesic to Morphine 10 mg IM*		Half-Life	Duration	Comment
	PO	IM	(h)	(h)	
Morphine	20–30 <sup>†</sup>	10	2–3	2–4	Standard for comparison
Morphine modified release	20–30	10	2–3	8–12	Various formulations are not bioequivalent
Oxycodone	20	—	2–3	3–4	
Oxycodone modified release	20	—	2–3	12	
Hydromorphone	7.5	1.5	2–3	2–4	Potency may be greater during prolonged use (ie, hydromorphone: morphine = 3:1 rather than 6.7:1)
Hydromorphone	7.5	1.5	2–3	24	
Methadone	20	10	12–190	4–12	Although 1:1 IM:IM potency ratio with morphine was found in a single-dose study, there is a change with chronic dosing and a large dose reduction (75–90%) is needed when switching to methadone
Oxymorphone	10	1	2–3	2–4	Available in injectable formulations
Levorphanol	4	2	12–15	4–6	
Fentanyl	—	—	7–12	—	Can be administered as a continuous IV or SQ infusion; based on clinical experience, 100 µg/h is roughly equianalgesic to morphine IV 4 mg/h
Fentanyl TTS	—	—	16–24	48–72	Based on clinical experience, 100 µg is roughly equianalgesic to morphine 4 mg/h IV. A ratio of oral morphine to transdermal fentanyl of 70:1 may also be used clinically.

Adapted from Derby S, Chin J, Portenoy RK. Systemic opioid therapy for chronic cancer pain: practical guidelines for converting drugs and routes of administration. *CNS Drugs* 1998;9:99–109.  
 IM = intramuscular; IV = intravenous; PO = oral; SQ = subcutaneous.  
 \*Studies to determine equianalgesic doses of opioids have used morphine by the IM route. The IM and IV routes are considered to be equivalent, and IV is the most common route used in clinical practice.  
<sup>†</sup>Although the PO to IM morphine ratio was 6:1 in a single-dose study, other observations indicate a ratio of 2 to 3:1 with repeated administration.

more responsive if the treatment-limiting toxicity can be addressed.

#### Constipation

The management of opioid-induced constipation begins with prevention. Nonessential constipating drugs should be eliminated and fluid and fiber intake increased. Fiber should not be increased in those with likely partial bowel obstruction or marked debility because of the potential for worsening obstruction. Laxative therapy should be administered prophylactically to patients who

are starting opioid therapy and have other risk factors for constipation, such as advanced age or limited mobility or fluid intake.

There are numerous types of laxatives, including bulk-forming agents, osmotic agents, lubricants, surfactants, contact cathartics, prokinetic drugs, agents for colonic lavage, and oral opioid antagonists.<sup>67</sup> The conventional first-line approach is a combination of a stool softener, such as docusate, and a cathartic agent, such as senna or bisacodyl. Most patients respond to this therapy. For patients who do not, lactulose (an

Table 6 Commonly Used Approaches in the Management of Opioid Side Effects

Side Effect	Treatment
Constipation	General approach
	Increase fluid intake and dietary fiber
	Encourage mobility and ambulation if appropriate
	Ensure comfort and convenience for defecation
	Rule out and treat impaction if present
	Pharmacologic approach
	Contact laxative plus stool softener (eg, senna plus docusate)
	Osmotic laxative (eg, Milk of Magnesia)
	Lavage agent (eg, oral propylene glycol)
	Prokinetic agent (eg, metoclopramide)
Nausea	Oral naloxone
	General approach
	Hydrate as appropriate
	Progressive alimentation
	Good mouth care
	Correct contributory factors
	Adjust medication
	Pharmacologic approach
	Vertigo → antihistamine (eg, scopolamine, meclizine)
	Early satiety → prokinetic (eg, metoclopramide)
Somnolence or cognitive impairment	Dopamine antagonists (eg, prochlorperazine, chlorpromazine, haloperidol, metoclopramide)
	General approach
	Reassurance
	Education
	Treatment of potential etiologies
	Pharmacologic approach
	If analgesia is satisfactory, reduce opioid dose by 25–50%
	If analgesia is satisfactory and the toxicity is somnolence, consider a trial of psychostimulant (eg, methylphenidate)

osmotic agent) or polyethylene glycol, a lavage agent, might be considered.<sup>68</sup> In refractory cases, a prokinetic drug, such as metoclopramide, can be added.

Oral opioid antagonist therapy can reverse opioid-induced constipation without causing systemic opioid withdrawal through local action on opioid receptors in the gut.<sup>69,70</sup> Oral naloxone can be administered at a starting dose of 0.8 mg daily; the dose is doubled every 2 to 3 days until favorable effects occur or side effects are experienced. Studies of other oral opioid antagonists, including alvimopan and methylnaltrexone,<sup>71,72</sup> have been favorable, and the advent of these drugs will expand the utility of this approach in the future.

#### Nausea and Vomiting

Opioid-induced nausea may affect as many as 10 to 30% of cancer patients.<sup>73</sup> Conventional antiemetic therapy can be administered on either an “as-needed” or fixed-schedule dosing regimen according to the persistence of symptoms.

Treatment of nausea is likely to be more effective if the drug is targeted toward the mechanism of nausea. Although the evidence in

support of this approach is meager, it is often pursued on empiric grounds.<sup>67</sup> Nausea can be caused by a direct effect on the brainstem’s chemoreceptor trigger zone, by gastroparesis and relaxation of the gastroesophageal sphincter, or by sensitization of the vestibular-labyrinthine system. Gastroparesis may be suspected if the patient complains of early satiety or postprandial nausea, and vestibular-related nausea is suspected if vertigo is present or nausea is worsened by movement.

Most patients with opioid-induced nausea respond promptly to drugs that are active at the chemoreceptor trigger zone. A dopamine agonist, such as prochlorperazine or haloperidol, is a reasonable initial therapy. Refractory nausea can be treated with a 5-hydroxytryptamine<sub>3</sub> antagonist, such as ondansetron, granisetron, or dolasetron. Although the antiemetic efficacy of corticosteroids is unexplained, these drugs are clearly beneficial for some patients. Others respond to the commercially available cannabinoid dronabinol.

Patients with postprandial nausea should be considered for a trial of a prokinetic drug, such as metoclopramide. A proton pump inhibitor often

is added. Nausea that is associated with vertigo or movement may be alleviated by an anticholinergic (eg, scopolamine), an antihistamine (eg, meclizine or promethazine), or a benzodiazepine (eg, lorazepam).

#### Somnolence and Cognitive Impairment

Prospective studies indicate that sedation or mental clouding occurs in 20 to 60% of patients starting oral opioid therapy for cancer pain.<sup>66</sup> Significant impairment disappears in most patients with prolonged exposure to the drug. However, there is wide variation in response, and persistent alterations in cognition, perception, and mood can occur. Cognitive disturbances may be influenced by many factors, including the evolving medical condition and concurrent therapies.

If neuropsychological side effects are mild, reassurance and education may be sufficient. When toxicity is severe or persistent enough to compromise the benefits of therapy, other interventions are needed. Treatment of potential etiologies other than the opioid (eg, elimination of another nonessential drug or treatment of a metabolic disturbance) is the first step to consider. If pain is well controlled, it also is reasonable to try an opioid dose reduction of 25 to 50%.

A trial of specific therapy may be appropriate, but few have been well studied in clinical trials. Evidence suggests that psychostimulants may ameliorate somnolence, fatigue, cognitive impairment, pain, and depression. For example, methylphenidate has been shown to decrease sedation in cancer patients taking opioids.<sup>74–76</sup> Other psychostimulants that have been used empirically include dextroamphetamine and amphetamine. Modafinil, a newer psychostimulant, has fewer sympathomimetic effects than the older drugs and is now favored by some clinicians.<sup>77</sup>

The strongest indication for a psychostimulant trial is the presence of uncomfortable somnolence or cognitive impairment associated with significant analgesia. Patients who are dysphoric also might benefit from the antidepressant effects of these drugs.<sup>78,79</sup> The safety of these drugs in cognitively impaired patients who are restless or agitated has not been established.

Therapy with a psychostimulant usually is initiated with methylphenidate at a dose of 5 to 10 mg/d or modafinil 100 mg/d. Dextroamphetamine and amphetamine, each at doses of 5 to 10 mg/d, are alternatives. A repeat dose at midday often is required for the short-acting drugs. Dose escalation usually is needed. In some cases, favorable effects are attained but appear to wane over time.

Patients should be monitored for side effects

from psychostimulants, including anorexia, insomnia, anxiety, cognitive changes (eg, subtle paranoid thinking), and sympathomimetic effects, such as hypertension and tachycardia. Relative contraindications include preexisting anorexia, severe insomnia, psychiatric disorder characterized by anxiety or paranoid ideation, cardiac disease, or poorly controlled hypertension.

### Other Approaches in the Management of Chronic Cancer Pain

Patients with pain that is poorly responsive to an opioid regimen also may be considered for any of a wide variety of alternative analgesic approaches, either pharmacologic or nonpharmacologic. If effective, these approaches reduce the need for the opioid regimen and sometimes eliminate it completely.

Interventional approaches include injection therapies, neural blockade, and the implantation of analgesic devices, usually providing spinal cord stimulation or neuraxial drug infusion. Neural blockade comprises a diverse group of procedures that transiently or permanently block sympathetic nerves, somatic nerves, or both.<sup>61,80</sup> Temporary nerve blocks may be diagnostic, prognostic, or therapeutic. Diagnostic blocks elucidate the afferent pathways involved in pain. Prognostic blocks are implemented prior to a proposed neurolytic procedure. The failure to achieve pain relief is a contraindication to a neurodestructive procedure. Therapeutic blocks include repeated use of a local anesthetic, continuous infusion of an epidural or perineural anesthetic, or administration of a neurolytic solution.

Neurolytic blockade is accomplished using a solution such as alcohol, phenol, or glycerol or through the use of intense heat or cold, to damage the peripheral nerve and partially denervate a particular area. The most widely accepted approach is celiac plexus blockade for the syndrome of rostral retroperitoneal pain, typically caused by pancreatic cancer. The favorable response to this block warrants its consideration whenever the typical pain syndrome occurs and the response to an opioid trial is not satisfactory.<sup>81</sup> Other neurolytic techniques are generally reserved for patients with far advanced cancer and the experience of severe regional pain that is poorly responsive to systemic therapies and occurs in an area that can be safely denervated without compromise of motor or autonomic function.

The role of neuraxial drug infusion for difficult-to-manage cancer pain may grow as a result of a controlled trial that demonstrated the benefits of this approach over conventional systemic opioid therapy in a population with cancer<sup>60</sup> and the recent availability of unique analgesic agents,

such as ziconotide. Neuraxial infusion should be considered in patients who are poorly responsive to a systemic opioid regimen as a result of treatment-limiting side effects.

Other analgesic strategies include the so-called rehabilitative treatments, psychological therapies, and complementary approaches. The potential for analgesia from rehabilitative approaches such as physical therapy, orthotics, and modalities such as heat and cold is insufficiently recognized. Although all of these techniques remain inadequately studied, clinical experience is favorable. Refractory movement-induced pain may be partially relieved by bracing the painful part, and a well-fitting prosthesis may reduce stump pain. Therapeutic exercise may lessen the pain associated with the complications of immobility, such as trigger points in muscle and joint ankylosis. The use of heat and cold, ultrasonography, and electrical stimulation for regional pain syndromes appears to benefit some patients.

Cognitive behavioral approaches have been applied successfully in the management of pain and related symptoms.<sup>82–85</sup> These approaches include specific techniques that may assist in pain control, such as relaxation training, distraction, hypnosis, and biofeedback. Several of these therapies can be taught by the nonspecialist. Other behavioral approaches designed specifically to improve functioning, which have achieved wide acceptance in the management of nonmalignant pain, are occasionally useful for patients whose functional impairment is disproportionate to the effects of the disease.

Complementary and alternative medicine approaches endorse a holistic strategy that may enhance a sense of personal control and lessen pain.<sup>86,87</sup> Some of these interventions, such as the mind-body therapies, nutritional support, acupuncture, and massage, have an emerging evidence base, are widely used, and should be considered mainstream. For example, one recent randomized controlled study demonstrated that auricular acupuncture significantly improved pain in cancer patients.<sup>88</sup> Others, such as homeopathy and naturopathy, have little scientific support. Clinicians should provide whatever data are available about complementary approaches and support informed decision making.

### Cancer Pain at the End of Life: Special Considerations

As the illness progresses, some patients' pain or suffering cannot be controlled despite the optimal use of pharmacotherapy and other approaches. In such cases, treatment options include the use of a drug to induce somnolence, a technique known as "palliative sedation."<sup>89</sup> Sedation should

be considered a medical therapy with defined indications and practices and a strong ethical foundation.<sup>90</sup> Decisions about this intervention are grounded in the "principle of double effect," a well-accepted ethical tenet that describes the appropriateness of actions that may produce harm (such as hastened death), when the intention (to relieve suffering) is beneficent and the need to relieve suffering is the most important goal. Palliative sedation must be clearly distinguished from euthanasia, in which the intended goal is the death of the patient.

Palliative sedation should be implemented only after thorough discussion with the patient, if possible, the family or surrogate decision maker, and involved staff. Informed consent should be sought after clearly establishing the goals of care. Once sedation is activated, ongoing information should be provided to the family and staff, questions should be answered, and ethical and legal implications should be clarified. In some cases, plans should be made to lighten sedation when appropriate to allow interactions with the family.

### Conclusion

Pain is a common and potentially devastating complication of cancer. Fortunately, relatively simple therapeutic approaches can provide effective relief in a large majority of patients. All clinicians who treat patients with cancer should develop competency in the assessment and management of pain, and pain management should be perceived as a clinical imperative in oncology practice.

# Cancer and Depression: Phenomenology and Pathophysiology

Diane S. Thompson, MD  
Charles L. Raison, MD  
Carolyn Jonas-Accardi, PhD  
Andrew H. Miller, MD

Receiving a diagnosis of cancer is a life-changing event that brings in its wake a host of psychological reactions, including fear, anger, denial, and intense uncertainty. This emotional turmoil is often compounded by the treatment for cancer, which can involve multiple bodily assaults, including surgery, radiation, and chemotherapy. Given these psychological and physiologic burdens, not surprisingly, a significant percentage of cancer patients develop an equally devastating emotional disorder: major depression. Although depression in the cancer patient can be readily managed, it is frequently not recognized (often being seen as a natural reaction to a difficult circumstance) and goes largely un- or undertreated. Complicating matters, many patients fail to present with the complaint of “depression” (and may actually deny it) and instead voice somatic concerns, including gastrointestinal distress, pain, or fatigue, coupled with worrisome social withdrawal (usually reported by family and friends) and a lack of interest in previously pleasurable pursuits. Of note, some cancer patients may be acutely aware of their depression but silently accept it as part of the cancer diagnosis, needlessly suffering while sparing the oncology staff the burden of their emotional distress.

Much attention has been paid to the psychosocial aspects of cancer and its treatment.<sup>1</sup> Nevertheless, more recently, advances have been made in understanding the biologic underpinnings of depression and other behavioral comorbidities in cancer patients.<sup>2,3</sup> Notable among these is an increasing appreciation of the role of neurobiologic, immunologic, and metabolic factors.

In an effort to support the recognition and treatment of depression in cancer patients, this chapter addresses relevant issues regarding the diagnosis of cancer-related depression. In addition, we explore potential biologic mechanisms that may provide clues as to when depressive

symptoms may arise and how they can be treated. Finally, this chapter provides a scientific framework wherein mental health providers and oncologists can collaborate to uncover novel approaches to depression before, during, and after the treatment of cancer.

## Clinical Manifestations

Although depressive symptoms may manifest differently depending on the type of cancer and its treatment, there are standardized psychiatric criteria that are used for making a diagnosis (Table 1). These criteria are based on the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV)*, published by the American Psychiatric Association.<sup>4</sup> To meet the criteria for major depressive disorder, at least five symptoms must be present for a period of not less than 2 weeks. Core symptoms that are required for every diagnosis include either depressed mood or anhedonia. As noted above, patients may be

less likely to endorse “depressed” mood but may endorse symptoms of anhedonia (lack of enjoyment in activities that were previously found to be pleasurable). Other symptoms of depression include decreased concentration, low self-esteem, guilt, suicidal ideation, impaired sleep, altered appetite, fatigue, and psychomotor agitation or retardation.

## Diagnosis

Diagnosing depression in patients with cancer has long been recognized to be problematic as a result of the symptom overlap between sickness and depression.<sup>5</sup> Indeed, nondepressed, sick individuals demonstrate many symptoms that are also experienced by medically healthy patients with major depression. Especially relevant in this regard are neurovegetative symptoms of depression that are often directly caused by pathophysiologic processes inherent to the illness itself or by concurrent treatment modalities, such as surgery, chemotherapy, or radiation. These symptoms include fatigue, weight loss, anorexia, loss of libido, sleep alterations, and psychomotor slowing. Thus, the clinical dilemma becomes when, if ever, neurovegetative symptoms should be counted toward a diagnosis of depression in cancer patients and who may have these symptoms simply because they are sick. How this question is answered significantly impacts the prevalence of depression in patients with cancer and affects when a clinician considers that treatment is appropriate.

## Inclusive versus Exclusive Approach

Various strategies to resolve this issue have been proposed. In their simplest iteration, they take two forms: an inclusive approach that counts all depressive symptoms toward a diagnosis of depression, regardless of putative etiology, and an

**Table 1** DSM-IV Diagnostic Criteria for Major Depression

5 or more symptoms for 2 wk or longer (must include depressed mood or decreased interest/enjoyment)
Depressed mood
Significant change in weight
Psychomotor agitation/retardation
Feelings of worthlessness or guilt
Suicidal ideation
Decreased interest/enjoyment in activities
Insomnia or hypersomnia
Fatigue/low energy
Poor concentration

*DSM-IV = Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition.*

exclusive approach that removes neurovegetative symptoms when these symptoms could likely be caused by underlying illness.<sup>6</sup> Refinements of these simpler approaches include (1) replacing the removed neurovegetative symptoms with alternate emotional symptoms (thus keeping the total number of required diagnostic symptoms the same)<sup>7</sup> and (2) privileging the time course of symptoms in the evaluation of neurovegetative symptoms such that these symptoms are counted toward a diagnosis of depression only if their onset co-occurs with or follows the onset of depressed mood or anhedonia.<sup>8</sup> Studies support the validity of both symptom substitution and temporal approaches; however, other data suggest that these exclusive strategies underdiagnose depression in the medically ill when compared with inclusive approaches.<sup>9</sup>

Inclusive approaches increase the likelihood that all patients who have a depression will be identified but run the risk of misclassifying patients with a mild mood or hedonic disturbance as having a full major depression when, in fact, they are only mildly depressed and very sick.

A second diagnostic complication involves the question of how much depression is enough to merit recognition and treatment in patients with cancer. This question is embedded within the larger psychiatric issue of whether mood disorders are best understood as categorical entities with firm boundaries or as a spectrum of conditions that differ from “normalcy” only by matters of degree. Defining normalcy when one has just been diagnosed with cancer or informed of a tumor recurrence is a difficult proposition, given that grief, fear, and other symptoms that define depression are extremely common under these circumstances. Many solutions have been proposed for determining when normal sadness has progressed to a clinically relevant disorder, but the problem remains a vexing one with clear diagnostic and treatment implications. Much of the mood disturbance observed in studies of cancer patients falls under the rubric of “adjustment disorder,” a diagnosis that is often interpreted as implying a mild and transient fluctuation in mood that requires little more than reassurance, support, and clinical patience.<sup>4</sup> However, studies increasingly indicate that even minor levels of depressive symptoms (regardless of putative etiology) significantly impair quality of life and physical functioning and may increase mortality in the context of medical illness.<sup>10–15</sup> Clearly, therapeutic errors of over- and undertreatment, can be committed; however, most data indicate that patients with cancer and depressive symptoms receive inadequate treatment.<sup>16</sup> We are increasingly aware that even mild cancer-related depressive syndromes respond to antidepressant treatment.<sup>17,18</sup> As data accumulate documenting the effectiveness of antidepressants in treating

many disease-related symptoms, there is growing support for treating even milder depressive presentations, especially in patients who are open to—or request—treatment and in patients with persistent symptoms.

A final diagnostic issue of great importance in the evaluation and treatment of dysphoric cancer patients involves distinguishing between mood disorders and delirium. Many patients with cancer will develop delirium as a result of chemotherapy or adjuvant pain medication or in the context of severe illness. Not infrequently, delirious patients demonstrate depressive affects and endorse profound dysphoria and/or anxiety. It is essential, therefore, for the clinician to carefully evaluate a patient’s orientation to time, place, and situation in contexts in which delirium is likely. If a patient is disoriented, especially if the disorientation has a recent and acute onset, delirium should be suspected and addressed prior to embarking on further treatment for depression. This issue is important because delirium does not respond to antidepressant therapy but usually abates or resolves promptly with the initiation of antipsychotic therapy.<sup>19,20</sup> Thus, missing delirium incurs the risk of initiating an ineffectual treatment (ie, antidepressants or benzodiazepines) that will add to a patient’s medication burden while depriving the patient of medications that resolve the dysphoria and anxiety that often accompany the condition.

### Rating Scales

The widespread tendency to excuse depression as a natural reaction to cancer and the overlap between sickness and depressive symptoms both point to the importance of accurately assessing depression in the context of neoplastic illness. Standardized instruments are especially valuable in this regard, including the Zung Self-Rating Depression Scale (SDS),<sup>21</sup> the Beck Depression Inventory (BDI),<sup>22</sup> and the Center for Epidemiologic Studies Depression Scale (CESD)<sup>23</sup> (Table 2). Self-report questionnaires have the advantage of not requiring the presence of a trained psychiatric interviewer and can thus be completed by patients while waiting to see the physician. Having patients complete such scales prior to office visits often provides the clinician with additional key information that time pressures may have otherwise precluded. These

scales have been used and validated in oncology patients; however, each of the scales has strengths and weaknesses. For example, the BDI emphasizes mood and cognitive symptoms that are more specific to depression than are neurovegetative symptoms shared by major depression and physical illness.<sup>22</sup> Even if circumstances do not permit the administration of self-report questionnaires, recent data suggest that simply asking cancer patients the single question “Do you feel depressed most of the time?” effectively identifies most subjects with clinically relevant mood disorders.<sup>24</sup> At the very least, such a simplified approach identifies patients who require a more thorough evaluation.

### Prevalence

The vast majority of studies indicate that the rates of both major depression and depressive symptoms are elevated in cancer patients compared with healthy controls. Reviews of the literature place median point prevalence rates between 15 and 29%,<sup>24,25</sup> which are significantly higher than prevalence rates for major depression in the general US population (Table 3).<sup>26</sup> Recent studies continue to report widely divergent rates of major depression in cancer patients, but findings from these studies are generally consistent with earlier work in terms of risk factors (see below) and depression prevalence. Moreover, even in studies with low rates of depression, prevalence is typically increased in cancer patients compared with rates in the general populations in the countries in which the studies were performed.<sup>27–30</sup>

Rather than being an impediment to managing depression in the context of cancer, we suggest that a great deal of useful clinical information can be gleaned from the factors that underlie the tremendous variations in depression prevalence

**Table 3** Prevalence of Major Depression in Different Types of Cancer

Tumor Site	Prevalence of Major Depression (%)
Pancreas	50
Oropharynx	22–40
Colon	13–25
Breast	10–32
Gynecologic	23
Lymphoma	17
Gastric	11

**Table 2** Representative Rating Scales for Assessing Depressive Symptom Severity

Scale	Relative Severity of Depressive Symptoms			
	Normal	Mild	Moderate	Severe
Zung Self-Rating Depression Scale	≤ 49	50–59	60–69	≥ 70
Beck Depression Inventory	0–9	10–16	17–29	30–63
Center for Epidemiologic Studies Depression Scale	≤ 15	16–20	21–25	26–60

reported in the world literature. We have already touched on one such reason: the lack of uniformity in how depression is defined in the context of medical illness. In this regard, depression is more common in cancer patients when it is diagnosed via inclusive methods. Indeed, several studies show that rates of depression approximately double in the same group of patients depending on whether an inclusive or exclusive diagnostic approach is employed.<sup>24,31</sup> This finding suggests that many cancer patients are significantly troubled by depression-related neurovegetative symptoms, such as fatigue and poor sleep or appetite, even while not endorsing sadness or loss of interest in life. This observation has clinical relevance for at least two reasons. First, the presence of neurovegetative and other sickness-related symptoms is a risk factor for the development of full depression in patients receiving cancer treatment. For example, sleep disturbance has been repeatedly found to predict both the future development of new depression and depressive relapse in remitted patients.<sup>32</sup> Second, increasing data demonstrate that antidepressants and related pharmacologic strategies effectively treat a number of sickness-related and neurovegetative symptoms, including sleep disturbance, decreased appetite, and pain (see below).<sup>33</sup>

A second debate that affects the prevalence of depression in cancer centers around how much depression is enough to qualify as a clinically relevant entity. Studies repeatedly show that the majority of cancer patients with mood disturbances meet the criteria for conditions other than major depression.<sup>29,34–36</sup> Consistent with this notion, a recent study found that although 23% of outpatients with cancer endorsed significant depressive symptoms, only a third of these patients met the criteria for major depression.<sup>29</sup> The most common mood-related *DSM* diagnosis in patients with cancer is adjustment disorder.<sup>35</sup> The essential components of an adjustment disorder with depressed mood include the following: (1) the presence of mood symptoms that do not meet the criteria for major depression, (2) the mood symptoms arise in response to an identifiable psychosocial stressor, and (3) the mood symptoms impair functioning.<sup>4</sup> These symptoms can persist indefinitely if the stressor is chronic. Given overwhelming data that stressors of all types profoundly increase the risk of depression<sup>37,38</sup> and given that many patients with cancer are, by definition, dealing with a severe and chronic stressor, the diagnosis of adjustment disorder seems impossible to credibly differentiate from a mild depression or dysthymic disorder. Increasing data consistently indicate that even mild depression profoundly interferes with both functioning and quality of life and has adverse health consequences.<sup>10,39</sup> These considerations raise the question of why a depressive syndrome

that arises from the known stressor of cancer (ie, an adjustment disorder) should be treated differently from symptomatically similar syndromes that arise for other reasons, especially given ample data that depressive syndromes, even when not meeting the criteria for major depression, are amenable to therapeutic intervention. On the other hand, the fact that most patients with mood symptoms meet adjustment disorder criteria also suggests that at least some of these patients may have a syndrome that will resolve in a reasonable time period without specific pharmacologic intervention. In this regard, accurate assessment of each patient will require some clinical judgment, but, again, the fact that depression prevalence is greatly affected by where the lower limits are set has important and clinically meaningful treatment implications.

### Risk Factors

In addition to diagnostic issues, prevalence rates of depression are affected by other factors, including premorbid patient characteristics, tumor characteristics, disease severity, the presence of pain, and the type of treatment administered (Table 4).<sup>3,5,34</sup> Several studies concur that patients with a history of psychiatric illness (including a history of depression) are at increased risk of developing depression in the context of cancer or its treatment.<sup>28,40</sup> Similarly, a family history of mood disorder has also been observed to be a risk factor for cancer-related depression.<sup>41</sup> Women appear to be more likely to develop mood disorders in the context of cancer, consistent with a worldwide body of literature suggesting that women are generally more prone to depression

than men.<sup>42</sup> It is increasingly recognized that patients' current mood and/or anxiety state strongly influence their emotional responses in the face of cancer's exigencies, both psychological and physiologic. So, for example, increased self-reported depression and anxiety at the time of cancer diagnosis (presumably caused or exacerbated by the psychological stress attendant on such a diagnosis) are associated with greater psychological distress 6 months later,<sup>43</sup> and numerous studies demonstrate that increased depressive and/or anxiety symptoms just prior to treatment predict the development of depression during interferon (IFN)- $\alpha$ 2b therapy—a regimen known to activate inflammatory pathways and produce high rates of depression.<sup>44</sup> The clinical implications of these data are clear: patients recently diagnosed or about to undergo depressogenic treatments should be evaluated for past and current mood and anxiety symptoms, as well as for a family history of depression. Patients with positive histories in these domains will likely benefit from closer monitoring and in some cases (especially in the context of depressogenic treatments) may merit prophylactic antidepressant treatment or treatment at the earliest signs of mood disturbance.

Prevalence of depression also appears to vary with tumor type and location (see Table 3). Depression rates are generally reported to be highest for pancreatic, oropharyngeal, and breast carcinomas and lowest for lymphoma, leukemia, and gastric cancers.<sup>5,45</sup> Brain tumors are also associated with high rates of depression, especially when tumors are located in the frontal lobe, especially on the left side—a brain area implicated in the genesis and treatment of depression in general.<sup>41,46</sup> Delirium and seizures are also extremely common in these patients. Both of these conditions have high rates of associated mood disturbance and hence need to be evaluated and ruled out prior to ascribing mood or anxiety symptoms to a mood disorder diagnosis.<sup>47</sup> As with medical illnesses in general,<sup>39</sup> rates of depression in cancer patients increase as disease severity intensifies.<sup>2,48,49</sup> The presence of metastases and pain have also been shown to correlate with depression, whether measured by inclusive- or exclusive-type approaches.<sup>49</sup>

The type of treatment patients undergo also affects the likelihood of developing depression (Table 5). As discussed below, cytokines such as IFN- $\alpha$  or interleukin (IL)-2, which are used in the treatment of several malignancies, are notorious for inducing depressive symptoms.<sup>50</sup> For example, the rates of developing major depression approach 50% in patients receiving chronic, high-dose, IFN- $\alpha$  therapy.<sup>51</sup> Other chemotherapeutic agents frequently associated with depression include procarbazine, L-asparaginase, vinblastine, and vincristine.<sup>52</sup> All of these treatments, along with

**Table 4** Risk Factors for Depression in Patients with Cancer

History of depression or anxiety disorder
Current subsyndromal depressive and/or anxiety symptoms
Lack of social support

Bicalutamide
Glucocorticoids
Cytokine therapies
Interferon- $\alpha$ , interleukin-2

surgical interventions, are associated with significant metabolic stress and inflammation, which may, in turn, mediate their effects on mood and brain function (see below).

Hormonal treatments also pose a significant risk factor for the development of depression in cancer patients. Tamoxifen and other antiestrogen therapies for breast cancer are particularly relevant in this regard. By displacing estrogen from its receptor, tamoxifen obviates estrogen's neuroprotective functions. Tamoxifen also directly inhibits serotonin release in peripheral mast cells, an effect that may also occur in the brain.<sup>53</sup> Depression rates in both male and female cancer patients undergoing tamoxifen therapy are  $\approx 15\%$ .<sup>54</sup> Of note, antiestrogen therapies are typically initiated during a period when many patients consider themselves in a "survivorship phase." Hence, the risk of medication-induced depression may not be as anticipated as with the mood changes that occur during "active" treatment with other chemotherapeutic regimens. Like estrogen, testosterone also plays a role in mood regulation.<sup>55</sup> Indeed, testosterone has been used to treat depression in some medically ill patients, including patients with acquired immune deficiency syndrome (AIDS),<sup>56</sup> and appears to be especially effective in alleviating fatigue.<sup>57</sup> Therefore, it is not surprising that drugs that reduce the availability of testosterone (leuprolide) or antagonize the testosterone receptor (flutamide or bicalutamide) have been associated with depression.<sup>58</sup> Finally, glucocorticoid hormones are notorious for causing mood alterations, including both depression and mania (as well as psychosis).<sup>47</sup>

Aside from the acute effects of cancer treatment regimens on mood, recent data suggest that some chemotherapies may have long-term neuropsychiatric effects. In a large study of adults who had survived childhood leukemia, Hodgkin's disease, or non-Hodgkin's lymphoma, depressive symptoms were significantly more common in cancer survivors than in nonaffected siblings.<sup>59</sup>

The intensity of chemotherapeutic exposure in childhood predicted the prevalence of depressive symptoms in adulthood in these patients.<sup>60</sup> Cancer treatment may also be associated with long-term cognitive effects. For example, 128 adults with a history of breast cancer or lymphoma were assessed for neurocognitive impairment 5 years after either local therapy or systemic chemotherapy. Consistent with several other studies, cognitive impairment was significantly worse in the patients who received chemotherapy.<sup>61</sup>

Aside from depression and cognitive dysfunction, anxiety is another persisting problem for many cancer patients. There is little doubt that cancer survivors fear recurrence. Nevertheless, although most survivors may use this slightly elevated "somatic concern" to their advantage with good follow-up compliance and vigilant monitoring, some may experience excessive anxiety and intrusive cancer-related thoughts and memories. These symptoms may become severe enough to warrant a diagnosis of post-traumatic stress disorder (PTSD).<sup>62</sup> Interestingly, small volume of the hippocampus (a brain region involved in learning and memory) has been associated with recurrent and intrusive memories related to cancer diagnosis and treatment in breast cancer survivors.<sup>63</sup> Of note, both major depression and PTSD also have been associated with small hippocampal volume. Future studies are needed to determine if patients with small hippocampal volume at baseline (prior to cancer diagnosis and treatment) are more likely to experience post-treatment symptoms of PTSD versus the potential for cancer or cancer treatment to induce hippocampal atrophy and thereby lead to symptoms consist with PTSD.

## Mechanisms

In exploring the mechanisms that underlie the development of significant depressive symptoms in patients with cancer, it is important to consider the possibility that manifest and treatable hematologic, infectious, endocrine, and metabolic alterations are relevant contributing factors. These factors must always be evaluated and treated before proceeding with other strategies that address nervous system pathways, including neurotransmitter function. Moreover, because mood disorders, regardless of etiology, may ultimately engage "downstream" brain processes involving serotonin, norepinephrine, and/or dopamine, amelioration of a depressive syndrome by antidepressants does not necessarily rule out the presence of "upstream" medical pathology that is treatable.

Recent advances in neurobiology and immunology have enriched our understanding of potential pathways that may play a role in the development of mood disorders in cancer

patients. In this section, we consider how inflammation and oxidative stress represent two processes that have been associated with depression and are common to multiple aspects of having been and being treated for cancer.

## Inflammation and Sickness Behavior

One explanation for the high rate of depression and other behavioral comorbidities in cancer patients is that depression in this context is an expression of "sickness behavior."

Sickness behavior is a constellation of signs and symptoms that accompany illness in general and inflammation or immune activation in particular. Caused by proinflammatory cytokines that are released in response to threats to bodily integrity (eg, infection, neoplasia, radiation treatment, and toxic chemotherapeutic regimens), sickness behavior includes behavioral symptoms of depressed mood, anhedonia, fatigue, psychomotor slowing, anorexia, social isolation, sleep disturbances, cognitive dysfunction, and increased sensitivity to pain (hyperalgesia).<sup>64,65</sup> The overlap of the symptoms of sickness behavior with the symptoms used to make a diagnosis of depression is considerable (Table 6) and has led many to consider that depression in many cancer patients is an outgrowth of the effects of cytokines and inflammation on the brain.

Relevant to understanding the pathophysiology and, ultimately, treatment of sickness behavior, an explosion of interest has focused on exploring how proinflammatory cytokines cause changes in the brain and behavior.<sup>65</sup> Cytokines are relatively large molecules that do not freely pass through the blood-brain barrier. Nevertheless, several pathways by which cytokine signals can reach the brain have been characterized, including (1) passage through leaky regions in the blood-brain barrier, (2) active transport, and (3) binding to relevant receptors on peripheral afferent nerve fibers, such as those derived from the vagus nerve. In addition, the complexity of the cytokine network within the brain, including the distribution of cytokine receptors and signaling pathways, is now being revealed. The contribution of specific cytokines to specific behaviors is also being explored.

At least five pathways have been elucidated by which proinflammatory cytokines may cause depression or sickness behavior (Table 7). First, proinflammatory cytokines have been shown to alter the metabolism of the monoamines, including norepinephrine, serotonin, and dopamine, all of which have been implicated in the pathophysiology of mood disorders.<sup>66</sup> Second, cytokines have been shown to have potent stimulatory effects on the hypothalamic-pituitary-adrenal (HPA) axis, in large part through activation of corticotropin-releasing hormone (CRH).<sup>67,68</sup> CRH has behavioral effects in animals that are similar to those

Cytokine inhibition of pathways involved in thyroid hormone metabolism (euthyroid sick syndrome).

seen in patients suffering from depression or sickness behavior, including alterations in activity, appetite, and sleep.<sup>69</sup> Moreover, patients with depression have been found to exhibit increased CRH activity as manifested by elevated concentrations of CRH in cerebrospinal fluid, increased messenger ribonucleic acid in the paraventricular nucleus of the hypothalamus, a blunted adrenocorticotrophic hormone (ACTH) response to CRH challenge (likely reflecting down-regulation of pituitary CRH receptors),<sup>70,71</sup> and down-regulation of receptors for CRH in the frontal

cortex of victims of suicide (presumably secondary to hypersecretion of CRH). Third, in vivo and in vitro studies suggest that proinflammatory cytokines, including IL-1, may induce resistance of nervous, endocrine, and immune system tissues to circulating glucocorticoid hormones through direct inhibitory effects on the expression and/or function of glucocorticoid receptors.<sup>72</sup> Glucocorticoid resistance has been repeatedly demonstrated in medically healthy patients with depression (as reflected in nonsuppression on the dexamethasone suppression test),<sup>73</sup> as well as cancer patients with depression,<sup>45,74</sup> and may contribute to impaired feedback regulation of CRH and the release of proinflammatory cytokines. Fourth, cytokines, including IFN- $\alpha$ , have been shown to reduce serum concentrations of L-tryptophan (TRP), likely secondary to changes in dietary intake (owing to anorexia) and the induction of the enzyme indoleamine 2,3-dioxygenase (IDO), which breaks down TRP into kynurenine.<sup>75–77</sup> TRP is the primary precursor of serotonin, and depletion of TRP has been associated with the precipitation of mood disturbances in vulnerable patients.<sup>78</sup> Finally, proinflammatory cytokines have been associated with euthyroid sick syndrome, which is characterized by normal thyroid-stimulating hormone (TSH) and thyroxine ( $T_4$ ) levels and reduced triiodothyronine ( $T_3$ ) levels in the early stages and by normal TSH and reduced  $T_3$  and  $T_4$  in the later stages.<sup>79</sup> Alterations in thyroid hormone availability are well known to influence mood regulation. The mechanism by which euthyroid sick syndrome occurs is believed to involve both direct effects of cytokines on thyroid gland function and inhibition of the metabolic enzymes (5'-deiodination) that convert peripheral  $T_4$  to  $T_3$  (the more biologically active form of thyroid hormone), especially in the liver.<sup>79</sup>

Early studies are beginning to provide support for the notion that inflammation and inflammatory cytokines may play a role in the development of depressive symptoms in cancer patients. In a study by Musselman and colleagues, depression was associated with significantly increased plasma concentrations of IL-6 in patients with a wide variety of cancers.<sup>74</sup> In addition, both IL-6 and IL-1 have been found to significantly correlate with fatigue in cancer patients undergoing treatment with radiation and/or chemotherapy.<sup>80–82</sup> Increased serum concentrations of IL-6 also have been found to correlate with increasing depressive symptom scores in patients undergoing abdominal surgery.<sup>83</sup> As discussed in detail below, treatment with cytokines such as IFN- $\alpha$ , which is a potent activator of the inflammatory cytokine network, including IL-6,<sup>84</sup> is associated with rates of depression that range from 30 to 50% depending on the dose.<sup>44</sup> Finally, it should be noted that there is a rich literature

demonstrating increased inflammatory markers, including IL-6 and C-reactive protein, in depressed patients who are medically healthy,<sup>85</sup> suggesting that the immune system may play a more fundamental role in mood regulation, even in patients without medical illnesses.

Although the symptom overlap between sickness and depression complicates the task of identifying and treating patients with cancer, it also offers clues to mechanisms by which the physiology of illness may contribute to the pathophysiology of depression. Moreover, as often happens, expanding knowledge has provided support for dichotomous positions previously perceived as being exclusive, in this case, giving credence to both inclusive and exclusive ways of understanding depression in the context of sickness. Indeed, accumulating data lend support for an emerging paradigm in which immune system activation is seen to induce physical and behavioral symptoms common to both illness and depression and to induce changes in central nervous and stress system pathways that additionally predispose vulnerable individuals to the development of profound mood and hedonic alterations in the context of sickness.

#### Cytokine-Mediated Models

To aid in separating immune from psychosocial contributions to depression in the context of medical illnesses, including cancer, researchers have employed treatment with IFN- $\alpha$  as a model system to study cytokine-mediated behavioral disturbance. IFN- $\alpha$  is a cytokine released early in viral infection that has both antiviral and antiproliferative activities.<sup>86</sup> In addition to direct effects on the immune system, IFN- $\alpha$  also potently stimulates the production of proinflammatory cytokines, including IL-6 and, to a lesser extent, tumor necrosis factor (TNF)- $\alpha$  and IL-1 $\alpha$  and IL-1 $\beta$ .<sup>84,87</sup> Because of its antiproliferative and antiviral activities, IFN- $\alpha$  is currently used for the treatment of several malignancies and viral infections.<sup>88</sup> Although frequently of benefit in each of these conditions, IFN- $\alpha$  has been repeatedly observed to cause a variety of neuropsychiatric side effects that closely resemble sickness behavior in animals and that meet symptom criteria for major depression in humans. Indeed, our group observed that nearly 50% of patients receiving high-dose IFN- $\alpha$  for malignant melanoma developed major depression over 3 months of treatment.<sup>51</sup> These results are especially striking given that depressive symptom scores were minimal in this population prior to treatment.

The possibility that antidepressant pretreatment might ameliorate neurobehavioral toxicity in patients receiving high doses of IFN- $\alpha$  for the treatment of malignant melanoma has been examined.<sup>51</sup> Forty patients with nonmetastatic disease were randomized in a double-blind

manner to receive either the serotonin reuptake inhibitor (SRI) paroxetine or placebo. Antidepressant (or placebo) treatment was commenced 2 weeks prior to the initiation of IFN- $\alpha$  and continued for an additional 12 weeks of IFN- $\alpha$  therapy. At the end of the study period, only 11% of patients receiving paroxetine had developed symptoms sufficient to meet the diagnostic criteria for major depression compared with 45% of patients receiving placebo.<sup>51</sup> Moreover, the rates of discontinuation from IFN- $\alpha$  were significantly lower in paroxetine-treated patients, 5% versus 35% for patients receiving placebo.

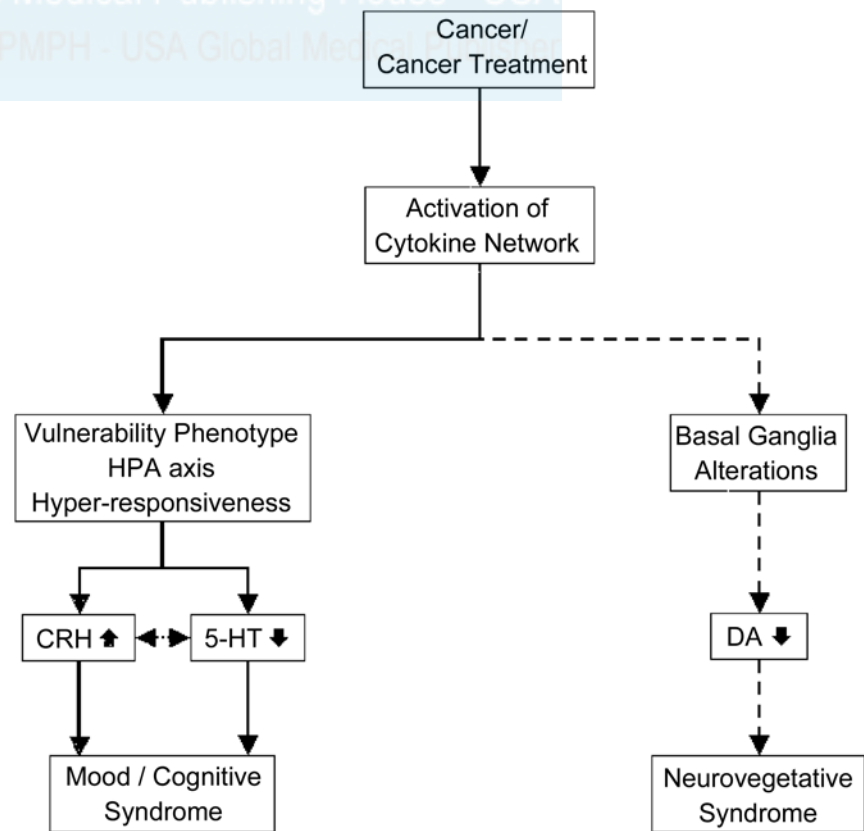

A recent study in rodents suggested that the SRI fluoxetine prevents cytokine-induced decrements in the gustatory hedonic domain while having no impact on cytokine-induced anorexia.<sup>89</sup> Given that major depression is a syndrome consisting of both mood or hedonic and neurovegetative symptoms (such as anorexia),<sup>4</sup> these findings raise the possibility that serotonergic antidepressants might be more effective in treating core depressive symptoms, such as hedonic drive, and less effective in resolving neurovegetative symptoms, such as anorexia. To examine this possibility, Capuron and colleagues evaluated whether paroxetine was equally effective in ameliorating all depressive symptoms in patients receiving INF- $\alpha$  for malignant melanoma or whether its ability to prevent major depression derived from a more limited spectrum of therapeutic efficacy.<sup>90</sup> A dimensional analysis revealed that symptoms more commonly seen in depression than in sickness, including depressed mood, loss of interest (anhedonia), suicidal thoughts, guilt, and anxiety, as well as subjective cognitive complaints, were prevented by SRI pretreatment, whereas neurovegetative symptoms, including fatigue, anorexia, and psychomotor retardation, were minimally responsive to the antidepressant. Additionally, neurovegetative and somatic complaints were noted to develop early during treatment (within the first 2 weeks) in the majority of patients, whereas depression-specific and cognitive symptoms developed later and tended to occur only in patients who met the *DSM-IV* criteria for major depression.

Similar patterns have been identified in the phenomenology and treatment response of behavioral disturbances in other cancer populations. In terms of phenomenology, a factor analysis in a large group of patients found that mood, anxiety, and cognitive symptoms clustered together, whereas fatigue, anorexia, and physical symptoms represented separate factors.<sup>91</sup> Consistent with SRI response patterns during IFN- $\alpha$  treatment, paroxetine was recently shown in a large, double-blind, placebo-controlled trial to ameliorate depression, but not fatigue, in cancer patients undergoing chemotherapy.<sup>17</sup> Taken

together, these findings support the notion that behavioral changes during immune activation may represent an amalgam of at least two subsyndromes: a neurovegetative or somatic syndrome that develops in most sick individuals appears early in the course of inflammation and is minimally responsive to SRI treatment and a mood, anxiety, and cognition syndrome that occurs in a subset of patients (who are also most likely to meet the full criteria for major depression). This syndrome develops after more prolonged inflammatory exposure and responds to SRI treatment.

The finding that both IFN- $\alpha$ -induced and cancer-related depression can be meaningfully subdivided on the basis of phenomenology and treatment response into a more depression-specific syndrome of mood, anxiety, and cognitive symptoms and a more generalized sickness syndrome composed of neurovegetative and somatic symptoms strongly suggests that separate pathophysiological mechanisms may underlie these syndromes, with the corollary that different symptoms may respond to different treatment strategies in depressed, medically ill patients (Figure 1).<sup>90</sup> Recent work aimed at delineating pathways by which immune activation produces behavioral disturbance is consistent with these ideas.

**TRP Depletion and Serotonin** As mentioned above, inflammatory stimuli (including IFN- $\alpha$  exposure) lead to a depletion of TRP via an immune-mediated induction of the enzyme IDO, which metabolizes TRP to kynurenine and hence reduces the amount of TRP that is available for the synthesis of serotonin.<sup>92,93</sup> It has been argued that IDO induction serves several adaptive purposes, including diminishing TRP availability for bacterial pathogens (for which TRP is also an essential amino acid) and promoting maternal T-cell tolerance toward the fetus during pregnancy.<sup>94</sup> Despite these evolutionary benefits, however, IDO induction might also be expected to increase the risk of developing depressive symptoms during conditions of immune activation, given evidence that TRP depletion is capable of rapidly inducing depressive symptoms in nondepressed but vulnerable individuals.<sup>60,95</sup> Data from patients receiving high IFN- $\alpha$  suggest that this is true: several studies report that treatment results in decreases in serum TRP and increases in kynurenine,<sup>92,93,96</sup> consistent with activation of IDO.<sup>97</sup> Moreover, the amount of reduction in TRP during treatment has been correlated with depressive symptom severity scores.<sup>93,96</sup> Similarly, it has been observed that antidepressant-free patients who met the criteria

**FIGURE 1** Differential Pathophysiological Mechanisms Underlying Interferon-Alpha-Induced Mood/Cognitive Syndrome and Neurovegetative Syndrome: A Model for Cytokine-Induced Neurobehavioral Alterations. Solid arrow: published data available. Dashed arrow: under investigation. (modified from Capuron, L., Miller, A.H. Cytokines and psychopathology: lessons from interferon alpha. *Biological Psychiatry*, 56(11):819–24, 2004).

for major depression during IFN- $\alpha$  therapy for malignant melanoma demonstrate significantly larger increases in kynurenine and the ratio of kynurenine to TRP and prolonged decreases in TRP during treatment when compared with patients who do not develop major depression.<sup>92</sup>

Interestingly, the relationship between major depression and TRP depletion resulted from a significant correlation between decreases in serum TRP concentrations and the development of mood, anxiety, and cognitive symptoms. No association was seen between TRP metabolism and neurovegetative symptoms or pain complaints. That alterations in TRP metabolism correlated with the same symptoms that responded to treatment with paroxetine but did not correlate with symptoms that were not responsive to the SRI<sup>90</sup> strongly suggests that serotonergic mechanisms contribute significantly to the expression of mood, anxiety, and cognitive complaints in these patients, a finding strengthened by the fact that no such correlation was observed in patients pretreated with paroxetine, which might be expected, via the effects of this medication on the serotonin reuptake pump, to compensate for IDO-induced decrements in serotonergic functioning. By the same logic, serotonergic mechanisms did not appear to play a central role in the mediation of neurovegetative or pain symptoms.

#### *Corticotropin-Releasing Hormone*

Because CRH hyperactivity is a frequently reported abnormality in major depression,<sup>73</sup> and because the inflammatory system robustly stimulates the HPA axis in animals and humans via stimulation of CRH, Capuron and colleagues used treatment with IFN- $\alpha$  as a model system to examine whether HPA axis hyperactivity represents a risk factor for developing depression during immune activation in humans.<sup>84</sup> In antidepressant-free patients, those who developed major depression during IFN- $\alpha$  treatment exhibited increased CRH activity in response to the first dose of IFN- $\alpha$  (as assessed by postinjection increases in serum concentrations of ACTH and cortisol). Of note, none of the patients met the criteria for depression at the time of the first injection.<sup>84</sup> Although the first dose of IFN- $\alpha$  also markedly increased serum concentrations of IL-6, no differences in this cytokine were observed between patients who did and did not go on to develop major depression, suggesting that the vulnerability to depression was accounted for by preexisting sensitivity of CRH pathways to an immune stimulus and not by an abnormality within the proinflammatory cytokine network itself.

Interestingly, both CRH pathway and cytokine responses to IFN- $\alpha$  rapidly attenuated with repeated treatment, such that within a week of initiating therapy, no differences were observed

in postinjection ACTH or cortisol responses between patients who did and did not subsequently develop major depression.<sup>84</sup> This finding is quite different from the temporal pattern observed between IDO-induced TRP depletion and depression, in which changes in TRP levels and the development of depressive symptoms were contemporaneous.<sup>92</sup> However, it is intriguing that patients who demonstrated CRH hyperactivity in response to an initial dose of IFN- $\alpha$  were also more likely to later demonstrate increased TRP depletion, indicating a possible link between CRH and serotonergic systems in the mediation of depressive symptoms in the context of immune activation. Moreover, as with IDO-induced TRP depletion, CRH hyperactivity predicted the subsequent development of major depression through an effect on mood, anxiety, and cognitive symptoms.<sup>84</sup> No correlation was observed between CRH hyperactivity and the later development of neurovegetative or somatic symptoms. Of note, previous studies have suggested that CRH hypersensitivity may result from early life stress or exposure to intense stressors in adulthood.<sup>98</sup> Family members of patients with depression have also exhibited evidence of CRH hypersensitivity.<sup>99</sup> Taken together, these findings suggest that patients with preexisting supersensitivity in CRH-mediated stress pathways may be at risk of developing mood, anxiety, and cognitive symptoms, not perhaps through ongoing abnormalities in stress system responses to immune stimulation but rather through as yet unidentified functional connections between CRH and serotonergic metabolism (see Figure 1). On the other hand, neurovegetative and physical symptoms that are frequent in the context of illness, even when more depression-specific symptoms are absent, may not be as directly related to alterations in CRH and/or serotonergic systems.

#### *Dopamine*

A first clue to the neural mechanisms by which activation of the cytokine network promotes the development of neurovegetative symptoms, such as fatigue or psychomotor slowing in patients with cancer, is provided by data linking abnormalities in central nervous system (CNS) dopamine with fatigue and psychomotor slowing in the context of medical illness. For example, human immunodeficiency virus (HIV) infection and Parkinson's disease, conditions in which fatigue and psychomotor slowing are prominent, are characterized by abnormalities in dopamine metabolism in the basal ganglia and by extreme sensitivity to medications, such as antipsychotic agents, that further reduce dopaminergic signaling via postsynaptic receptor blockade.<sup>100,101</sup> Consistent with this, even in medically healthy depressed patients, affective flattening and psychomotor retardation are associated with

evidence of altered dopaminergic functioning in the left caudate nucleus.<sup>102</sup> Finally, agents with dopaminergic activity have been repeatedly shown to effectively treat fatigue in a number of medical conditions.<sup>103–105</sup>

Chronic immune activation appears to inhibit dopamine signaling within frontostriatal circuits within the CNS. Rodents treated chronically with IFN- $\alpha$  demonstrate inhibition of dopaminergic neural activity and CNS dopamine metabolism, with concomitant decrements in motor activity.<sup>106</sup> In humans, high-dose IFN- $\alpha$  reliably slows reaction time on standardized neuropsychological tests and in extreme cases has been reported to produce frankly parkinsonian states that are responsive to treatment with levodopa.<sup>50,107</sup>

These findings support the possibility that psychomotor retardation and fatigue observed during states of immune activation may be related in part to cytokine-induced reductions in dopamine activity. Cytokine receptors are expressed in abundance in key areas of the basal ganglia–thalamocortical circuitry, including the striatum and cerebral cortex,<sup>108</sup> and therefore are uniquely poised to influence dopamine neuronal activity in these brain regions. Moreover, chronic infusion of bacterial endotoxin (a potent inducer of the inflammatory cytokine network) into rat brain leads to delayed and selective degeneration of dopaminergic neurons in the substantia nigra through microglial activation.<sup>109</sup> Finally, the targeting of basal ganglia and dopamine pathways during activation of the cytokine network is suggested by involvement of these pathways in infectious diseases associated with neuropsychiatric alterations, including HIV.<sup>101</sup>

Taken together, these data suggest that alterations in basal ganglia, notably in dopamine neurotransmission, may contribute to the development of core neurovegetative symptoms of IFN- $\alpha$ -induced depression, including psychomotor slowing (see Figure 1). Consistent with this, preliminary data from our group and others demonstrate altered glucose metabolism in the basal ganglia of IFN- $\alpha$ -treated patients.<sup>110,111</sup>

#### Implications

The concept of sickness behavior promotes an awareness that many symptoms of both physical and emotional distress in cancer patients may have a significant biologic component, arising out of the body's own attempt to fight disease and at the same time maintain homeostatic balance. This perspective discourages simple dichotomies between emotional and physical suffering in the context of cancer and points to the clinical utility of broadening therapeutic concerns beyond depression into the larger sickness syndrome, of which depression in the medically ill is a component. Such a perspective argues for an

inclusive approach to identifying patients with clinically relevant behavioral disturbances, even when these disturbances do not meet the criteria for currently recognized *DSM-IV* mood disorders. Moreover, recognizing that inflammation provides a physiologic substrate that promotes mood disturbance implies that markers of inflammation may provide an additional diagnostic tool to identify individuals at risk of developing depressive disorders. Such inflammatory risk markers were recently identified for both diabetes and coronary artery disease—conditions that, like cancer, are associated with increased rates of depression. Relevant in this regard are the previously noted data that patients with cancer who develop depression have significantly higher levels of IL-6 than cancer patients without depression.<sup>74</sup> Other abnormalities that may hold promise as predictive markers for depressive disorders include IDO-mediated decreases in plasma TRP and alterations in the production of HPA axis hormones, such as ACTH and cortisol, as discussed above. Similarly, imaging studies of patients undergoing cytokine exposure may, in the future, cast light on neural circuits that mediate both the risk and expression of behavioral toxicity.

However, if the elucidation of sickness behavior promotes an inclusive approach to behavioral symptoms in patients with cancer, findings on depressive subsyndromes and the pathways that underlie these different symptom dimensions argue for the wisdom inherent in exclusive approaches that privilege more depression-specific symptoms and downplay the importance of neurovegetative symptoms. Specifically, studies in patients undergoing immune activation strongly suggest that sickness symptoms, including fatigue and other neurovegetative symptoms, are widespread and serve as a physiologic base from which a smaller number of vulnerable individuals progress to develop symptoms most classically associated with mood disturbances, including sadness, loss of pleasure, anxiety, hopelessness, helplessness, and suicidal ideation. A strong rationale for privileging these symptoms comes from studies over the last several years suggesting that these symptoms may be the primary mediators of the relationship between depression and poor health outcomes.<sup>8,112</sup>

Although the identification of vulnerability factors for depression-specific symptoms is in its infancy, data indicate that patients with sensitized CRH pathways—as a result of genetic endowment, previous stressor exposure, or both—are at increased risk of developing depression-specific symptoms and of meeting the full criteria for major depression when exposed to an immune challenge. Similarly, patients who respond to an immune challenge with heightened IDO activity and resultant decrements in TRP also appear to

be at increased risk of progressing from sickness to full depression when exposed to inflammatory activation.

Recent evidence suggests that both inclusive and exclusive approaches to depression in patients with cancer have important clinical implications and that, although apparently contradictory, both approaches should be held in mind for clinicians to optimally relieve suffering in the context of neoplasia. As discussed above, with the development of the concept of sickness behavior, a coherent rationale is provided for addressing a more inclusive range of emotional, neurovegetative, and physical symptoms than would be targeted under strict definitions of current *DSM-IV* mood disorders.

Although sickness behavior in general supports a broadening of the terrain that is appropriate for therapeutic intervention, recent evidence that cytokine and oxidative stress-induced depression is not a unitary phenomenon but rather represents an amalgam of at least two separable subsyndromes provides a rationale for privileging depression-specific symptoms that are core features of exclusive diagnostic approaches to depression in the medically ill.

### Oxidative Stress

In addition to the effects of inflammation or cytokine pathology on behavior, another important potential mediator of behavioral pathology in cancer patients is oxidative stress. Considerable evidence implicates oxidative stress and depletion of the critical antioxidant glutathione (GSH) in neurodegenerative processes. GSH deficiency leaves the brain susceptible to oxidant-mediated injury that leads to neuronal cell dysfunction and death.<sup>113,114</sup> Significant loss of both systemic and brain GSH pools has been associated with a range of cognitive dysfunctions related to Parkinson's disease, Alzheimer's disease, and schizophrenia.<sup>113–115</sup> Furthermore, the extent of systemic GSH depletion was a highly significant and independent predictor of the severity of cognitive impairment in a recent prospective study of individuals with Alzheimer's disease.<sup>116</sup> It is not known whether perturbations in systemic GSH status contribute to chemotherapy-associated neurocognitive dysfunction; however, various chemotherapeutic agents have been shown to induce significant and acute declines in circulating GSH concentrations in cancer patients,<sup>117,118</sup> which may exacerbate hematologic toxicity, nephrotoxicity, and neurotoxicity.<sup>119,120</sup> Jonas and colleagues demonstrated that chemotherapy regimens administered during bone marrow transplantation progressively decreased and oxidized plasma GSH pools over a prolonged 14-day period post-treatment (Figure 2).<sup>117</sup> There are data suggesting a role for GSH deficiency in the development of neurotoxicity in patients receiving multiple

**FIGURE 2** Mean ( $\pm$ SE) plasma GSH ( $\mu$ mol/L) over time in patients receiving bone marrow transplantation. Pre-chemotherapy values were obtained at the time of admission and post-chemotherapy values were obtained on days 1, 3, 7, 10, and 14 after conditioning therapy. GSH concentrations decreased significantly over time reaching well below the normal reference range for healthy populations ( $P < 0.001$ ; effect of time).

cycles of chemotherapy. In patients with advanced colorectal cancer, clinically evident neuropathy induced by oxaliplatin-based chemotherapy was markedly reduced with bimonthly GSH infusion by the eighth treatment cycle.<sup>119</sup>

GSH is an abundantly present antioxidant found in all cells and extracellular fluids in humans. GSH functions in detoxification, acts as a reservoir for cysteine, maintains other functional antioxidants, and is central to control of protein thiol-disulfide balance, ultimately regulating thiol-dependent cellular functions. Compromised GSH metabolism may contribute to oxidative stress, sensitivity to toxicants, and alterations in oxidative metabolism, all of which have been implicated in neurologic disorders.<sup>121</sup>

GSH depletion may represent a key mechanism in neuronal cell injury and dysfunction. The brain is particularly susceptible to oxidative stress owing to high rates of oxidative metabolism, the abundance of polyunsaturated fatty acids in cell membranes, and the comparatively low antioxidant activity relative to other tissues.<sup>122</sup> Oxidative stress and substantial GSH losses have been demonstrated in neurodegenerative disorders and have been linked with the progressive degeneration of dopaminergic neurons in preclinical stages of Parkinson's disease.<sup>123</sup> Evidence indicates that GSH deficiency may cause or worsen neuronal dysfunction through multiple mechanisms. In addition to increasing neuronal cell susceptibility to reactive oxygen species (eg,  $H_2O_2$ ) and to neurotoxicants, GSH loss and oxidative stress result in neuronal dysfunction through the accumulation and aggregation of oxidized proteins and through the signaling of redox-sensitive cell death pathways.<sup>114,124</sup> Whether abnormalities in the systemic GSH redox state relate to defects in brain GSH metabolism, oxidative stress, and neuronal cell fate is not established. Nonetheless, blood GSH levels reflect oxidative stress found

to be pathogenic in other disease states, such as macular degeneration, diabetes, AIDS, and cancer.<sup>125–127</sup>

GSH redox is a means to clinically assess oxidative stress. In humans, the balance between GSH and glutathione disulfide (GSSG), determined by the balance of oxidative reactions and the capacity of the reduced nicotinamide adenine dinucleotide phosphate–dependent reductase to reduce GSSG back to GSH, provides a means to clinically measure oxidative stress. Previous clinical studies show differences in plasma GSH redox in humans, which are related to states of oxidative stress, such as in aging, chemotherapy treatment, and critical illness.<sup>118–120,128</sup> Progressive oxidation of the plasma GSH pool may correlate with intracellular GSH depletion in various organ systems, as well as loss of redox potential in extracellular compartments particularly important to the CNS, as has been shown in cerebrospinal fluid during aging.<sup>125</sup> Because of continuous cycling of GSH pools between peripheral tissue or plasma and the brain (likely through substrate cycling via the blood-brain barrier) plasma measurements may indirectly reflect brain redox conditions of potential relevance to neurodegenerative changes.

Alterations in cytokines, such as TNF- $\alpha$ , IL-2, IL-6, and IFN- $\gamma$ , are documented responses to chemotherapeutic regimens that may be important to treatment-induced toxicity in breast cancer patients. Oxidative stress is directly linked to proinflammatory cytokine activation. Given evidence (discussed above) that cytokine activation may contribute to neurobehavioral disturbances in the context of cancer and its treatment, the possibility arises that changes in oxidative state may be a mechanism by which inflammation alters neuronal and, ultimately, psychiatric functioning. Studies are currently under way to evaluate this intriguing hypothesis. If findings corroborate this idea, the road will be opened for nutritional intervention studies aimed at improving resilience to redox state perturbations during cancer chemotherapy. Indeed, diets rich in vegetables, plant-derived extracts, amino acid substrates, and micronutrients have been shown to protect against oxidative stress, and such dietary manipulations could be used to protect patients during chemotherapeutic treatments and prevent neuropsychiatric problems before they occur.

Although evidence has been provided that oxidative stress may contribute to the development of behavioral pathology in cancer patients, it should be noted that several studies have suggested that higher GSH concentrations in the mitochondria may act as a redox buffer and inhibit mitochondrial alterations associated with apoptosis secondary to chemotherapeutic agents, notably cisplatin.<sup>129</sup> Most recently, GSH synthesis has been identified as an essential component

for the apoptotic inhibitor of cisplatin (Bcl-2). This activity cannot be explained by DNA adduct formation or damage repair and is likely to be regulated through mitochondrial or cellular homeostasis.<sup>130</sup> Thus, balancing levels of GSH to offer neuroprotective effects while maintaining the cytotoxic or apoptotic properties of chemotherapy agents represents a challenge for future translational studies.

## Summary

Based on a rich literature, there is compelling evidence that depression is a common comorbidity in oncology patients. However, diagnosing depression in the cancer patient can present a challenge because both somatic and psychic complaints intertwine. Nevertheless, with the use of appropriate rating scales and a more “inclusive” approach to diagnosis, fewer depressed patients will go unrecognized and untreated. With new developments in the understanding of the potential pathophysiologic mechanisms involved in symptom expression, it is also becoming increasingly clear which patients are at risk and when. Moreover, therapeutic strategies targeting specific symptom dimensions have been identified and are available. Future studies investigating the multiple neurobiologic, immunologic, and genetic pathways involved in symptom development will help elaborate new treatment and prevention strategies and help patients better negotiate the short- and long-term neuropsychiatric challenges of cancer and its treatment.

# Sleep Disorders in the Cancer Patient

Colleen G. Lance, MD

Karen O. Anderson, PhD, MPH

Sleep disturbance is a frequent complaint among cancer patients, as clinicians caring for patients can attest. A sleep disturbance can be defined as any disruption that causes a person to have difficulty falling asleep or maintaining sleep, to feel not rested after a night's sleep, or to require a nap during the day.<sup>1</sup> Having a sleep disturbance affects all aspects of a patient's well-being, which, in turn, affects the patient's response to cancer treatment. The body of literature and amount of research invested into this common symptom are relatively limited. One reason might be the small amount of time clinicians spend on sleep disorders during medical school: on average, only 2 hours over the course of 4 years.<sup>2</sup> Also, sleep disturbance complaints are very subjective, which makes developing tools for quantitative measurement difficult.

Sleep disturbances within the cancer population, whether caused by the cancer itself, cancer-related adjustment disorders, or treatment interventions, are even more frequent than for the general population. Research among various cancer groups has found a prevalence of sleep disturbance ranging from as low as 24%<sup>3</sup> to as high as 95%.<sup>4</sup> One recent study found that 62% of those studied had moderate to severe sleep disturbance.<sup>1</sup> The importance of this symptom to cancer patients was brought to light by Derogatis and colleagues, who looked at psychotropic medications prescribed for almost 1,600 cancer patients.<sup>5</sup> Of all of the prescriptions written, 48% were for hypnotics.

Although most studies to date have been nonspecific questionnaire studies, they have helped bring quality of life issues to the forefront. For example, patients who received radiation treatment and who had lower Karnofsky Performance Status scores reported more sleep disturbances.<sup>6</sup> Also, a recent questionnaire study of metastatic breast cancer patients showed that 63% reported one or more kinds of sleep complaints.<sup>7</sup>

A few studies that focused on specific cancer populations used polysomnography to investigate sleep architecture. One such study examined the sleep architecture and psychological state of

breast and lung cancer patients. Using insomniacs as a control group, investigators found that lung cancer patients had more disturbed sleep than insomniacs yet underreported their symptoms. The lung cancer patients had to stay in bed much longer to obtain the same quantity of sleep, had lengthy sleep disruptions through the night, and took longer daytime naps. The breast cancer group also reported more sleep difficulties than the controls, but an examination of the sleep architecture indicated that they actually had slept well.<sup>8</sup>

## Diagnosing Sleep Disturbance

Prompt referral to a sleep medicine specialist should be made whenever a patient's sleep complaint is disrupting his or her daytime routine or cancer treatment. The following is what to expect from a sleep medicine consultation and may help the clinician in deciding when to refer a patient. Two helpful Web sites are <[www.absm.org](http://www.absm.org)> for finding board-certified sleep physicians and <[www.sleepfoundation.org](http://www.sleepfoundation.org)> for sleep tools.

## The Sleep History

The initial step in characterizing a patient's sleep disturbance is taking a sleep history. A cancer patient's sleep complaints are most often mixed with other complaints and may be far down on the patient's list of concerns. A sleep history asks the patient and, if possible, the patient's sleep partner a variety of descriptive questions about the nature of the patient's sleep experience (Table 1).

A sleep history may reveal that the sleep difficulties are being caused by treatable conditions. For example, certain medical ailments may have nocturnal presentations: patients may complain of shortness of breath or chest pain with cardiopulmonary conditions, heartburn or abdominal pain with gastrointestinal conditions, headaches with carbon dioxide retention, or jaw pain with temporomandibular joint disorder. Medications, such as bronchodilators and psychotropic, gastrointestinal, and pain medications, also may contribute to sleep difficulties. A detailed review of the patient's intake of medication, herbal

**Table 1** Sleep History Sample Questions

<p>What time do you go to bed?          Do you have difficulty falling asleep?*</p> <p>Do you have racing thoughts while trying to fall asleep?*</p> <p>How many times do you awaken during the night?*</p> <p>    What awakens you?          How long until you fall back to sleep?</p> <p>What time do you awaken to start your day?          Do you wake up refreshed?          Do you snore at night?***          Are you sleepy during the day?          Do others tell you that you have pauses in breathing or gasping for air?†</p> <p>Does your bed partner have to sleep in another room because of the way you sleep?†</p> <p>Do you ever have sudden loss of strength in your arms or legs during the day?‡          If yes, are these episodes brought on by fright or laughter?</p> <p>Do you take naps?‡          If yes, how often and for how long?          How do you feel after these naps?</p> <p>Do you ever awaken feeling paralyzed?‡          Do you kick or twitch at night?‡          How much caffeine or nicotine do you consume?§          Do you have a restless feeling in your legs while trying to sleep?§          If yes, how often?</p>
--

\*Insomnia.

†Sleep-disordered breathing.

‡Narcolepsy.

§Periodic limb movement and restless legs.

supplements, nicotine, and caffeine may indicate the need to change a medication altogether or simply to change the time of day that it is given.

Social history provides useful information about normal daily routines and possible interruptions from the cancer or cancer treatment. A social history interview should include the patient and all household members as cancer treatment may be severely disruptive to the entire household and can require difficult adjustments from both the patient and the family. Particular attention should be given to the state of the

patient's relationships with his or her spouse, children, and coworkers.

### The Sleep Physical

The physical examination of a patient with a sleep complaint begins the moment the physician enters the room. A disheveled appearance or altered affect may indicate a psychiatric disorder as a primary diagnosis. A large body habitus and central obesity may be indicators of sleep-disordered breathing or obesity hypoventilation.

The head and neck examination is of paramount importance. A neck circumference greater than 17 inches or thyromegaly may indicate increased adipose tissue around the airway. Craniofacial abnormalities associated with head and neck cancer or the treatment of such tumors may signify sleep-disordered breathing. Cardio-pulmonary examination may reveal medical conditions contributing to nocturnal sleep difficulties. Chest wall abnormalities such as kyphosis or pectus excavatum are associated with restrictive lung defects. Wheezing can signify nocturnal asthma attacks. Hypertension, cardiac thrust, or signs of pulmonary hypertension may be signs of sleep-disordered breathing, with signs of heart failure, such as hepatomegaly, ascites, and peripheral edema, in the most severe cases.

Neurologic examination may uncover reasons for disturbed sleep. Impaired mentation may suggest an underlying dementia that causes insomnia, hypersomnolence, or a circadian rhythm disorder. Use of sedatives and/or stimulants (prescription or illicit) may be apparent on initial examination. Prolonged alcohol abuse may be apparent, with hepatomegaly, ascites, spider telangiectasis, or jaundice. Peripheral neuropathy or joint abnormalities may cause nocturnal pain and sleep disturbance.

### Diagnostic Tools

Given that neither patients nor clinicians may initiate a discussion of sleep problems, screening questionnaires can help identify patients who are experiencing sleep difficulties. A checklist of common cancer-related symptoms, such as the M.D. Anderson Symptom Inventory<sup>9</sup> or the Symptom Distress Scale,<sup>10</sup> can be used as an initial screening tool. These brief and easily administered scales include one sleep disturbance item that can be used to identify patients with potential sleep disorders. If the patient responds positively to a sleep disturbance item, then a more detailed sleep questionnaire can be used to further define the problem. For cancer populations that are particularly at risk of sleep disorders, it may be helpful to include a brief sleep questionnaire as part of the initial workup.

The 19-item Pittsburgh Sleep Quality Index (PSQI), developed to measure sleep quality and quantity, has been evaluated in healthy samples

and samples of individuals with chronic diseases.<sup>11</sup> The scale yields a global sleep quality score and seven component scores: subjective sleep quality, sleep latency, duration, habitual sleep efficiency, sleep disturbances, use of sleeping medication, and daytime dysfunction. The PSQI has been evaluated in samples of patients with cancer.<sup>12–15</sup> This global sleep quality scale has demonstrated good internal reliability and construct validity in samples of breast cancer patients and patients with diverse cancer diagnoses.

The 12-item Medical Outcomes Study (MOS) Sleep Scale provides a concise assessment of several sleep dimensions and yields a sleep problems index and six scale scores: sleep disturbance, sleep adequacy, daytime somnolence, snoring, shortness of breath or headache, and quantity of sleep.<sup>16</sup> Evidence of the reliability and validity of the scale was provided in studies of individuals with chronic illness<sup>17</sup> and a nationally representative sample of adults.<sup>16</sup> In addition, the MOS Sleep Scale was sensitive to change in a sample of patients with neuropathic pain enrolled in a clinical drug trial.<sup>16</sup> This scale is brief and easy to administer, and a computer program is available for scoring. The scale has not been evaluated in samples of patients with cancer but appears to have potential utility owing to its brevity.

Other sleep questionnaires were designed to screen for obstructive sleep apnea (OSA), daytime somnolence, or other specific disorders.<sup>18–21</sup> These measures may be helpful if initial screening suggests a specific sleep disorder. The Epworth Sleepiness Scale was designed to differentiate persons with excessive daytime sleepiness from alert individuals by measuring their sleep propensity.<sup>19</sup> The scale asks individuals how likely they are to sleep in eight different situations.

### The Sleep Diary

When a sleep problem is indicated by a screening questionnaire or medical history, a sleep log or diary is often used to obtain additional information. Sleep logs provide a daily account of all sleep activities, including sleep latency (the time from lights out until sleep onset), sleep duration, number of nighttime awakenings, perceived sleep quality, and daytime naps. Such sleep logs are relatively easy to complete and cost little. A sleep diary of at least 2 weeks' duration is one of the most important tools in evaluating a sleep disturbance. The diary tracks the bedtime, time to sleep onset, the number and timing of nocturnal awakenings, time of final awakening, naps, and the subject's feelings on arising. This is particularly helpful in diagnosing circadian rhythm disorders and in managing insomnia.

### Actigraphy

Actigraphy is a tool used to assess activity level. It uses a device that can be worn on any limb for

several days to several weeks and that transfers a mechanical or digital signal with movement of the limb. The information is downloaded at the end of the study period. Actigraphy is useful for clarifying the level of insomnia and diagnosing circadian rhythm disorders and is an accurate measure of the sleep-wake cycle, with only a few exceptions. Validation studies comparing actigraphy with minute-by-minute polysomnography scoring show an 80 to 90% agreement when differentiating the sleep state from the wakeful state.<sup>22</sup>

### Polysomnography

The gold standard in sleep measurement is the attended nocturnal polysomnography (NPSG), in which a polygraphic recording of multiple physiologic variables is made during sleep. "Attended" means that a qualified technician remains with the subject throughout the study to monitor for technical adequacy and patient compliance. NPSG measures several biologic parameters simultaneously. These usually include electroencephalography, electro-oculography, electromyography, electrocardiography, body position, respiratory effort, airflow, and pulse oximetry. Other parameters may be added, such as esophageal pH to diagnose gastroesophageal reflux disease, esophageal pressure monitoring for the diagnosis of upper airway resistance syndrome, or end-tidal CO<sub>2</sub>. The Multiple Sleep Latency Test is a series of nap opportunities and recording of electroencephalography, electro-oculography, and chin electromyography. Performed the day after NPSG, it is used to evaluate hypersomnias, such as narcolepsy and idiopathic hypersomnia. Indications for NPSG are found in Table 2.<sup>23</sup>

## Specific Sleep Disorders in the Cancer Patient

### Insomnias

Insomnia is characterized by difficulty initiating or maintaining sleep or by nonrestorative sleep that causes significant distress or impairment in daily functioning. Insomnia is considered acute if the sleep problem lasts for one to three nights per week, with no episode lasting longer than several weeks, or chronic if the sleep difficulties last for three or more nights per week for 1 month or longer.<sup>24</sup> Patients with insomnia may also complain of daytime fatigue, irritability, decreased memory and concentration, and general malaise. The variables associated with increased risk of insomnia are fatigue, younger age, leg restlessness, use of sedatives or hypnotics, depression, dreams, concerns, and recent surgery.

Epidemiologic surveys that use diagnostic criteria for insomnia estimate the prevalence in the general population as 9 to 12%.<sup>25,26</sup> Cancer

**Table 2** Indications for Polysomnography

Snoring without daytime somnolence	Not responding to therapy
MSLT = Multiple Sleep Latency Test.	

patients appear to be at greater risk of insomnia than the general population. In a recent survey of over 900 cancer patients, 31% of the patients reported insomnia.<sup>27</sup> The most frequent patient-reported reasons for insomnia were pain, health concerns, concerns about family or friends, and the cancer itself.

The prevalence of insomnia among cancer patients has been evaluated in several descriptive studies. Savard and colleagues found that one-third of breast cancer patients with insomnia reported the onset of their sleep disturbance following their cancer diagnosis.<sup>28</sup> Thus, their insomnia appeared to be secondary to the cancer. In a larger heterogeneous sample of cancer patients, 48% indicated that their insomnia began around the time of cancer diagnosis.<sup>27</sup> Approximately 40% of the patients reported insomnia symptoms that began years prior to the cancer diagnosis. Another study of women with breast cancer found that 25% of the women reported difficulty falling asleep and 44% reported problems with nighttime awakenings.<sup>7</sup> Risk factors for sleep disturbance included pain, depression, and lower levels of social support. Another descriptive study of women with breast cancer found that 50% reported insomnia symptoms and 19% met diagnostic criteria for insomnia.<sup>28</sup>

The primary care physician or oncologist should screen patients for symptoms of insomnia during clinic visits. Patients with cancer may be reluctant to report poor sleep quality owing to a belief that insomnia is an expected reaction to having cancer or a reluctance to distract the physician from focusing on the cancer treatment. A telephone survey of breast and lung cancer patients experiencing sleep problems found that only 17% of the patients had discussed sleep with their physicians.<sup>29</sup> As noted previously, a brief symptom checklist completed prior to a clinic visit may help identify patients who are experiencing insomnia. When an initial screen indicates that insomnia is a problem, then a complete sleep history and physical examination, possibly by a

sleep specialist, is needed to determine the etiology of the insomnia. Polysomnography is not recommended for routine screening or diagnosis of insomnia, unless a sleep-related breathing or movement disorder is suspected.<sup>30</sup> Below are listed the most common causes of insomnia in the cancer patient:

- Behavioral
  - Inadequate sleep hygiene
  - Psychophysiological insomnia
- Environmental
  - Hospitalization
- Psychiatric
  - Psychosis
  - Mood disorders
  - Anxiety disorders
- Medications
  - Bronchodilators
  - Antihypertensives
  - Anticholinergics
  - Diuretics
  - Antidepressants (ie, selective serotonin reuptake inhibitors)
  - Decongestants
  - Chemotherapy (Table 10-3)
  - Hormone therapy: antiestrogens, antiandrogens
  - Substance abuse
- Medical conditions
  - Gastroesophageal reflux
  - Arrhythmias

**Table 3** Biochemotherapy Agents Associated with Insomnia

Busulfan
Mechlorethamine
Cladribine
Pentostatin
Fludarabine
Procarbazine
Irinotecan
Rituximab

- Coronary disease
- Reactive airway disease (Table 10-4)
- Movement disorders
  - Restless legs syndrome (RLS)
  - Periodic limb movement disorder (PLMD)
  - Nocturnal leg cramps
- Neurologic
  - Parkinson's disease
  - Dementia
  - Epilepsy
  - Tumor related
- Sleep-disordered breathing
  - Mild to moderate sleep apnea
  - Central sleep apnea (CSA)

Pain also is a risk factor for insomnia in patients with cancer. Patients receiving active cancer treatment often experience pain, and more than 60% of patients with advanced disease report pain.<sup>31,32</sup> Descriptive studies of cancer patients with pain have found that over half of the patients experienced sleep disturbance that they attributed to pain.<sup>32-35</sup> Difficulty initiating sleep and nighttime awakenings were frequently reported. Optimal pain management is necessary to eliminate pain as a stimulus that can disrupt sleep. For patients with complicated pain syndromes, referral to a pain specialist may be indicated.

Certain behaviors may lead to insomnia. Inadequate sleep hygiene refers to insomnia resulting from behaviors that increase bedtime arousal or disrupt sleep patterns. Examples of such behaviors include working or exercising late at night, taking excessive daytime naps, and keeping irregular sleep hours. Using stimulants such as caffeine and nicotine or substances such as alcohol near bedtime also can disrupt sleep. Patients with cancer may develop maladaptive sleep hygiene behaviors if their cancer treatment interferes with their usual sleep schedule.

In descriptive studies of cancer patients, the prevalence of mood disorders ranges from 13% to as high as 50%.<sup>36,37</sup> Mood disorders alone, however, do not explain the high rate of sleep disorders among cancer patients. One survey study found that only 21% of cancer patients reported insomnia and demonstrated a concurrent psychiatric diagnosis.<sup>38</sup> Common patterns seen include early morning awakening in depressed patients and frequent arousals in those with anxiety disorders. Early referral to a psychiatrist in conjunction with a sleep specialist is warranted.

#### Nonpharmacologic Treatments of Insomnia

Behavioral and cognitive-behavioral treatments have been used successfully to treat insomnia in the general population. Two recent meta-analyses of research studies evaluating these treatments concluded that behavioral and cognitive-behavioral interventions were effective and typically produced significant improvements in

sleep-onset latency, sleep quality ratings, the duration of nighttime awakenings, total sleep time, and the number of awakenings.<sup>39,40</sup> The amount of improvement demonstrated on most outcome variables was comparable to that seen in studies of hypnotic medications.<sup>41</sup> In addition, many studies have found that the improvements associated with behavioral and cognitive-behavioral interventions for insomnia were maintained up to 2 years after the initial treatment.<sup>39,40</sup>

Education on sleep hygiene is often included in behavioral and cognitive-behavioral treatments for insomnia. This education focuses on behaviors and environmental factors that affect sleep. Patients are taught to avoid alcohol and stimulants such as caffeine and nicotine close to bedtime. They also are advised to avoid heavy meals close to bedtime and to keep their bedroom a comfortable, dark, and quiet environment. Regular exercise is recommended, but not close to bedtime. Research evaluating sleep hygiene education alone has found that this intervention is modestly beneficial.

Cognitive-behavioral treatment usually requires the assistance of someone trained in these techniques, such as a psychologist. Techniques include

- Stimulus control
- Sleep restriction
- Relaxation techniques
  - Muscle relaxation
  - Biofeedback
  - Meditation
  - Imagery training
  - Hypnosis
  - Autogenic therapy
- Cognitive interventions

Only a few studies have evaluated behavioral and cognitive-behavioral interventions for insomnia in samples of cancer patients, but the results suggest that such interventions are effective for that population. In a small sample of patients with cancer, a cognitive-behavioral group intervention was associated with significant improvements in sleep efficiency, sleep quality, and nighttime awakenings.<sup>42</sup> A larger randomized controlled study of a stress reduction intervention for women with breast cancer found that women who reported frequent practice of mindfulness meditation improved more on a sleep quality measure than women who reported less practice.<sup>43</sup> A recent randomized controlled trial of cognitive-behavioral treatments for insomnia in cancer patients compared a multimodal package that included a relaxation technique with one that included an autogenic intervention.<sup>44</sup> Both treatment groups demonstrated significant improvements compared with a control group on measures of sleep latency, duration, efficiency, quality, use of sleep medication, and daytime dysfunction.

### Pharmacologic Treatment of Insomnia

The first step in pharmacologic management of insomnia is to eliminate, if possible, any agents that may be causing insomnia. Common medications that cause insomnia include anticholinergics, antidepressants, bronchodilators, corticosteroids, central nervous system stimulants, weight loss medications, decongestants, and diuretics.

Insomnia may be treated with any of several available sedative-hypnotic agents, including benzodiazepines, nonbenzodiazepine hypnotics, and sedating antihistamines and antidepressants. Ideally, these agents should be prescribed at the lowest dose possible for the shortest time possible and combined with the nonpharmacologic treatments described previously. Sedating antihistamines and antidepressants usually have only a transitory effect on alleviating insomnia. Antihistamines have some undesirable side effects, including constipation, urinary retention, and dry mouth. Benzodiazepines cause muscle relaxation, which can be a problem for those with sleep-disordered breathing and can produce rebound insomnia when stopped. The newer nonbenzodiazepine hypnotics do not cause muscle relaxation or rebound insomnia, nor do they suppress rapid eye movement (REM) and slow-wave sleep. The newest class of drug is the melatonin agonist ramelteon, which has US Food and Drug Administration (FDA) approval for insomnia. This drug also does not suppress REM or slow-wave sleep as the benzodiazepines do. Figure 10-1 is for the treatment of insomnia; treatment options are not mutually exclusive.

### Circadian Rhythm Disorders

We each have a 24-hour internal circadian “clock” that helps keep us synchronized with internal and external environments. This clock, the suprachiasmatic nucleus, is found in the anterior hypothalamus. It is entrained, or resynchronized, by external cues, the strongest being light.<sup>45</sup> When light stimulus is withdrawn from the suprachiasmatic nucleus, melatonin is released from the pineal gland, which, in turn, causes a decrease in body temperature and helps induce sleep. Abnormalities in this cycle are termed *circadian rhythm disorders*.

Delayed sleep phase syndrome is a disorder in which patients are unable to fall asleep until some time between 2:00 am and 6:00 am and then arise between 10:00 am and 1:00 pm; the clock is delayed. The prevalence of delayed sleep phase disorder in sleep clinics has been found to be as high as 16%.<sup>46</sup> The complaint is typically one of sleep initiation insomnia, and patients usually use sedative-hypnotics or alcohol to help initiate sleep; this is then followed by excessive daytime somnolence. Advanced sleep phase syndrome is a

disorder in which the clock is advanced so that the patient falls asleep much earlier than expected and wakes between 2:00 and 5:00 am. Diagnosis is made by history, sleep diaries, and sometimes actigraphy.

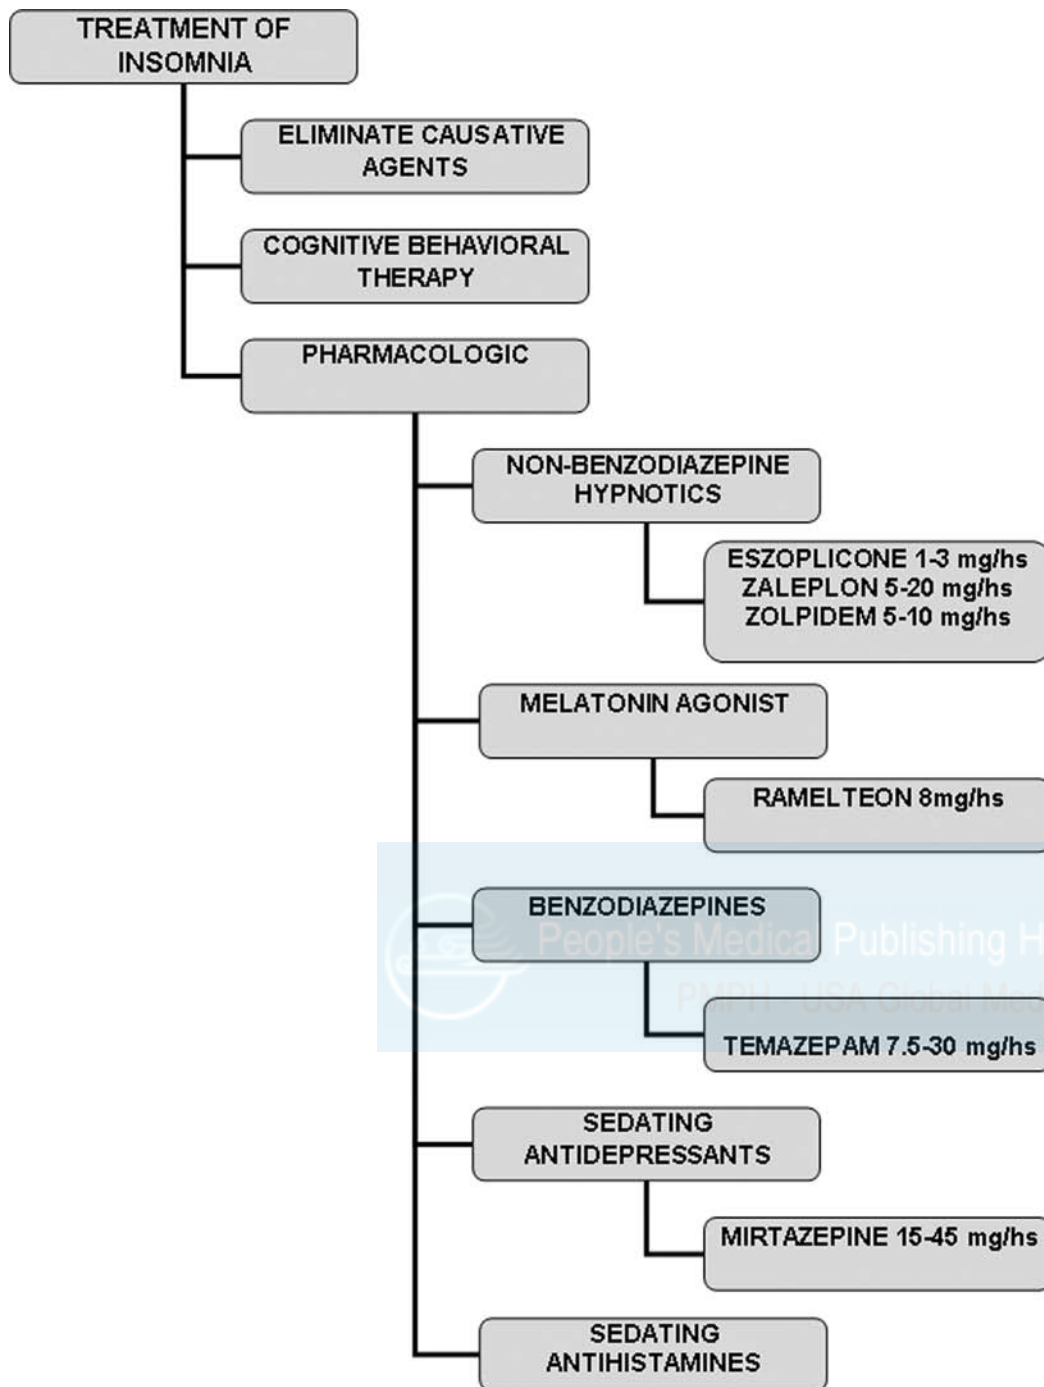

Several studies have used actigraphy and diurnal cortisol levels to look at circadian rhythm disruption within the cancer population. On the whole, daytime inactivity was correlated with nighttime restlessness and excessive daytime fatigue. Breast cancer patients undergoing adjuvant chemotherapy were found to have levels of fatigue that followed a “roller-coaster” pattern throughout treatment and that was negatively correlated with nighttime restlessness.<sup>47</sup> This has also been found in patients receiving treatment for metastatic colorectal carcinoma and those undergoing radiation treatment for various cancers.<sup>48</sup> Advanced sleep phase syndrome was found in some groups undergoing cancer chemotherapy, whereas others remained normal.<sup>49</sup> There are also reports in the literature of children with central nervous system neoplasms having circadian rhythm disturbance.<sup>50</sup> These findings imply that, for cancer patients, daytime naps and inactivity cause disruption to the circadian rhythm and hence greater fatigue.

Accordingly, treatment of these disorders parallels the treatment of cancer-related fatigue. Patients are placed on a mild exercise regimen, if they are able, to keep them active during the daytime and thus help consolidate nocturnal sleep. Elimination of daytime naps also may help improve nocturnal sleep. The above recommendations are thought to increase a person’s exposure to bright sunlight, which in itself promotes daytime alertness by activating certain centers in the brain that promote vigilance, as has been supported in animal research.<sup>51</sup>

Other treatment options include the use of melatonin in combination with bright-light therapy. Melatonin (5 mg) is taken at bedtime as a mild hypnotic; it must be combined with bright-light therapy because melatonin alone does not restore the circadian rhythm. Bright-light therapy attempts to promote alertness during the day and thus to adjust the patient’s circadian rhythm toward appropriate nocturnal sleep. It also needs to be prescribed by a sleep medicine specialist since timing of the bright light is critical. A new pharmacologic agent, ramelteon, is a melatonin agonist that may prove to be helpful in the future; it does not yet have FDA approval in the use of circadian rhythm disorders.

### Sleep-Disordered Breathing

The term *sleep-disordered breathing* refers to a spectrum of diseases that can be described as varying degrees of airway obstruction, in which increasing severity causes increased morbidity.

**FIGURE 1** Flow Chart for the Treatment of Insomnia

These include primary snoring, upper airway resistance syndrome, obstructive sleep hypopnea syndrome, obstructive sleep apnea-hypopnea syndrome, obstructive sleep apnea (OSA) syndrome, and mixed sleep apnea syndrome. Apnea is defined as complete cessation of airflow for at least 10 seconds; the obstruction can occur anywhere from the nasal passages to the larynx.<sup>52</sup> A central apnea is one that has cessation of both airflow and ventilatory effort.

#### Obstructive Sleep Apnea Syndrome

The prevalence of OSA in the general population ranges from 2 to 9% among women and 4 to 24%

among men.<sup>53,54</sup> It is estimated that 80% of those with the disease have not yet been diagnosed,<sup>53</sup> which means that most cancer patients with OSA have not been diagnosed. Presentation of OSA includes both nocturnal and daytime symptomatology. The nighttime complaints include snoring, gasping for air, observed apneas, frequent arousals, nocturia, and palpitations; some patients with mild to moderate OSA complain of sleep maintenance insomnia. Daytime complaints include excessive daytime somnolence, decreased concentration, depression, impotence, dry mouth, morning headaches, and forgetfulness. Some patients with severe sleep-disordered

breathing may not have any complaints but are brought by family members for evaluation. Excessive daytime sleepiness can be evaluated with the Epworth Sleepiness Scale,<sup>25</sup> which can be used in the initial evaluation and in treatment follow-up.<sup>55</sup>

Although relatively few studies have described sleep-disordered breathing in those with head and neck cancer,<sup>56</sup> space-occupying lesions are known to impinge on the airway and cause OSA. Treatment of head and neck cancers has been associated with OSA after both radiation and resection. Radiation causes OSA through post-treatment inflammation and by scarring, although one theory postulates that scarring may actually reduce obstruction by tightening the soft tissue. One large study looked at the incidence of OSA in patients who were treated with radiation or surgical resection for head and neck cancer. Of 24 patients, 91.7% had significant OSA after treatment: 100% of the radiation group and 78.5% of the surgical resection group.<sup>57</sup> Mandibulectomy precipitates OSA by altering the anatomy of the skeletal structure, whereas flap procedures and rigid reconstruction of the lower jaw help prevent the development of OSA.<sup>58</sup> Laryngectomies have caused OSA at the reconstruction site in the postoperative setting, requiring prolonged treatment.<sup>59</sup> There are case reports of lymphoproliferative diseases leading to OSA, in which the apnea improves as patients receive chemotherapy.<sup>60</sup> The anatomy of the neck is also an important factor. A neck larger than 17 inches in a man or 16 inches in a woman is associated with OSA. More common in the head and neck cancer group is cervical kyphosis, which shortens the thyromental distance.

If sleep-disordered breathing is a diagnostic possibility in a cancer patient, then a full NPSG is indicated. Ideally, the test is performed for one full diagnostic night, and if sleep-disordered breathing is diagnosed, a second treatment night is added for titration of positive airway pressure. Alternatively, split-night polysomnography allows 2 to 4 hours for diagnosis and determination of disease severity, followed by titration of positive airway pressure.

Treatment of sleep-disordered breathing depends on its level of severity and usually requires the assistance of a sleep specialist. Control of body weight is key in an era of increasing obesity, even with cancer patients, for whom weight loss may be a distressing but inescapable subject. The avoidance of precipitating factors such as alcohol and sedating medications is also important, especially for the cancer patient, who may be tempted to increase the use of alcohol as a coping mechanism. Further, many pharmacologic agents used in this population adversely affect the upper airway. Benzodiazepines have a mixed reputation for patients with OSA: the older benzodiazepines have muscle-relaxant properties that may

adversely affect the airway, whereas the newer nonbenzodiazepine hypnotics, such as zolpidem and zaleplon, do not have myorelaxant or respiratory depressant effects. Narcotics, on the other hand, have powerful respiratory depressant effects. It has been shown that a single dose of morphine 10 mg to a normal person can suppress the hypoxic and hypercapnic respiratory drives by 60% and increase arterial carbon dioxide partial pressure ( $P_{CO_2}$ ).<sup>61</sup> It may be difficult to avoid using these agents in a patient with cancer. Once the patient is adequately treated with positive airway pressure, however, these medications could be used with caution.

Continuous positive airway pressure (CPAP) given for OSA is delivered either by a nasal or an oral route to create a pneumatic splint for the airway.<sup>62</sup> If prescribed and used with close follow-up, CPAP can treat OSA with minimal side effects. It can be adjusted over time to suit a patient's changing needs and stopped at any time without untoward effect. Over the last decade, the equipment has improved exponentially. The units are small, quiet, portable, and adjustable to different altitudes. The masks are available in a number of types and styles, which is especially helpful for the head and neck cancer patient, whose anatomy may make using the older types of CPAP masks difficult. There are masks that deliver pressure either nasally or orally and heated humidifiers to help with nasal congestion. Some units can autotitrate so that the pressure will automatically adjust to the level needed by the patient. Patients who have difficulty adjusting to the amount of pressure needed to maintain an open airway can use either ramp CPAP, in which the pressure starts low and increases to therapeutic levels, or bilevel CPAP, in which the pressure at exhalation is lower than the pressure at inhalation.

For patients who have tumors causing the obstruction, CPAP is an effective means of treatment.<sup>63</sup> CPAP can be used by head and neck cancer patients who are awaiting surgery or who experience OSA as a result of their therapy. After resection of an obstructing tumor, polysomnography should be repeated to ensure that sleep-disordered breathing issues have been resolved.

#### Central Sleep Apnea

CSA is a condition in which there are repeated events of apnea with no ventilatory effort.<sup>64</sup> Diagnosis is also made with full NPSG. Patients with severe OSA may also have mixed apneic events with features of both CSA and OSA. The control of ventilation is a combination of metabolic and behavioral factors during wakefulness; during sleep, the control is predominantly metabolic. Ventilation is linked to input from chemoreceptors in the carotid body for hypoxemia, medullary chemoreceptors for hypercapnia, vagal intrapulmonary receptors, and brainstem

mechanisms to process the information.<sup>65</sup> For cancer patients, this means that any process or tumor that affects these areas in the brainstem can cause CSA.

Diseases that have autonomic instability, such as Shy-Drager syndrome and diabetes mellitus, or diseases that directly affect the medullary centers, such as stroke and encephalitis, also cause CSA.<sup>66,67</sup> Cheyne-Stokes respiration, a variant of central sleep apnea, is associated with stroke and congestive heart failure and carries a high mortality. Since the typical cancer patient is older than the average primary care practice patient, these disease processes are also more common in the cancer patient.

The manner in which CSA presents depends on its type. Patients with hypercapnia present with daytime somnolence, snoring, polycythemia, cor pulmonale, peripheral edema, and respiratory failure. Those with nonhypercapnia usually present with insomnia, awakenings associated with choking, and witnessed apneas and have a normal body habitus.<sup>68</sup> Patients with Cheyne-Stokes respiration can present with any of the above complaints.

Treatment of CSA also depends on its type. Patients with nonhypercapnic CSA have several treatment options. Sometimes their CSA resolves spontaneously, whereas at other times it improves with aggressive management of the underlying problem. If this is not the case, then medication can be tried. A small series of six patients showed improvement in hypersomnolence with acetazolamide, which causes a metabolic acidosis that shifts the  $P_{CO_2}$  lower threshold.<sup>69</sup> Other medications, such as medroxyprogesterone, theophylline, naloxone, and clomipramine, have been tried, but their success has not been well documented. Positive airway pressure is the mainstay of therapy for hypercapnic and nonhypercapnic CSA and has a well-documented therapeutic effect. For Cheyne-Stokes respiration, both CPAP and bilevel positive pressure ventilation have been shown to improve symptoms. If Cheyne-Stokes respiration in a congestive heart failure patient is treated, there is an 80% decrease in 2-year mortality.<sup>70</sup>

#### Asthma and Chronic Obstructive Pulmonary Disease

The circadian variation in airway caliber is exaggerated for those with asthma,<sup>71</sup> most of whom have their lowest peak flows between 10:00 pm and 8:00 am. The largest amount of REM sleep is obtained in the latter third of the rest period, and some data suggest that peak flows are lowest when subjects are awakened from REM sleep.<sup>72</sup> In addition to their cancer treatment, patients with asthma may also be receiving medication that decreases respiratory drive, worsens gastroesophageal reflux, or even causes bronchospasm.

Patients with chronic obstructive pulmonary disease have several pathophysiologic factors that are exaggerated during sleep. REM sleep is particularly vulnerable to oxygen desaturation, hypoventilation, and ventilation-perfusion mismatch. Hypoventilation is the main reason for severe oxygen desaturation in REM sleep. A subset of patients with chronic obstructive pulmonary disease also have OSA. This population is much more likely to have pulmonary hypertension, right-sided heart failure, and hypercapnea.<sup>73</sup>

Cancer therapy may exacerbate an underlying pulmonary condition. Amphotericin, an antifungal commonly used in the oncologic setting, can cause bronchospasm. Certain chemotherapy agents also are associated with bronchospasm (Table 4). When patients are receiving these medications, the physicians caring for them during the night should be prepared for the possibility of bronchoconstriction.

#### Movement Disorders

RLS is a persistent, uncomfortable feeling in the legs that is most noticeable when lying down to sleep at night. Patients with RLS describe a constant need to move the legs because of a "creeping and crawling" or "pins and needles" sensation that is aggravated by rest and relieved with limb movement. Although RLS typically presents with sleep-onset insomnia, it may also present with daytime somnolence since 80% of those with RLS also have PLMD, in which involuntary leg cramps or jerking movements during sleep cause frequent awakening and nonrestorative sleep. RLS is a diagnosis made by history.

The rhythmic jerking movements of PLMD occur every 20 to 40 seconds and last 0.5 to

**Table 4** Oncologic Treatments Associated with Bronchospasm

5 seconds each. The jerking includes extension of the great toe, dorsiflexion of the ankle, and flexion of the knee and hip. It occurs more frequently in the first third of the sleep period but may last throughout the night. Seventeen percent of patients complaining of sleep maintenance insomnia and 11% of those complaining of daytime somnolence are afflicted with PLMD.<sup>74</sup> The frequency increases with age. Although no formal studies have evaluated the frequency of PLMD in cancer patients, one study documented an increased incidence of periodic limb movement in breast cancer patients complaining of insomnia.<sup>8</sup> Since the conditions associated with PLMD are found more frequently in the cancer population than the general population, however, it stands to reason that PLMD is also found more frequently among cancer patients.

PLMD is thought to be caused by a central dopamine problem. Since iron is required in the synthesis of dopamine, it makes sense that iron deficiency anemia is associated with PLMD. Other conditions associated with this condition include uremia, peripheral neuropathies, and electrolyte abnormalities. Evaluation of a person with suspected PLMD or RLS should include a check of electrolytes, including magnesium, iron, ferritin, vitamin B<sub>12</sub>, and folate. PLMD is diagnosed only by NPSG; two-night NPSG is recommended.

Treatment of both RLS and PLMD focuses first on the underlying cause. Because caffeine, nicotine, fatigue, and extremes of temperatures are exacerbating factors for both RLS and PLMD, patients are first counseled to abstain from caffeine and nicotine. They are advised to do mental alerting activities during the times they normally would have symptoms. There is a circadian rhythm to these disorders in that there are several protected hours from around 5:00 to 9:00 am when patients are usually free of symptoms. If able, the patient can sleep later in the morning to obtain a full night's rest. Certain classes of medications, including serotonin reuptake inhibitors, neuroleptics, antiemetics, and antihistamines, can precipitate RLS and PLMD and may need to be limited.

Medications may be used in the treatment of RLS and PLMD (Table 5), although even these

may have side effects. Augmentation is a side effect of dopaminergic agents in which symptoms worsen and require higher dosing of medications. This side effect is a particular problem for carbidopa/levodopa, which should be reserved for short-term use when there is a particular inciting event, such as a few days of bed rest in the hospital. Clonazepam is safe to use if the patient does not have a history consistent with OSA. If single agents alone are not successful, another class of agent or a combination of those listed can be tried.<sup>75</sup>

### Other Causes of Excessive Daytime Somnolence

Somnolence syndrome, as described in the literature, is associated with hypersomnolence, extreme lethargy, and anorexia. It is seen in patients who have undergone radiation treatment of the brain and occurs as an early delayed reaction, meaning that it appears approximately 4 to 6 weeks after receiving brain irradiation, with a slow recovery.<sup>76</sup>

Some cancer treatment medications have somnolence as a side effect; these include narcotics, gabapentin, and seizure medications used for tumors involving the central nervous system. Specific biochemotherapeutic agents with this side effect are listed in Table 6.

A tumor involving the central nervous system can also cause hypersomnolence. Lesions in the hypothalamus or suprasellar regions can cause hypersomnia or even narcolepsy in some cases.<sup>77</sup> Narcolepsy is a sleep disorder that is characterized by REM sleep abnormalities with a tetrad of symptoms: hypersomnolence, cataplexy, sleep paralysis, and hypnagogic hallucinations. Diagnosing the cause of hypersomnolence requires an NPSG to evaluate for sleep-disordered breathing and PLMD. In some cases, a Multiple Sleep Latency Test is needed to evaluate for narcolepsy.

The first line of attack in treating hypersomnolence is to establish good sleep hygiene and to increase the level of daytime activity. Medications that may be causing this symptom should be limited. Stimulant medications (Table 7) may be prescribed to treat hypersomnolence not

Dextroamphetamine	15–100
Methamphetamine	15–80

caused by sleep-disordered breathing or PLMD. The advantage of modafinil is that it is a centrally acting agent and lacks the peripheral side effects of the other stimulants. It also does not require triplicate prescriptions. There is a case report of improvement with donepezil for opioid-induced hypersomnolence.<sup>78</sup>

### Chronobiology

The “circadian clock” that mediates sleep also plays a role in mediating hormones that influence the growth of cancer cells. For example, melatonin, which is released at the onset of darkness and triggers a temperature drop to signal sleep onset, is thought to have a mitigating effect on cancer cells. It has been found to reverse the tumorigenesis by carcinogens, to have antimetabolic activity, and to modulate receptors in breast cancer cells. The addition of large doses of melatonin to chemotherapy or radiation therapy has improved survival.<sup>79</sup>

Conversely, the risk of developing cancer has also been linked to the circadian rhythm of hormone levels. Suppression of melatonin in those doing graveyard shift work has been associated with an increased risk of breast cancer,<sup>80</sup> although this is still under investigation. Also, the circadian rhythm of cortisol has also been used to predict survival in breast cancer patients as those with a flattened diurnal cortisol rhythm were found to have a higher mortality.<sup>81</sup> A higher amplitude in the cortisol diurnal rhythm is also associated with fewer sleep disturbances and improved quality of life.<sup>82</sup>

**Table 5** Medications for the Treatment of Restless Legs Syndrome and Periodic Limb Movement Disorder

Medication	Dosing
Pramipexole	0.125–2 mg, 2 h before bedtime
Ropinirole	0.25–2 mg, 2 h before bedtime
Carbidopa/levodopa	25/100, at bedtime
Clonazepam	0.5–2 mg at bedtime
Propoxyphene napsylate	100–200 mg
Tramadone	50–100 mg
Gabapentin	100–1,800 mg daily

**Table 8 Circadian Timing of Chemotherapeutic Agents to Maximize Antitumor Effect and Minimize Side Effects**

Agent	Administration	Circadian-Dependent Toxicities
Doxorubicin and etoposide	Midsleep	Marrow suppression, intestinal toxicity
Cisplatin and oxaliplatin	Late evening	Nephrotoxicity, marrow suppression, intestinal toxicity
5-FU and FUDR	Late evening	Leukopenia, intestinal toxicity
6-MP	Evening	Marrow suppression, intestinal toxicity
Methotrexate	evening	Marrow suppression, intestinal toxicity
Interferon	Evening	Flu-like symptoms, marrow suppression, renal and hepatic toxicity, somnolence

5-FU = 5-fluorouracil; FUDR = 5-fluorouracil deoxyribonucleoside; 6-MP = 6-mercaptopurine.

## Chronotherapy

The idea of choosing a time within the circadian cycle that will maximize therapeutic effect and minimize side effects is called chronotherapy. There are circadian variations in tumor blood flow, corticosterone levels, tumor surface temperature, cell division, tumor markers, and enzyme levels.<sup>83</sup> There is also circadian variation in hepatic blood flow, enzymatic degradation, and elimination of drug products.<sup>84</sup> Because there appears to be a circadian rhythm in how tumors behave, it makes sense to tailor treatment to that rhythm. Table 8 summarizes the circadian timing of a few chemotherapeutic agents to maximize the antitumor effect and minimize side effects.<sup>84,85</sup>

## Summary

Sleep medicine is a relatively new area of study in the field of oncology. Patients come with undiagnosed preexisting sleep disorders and develop sleep disturbances during cancer therapy. Cancer survivors also are at an increased risk of developing sleep disorders. Through the study of cancer-related sleep disturbances, we have an opportunity to improve patient outcomes and decrease the burden of symptoms. In the next few years, basic science and clinical research should bring new ways of managing our cancer patients who have sleep complaints.

# Nausea

John T. Patlan, MD

Nausea and vomiting, which are very common problems in cancer patients, may be due to the cancer itself or, quite often, the side effects of chemotherapy or radiotherapy. Nausea can be extremely debilitating and distressing and can significantly interfere with patients' quality of life. Patients rank nausea and vomiting among the most disturbing side effects of cancer therapy. Approximately 75% of cancer patients who receive chemotherapy experience treatment-induced nausea and vomiting; of these, 46% have thought about stopping their treatment.<sup>1</sup> Up to 50% of people with cancer may actually refuse or delay chemotherapy because they are afraid of the nausea and vomiting it may cause.<sup>2</sup> Even in the era of effective and well-tolerated antiemetics, patients still rank nausea and vomiting among the most significant adverse effects of cancer treatment.<sup>3,4</sup>

## Clinical Manifestations

Nausea is difficult for some patients to describe, but clinicians define it as the unpleasant subjective sensation of being about to vomit or feeling a need to vomit. Nausea can occur alone or with vomiting (emesis), the forceful oral expulsion of gastric contents resulting from contractions of the gut and abdominal wall musculature, or with retching, the same forceful contractions without expulsion of upper gastrointestinal contents. It should be distinguished from regurgitation, the effortless passage of gastric or esophageal contents to the hypopharynx, which may be accompanied by rumination, or rechewing and reswallowing of these contents.<sup>5</sup>

Nausea often lasts longer than vomiting and may therefore be more distressing to patients and contribute to the cachexia seen in many cancer patients. In addition, vomiting or retching may exacerbate cancer-related headache or pain in the abdomen or back.

Protracted nausea and vomiting may also produce a number of complications, most often metabolic disturbances such as hypovolemia, hyponatremia, hypokalemia, hypochloremic metabolic alkalosis, and, importantly, malnutrition and failure to thrive owing to decreased caloric intake. Occasionally, forceful vomiting

may cause gastrointestinal bleeding owing to esophageal Mallory-Weiss tears or esophageal rupture (Boerhaave's syndrome).

In addition, protracted nausea and vomiting and the subsequent malnutrition and electrolyte disturbances can lead to a decline in functional status, diminished cognitive ability, poor wound healing or dehiscence, and, as previously mentioned, withdrawal from potentially curative cancer therapy.

## Pathophysiology

### Nausea

The mechanisms of nausea are not well understood, but because it is a conscious perception and because some patients develop anticipatory nausea before chemotherapy, the development of nausea likely requires cerebral cortical mediation. Studies of induced motion sickness in humans have shown that the perception of nausea followed and was proportional to abnormal gastric myoelectric activity.<sup>6</sup>

### Vomiting

The coordinated and stereotypic actions of vomiting are better understood. Pioneering studies by Borison and Wang in the 1950s identified two areas in the brainstem that control the emetic reflex.<sup>7</sup>

#### Emetic Center

Originally conceived as a single locus in the medullary reticular formation, the "vomiting center" is now recognized to consist of multiple parts. Several anatomically separate receptor and effector brainstem nuclei, most in the nucleus tractus solitarius, receive afferent input from a variety of sources and coordinate the efferent pathways associated with the act of vomiting (including the contraction of thoracic and abdominal wall muscles to produce high intrathoracic and intra-abdominal pressures to propel the expulsion of gastric contents, the herniation of the gastric cardia across the diaphragm, and the upward movement of the larynx to promote oral propulsion of the vomitus). The emetic center is the final common pathway by which a variety of afferent stimuli can initiate vomiting.<sup>8,9</sup>

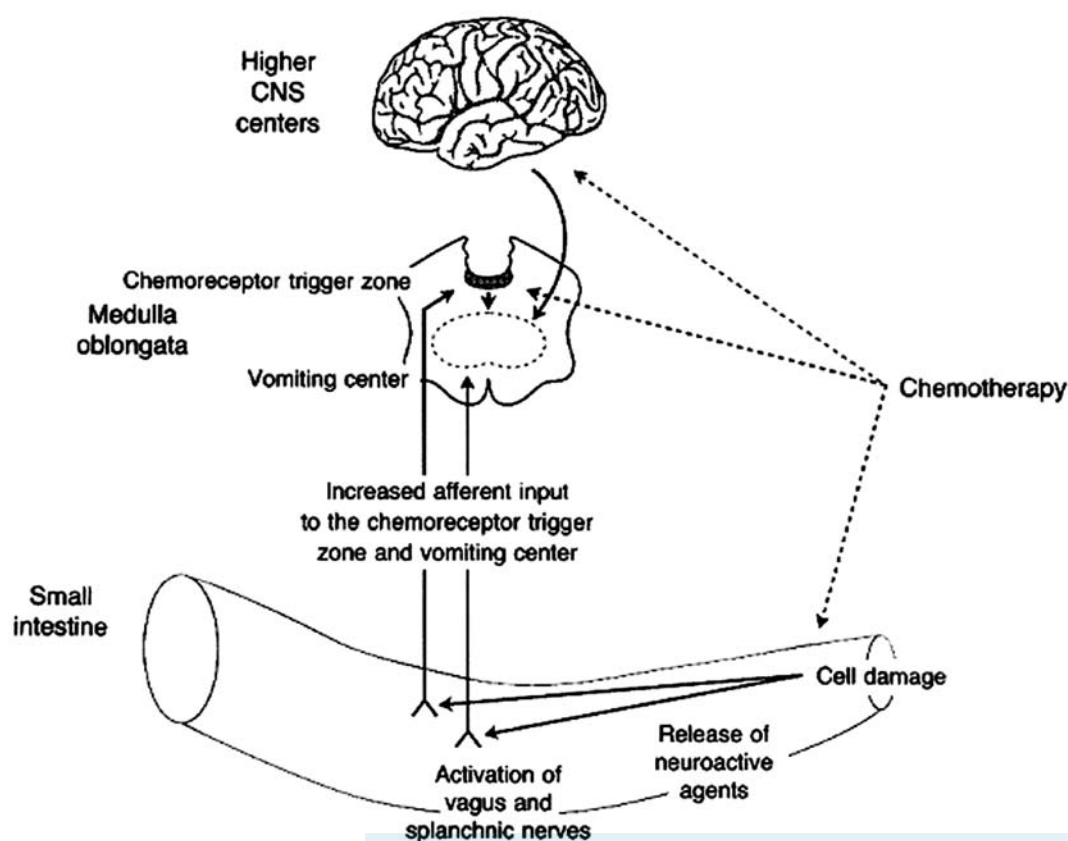

#### Chemoreceptor Trigger Zone

Located in the area postrema on the floor of the fourth ventricle, outside the blood-brain barrier, the chemoreceptor trigger zone (CTZ) is responsive to various chemical stimuli from the bloodstream and the cerebrospinal fluid. A number of metabolic derangements (such as uremia and diabetic ketoacidosis) and drugs (such as opiates, digitalis, and syrup of ipecac) stimulate the CTZ to cause vomiting. The CTZ is a major source of afferent input to the emetic center and an important site for a number of neurotransmitter receptors, as discussed below, which have provided targets for the development of antiemetic agents.<sup>10</sup>

Other sources of afferent input to the emetic center include higher brainstem and cortical structures. Input from the hypopharynx and the gastrointestinal tract is conveyed by the vagus and splanchnic nerves. Figure 1 shows the pathways by which chemotherapeutic drugs or other emetogenic stimuli may induce emesis.

A number of neurotransmitter receptors are found in the CTZ, the emetic center, and the gastrointestinal tract, and these receptors may play a role in stimulating vomiting. The three most clinically relevant neurotransmitters and their receptors are dopamine (D<sub>2</sub> receptors), serotonin or 5-hydroxytryptamine (5-HT<sub>3</sub> receptors), and substance P or neurokinin 1 (NK<sub>1</sub> receptors).

Medications designed to antagonize these neurotransmitters have been the major focus of the development of antiemetics, first with the development of antidopaminergic medications in the 1960s.<sup>11</sup> The relatively low efficacy and unfavorable side-effect profile (hypotension and extrapyramidal syndromes) of the antidopaminergic phenothiazines led to the search for other antiemetics. The development of high-dose metoclopramide improved the efficacy of nausea control but raised some questions. Since metoclopramide binds with high affinity to dopamine receptors, it appeared that low doses would saturate the available receptors. A new mechanism of action was postulated when it was discovered that metoclopramide blocks 5-HT<sub>3</sub> receptors, but with less affinity than D<sub>2</sub> receptors. This discovery led to the development of highly selective 5-HT<sub>3</sub> antagonists in the 1980s and 1990s.<sup>12</sup> Because of

**FIGURE 1** Chemotherapeutic agents may induce vomiting through cytotoxic effects in the gastrointestinal tract and stimulating vagal and splanchnic afferents, through direct effects on the chemoreceptor trigger zone, or through higher cortical responses (conditioned responses such as anticipatory nausea). Reproduced with permission from Grunberg SM, Hesketh PJ. Drug therapy: control of chemotherapy-induced emesis. *N Engl J Med* 1993;329:1790. CNS = central nervous system.

their efficacy and favorable side-effect profile, 5-HT<sub>3</sub> receptor antagonists have become the mainstay of antiemetic therapy for cancer patients. It was hypothesized that chemotherapy-induced emesis is mediated by serotonin itself and that chemotherapy may stimulate the liberation of endogenous serotonin from the small bowel, which might directly stimulate central nervous system 5-HT<sub>3</sub> receptors or act through vagal mediation to cause emesis. But the fact that 5-HT<sub>3</sub> antagonists at high doses cannot completely block emesis and the fact that nausea and vomiting are not prominent symptoms in carcinoid syndrome, where serotonin levels (as measured by 5-hydroxyindoleacetic acid excretion) are very high, led to the search for greater understanding of the neuropharmacology of emesis.<sup>13</sup> More recently, antagonists of substance P, which exerts its emetogenic effect by binding to the NK<sub>1</sub> receptor, have been shown to be potent antiemetics.<sup>14</sup> Other neuroreceptors in the central nervous system or vestibular system that may stimulate vomiting include the muscarinic acetylcholine receptors and receptors to corticosteroids, histamine, cannabinoids, and opiates.<sup>15</sup> Of these receptors, M<sub>1</sub> muscarinic antagonists (such as

scopolamine) and H<sub>1</sub> antihistamines (such as diphenhydramine or meclizine) are most useful in treating or preventing motion sickness but have limited utility in the treatment of cancer-related nausea and vomiting.

## Etiology

### Gastrointestinal Disorders

Cancer patients may experience nausea and vomiting owing to the same causes as any other patient would, and it should never be assumed that these symptoms are due to the cancer or its treatment. Gastroenteritis, biliary colic or acute cholecystitis, acute or chronic pancreatitis, and acute hepatitis are among the primary gastrointestinal disorders that may cause nausea and vomiting. In addition, patients may experience gastroparesis that is tumor induced or is secondary to medications (such as opiates) or some chemotherapeutic agents (such as vincristine).

### Metabolic Causes

The metabolic causes of nausea and vomiting, which may merit special concern in cancer patients, include adrenal insufficiency owing to

metastatic involvement of the adrenal glands or to the use of corticosteroids in chemotherapeutic regimens. Uremia due to bilateral ureteral obstruction in pelvic tumors or to nephrotoxic agents may also occur. Hypercalcemia owing to osseous metastases or as a paraneoplastic syndrome is quite common and should be considered.

## Medications

The side effects of nonchemotherapeutic medications may induce nausea and vomiting. Many antibiotics, digoxin, and oral contraceptives are associated with nausea. Because many cancer patients require regular use of narcotic analgesics for control of cancer-related pain, this class of medications deserves special mention. Any narcotic medication may induce nausea and should be suspected if the onset of symptoms coincides with the start of a new narcotic regimen. In addition, because narcotics slow gastrointestinal motility, they may cause constipation, adynamic ileus, or even colonic pseudo-obstruction.

## Tumor Effects

The direct effects of tumors include nausea and vomiting. These symptoms may be a prominent feature of primary gastrointestinal cancers, such as esophageal, gastric, or colorectal malignancies. These symptoms can also occur by direct tumor extension or because of abdominal or peritoneal metastases of nongastrointestinal cancers. Nausea and vomiting can be due to mass effect and may be the presenting symptom of partial or complete bowel obstruction. In patients for whom metastatic disease is highly suspicious, brain metastases should always be considered, particularly if no other apparent gastrointestinal, metabolic, or medication-related cause is present.

## Treatment-Related Causes

### Radiotherapy

Nausea and vomiting after radiotherapy are fairly common but are less well understood than chemotherapy-induced emesis. Radiotherapy-induced emesis seems to be multifactorial and is related to the site treated, the size of the radiation field and dose delivered, overall patient metabolic status, concomitant use of chemotherapy (such as cisplatin in many head and neck malignancies), and other factors.

The cumulative incidence of radiotherapy-induced nausea and vomiting is about 33%.<sup>16</sup> The highest risk appears to be for patients who receive total-body, half-body, or abdominal radiotherapy. In patients who receive conventional fractionated radiotherapy (200 cGy per fraction) to the upper abdomen, half will experience radiation-induced nausea and vomiting within 2 to 3 weeks. It occurs more quickly and

in more than 90% of patients who receive total-body irradiation before bone marrow transplantation.<sup>17</sup>

### Chemotherapy

Chemotherapy-induced emesis is much better studied. Three distinct phases or patterns of chemotherapy-induced emesis have been identified:

1. Acute-onset emesis most commonly begins within 1 to 2 hours, peaks in the first 4 to 6 hours, and resolves within the first 24 hours. Exceptions to this temporal pattern include carboplatin and cyclophosphamide, which tend to cause later onset of nausea and vomiting in patients not given antiemetics, as late as 9 to 18 hours after chemotherapy. Acute emesis is the best studied and understood of the three emetic syndromes.
2. Delayed-onset emesis is somewhat arbitrarily defined as nausea and vomiting that occur more than 24 hours after chemotherapy. It was first recognized as a problem after effective antiemetics for acute emesis were developed but nausea and vomiting persisted for several days in some patients. This syndrome commonly develops after high-dose cisplatin but can also occur with carboplatin, cyclophosphamide, or doxorubicin.<sup>18</sup> Delayed emesis after cisplatin generally reaches maximal severity at 48 to 72 hours and then gradually subsides, and it can last 5 to 6 days. It is generally less severe than acute emesis and is not considered just a deferral of symptom onset.<sup>19</sup> Different patterns of vomiting beyond the initial period have been observed. In one study of patients treated with cisplatin who received metoclopramide, ondansetron, or placebo, there were two peak incidences of emesis, at 4 hours and 18 hours, with little vomiting between them, suggesting a bimodal incidence of vomiting.<sup>18</sup> In a later study of patients treated with high-dose cisplatin who received dexamethasone and serotonin antagonist antiemetics, there was a uniform distribution of vomiting during the study period.<sup>20</sup> Some authors have suggested reserving the term *delayed emesis* for the biphasic pattern of emesis after cisplatin therapy and using the term *prolonged emesis* for the late nausea and vomiting that occur after noncisplatin chemotherapy.<sup>21</sup>
3. Anticipatory emesis is defined as nausea or vomiting that begins before the administration of chemotherapy. It is believed to be a learned or conditioned response in patients who have had poor nausea control and acute or delayed emesis during previous chemotherapy. It has even been described in patients who have not yet received chemotherapy but

who have a high expectation of experiencing nausea.<sup>22</sup> Anticipatory nausea is more common than vomiting, but either or both symptoms may develop in up to 25% of patients by their fourth treatment cycle and can be induced by a variety of sensory cues associated with receiving treatment or even cognitive anticipation.<sup>23</sup> With the development of more effective antiemetics, the incidence of anticipatory emesis appears to be declining.<sup>23</sup>

In the current era of modern antiemetics, two other syndromes deserve mention:

- Breakthrough emesis is defined as nausea and vomiting that occur despite the use of prophylactic treatment. Breakthrough emesis requires “rescue” medications.
- Refractory emesis refers to nausea and vomiting that occur during later courses of treatment when antiemetic prophylaxis or rescue has failed in earlier cycles.<sup>24</sup>

## Predictive Factors

### Patient-Related Factors

Some patient-related factors associated with increased risk of chemotherapy-induced nausea and vomiting are female gender, younger age, and a history of chemotherapy. A history of chronic heavy alcohol consumption seems to confer a lower risk of treatment-induced nausea.<sup>25</sup> This history may include a previous rather than a current history of high alcohol use, but a history of high alcohol use (eg, more than 100 g of alcohol or five mixed drinks per day for several years) seems to confer a lower risk of chemotherapy-induced emesis. Preexisting nausea and a low functional status or high fatigue score also seem to be correlated with a higher risk of nausea and vomiting.<sup>26</sup> If patients experienced nausea with previous chemotherapy, they are at higher risk of chemotherapy-induced emesis than treatment-naïve patients are. Conversely, among patients who received prior chemotherapy but did not experience nausea or vomiting, the majority will remain free of chemotherapy-induced emesis during later treatments.<sup>27</sup> Anticipatory emesis occurs in patients who have had poorly controlled acute or delayed emesis and may be more likely to develop in patients who have a history of motion sickness.<sup>28</sup>

### Acute Emesis

A number of treatment-related factors have been associated with the development of acute emesis, including chemotherapy dosage and the route and rate of administration.<sup>29</sup> But the most important factor by far is the intrinsic emetogenic potential of the specific chemotherapeutic agent. Several classification schemes have been

developed in an effort to devise specific guidelines for antiemetic therapy based on the expected risk of emesis, but none of the early classification systems had enough clinical utility to gain universal acceptance. In 1997, Hesketh and colleagues developed a classification of the acute emetogenicity of specific chemotherapeutic agents.<sup>30</sup> The classification was based on clinical trials, review articles, and consensus expert opinion. In that scheme, the chemotherapy rate and route of administration were standardized. It attempted to stratify the intrinsic emetogenicity of chemotherapeutic drugs into five levels of risk based on the percentage of patients who developed acute emesis after receiving the chemotherapeutic agent and no antiemetic prophylaxis. Level 5 (highest risk) drugs caused emesis in more than 90% of patients, level 4 drugs in 60 to 90%, level 3 drugs in 30 to 60%, level 2 drugs in 10 to 30%, and level 1 (lowest risk) drugs in less than 10% of patients.

Several difficulties with the original Hesketh schema existed. Because of the relative lack of objective data, the classification relied heavily on the expert opinion of the authors. In addition, the scheme focused on acute emesis. Research studies tend to divide emesis into acute and delayed phases, but in clinical practice and from the patient’s perspective, nausea and vomiting tend to occur on a continuum for several days after chemotherapy. Finally, with the growing use of oral cytotoxic agents for a period of days or weeks, the concept of acute versus delayed emesis loses some clinical relevance.

Consequently, in an effort to simplify the classification scheme and make it more straightforward and easier to use by practitioners in the everyday clinical setting, a new scheme was devised. It encompasses both the acute and the delayed risk of emesis owing to chemotherapy and the emetogenic potential of single oral chemotherapeutic agents (Table 1).

There is also a system with which to assess the emetic risk of combination chemotherapy. Hesketh and colleagues proposed an algorithm for assessing the relative contribution of combination therapy (Table 2).<sup>30</sup>

### Delayed Emesis

The phenomenon of delayed emesis is less well studied and less well understood than acute emesis for several reasons: it is generally less severe than acute emesis, and it tends to occur when patients have left the clinic and are no longer being observed by their treating oncologist. Even experienced oncologists and oncology nurses tend to underestimate the incidence of delayed nausea after patients have left the hospital or clinic and are no longer directly observable.<sup>4</sup> Because cisplatin is so highly emetogenic and the risk of delayed emesis is highest with this drug than any other, most studies on delayed emesis

Table 1

High-risk drugs (level 5: > 90% frequency of emesis)

Carmustine (> 250 mg/m<sup>2</sup>)  
 Cisplatin (> 50 mg/m<sup>2</sup>)  
 Cyclophosphamide (> 1,500 mg/m<sup>2</sup>)  
 Dacarbazine  
 Dactinomycin  
 Lomustine (> 60 mg/m<sup>2</sup>)  
 Mechlorethamine  
 Streptozocin

Moderate-risk drugs (levels 3–4: 30–90% frequency of emesis)

Amifostine (> 500 mg/m<sup>2</sup>)  
 Arsenic trioxide  
 Busulfan (> 4 mg/d)  
 Carboplatin  
 Carmustine (< 250 mg/m<sup>2</sup>)  
 Cisplatin (< 50 mg/m<sup>2</sup>)  
 Cyclophosphamide (PO or < 1,500 mg/m<sup>2</sup>)  
 Cytarabine (> 1 g/m<sup>2</sup>)  
 Dactinomycin  
 Doxorubicin  
 Epirubicin  
 Hexamethylmelamine (PO)  
 Idarubicin  
 Ifosfamide  
 Interleukin-2 (> 12–15 million U/m<sup>2</sup>)  
 Irinotecan  
 Melphalan (> 50 mg/m<sup>2</sup>)  
 Methotrexate (250–1,000 mg/m<sup>2</sup>)  
 Mitoxantrone (> 12 mg/m<sup>2</sup>)  
 Oxaliplatin (> 7.5 mg/m<sup>2</sup>)  
 Procarbazine (PO)

Low-risk drugs (level 2: 10–30% frequency of emesis)

Amifostine (< 300 mg/m<sup>2</sup>)  
 Asparaginase  
 Bexarotene  
 Capecitabine  
 Cytarabine (100–200 mg/m<sup>2</sup>)  
 Docetaxel  
 Doxorubicin (< 250 mg/m<sup>2</sup>)  
 Etoposide  
 5-Fluorouracil  
 Gemcitabine  
 Methotrexate (50–250 mg/m<sup>2</sup>)  
 Mitomycin  
 Paclitaxel  
 Pemetrexed  
 Temozolomide  
 Thiopeta  
 Topotecan

Minimal-risk drugs (level 1: < 10% frequency of emesis)

Alemtuzumab  
 Bevacizumab  
 Bleomycin  
 Bortezomib  
 Cetuximab  
 Chlorambucil (PO)  
 Cladribine  
 Denileukin diftitox  
 Dexrazoxane

Table 1 (Continued)

Fludarabine  
 Gefitinib  
 Gemtuzumab ozogamicin  
 Hydroxyurea  
 Imatinib mesylate  
 $\alpha$ -Interferon

Melphalan (oral low dose)  
 Methotrexate (< 50 mg/m<sup>2</sup>)  
 Pentostatin  
 Rituximab  
 Thioguanine (PO)  
 Trastuzumab  
 Valrubicin  
 Vinblastine  
 Vincristine  
 Vinorelbine

Table 2 Combination Chemotherapy Algorithm

1. Identify the most emetogenic agent in the combination.
2. Assess the relative contribution of other agents to the emetic potential of the combination. When considering other agents, the following rules apply:
  - a. Level 1 agents do not contribute to the emetogenicity of the regimen.
  - b. Adding one or more level 2 agents increases the emetogenicity of the combination by one level greater than the most emetogenic agent in the combination.
  - c. Adding level 3 or 4 agents increases the emetogenicity of the combination by one level per agent.

Adapted from Hesketh PJ, et al.<sup>32</sup>

have been done with patients treated with cisplatin-containing regimens. Without antiemetic pretreatment, the incidence of delayed emesis owing to cisplatin was between 60 and 90%. In these studies, the most significant risk factor for delayed emesis was a lack of emetic control during the first 24 hours.<sup>31</sup> In patients followed for three cycles of treatment, the rate of delayed vomiting in each cycle was related to the degree of control of acute emesis in the first 24 hours. The dose of cisplatin was also an important prognostic factor: patients who received less than 90 mg/m<sup>2</sup> had a 19 to 22% incidence of emesis, whereas patients who received more than 90 mg/m<sup>2</sup> had an incidence of 43 to 47%.<sup>31</sup>

Patients who receive moderately emetogenic chemotherapy are also at risk of delayed emesis. In a study of patients who received carboplatin,

cyclophosphamide, doxorubicin, or epirubicin but no antiemetic prophylaxis after the first 24 hours, the incidence of delayed nausea and vomiting was 20 to 25%.<sup>32</sup> In these patients, as in cisplatin-treated patients, the most important prognostic factor was receiving effective antiemetic prophylaxis during the first 24 hours. In patients who had ineffective control and experienced acute nausea and vomiting after moderately emetogenic chemotherapy, the rate of delayed nausea and vomiting was 55 to 75%.<sup>32</sup>

### Anticipatory Emesis

As described above, anticipatory emesis is usually a conditioned response in patients who have experienced nausea and vomiting with previous chemotherapy cycles. A number of studies have concluded that classic or Pavlovian conditioning contributes to the development of anticipatory emesis in cancer patients.<sup>33</sup> One of the most important prognostic factors, then, is the development of nausea and vomiting after previous chemotherapy. Other risk factors are age less than 50 years; “moderate, severe, or intolerable” nausea after the last cycle; a side effect of treatment as feeling “warm or hot all over”; susceptibility to motion sickness; diaphoresis with the previous cycle; and “generalized weakness” with the previous cycle.<sup>34</sup>

### Diagnosis

The diagnosis of chemotherapy- or radiotherapy-induced emesis can usually be readily established by the appropriate history of recent treatment and the appropriate temporal relationship to the onset of symptoms. The caveat, of course, is that treatment-related nausea and vomiting are essentially a diagnosis of exclusion. Consideration should always be given to other non-treatment-related causes of nausea, and some screening by history and physical examination is essential to reasonably exclude other, potentially more serious or otherwise treatable conditions that occur with nausea.

Patients with prominent abdominal pain require some investigation for primary intra-abdominal causes of nausea, such as acute pancreatitis or renal or biliary colic. If there is abdominal distention along with pain, evaluation for partial or complete bowel obstruction is required.

Vomiting in a febrile patient may be a nonspecific symptom related to sepsis or, if it is accompanied by abdominal tenderness or signs of peritoneal irritation, suggests serious abdominal pathology (such as bowel perforation or acute appendicitis). Thorough evaluation, including surgical consultation, would be indicated.

Vomiting that is persistent but not in the time period expected in relation to chemotherapy

or radiotherapy suggests some other cause, perhaps electrolyte disturbance (such as hypercalcemia) or cerebral metastases. A higher clinical suspicion for a central nervous system cause of nausea should exist, especially if there is headache, any neurologic signs or symptoms, or projectile or positional vomiting.

In addition to a history and a physical examination, an evaluation of serum chemistries in a patient with persistent vomiting is generally indicated to look for electrolyte disturbances, either as a cause or an effect of the vomiting. Obtaining plain radiographs, usually an abdominal series, is a good starting point if there is significant abdominal pain or distention to look for bowel obstruction or evidence of perforation.

Computed tomographic scans of the abdomen or brain should be obtained if there is sufficient suspicion of serious abdominal or central nervous system pathology as the cause of vomiting.

## Treatment

### Serotonin (5-HT<sub>3</sub>) Receptor Antagonists

5-HT<sub>3</sub> receptor antagonists are the mainstay of therapy for the prevention and treatment of acute emesis in patients who receive high- or moderate-risk chemotherapy. In the 1980s, such patients were treated with high-dose metoclopramide usually along with steroids, which had between 40 and 60% efficacy in preventing emesis. Specific 5-HT<sub>3</sub> receptor antagonists developed later were more effective as single agents than high-dose metoclopramide and more effective when given with dexamethasone than was the combination of metoclopramide and steroids.<sup>35</sup> In addition to increased efficacy, 5-HT<sub>3</sub> receptor antagonists may be administered orally or intravenously, and they have a much lower incidence of unfavorable side effects. In the United States, currently four serotonin antagonists are approved for use: ondansetron (Zofran), granisetron (Kytril), dolasetron (Anzemet), and the newest member of the class, palonosetron (Aloxi).

Regarding the first three of those serotonin antagonists, a number of comparative trials have been performed. These trials have failed to show any clinically significant differences between them when used at appropriate doses.<sup>36,37</sup> In general, the 5-HT<sub>3</sub> antagonists are equally efficacious and have favorable side-effect profiles. The relatively mild side effects include headache in 15 to 20% of patients, asthenia and constipation in 5 to 10%, and dizziness in 5 to 10%.<sup>38</sup> There may also be mild transient elevation in transaminases or prolongation of cardiac intervals. Importantly, the extrapyramidal symptoms (such as dystonic reactions or akathisia) and limiting side effects of older antiemetics do not occur, even with

multiple doses on subsequent days.

Several clinically important points in the use of these drugs should be noted. First, they have good bioavailability (50–80%) and good oral absorption.<sup>39</sup> Oral administration appears to be as effective as intravenous administration in preventing emesis.<sup>38</sup> Oral administration may be particularly useful because there are so many 5-HT<sub>3</sub> receptors in the enterochromaffin cells in the gastrointestinal tract, which may be involved in stimulating nausea. Second, a single dose given before chemotherapy is as effective as multiple doses in preventing emesis.<sup>40,41</sup> For both oral and intravenous administration of serotonin antagonists, efficacy is increased when they are used with corticosteroids.<sup>42</sup> Finally, for each of the serotonin antagonists, there is a plateau of efficacy at a given dose level, beyond which increased dosing does not yield any clinical benefit, presumably because the relevant receptors are saturated.<sup>39</sup>

Palonosetron is pharmacologically distinct from the other three 5-HT<sub>3</sub> receptor antagonists and may offer some clinical advantages over them. It has an approximately 100-fold higher binding affinity for the 5-HT<sub>3</sub> receptor and a longer half-life (approximately 40 hours). In two studies, it was shown to have greater control of emesis in patients who received moderately emetogenic chemotherapy than did ondansetron or dolasetron when used as single agents.<sup>43</sup> In one study, a single dose of intravenous palonosetron was equivalent to a single dose of dolasetron in preventing acute emesis but was superior to dolasetron in preventing delayed chemotherapy-induced nausea and vomiting, perhaps because of the longer half-life.<sup>44</sup> In these trials, no significant differences in efficacy were found between the 0.25 and 0.75 mg doses of palonosetron. The drug was approved for use in the United States in 2003 with a recommended dose of 0.25 mg intravenously 30 minutes before the start of chemotherapy. Because of the long half-life, lack of additional benefit with a higher dose, and lack of safety or efficacy data with serial administration, repeated dosing within 7 days is not recommended.<sup>45</sup> The standard dosing of the 5-HT<sub>3</sub> antagonists is shown in Table 3.

### Corticosteroids

Corticosteroids have a very high therapeutic index when used as antiemetics for chemotherapy-induced nausea. They have been studied extensively, both as single agents and as part of combination therapy. They are effective and well tolerated; insomnia, mood changes, and disturbance of glucose metabolism are among the most common side effects. The exact mechanism of action of corticosteroids is not completely understood. A variety of corticosteroids have been studied, but comparison trials are lacking. The most extensively studied steroid, dexamethasone,

has the advantage of being available in a number of dose formulations and as a low-cost generic formulation.

A meta-analysis of 32 randomized trials compared dexamethasone with no treatment, placebo, and metoclopramide. Dexamethasone was superior to no therapy and to placebo in preventing both acute and delayed emesis and was at least as good as metoclopramide in preventing acute emesis.<sup>46</sup> For more than 90% of patients receiving mildly or moderately emetogenic chemotherapy (level 2 agents, emetic risk 10–30%), dexamethasone is routinely used as a single-agent emesis prophylaxis.<sup>47</sup>

For patients receiving moderately or highly emetogenic chemotherapy (level 3–5 agents, emesis risk higher than 30%), single-agent corticosteroids do not reliably prevent emesis, but they are extremely useful when combined with 5-HT<sub>3</sub> antagonists. In a study of dexamethasone, granisetron, or both in patients who received moderately emetogenic chemotherapy, the combination therapy offered significantly better protection against emesis than either agent alone.<sup>48</sup> In an attempt to quantify the degree of benefit conferred by the addition of dexamethasone to serotonin antagonists, a meta-analysis looked at 22 randomized trials comparing combination therapy and single-agent 5-HT<sub>3</sub> antagonists or 5-HT<sub>3</sub> antagonist plus placebo and found that the addition of dexamethasone enhanced protection from vomiting by 25%.<sup>46</sup>

To find the optimal dose of dexamethasone in patients receiving highly emetic chemotherapy, a randomized trial was conducted in patients who received cisplatin (more than 50 mg/m<sup>2</sup>). Single dexamethasone doses of 4, 8, 12, and 20 mg were studied, and all patients received standard dosing of ondansetron. The 20 mg dose provided the best protection against both nausea and vomiting, although the differences between the 12 and 20 mg doses were not statistically significant. No increase in adverse effects was seen at the 20 mg dose compared with the lower doses.

The results of other trials seem to indicate that single corticosteroid dosing is as effective as multiple dosing and that administration of corticosteroids immediately before chemotherapy is as effective as giving it the day before chemotherapy.<sup>49</sup> Consequently, a dose of 12 to 20 mg intravenously before highly emetogenic chemotherapy is generally recommended.

To compare single intravenous doses of 8 and 24 mg of dexamethasone before chemotherapy and a dexamethasone regimen of 8 mg intravenously before chemotherapy followed by 4 mg orally every 6 hours, a study was conducted using patients who received moderately or highly emetogenic chemotherapy (but no cisplatin) and a standard dosing of ondansetron.<sup>50</sup> No significant differences were found between the groups.

Table 3 Recommended Doses of Antiemetic Drugs

Drug	Dose range	Schedule	
		Acute emesis	Delayed emesis
<b>5-HT<sub>3</sub> receptor antagonists</b>			
Ondansetron IV	8 mg or 0.15 mg/kg IV	Once, prechemotherapy	
Ondansetron PO	16–24 mg for acute emesis, 8 mg in delayed emesis	Once, prechemotherapy	BID x 2–3 days
Granisetron IV	1 mg or 0.010 mg/kg IV	Once, prechemotherapy	
Granisetron PO	2 mg PO	Once, prechemotherapy	
Dolasetron IV	100 mg or 1.8 mg/kg IV	Once, prechemotherapy	
Dolasetron PO	100 mg PO	Once, prechemotherapy	
Palonosetron	0.25 mg IV	Once, prechemotherapy	
<b>Corticosteroids</b>			
Dexamethasone IV	8 to 20 mg IV	Once, prechemotherapy	
Dexamethasone PO	Oral doses not well studied for acute emesis. For delayed emesis 4–8 mg PO		8 mg PO daily starting 24 hours after the start of chemotherapy for 4 days (cisplatin); 8 mg PO bid for 2 days (non-cisplatin)
<b>Neurokinin 1 antagonists</b>			
Aprepitant	125 mg PO prechemotherapy 80 mg PO postchemotherapy	125 mg once, prechemotherapy	80 mg PO daily for two days starting 24 hours after the start of chemotherapy
<b>Dopaminergic antagonists</b>			
Metoclopramide IV	2–3 mg/kg IV	Prechemotherapy and 2 hours post chemotherapy	
Metoclopramide PO	20 mg or 0.5 mg/kg PO in delayed emesis		QID starting 24 hours after the start of chemotherapy for 3–4 days
Prochlorperazine IV	10 mg IV	Q 3–4 hours PRN	
Prochlorperazine PO	10 mg PO	Q 3–4 hours PRN	

As effective as the combination of serotonin antagonists and corticosteroids is, many patients who receive highly emetogenic chemotherapy will still experience nausea and vomiting. In a study of patients who received cisplatin (more than 100 mg/m<sup>2</sup>), the combination of ondansetron and dexamethasone failed to prevent emesis in 39% of patients.<sup>51</sup>

### NK<sub>1</sub> Receptor Antagonists

As described previously, agents that block the binding of substance P at NK<sub>1</sub> receptors in the central nervous system are potent antiemetics and seem to provide a complementary mechanism of action to the blockade of 5-HT<sub>3</sub> or other emetogenic neuroreceptors. In 2003, the NK<sub>1</sub> receptor antagonist aprepitant (Emend) was approved for use in the United States by the Food and Drug Administration (FDA).

The use of aprepitant is best studied in the setting where best standard therapy fails a significant proportion of patients (such as patients who receive highly emetogenic chemotherapy, including cisplatin). Phase III trials have compared standard therapy with ondansetron and

dexamethasone plus placebo versus standard therapy plus aprepitant in patients who received cisplatin-containing chemotherapy (>70 mg/m<sup>2</sup>). Aprepitant was given as 125 mg orally on day 1 and 80 mg orally on days 2 and 3. Compared with ondansetron and dexamethasone alone, aprepitant significantly reduced the incidence of both acute and delayed emesis.<sup>52</sup> Another study looked at the use of granisetron plus dexamethasone versus aprepitant plus dexamethasone versus the combination of all three agents in patients who received cisplatin-containing chemotherapy; the triple combination provided the best protection against both acute and delayed emesis.<sup>53</sup>

A recent study showed that the addition of aprepitant to standard antiemetic therapy in patients who received moderately emetogenic (non-cisplatin containing) chemotherapy enhanced the control of acute and delayed emesis. In this trial, breast cancer patients who received cyclophosphamide plus doxorubicin or epirubicin were treated with ondansetron and dexamethasone with or without aprepitant. A significantly higher percentage of patients in the aprepitant group achieved a complete response

with no vomiting or use of rescue medications during both the acute and delayed phases.<sup>54</sup>

### Dopamine (D<sub>2</sub>) Receptor Antagonists

The oldest of the antiemetic classes and still widely used, there are three chemical subgroups of antidopaminergics that may be used in cancer patients.

#### Phenothiazines

Phenothiazines act primarily at D<sub>2</sub> receptors in the CTZ. The main drugs in current use are prochlorperazine (Compazine) and chlorpromazine (Thorazine). Prochlorperazine can be given orally, intravenously, or intramuscularly; is believed to be less effective than metoclopramide or dexamethasone; and is approximately equivalent in antiemetic efficacy to tetrahydrocannabinol (THC). It is useful in mildly and moderately emetogenic chemotherapy but not in highly emetic treatment.<sup>55</sup> Chlorpromazine is used less often as an antiemetic and is more often given for intractable hiccups. This agent is limited by the side effect of hypotension, which is more common in the elderly or when administered intravenously. Other side effects of chlorpromazine are the same as those of all of the dopamine receptor antagonists, namely extrapyramidal reactions such as dystonia or akathisia, which may be treated with anticholinergics such as benztropine (Cogentin) or diphenhydramine (Benadryl).

#### Butyrophenones

The butyrophenone neuroleptics droperidol (Inapsine) and haloperidol (Haldol) have some antiemetic effect, and no substantial difference in efficacy between the two has been documented. The half-life of haloperidol is 14 to 36 hours after a single dose, which can limit its use as an antiemetic because of prolonged side effects; the half-life of droperidol is shorter. These drugs, often called major tranquilizers, are quite sedating and have the same extrapyramidal side effects as other agents in this class, including the development of tardive dyskinesia if used chronically.<sup>11</sup>

#### Benzamides

As mentioned earlier, the benzamide metoclopramide (Reglan) causes central and peripheral antagonism of D<sub>2</sub> receptors at low doses and weaker 5-HT<sub>3</sub> antagonism at higher doses. It is a moderately effective antiemetic and has the effect of promoting gastric emptying and improving gastroparesis by stimulating the cholinergic receptors on gastric smooth muscle.<sup>56</sup> These effects make metoclopramide useful in alleviating the nausea and gastroparesis that often occur in cancer patients who require chronic narcotic analgesics. As an antiemetic, metoclopramide is less effective than serotonin antagonists and can

produce the extrapyramidal side effects of other members of the class, so it has largely been replaced by serotonin antagonists. Dromperidone (Motilium) is a D<sub>2</sub> antagonist with selective activity in the upper gastrointestinal tract. It does not cross the blood-brain barrier and so does not produce extrapyramidal side effects, but it is not available for use in the United States.

### Anticholinergics

The anticholinergic scopolamine (TransDerm Scop) is frequently used as an antiemetic to prevent motion sickness. It has not been demonstrated to be useful in treating or preventing chemotherapy-induced emesis. The major side effects of scopolamine are amnesia, dry mouth, urinary retention, and constipation.

### Antihistamines

Promethazine (Phenergan) is the antihistamine medication most often used as an antiemetic in cancer patients. It is a phenothiazine derivative, but it has much less affinity for dopamine receptors than prochlorperazine does, and like the other members of this class, it also blocks H<sub>1</sub> and acetylcholine receptors. The other antihistamines commonly used as antiemetics, meclizine (Antivert) and diphenhydramine (Benadryl), are used primarily for motion sickness, but they can be useful in alleviating the extrapyramidal side effects of antidopaminergics (such as prochlorperazine and haloperidol) when they are used for antiemesis. The major side effects of this class of drugs are sedation and the anticholinergic side effects described above.

### Benzodiazepines

The most common benzodiazepines used for cancer antiemesis are lorazepam (Ativan) and alprazolam (Xanax). They are not potent single-agent antiemetics but are most often given in combination therapy to help reduce anxiety and akathisia related to the use of corticosteroids and antidopaminergics.<sup>57</sup> Benzodiazepines may also be helpful in alleviating anticipatory emesis, as is described below. More recently, the thienobenzodiazepine olanzapine (Zyprexa), which has affinity for a number of receptors (including serotonin, dopamine, and histamine), was found in a phase II trial to be effective in preventing acute and delayed emesis in patients who received moderately or highly emetic chemotherapy.<sup>58</sup>

### Cannabinoids

The medicinal use of cannabinoids has two aspects, scientific and political. The scientific interest in using cannabinoids arose because of anecdotal reports of an antiemetic effect by patients who used marijuana during chemotherapy. Studies of medicinal use of cannabinoids

have primarily used nabilone, a synthetic cannabinoid, or dronabinol (Marinol), a purified Δ<sup>9</sup>-THC. These two agents have been found to be superior to placebo and equivalent to or slightly more effective than prochlorperazine as antiemetics.<sup>59</sup> In a double-blind randomized trial of patients who received highly emetic chemotherapy, however, high-dose metoclopramide was three times more effective than dronabinol and had fewer side effects.<sup>60</sup> Whether inhaled marijuana is more effective than oral THC as an antiemetic has been addressed in a double-blind randomized crossover trial. Patients who received cisplatin or cyclophosphamide were given inhaled marijuana plus a placebo THC capsule or a THC capsule plus an inhaled placebo cigarette and were crossed over to the opposite treatment with the next course of treatment. Neither treatment was highly effective, and there was a trend toward patient preference for THC.<sup>61</sup> In all of the cannabinoid trials, side effects were prominent, including sedation, dry mouth, ataxia, dizziness, and mood alteration, either euphoria (feeling “high”) or dysphoria.

Despite the findings that metoclopramide and the serotonin antagonists are more efficacious than cannabinoids and have fewer side effects, a systematic review of cannabinoid studies showed that in crossover studies, between 38 and 90% of patients preferred the cannabinoids.<sup>62</sup> Perhaps many of the side effects of cannabinoids, such as euphoria or even sedation or somnolence, could be viewed as favorable, especially when patients are experiencing many other unpleasant effects of their disease or its treatment.

Strong interest continues in the medicinal use of cannabinoids in the United States. In a 2004 poll commissioned by the American Association of Retired Persons, 72% of Americans aged 45 years and older thought that marijuana should be legal for medicinal purposes if recommended by a doctor. Currently, state laws that effectively remove criminal penalties for growing or possessing medical marijuana are in place in Alaska, California, Colorado, Hawaii, Maine, Maryland, Montana, Nevada, Oregon, Vermont, and Washington. However, in June 2005, the US Supreme Court ruled that physicians can be blocked from prescribing marijuana for patients even in states that have compassionate-use law. Currently, then, the political and legal status of medical marijuana is even murkier than its medical and scientific status.

### Acupuncture

Interest in acupuncture as a nonpharmacologic and adjunctive therapy is based on its long history of use in the Far East and the speculation that it may modulate endogenous opiates, substance P, or serotonin. Data are conflicting regarding the efficacy of acupuncture as an antiemetic therapy, and much skepticism has been centered on a

possible placebo effect or differences related to the amount of clinician attention and treatment. To address these possibilities, a trial of 104 women who received myeloablative chemotherapy compared combination antiemetic therapy alone (prochlorperazine, lorazepam, and diphenhydramine) with the same pharmacotherapy plus electroacupuncture at classic antiemetic acupuncture points and with the same pharmacotherapy plus minimal needling at control points with mock electrostimulation. The median number of emesis episodes per patient over 5 days was lower in the electroacupuncture group (5 episodes) and the minimal needling group (10 episodes) than in the pharmacotherapy-alone group (15 episodes).<sup>63</sup> In a contrasting placebo-controlled study, however, no differences between treatment groups were observed when 80 patients who underwent high-dose chemotherapy received ondansetron plus either invasive acupuncture or non-skin-penetrating placebo acupuncture.<sup>64</sup>

### Treatment Guidelines for the Prevention of Acute and Delayed Emesis

Antiemetic guidelines have been devised and published by a number of organizations.<sup>24,65–67</sup> These guidelines are not in universal agreement, and they differ somewhat in emesis risk stratification and in recommendations regarding specific antiemetic agents. Their differences may stem from the fact that newer guidelines reflect newer data, the interpretation of trial data, or the perceived relative importance of the pharmacoeconomics of treatment. The algorithm in Figure 2 is derived primarily from the National Comprehensive Cancer Network (NCCN) Practice Guidelines in Oncology regarding Antiemesis, version 1.2005.

### Special Emetic Problems

#### Anticipatory Emesis

It is widely believed that the most effective means of preventing anticipatory nausea and vomiting is to ensure good control of acute and delayed nausea. Both the American Society of Clinical Oncology (ASCO) and the Multinational Association of Supportive Care in Cancer (MASCC) recommend that the best treatment for anticipatory emesis is the best possible control of acute and delayed emesis.<sup>68</sup> No formal prospective trial has been performed to compare levels of control of acute emesis and its effect on the development of anticipatory emesis. However, observational data showed that in patients given highly effective antiemetics (such as granisetron) in each cycle of chemotherapy, the incidence of anticipatory nausea was fairly low, at 10% per cycle, and the incidence of anticipatory vomiting was even lower, at 2%.<sup>69</sup> These rates compare favorably

incidence of anticipatory nausea. In a randomized trial to evaluate the efficacy of lorazepam as part of an antiemetic regimen, patients who received high-dose cisplatin infusion received dexamethasone, metoclopramide, and either an antihistamine or lorazepam. The lorazepam group experienced significantly less acute and anticipatory nausea and fewer of the expected side effects of mild sedation and amnesia.<sup>71</sup> In a small, double-blind, placebo-controlled study of breast cancer patients who received adjuvant chemotherapy, the addition of low-dose alprazolam to a psychological support program including relaxation training significantly reduced the incidence of anticipatory nausea (0% with lorazepam and 18% with placebo) and the need for hypnotic therapy to control sleep disturbances associated with the cancer treatment.<sup>72</sup>

### Behavioral and Psychological Interventions

Given that anticipatory nausea is viewed as primarily a psychological phenomenon, a variety of psychological and behavioral interventions have been studied to reduce symptoms, such as systematic desensitization, progressive muscle relaxation training, hypnosis, biofeedback, guided imagery, and music therapy. Two recent reviews of published studies concluded that such interventions are effective in reducing the incidence of anticipatory nausea in adult and pediatric patients receiving chemotherapy.<sup>73,74</sup> The evidence for the efficacy of behavioral interventions in controlling chemotherapy-induced nausea and vomiting is mixed. However, a recent study assessing the ability of progressive muscle relaxation training (PMRT) to prevent postchemotherapy emesis produced mixed results. Patients were randomly assigned to receive dexamethasone plus metoclopramide or the same two antiemetics along with PMRT (25-minute sessions along with guided imagery techniques) 1 hour before chemotherapy and then daily PMRT sessions for the next 5 days. PMRT decreased the duration of nausea and vomiting in the group that received PMRT, but there was no significant difference in the incidence of emesis or the intensity of symptoms between the two treatment groups.<sup>75</sup>

### Multiple-Day Chemotherapy

Most antiemetic studies have been conducted using patients receiving single-day treatment with highly or moderately emetogenic agents. Fewer data are available regarding the management of patients receiving multiple-day chemotherapy (such as cisplatin combination chemotherapy in patients with germ cell tumors). The standard treatment for testicular cancer, for example, includes bleomycin, etoposide, and cisplatin (20 mg/m<sup>2</sup> for 5 consecutive days). Historically, patients who received this 5-day course of cisplatin had the most severe nausea and vomiting

with those from older studies using less effective antiemetics, for which the incidence of acute and delayed nausea and vomiting was very high, between 86 and 92%, that of anticipatory nausea was 31 to 33%, and that of anticipatory vomiting was 10 to 11%.<sup>70</sup>

### Benzodiazepines

The use of benzodiazepines has been studied both as part of an antiemetic combination therapy to reduce the symptoms of acute, delayed, and anticipatory nausea and as an adjunct to a psychological support program to reduce the

on day 1 and gradually diminishing emetic symptoms over the next several days. With the development of highly effective antiemetics such as the 5-HT<sub>3</sub> antagonists, the opposite pattern is now seen: there is often complete emetic control the first 1 to 2 days and then worsening nausea and some vomiting on days 3 to 5.<sup>76</sup>

Several studies have established the value of giving a repetitive dosing of 5-HT<sub>3</sub> antagonists on each day of cisplatin for the control of acute nausea and vomiting.<sup>77</sup> Control of later-onset symptoms has been the focus of discussion. There is disagreement regarding the dosing of dexamethasone. Concern has been expressed about the side effects of dexamethasone if given for all 5 days of cisplatin. One recommendation is to give oral dexamethasone as a single 20 mg dose on days 1 and 2 for control of acute emesis, then as an 8 mg dose twice daily on days 6 and 7, and finally as a 4 mg dose twice on day 8 for control of delayed symptoms.<sup>76</sup> The NCCN guidelines recommend that for multiple-day chemotherapy regimens, a 5-HT<sub>3</sub> receptor antagonist be administered before each day's first dose of highly or moderately emetogenic chemotherapy and that dexamethasone be administered daily during chemotherapy and then for 2 to 3 days afterward if the regimen is likely to cause delayed emesis.<sup>24</sup>

Palonosetron, the long-acting serotonin antagonist, has not been studied in multiple-day chemotherapy regimens. However, the long half-life and duration of action of this agent may make it particularly well suited to this situation. The NCCN guidelines offer that palonosetron may be used before the start of a multiple-day chemotherapy regimen. In the acute emesis guidelines, it is recommended as a single 0.25 mg dose to cover both the acute and delayed periods, but in multiple-day regimens, repeat dosing may be required. On the basis of results from a phase II trial in which doses up to 30 times the FDA-approved dose were administered and from several phase III trials in which a single dose of 0.75 mg was evaluated, repeated dosing of the 0.25 mg dose is likely to be safe.<sup>24</sup>

Aprepitant, the NK<sub>1</sub> antagonist, has not been studied in multiple-day chemotherapy regimens. The NCCN guidelines suggest that for multiple-day regimens with highly emetogenic chemotherapy, this agent may be administered as a 125 mg oral dose before chemotherapy on day 1 and then as an 80 mg oral dose on days 2 and 3, as one would do for highly emetogenic single-day chemotherapy. The guidelines further state that on the basis of phase II data, additional 80 mg oral doses can be safely administered on days 4 and 5 of a multiple-day regimen.<sup>24</sup> Data regarding the efficacy of additional dosing are not available.

### High-Dose Chemotherapy

Treatment-related nausea and vomiting are especially difficult problems for patients receiving

high-dose chemotherapy in association with a bone marrow or peripheral blood stem cell transplant. In addition to the use of highly and moderately emetogenic chemotherapy agents, there are a number of exacerbating factors, such as multiple-day administration, concurrent use of prophylactic antibiotics and narcotic analgesics, and the use of radiotherapy (including highly emetogenic total-body irradiation). There are very few studies regarding the use of antiemetics in patients receiving high-dose therapy; most are phase II studies of 5-HT<sub>3</sub> receptor antagonists, with or without dexamethasone. The efficacy of 5-HT<sub>3</sub> receptor antagonists has ranged from a low of 30% among breast cancer patients, who achieved complete or partial nausea protection from granisetron plus dexamethasone,<sup>78</sup> to a high of 98% among patients treated with high-dose cyclophosphamide and total-body irradiation, who achieved complete (50%) or partial (48%) emesis protection from granisetron plus dexamethasone.<sup>79</sup> In general, the antiemetic effects of current treatment appear to be less effective in this setting than in standard-dose highly emetogenic chemotherapy. The general consensus is that the standard of care should be a combination of a 5-HT<sub>3</sub> receptor along with dexamethasone.<sup>80</sup> Neither palonosetron nor aprepitant has been studied in this patient population.

### Radiation-Induced Nausea

Similar to the risk stratification in chemotherapy-induced nausea, efforts have been made to predict the emetic risk of radiotherapy, based primarily on the site of irradiation. The following classification has been proposed<sup>81</sup>:

- Greater than 90% emetic risk: total-body or total-node irradiation
- A 60 to 90% emetic risk: upper hemibody, upper abdomen, or whole-abdomen irradiation
- A 30 to 60% emetic risk: lower hemibody irradiation, lower thoracic or pelvic region irradiation, craniospinal irradiation, or cranial radiosurgery
- Less than 30% emetic risk: irradiation of the head and neck, extremities, or extra-abdominal areas

For the high-risk category (>90% risk), MASCC and ASCO guidelines recommend prophylaxis with 5-HT<sub>3</sub> antagonists plus dexamethasone. For the moderate-risk category (60–90% risk), both guidelines recommend prophylaxis with a 5-HT<sub>3</sub> antagonist. For the low-risk category (30–60% risk), either prophylaxis or rescue with 5-HT<sub>3</sub> antagonists can be used. In the minimal-risk category (<30% risk), rescue with a dopamine receptor antagonist or a 5-HT<sub>3</sub> antagonist can be used.<sup>82</sup>

Several points about these guidelines deserve mention. First, few randomized trials have compared the efficacy of antiemetics in radiation-induced emesis; most included patients receiving total-body, upper hemibody, or upper abdominal irradiation because these treatments carry the highest risk of emesis. Second, although some trials have demonstrated the efficacy of 5-HT<sub>3</sub> antagonists and of dexamethasone over placebo in radiation-induced nausea, no trials have compared dexamethasone plus a 5-HT<sub>3</sub> antagonist against the use of 5-HT<sub>3</sub> antagonist alone in this setting. Recommendations regarding the use of both drugs together are based on data showing the efficacy of dexamethasone plus ondansetron versus placebo or ondansetron plus dexamethasone versus metoclopramide plus dexamethasone<sup>83</sup> and on some extrapolation from the data regarding the use of corticosteroids and serotonin antagonists in highly emetogenic chemotherapy. Finally, neither the MASCC nor the ASCO guidelines address the prevention of emesis when patients are receiving both chemotherapy and radiotherapy. In the NCCN guidelines, the emetic risk of patients receiving chemoradiation is determined by the emetogenic potential of the chemotherapy. Thus, the same antiemetic prophylaxis is used for patients receiving both chemotherapy and radiotherapy as that used for patients receiving chemotherapy alone.<sup>24</sup>

### Breakthrough or Refractory Emesis

Despite the development of highly effective emetic prophylaxis, a significant number of patients will develop treatment-related nausea and vomiting. Antiemetic medications are effective at preventing the onset of nausea and vomiting, but once persistent emesis is established, pharmacologic intervention is much less effective.

When patients present with breakthrough emesis after chemotherapy, the management should be threefold. First, the clinician must try to discern whether the nausea and vomiting are due not to the chemotherapy but to some other cause (such as hypercalcemia), are a side effect of other medications (such as narcotics), are a manifestation of brain metastases, or are a primary gastrointestinal disorder (such as bowel obstruction). Second, the treating physician must ensure that the patient is receiving optimal antiemetic prophylaxis. Despite consensus guidelines regarding best-evidence management of any clinical problem, practice patterns are often slow to be adopted. As an example, a 2000 survey of Italian cancer centers after the promulgation of treatment guidelines for chemotherapy-induced emesis revealed that a significant number of patients received treatment that was considered suboptimal according to the new guidelines: 22% of the patients being treated with highly emetogenic chemotherapy received a 5-HT<sub>3</sub>

antagonist and no dexamethasone during the acute emesis phase, and 41% of the patients received no antiemetic during the delayed emesis phase.<sup>84</sup>

Third, if a patient has received prophylaxis and still experiences nausea and vomiting, the general principle of breakthrough therapy is to add an additional agent from a different drug class. Since there are multiple neurotransmitter receptors in the important emetogenic pathways, blockade of an additional pathway might provide additional clinical benefit. And since oral medications cannot generally be tolerated in the presence of intractable vomiting, intravenous administration is generally necessary. If the patient seemed to have derived benefit from the original antiemetic regimen (such as a serotonin antagonist), then that regimen should be retained and an additional medication with a different mechanism of action (such as an antidopaminergic) should be added.<sup>24</sup> Multiple antiemetic agents on an alternating schedule may be necessary.

If a patient has received chemotherapy with a lower emetic potential and thus has received less aggressive emesis prophylaxis, the antiemetic therapy could be changed to a higher-level therapy typically used for a higher-risk group. For example, a patient who has received only dexamethasone for delayed symptoms may require the addition of a 5-HT<sub>3</sub> antagonist.

It has been assumed that because of their similar chemical structure, failure of one 5-HT<sub>3</sub> receptor antagonist predicts the failure of the entire class. However, there may be patient variability in response, and if a patient who has received a 5-HT<sub>3</sub> antagonist develops emesis, a different serotonin antagonist could be considered. In a double-blind trial of 40 patients who received ondansetron plus dexamethasone after highly emetogenic chemotherapy yet experienced nausea and vomiting in the first 24 hours, the patients were randomly assigned to continue the same therapy or to switch to granisetron plus dexamethasone. The rate of complete protection from emesis was significantly higher in the patients who switched to granisetron than in those who continued with the same regimen.<sup>85</sup> It should be noted that in that small study, a high dose of granisetron (3 mg) was compared with a relatively low dose of ondansetron (8 mg). There could be a lack of complete cross-resistance between the serotonin antagonists, or the recommended dosing may be inadequate for some patients.

## Patients with Advanced Cancer

In contrast to the large number of trials designed to address the problem of chemotherapy-induced emesis, relatively few have been performed to study the clinical problem of nausea and vomiting not related to chemotherapy in patients with

advanced cancer. Yet the symptoms are very common in both patient groups and very vexing in patients with advanced cancer: 60% experience nausea and 30% complain of vomiting.<sup>86</sup> The list of potential causes of nausea and vomiting in this population is long, and often these symptoms are multifactorial. Palliative care specialists may use a “mechanistic” approach to treat nausea and attempt to deduce the pathophysiologic mechanism of emesis from their clinical evaluation and administer treatment accordingly, or they may use an “empiric” approach and use antiemetics until they find one that is effective. Favoring the mechanistic approach, a randomized controlled trial found that metoclopramide was 75% effective in relieving symptoms of cancer-related dyspepsia thought to be due to a gastroparetic mechanism.<sup>87</sup>

Patients with inoperable malignant bowel obstruction represent a special clinical scenario that may result in nausea and vomiting. For palliative care patients, the relief of symptoms of colicky abdominal pain and vomiting is paramount. Although nasogastric tube decompression of the gastrointestinal tract is standard care for such patients, it is very uncomfortable. Placement of a draining gastrostomy tube is another option if the clinical situation is persistent and not likely to resolve. Corticosteroids such as intravenous dexamethasone are often used in palliative care practice to reduce the inflammation associated with a malignant lesion and thus relieve the obstruction. The results from several trials have suggested a trend toward a benefit from this therapy, although the advantages have been small and have not reached statistical significance.<sup>88,89</sup>

Regarding the use of 5-HT<sub>3</sub> antagonists in patients with advanced cancer, there has been some concern over the acquisition costs (eg, for patients in hospice care) and the side effects, such as constipation, for which this patient population is at high risk. One small study found a trend toward superiority of ondansetron over placebo in the treatment of opioid-induced nausea and vomiting, but this trend did not achieve statistical significance.<sup>90</sup> In another study, the serotonin antagonist tropisetron was significantly better than metoclopramide or chlorpromazine in patients with advanced cancer.<sup>91</sup>

## Summary

More than 20 years ago, patients who received chemotherapy rated nausea and vomiting as the most distressing aspects of their treatment.<sup>1</sup> There have since been considerable advances in understanding the pathophysiology of nausea and vomiting, the predictive factors to stratify emetic risk, and the development of highly effective and well-tolerated antiemetic drugs. Complete prevention of chemotherapy-induced emesis is achievable with currently available ther-

apy in most patients and should be the goal of all patients receiving treatment. To accomplish this objective, the following key facts should be kept in mind:

- Several neurotransmitter receptors in the CTZ are involved in triggering emesis, the most important of which are the D<sub>2</sub>, 5-HT<sub>3</sub>, and NK<sub>1</sub> receptors. These receptors are the targets of antiemetic drugs. Blockade of only one receptor class is often insufficient to completely prevent nausea and vomiting.
- Cancer patients should always be assessed for other causes of nausea and vomiting, such as electrolyte disturbances, medication side effects, and primary gastrointestinal disorders (such as bowel obstruction), before the emesis is attributed to chemotherapy side effects.
- The most important factor in assessing emetic risk is the intrinsic emetic potential of the chemotherapeutic agent. Antiemetic treatment should be guided by the predicted level of emetogenicity and by known patient factors.
- The risk of emesis for patients receiving moderate- to high-emetic risk chemotherapy lasts for 4 to 5 days; patients require preventive treatment for that entire period.
- Anticipatory nausea is a conditioned response occurring after poor control of acute or delayed emesis. The best treatment is to prevent acute or delayed symptoms in the first place by optimal antiemetic therapy during every cycle. Behavioral interventions or benzodiazepines may also be helpful.
- Prophylaxis for radiation-induced nausea and vomiting may be tailored according to the risk stratification based on the body site treated. Patients receiving concurrent chemotherapy should receive antiemetic treatment according to the emetogenic potential of their chemotherapy regimen.
- Breakthrough emesis is generally managed by adding an antiemetic agent from a different class or by stepping up therapy to that used for higher-risk chemotherapy.
- In patients with advanced cancer, nausea unrelated to chemotherapy may be multifactorial. A mechanistic approach to identify the pathophysiologic cause of emesis can guide therapy.

# Fever

Maria E. Cabanillas, MD  
Ricardo H. Alvarez, MD

The past two decades have witnessed an increase in the number of patients who are immunocompromised as a consequence of primary or secondary immunodeficiency disorders or from the use of agents that depress one or more components of the immune system. Cancer patients are considered immunocompromised hosts who have an alteration in phagocytic, cellular, or humoral immunity. In this scenario, fever is a very common problem and can be secondary to infections, inflammation, transfusions, antineoplastics, antimicrobials, or tumor necrosis. Despite significant advancements in supportive care of patients with cancer, infections continue to be the major cause of morbidity and mortality in patients with cancer because of alterations in normal host defenses. This chapter reviews the potential causes and pathophysiologic mechanisms of fever in patients with cancer.

## History

One of the first references about fever comes from the ancient Sumerian pictogram in the sixth century BC. Centuries later, Celso, a Roman writer of the first century AD, first listed the four cardinal signs of inflammation: redness, swelling, heat, and pain. In this description, fever was represented by local heat. Ultimately, Claude Bernard first recognized the metabolic process occurring within the body and the result of body heat. For many years, physicians monitored body temperature as a complementary diagnostic tool; however, the real impact in diagnosis was uncertain. The first scientific publication reported was in 1868 by Carl Reinhold August Wunderlich in a paper entitled “The Course of Temperature in Disease.”<sup>1</sup> In his description, made after 1 million observations in 25,000 subjects, he put emphasis on the normal diurnal variation and posited 38°C (100.4°F) as the upper limit of the normal range. Most of his work was done using axillary measurement of temperature.

## Definitions

One of the most common definitions of fever is promulgated by the International Union of

Physiological Sciences Thermal Commission.<sup>2</sup> It defines fever as a state of elevated core temperature, which is often but not necessarily part of the defensive responses of multicellular organism (host) to the invasion of live (microorganism) or inanimate matter recognized as pathogenic or alien by the host. Fever develops when a pyrogen, a term used to describe any substance that causes fever, elevates the set point—determined core body temperature above normal. The genesis of fever requires the presence of an intact thermoregulatory mechanism.

With regard to the upper limit of the normal oral temperature, medical societies and modern textbooks differ in their definition. According to the 1977 guidelines from the Infectious Disease Society of America, fever is defined as a single oral temperature more than 38.3°C (101°F) or an elevation of 38°C (100.4°F) for at least 1 hour in the absence of obvious environmental causes.<sup>3</sup>

Unlike fever, hyperthermia represents a failure of thermoregulatory homeostasis in which cytokines are not involved and therapies with antipyretics are ineffective. Heat stroke is one example of hyperthermia and is defined as a body temperature > 40.5°C (105°F) with associated central nervous system (CNS) dysfunction, including seizure, delirium, and coma, in the setting of a large environmental heat load that cannot be dissipated. Hyperthermia is also caused by drugs in three different scenarios: neuroleptic malignant syndrome, malignant hyperthermia, and serotonin syndrome.<sup>4</sup>

The term *hyperpyrexia* denotes fever of more than 41.5°C (106.7°F) and occurs in patients with severe infections but most commonly occurs in patients with CNS hemorrhages.

## Thermometric Variability

Thermometric measurements involve a number of basic technical details that are very important in the final temperature reading. Core body temperature refers to the temperature of the cranium, thorax, and abdominal cavities. The gold standard for core body temperature measurement is the pulmonary artery catheter, which approximates the temperature of the heart. However,

because this method is invasive, it is not practical for use on all patients. Peripheral temperature measurements are only an estimate of the core temperature owing to compensatory mechanisms such as vasoconstriction, which can change the peripheral temperature in relation to the core temperature. Noninvasive sites, such as the tympanic membrane, posterior sublingual pocket (oral), rectum, and axilla, are the most commonly used.

The tympanic membrane is an ideal site for estimating the core temperature because the arterial irrigation of the tympanic membrane is in proximity to the artery supplying the hypothalamic area, and it is considered to be the closest body temperature to the thermoregulatory center. The accessibility is optimal; however, proper technique is a major factor influencing accuracy. When the probe is placed incorrectly, the temperature reading may be that of the skin, the external ear canal, or the cerumen instead of the tympanic membrane.<sup>5</sup> With proper training and use, this method can provide rapid and accurate measurements.

Oral temperature measurement is the most common site used because it is accessible and responds promptly to changes in the core temperature. The sublingual pocket is irrigated by a main artery, which is a branch of the external carotid artery. Several factors can alter the final reading of oral temperature. Mastication and smoking both cause significant and persistent increases in the oral temperature, whereas drinking ice beverages, mouth breathing, and aerosol treatments may cause transient decreases in the oral temperature. This method is convenient and reliable in proper candidates.

A rectal temperature reading provides higher levels than those obtained at other sites and is no longer considered the gold standard. This increased rectal temperature may be secondary to heat generated as a result of the metabolic activity of fecal bacteria. This site is used in the hospital setting; however, in patients with hemodynamic shock, the arterial perfusion of the rectum may be severely impaired. For this reason, this site provides a reliable approximation only in patients who have a thermal balance.

Although more convenient, axillary readings do not accurately reflect core body temperature and should be used only when it is impossible to obtain a temperature reading by any other means.<sup>6-8</sup>

## Physiologic Variables

Several variables in body temperature registration change with regard to age, sex, and circadian rhythm. For many years, there was a tendency to believe that older people have lower body temperatures than their younger counterparts. However, a recent investigation showed that healthy elderly subjects (mean age 80.3 years; range 62–99 years) have the same average core temperature than healthy younger people.<sup>9</sup> Women exhibit increases in body temperature of about 0.5°C (0.9°F) at the time of ovulation. They have a slightly higher average oral temperature than men (36.9°C vs 36.7°C) but do not exhibit greater average diurnal temperature oscillations than their male counterparts (0.56°C vs 0.54°C).

Body temperature exhibits circadian rhythmicity that is associated with the sleep-wake cycle. During normal circadian cycle, the core temperature reaches its highest levels in the late afternoon or early evening and its nadir in the early morning. The adaptations to night shift work cause a reversal in this pattern. Therefore, when clinical thermometric measurements are made, it is important to consider not only the time and site of measurement but also the sleep-wake cycle of the subject being studied (Table 1).

## Clinical Manifestations

Broadly defined, an immunocompromised host has an alteration in phagocytic, cellular, or humoral immunity that increases the risk of infectious complications or opportunistic infections. Fever is the principal, and sometimes the only, manifestation of serious infection in the cancer patient.

Fever has two components. One is objective and is represented by a temperature measurement above the normal range. The other component is subjective and is represented by a constellation of symptoms (chills, shivering, and sweating), which are produced by the elevation of core temperature. These two components are commonly defined as febrile response, which is the result of an innate physiologic reaction,

including cytokine production and activation of multiple endocrine, immunologic, and hematologic systems.

Although a number of fever patterns have been associated with various infectious or non-infectious illnesses, no pathognomonic pattern or degree of fever has been clearly associated with a specific infection in immunocompromised patients.

Febrile episodes are characterized by three different phases: initiation, steady state, and defervescent.<sup>10</sup> During initiation, a pyrogen elevates the thermoregulatory set point above normal. The individual experiences cutaneous vasoconstriction, which leads to heat retention, followed by shivering that generates additional heat to achieve the new set point. At steady state, heat production is equivalent to heat loss, and shivering stops. After lowering the set point, defervescence commences with cutaneous vasodilatation and sweating, which lead to radiant and evaporative heat loss, respectively.

## Pathophysiologic Mechanism

The mechanism responsible for the body temperature is localized in the hypothalamus. The suprachiasmatic nuclei and the preoptic and anterior hypothalamus appear to be responsible for this exquisite thermoregulation. Several studies suggest that the preoptic region regulates body temperature by integrating thermal input signals from thermosensors in the skin and CNS. A variety of endogenous and exogenous pyrogens, including drugs, appear to affect temperature regulation by altering the activity of hypothalamic neurons. Exogenous pyrogens are, for the most part, microorganisms and toxin products of microbial origin. According to current concepts, exogenous pyrogens depend on their physicochemical structure and initiate fever by inducing the macrophages to produce endogenous pyrogens. These endogenous pyrogens, also called cytokines, cross the blood-brain barrier and activate thermosensitive neurons. Four major pyrogenic cytokines have been described: interleukin (IL)-1, tumor necrosis factor (TNF) $\alpha$ , IL-6, and interferon (IFN)- $\gamma$ . In healthy subjects, the pyrogenic cytokines are undetectable in serum under basal conditions and have a very short intravascular half-life. Interestingly, the pyrogenic cytokines are pleiotropic, in that they interact with receptors present on many different types of host cells in picomolar quantities.

## Acute-Phase Changes

Body temperature may change under several factors, such as infection, trauma, inflammatory process, and malignant disease. This physiologic response is nonspecific and is generally referred to as the acute-phase reaction, although it is seen in both chronic and acute inflammatory states.

The full spectrum of the response includes dramatic increases (ie, C-reactive protein, fibrinogen, and ferritin) or decreases (ie, albumin, transferrin, and transthyretin) in the synthesis of several hepatic proteins. Table 2 shows the list of important plasma proteins that increase during the acute-phase response.

One of the most important acute-phase proteins, C-reactive protein (CRP), is synthesized by the liver, mainly in response to IL-6. CRP is thought to activate the complement system by binding to polysaccharides present on bacteria, fungi, and parasites. In vitro, CRP activates neutrophils, promotes platelet degradation, and enhances natural killer cell activity. The secretion of CRP occurs rapidly after the stimulus and falls rapidly after the disappearance of the stimulus. Despite the lack of specificity, it is useful in clinical practice because it reflects the presence and intensity of the inflammatory process. It is also an inexpensive and widely available test.<sup>11,12</sup>

Fever may be present in conjunction with lethargy and increased sleep. Leukocytosis with immature neutrophils is also common. Dysfunction of the thyroid gland and abnormal glucose and lipid metabolism are frequently seen. Oligoelements such as zinc and serum iron are depressed. Another metabolic change related to the acute-phase reaction is an increase in liver gluconeogenesis, energy expenditure, and muscle proteolysis, all of which contribute to weight loss.

The most florid manifestation of the acute-phase response is observed in patients with acute

Table 1 Normal Variations in Temperature

Temperature Diurnal/Evening	Tympanic Membrane	Oral	Rectal
6:00 am	36.6°C (98°F)	37.2°C (98.9°F)	37.6°C (99.6°F)
4:00 pm	37.3°C (99°F)	37.7°C (99°F)	38.1°C (100.6°F)

Table 2 Plasma Proteins that Increase during the Acute-Phase Response

bacterial infection, extensive body surface area burns, or multiple and traumatic injuries. However, occult infections, chronic illnesses such as rheumatoid arthritis, Crohn's disease, and other autoimmune diseases also are characterized by acute-phase response elevation. In several cases, the acute-phase response serves as an indicator of silent disease in some cancers, particularly renal cell carcinoma and Hodgkin's disease.

### Induction of the Acute-Phase Response

The initiation of the acute-phase response is linked to the production of cytokines elicited by infections, injuries, inflammation, and immunologic reactions. Cytokines are proteins produced by many cell types (principally activated lymphocytes and macrophages, but also endothelium, epithelium, and connective tissue cells) that modulate the function of other cell types. These proteins are pleotropic in that they can act on different cell types. Cytokine effects are often redundant and can influence the synthesis or action of other cytokines. They are multifunctional in that individual cytokines may have both positive and negative regulatory actions. Cytokines mediate their effects by binding to specific receptors on target cells. The expression of cytokine receptors can be regulated by a variety of exogenous and endogenous signals. For some responsive cells, cytokines stimulate cell proliferation, acting as traditional growth factors.

Cytokines can be grouped into five classes:

1. Cytokines that regulate lymphocyte function: these cytokines regulate lymphocyte activation, growth, and differentiation. IL-2 and IL-4 act in lymphocyte growth, as well as IL-10 and transforming growth factor  $\beta$ , which are negative regulators of immune responses.
2. Cytokines involved with natural immunity: these include two major inflammatory cytokines, TNF- $\alpha$  and IL-1 $\beta$ .
3. Cytokines that activate inflammatory cells: these cytokines activate macrophages during the cell-mediated immune response and include IFN- $\gamma$ , TNF- $\alpha$ , TNF- $\beta$  (lymphotoxin), IL-5, IL-10, and IL-12.
4. Chemokines: this group of cytokines is characterized by chemotactic activity for various leukocytes.
5. Cytokines that stimulate hematopoiesis: these mediate immature leukocyte growth and differentiation and include IL-3, IL-7, c-kit ligand, G-CSF, and granulocyte-macrophage colony-stimulating factor.

Several cytokines induce acute-phase changes: IL-1, TNF- $\alpha$ , IFN- $\gamma$ , IL-6, leukemia inhibitory factor, ciliary neurotropic factor, oncostatin M, and IL-11.

The development of the acute-phase response in a patient with a localized bacterial infection starts 1 to 2 hours after blood monocytes and tissue macrophages become activated by phagocytosis or microorganism exposure to its products or toxins. These mediators enter the circulation and reach the brain, where they initiate fever. Within 8 to 12 hours after the onset of infection or trauma, the liver increases the synthesis of acute-phase proteins. In addition, several normal plasma proteins increase several-fold during the acute-phase response, including haptoglobin, certain protease inhibitors, complement components, ceruloplasmin, and fibrinogen.

Despite the anabolic processes of the liver, the acute-phase response is accompanied by marked catabolism of muscle protein associated with loss of body weight and overall negative nitrogen balance.

### Etiology

Thirty percent of patients with cancer develop fever at some point during the course of their malignancy,<sup>13</sup> with the majority having an underlying infection. Infection, tumor, and drugs are among the most common causes of fever in patients with cancer (Figure 1). The major differential point in determining whether the fever is due to infection is the presence or absence of neutropenia. In patients with low white blood cell counts, infection causes more than two-thirds of all fevers, whereas patients with normal white blood cell counts are infected far less frequently. The wide variation in fever frequency reflected in Table 3 relates to differences in the definition of fever, the population studied, the primary tumor site, and medical advances during the period studied.<sup>10</sup>

There are two clinical conditions associated with a risk of life-threatening infections: severe neutropenia (ie, an absolute neutrophil count of less than 500/mm<sup>3</sup>) and a history of splenectomy. In both situations, rapidly progressive infections may be life-threatening if untreated.<sup>14</sup>

### Fever Caused by Infection

Infection is a leading cause of fever in both the neutropenic and non-neutropenic patient. A risk stratification model was proposed in the cancer patient setting and is described in Table 4.<sup>15</sup> Patients with cancer have a perturbation in the host mechanism of defense. Usually, these patients have aberrations of skin and mucosa, with disorders of neutrophils, T lymphocytes, plasma cells, and complement system. These abnormalities will predispose patients to specific infections; therefore, the physician must identify the probable immune defect (often there will be more than one) in the febrile cancer patient.

Acute fever in non-neutropenic cancer patients, if clinical signs suggest infection, should be managed similarly to fever in patients without cancer. Special attention should be given to a possible cancer causing an obstruction in natural passages, for example, pneumonia in bronchial cancer, pyelitis in bladder or prostatic cancer, and cholangitis in pancreatic carcinoma. Obstruction is also frequently responsible for relapses of infection after successful therapy. *Streptococcus pneumoniae* remains a major pathogen in lung cancer patients, whereas *Escherichia coli* and *Streptococcus faecalis* are often isolated in patients with pancreatic and hepatobiliary tumors. Colon carcinomas are associated with an increased frequency of *Streptococcus bovis* bacteremia and endocarditis.

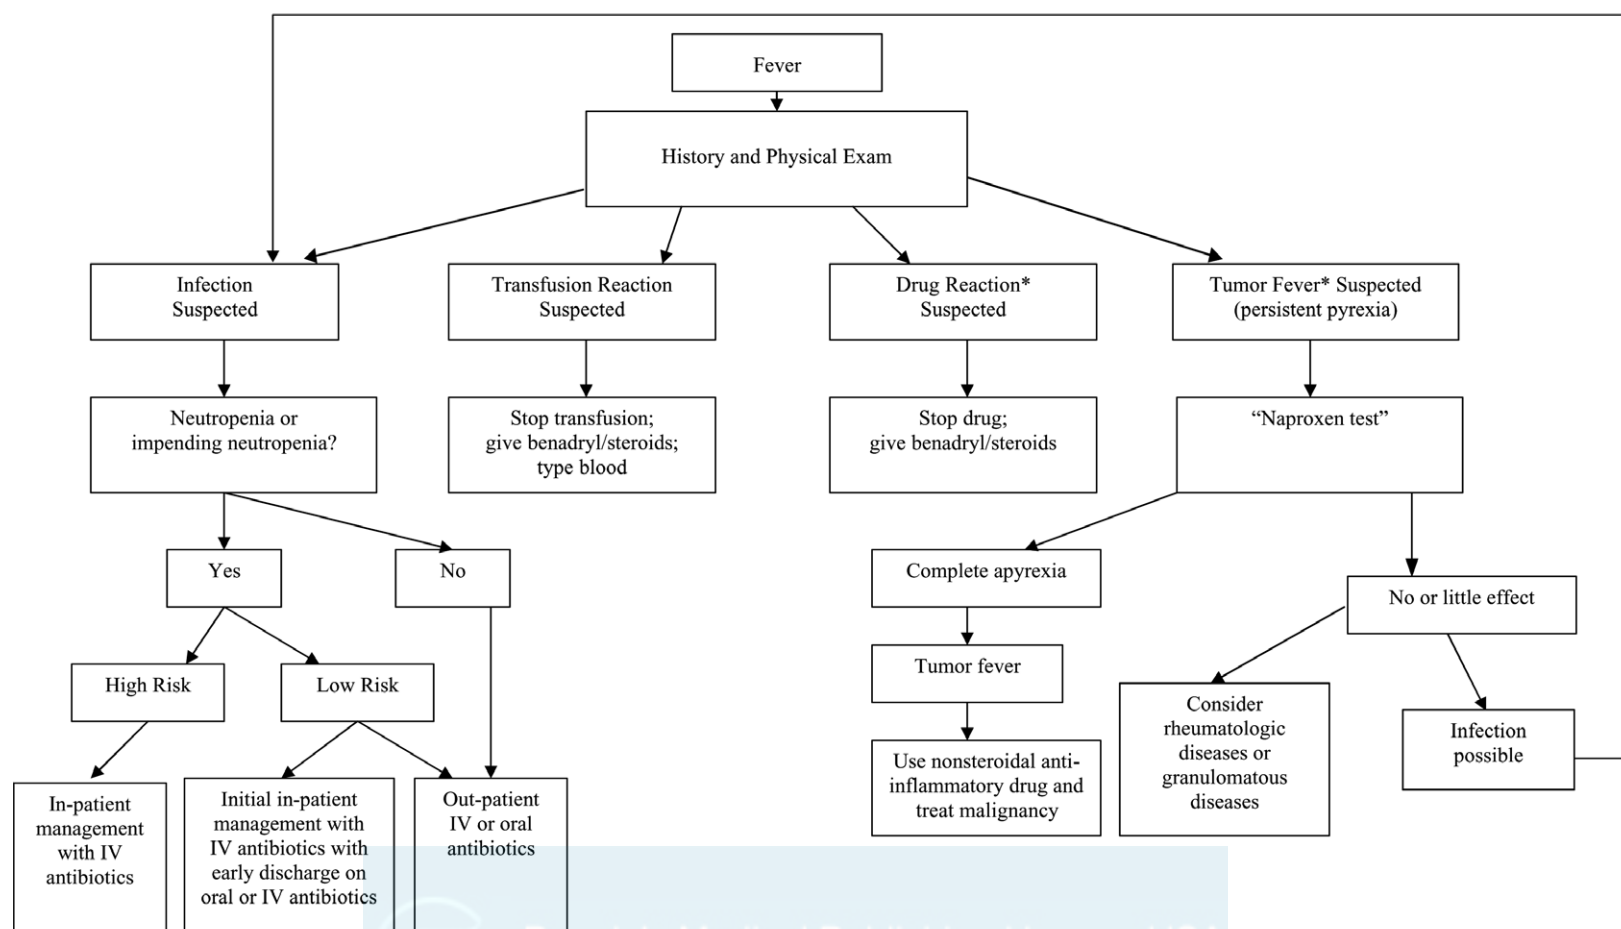

### Central Nervous System

Infection of the CNS should be suspected in a febrile cancer patient with altered mental status. Common bacterial pathogens causing meningitis in patients with or without cancer include *S. pneumoniae* and *Neisseria meningitidis*. Patients who have undergone a neurosurgical procedure are at increased risk of meningitis caused by gram-negative bacilli. The incidence of *Listeria meningitis* is increased in the elderly and patients with decreased cell-mediated immunity. Patients with subcutaneous reservoirs and ventricular catheters (eg, Ommaya reservoir) are at increased risk of meningitis owing to *Pseudomonas*, *Propionibacterium acnes*, and staphylococci. Although *Coccidioides immitis*, *Histoplasma capsulatum*, and *Cryptococcus neoformans* are the major fungal CNS pathogens in the United States, the latter is the most common cause of meningitis in cancer patients. The onset is often insidious but may be more acute in patients receiving corticosteroids or another immunosuppressive therapy.

### Indwelling Catheters

The use of indwelling intravenous catheters has become a commonplace source of infection in patients with cancer. Infectious complications are of two types: local infections involving the subcutaneous tunnel or exit site and such as bacteremia. Unfortunately, local signs and symptoms are unreliable indicators of catheter infections. Many catheters responsible for bacteremia appear to be totally innocuous, and this is particularly true for neutropenic patients. It became clear early in the use of indwelling central venous catheters that the treatment of catheter infections did not always require removal of the offending device. The gold standard for the diagnosis of a catheter-related infection has been the demonstration of  $\geq 15$  colony-forming units per catheter tip.<sup>16</sup> However, the success of treatment is dependent on the pathogenicity of the offending organism, and many authorities recommend removal of the

Condition	Risk Stratification	Major Risk Factor	Predominant Causes of Fever
Cancer	Low	Underlying disease, therapy, neutropenia < 10 d, altered mucosal immunity, indwelling catheter	FUO Gram-positive or gram-negative bacteria, respiratory viruses or herpesviruses
	High	Underlying disease, therapy, neutropenia > 10 d, altered mucosal immunity, defects in humoral or cellular immunity, indwelling catheter	FUO Bacteria: gram-positive or gram-negative aerobes, anaerobes at sites of mixed infection Viruses: RSV, parainfluenza virus, adenovirus, HSV, CMV Fungi: <i>Candida</i> , <i>Aspergillus</i> , <i>Cryptococcus</i> , <i>Trichosporon</i> , <i>Fusarium</i>
Bone marrow transplantation	High	Risk factors for high-risk cancer, plus immunosuppressive regimen, previous infection with CMV, GVHD	Similar to those with high-risk cancer; pattern of infection is influenced by time since transplantation and type of procedure (ie, autologous or allogeneic)

Adapted from Pizzo PA.<sup>15</sup>  
CMV = cytomegalovirus; FUO = fever of unknown origin; GVHD = graft-versus-host disease; HSV = herpes simplex virus; RSV = respiratory syncytial virus.

catheter when *Staphylococcus aureus*, *Pseudomonas* sp, *Candida* sp, or polymicrobial infection are encountered. In addition, a consensus exists that the majority of exit-site infections can be treated with antibiotics alone, whereas tunnel infections often require catheter removal.

#### Skin

The differential diagnosis of fever in cancer patients with dermatologic signs is challenging. Numerous infections have been associated with skin lesions, but underlying malignancy and hypersensitivity drug reactions can involve the skin. Common dermatologic infections occurring in normal hosts, such as staphylococcal cellulitis, are readily diagnosed and treated. These infections are frequently caused by intravenous catheters, trauma, or other breaches of the skin. The morphology of the lesions may be atypical in the immunosuppressed host, and a new rash or nodule may be the earliest or the only warning sign of a serious systemic process. A prompt biopsy with histologic staining and culture for bacteria, mycobacteria, viruses, and fungi can provide prompt information on which to base treatment.

#### Gastrointestinal Tract

Infection can occur anywhere in the gastrointestinal tract, and the risk of gastrointestinal infections in cancer patients includes decreased cell-mediated immunity, radiation therapy, chemotherapy, and broad-spectrum antibiotics. The oral cavity is a common site of infection in cancer patients. In a classic prospective clinical study in hematologic cancer patients, 20% of patients had an acute oral infection without signs of an extraoral infection and two-thirds of patient had both oral and extraoral infections. The most common oral infection was *Candida*.<sup>17</sup> In the setting of

chemotherapy-induced mucositis, streptococci, enterobacteriaceae, and anaerobes are the prevalent organisms. Esophagitis should be suspected in patients with odynophagia or dysphagia with fever. *Candida*, cytomegalovirus, and herpes simplex viruses are common causes of esophagitis in patients with acquired immune deficiency syndrome (AIDS), hematologic malignancies, and organ transplant. Esophagoscopy with biopsy and culture is required for a definitive diagnosis. The symptoms of pseudomembranous colitis caused by *Clostridium difficile* include a high fever, bloody diarrhea, and abdominal pain. One survey found *C. difficile* in the stool of up to 12% of asymptomatic leukemic patients compared with 5% of asymptomatic healthy volunteers.<sup>18</sup> Infection usually occurs during or following antibiotic therapy but can be secondary to chemotherapy agents as well.

Neutropenia predisposes the patient to severe and rapidly progressing infection by bacterial and fungal pathogens; therefore, empiric therapy has become an accepted practice and should be designed to cover the most likely pathogens, namely gram-negative rods, especially *Pseudomonas aeruginosa*.

#### Tumor Fever

In the absence of infection, it is thought that cancer cells can produce cytokines, which are responsible for tumor fever. Renal cell carcinoma is the most common cancer associated with fever, with fever occurring in up to half of patients.<sup>19</sup> Hepatoma patients develop fever one-third of the time.<sup>20</sup> Fever may play a role in the staging of some cancers. The Ann Arbor Staging System for Hodgkin's disease includes B symptoms such as persistent or recurrent fever, weight loss, or night sweats. Pel-Ebstein fever (persistent fever for days to weeks followed by afebrile intervals and then recurrent fever) is seen in patients with Hodgkin's

disease and is an important prognostic feature in the disease.

Clinical characteristics may be useful to distinguish between infectious and neoplastic fevers, but no one feature reliably differentiates them. Therefore, tumor fever is a diagnosis of exclusion, made after an exhaustive evaluation for infection and when exclusion of other causes of fever has been made. Diagnostic criteria for tumor fever are described in Table 5.

The infected patient is often ill, or even toxic, with chills, tachycardia, and possible hypotension. In the case of fever related to cancer, chills and tachycardia are lacking or minimal. Aspirin and acetaminophen have little effect on fever caused by a malignant tumor, whereas a dramatic response to nonsteroidal anti-inflammatory drugs occurs. Consequently, some investigators use the response to nonsteroidal anti-inflammatory drugs to differentiate fever caused

Table 5 Diagnostic Criteria for Neoplastic Fever

I.	Temperature over 37.8°C (100°F) at least once each day
II.	Duration of fever over 2 wk
III.	Lack of evidence of infection on <ol style="list-style-type: none"> <li>A. Physical examination</li> <li>B. Laboratory examination, eg, cultures from sputum, blood, urine, bone marrow, spinal fluid, stool, pleural fluid, and skin lesions</li> <li>C. Imaging studies</li> </ol>
IV.	Absence of drug or transfusion reaction
V.	Lack of response of fever to empiric, adequate antibiotic therapy for at least 7 d
VI.	Prompt, complete resolution of fever by the naproxen test

Adapted from Zell JA and Chang JC.<sup>33</sup>

by infection from that caused by a tumor. In two separate studies, the response to indomethacin and naproxen was associated with a high incidence of tumor-related fever compared with infectious causes.<sup>21,22</sup> Based on these observations, the “naproxen test” (three doses of 375 mg of naproxen at 12-hour intervals) has been proposed for the diagnosis of cancer fever; it should result in complete resolution of pyrexia, and the patient should experience sustained normal temperature while receiving naproxen.

### Fever Caused by Transfusion

Oncology patients, like other transfusion recipients, experience adverse reactions to blood components. Most reactions occur during or shortly after a blood transfusion, but reactions may present several hours to days later. Typically, febrile reactions are benign and rarely lead to serious sequelae, such as death. There are two categories of transfusion reactions: immunologic and nonimmunologic. Hemolytic and nonhemolytic reactions are included in the immunologic category, both of which involve antigen-antibody complex formation. Pseudo-hemolytic transfusion reactions are nonimmunologic reactions, whereby bacterial contamination of the blood product and disease transmission are the cause of fever.<sup>23</sup> Only transfusion reactions that lead to fever are discussed here.

#### Hemolytic Transfusion Reactions

Acute hemolytic transfusion reactions are reactions that result in the destruction of red blood cells and are caused by antigen-antibody interactions. The most common symptoms are fever and chills but also include chest pain, hypotension, nausea, flushing, dyspnea, anuria, and hemoglobinuria. Laboratory testing reveals anemia, elevation of indirect bilirubin, a positive Coombs' test, and decreased haptoglobin levels. Bleeding from disseminated intravascular coagulation, renal failure, and death are the most serious outcomes of hemolytic transfusion reactions. The most common cause of hemolytic transfusion reactions is human error as a result of misidentification of the recipient or of the patient sample, resulting in transfusion of incompatible blood. Other causes are technician failure to identify an antibody in the donor or recipient serum and the presence of antibodies that are not detectable by current testing methods. Therapy for hemolytic transfusion reactions involves stopping the transfusion and measures to maintain blood pressure and perfusion to the kidneys with intravenous fluids.<sup>24</sup> Use of furosemide and “renal dose” dopamine has been described in the literature.

Delayed hemolytic transfusion reactions involve the extravascular clearance of antibody-coated red blood cells by the reticuloendothelial system. The clinical course is benign, but severe

reactions have been reported. These reactions occur in patients previously sensitized to red blood cell alloantigens but with levels too low to detect on screening. Thus, when the patient is reexposed to the antigen, an anamnestic response results in production of alloantibody that binds donor red blood cells. They typically occur 7 to 14 days after the transfusion but may occur earlier, within 2 to 4 days. Fever, jaundice, and hemoglobinuria are common symptoms. Laboratory testing reveals anemia, elevation of indirect bilirubin, and a normal haptoglobin level. When necessary, treatment with general support and transfusion of antigen-negative red cells should be provided.<sup>23,25</sup>

#### Nonhemolytic Reactions that Cause Fever

The febrile nonhemolytic reaction is the most common adverse reaction to blood transfusion and is presumably caused by antibodies (leukoagglutinins) in the recipient that are directed against human leukocyte antibody-specific or leukocyte-specific antigens, or both, on donor blood cells and platelets. It is related to previous exposure to foreign leukocyte antigens; therefore, patients have a history of multiple transfusions or pregnancy. Common symptoms include fever, chills, headache, myalgias, nausea, and nonproductive cough. Less commonly, hypotension, chest pain, vomiting, and dyspnea may occur. Premedication with antipyretics, such as acetaminophen, may minimize mild febrile nonhemolytic reactions. Antihistamines do not prevent or treat febrile nonhemolytic reactions, and corticosteroids can minimize it if they are administered several hours before the transfusion. Leukoreduction of blood components decreases but does not eliminate the frequency of febrile nonhemolytic reactions. Another way to prevent febrile nonhemolytic reactions is to use single donor platelets instead of pooled random donor platelets because the former may contain fewer leukocytes than the latter.<sup>26</sup>

Transfusion-associated graft-versus-host disease (TA-GVHD) is a fulminant and often fatal nonhemolytic reaction caused by the transfusion of viable donor lymphocytes into immunosuppressed patients. The transfused lymphocytes are able to proliferate, engraft, and recognize the recipient's tissue as foreign. Fever usually presents 7 to 10 days after transfusion, and death usually occurs 3 to 4 weeks after transfusion. In addition, depending on the organs involved, skin rash, diarrhea, hepatitis, bone marrow suppression, and infection may occur. The diagnosis is made by demonstrating donor cells in the involved tissue or circulating as peripheral blood chimerism. Irradiation of blood containing lymphocytes is the only effective means to prevent TA-GVHD.<sup>27</sup>

#### Pseudo-hemolytic Transfusion Reactions that Cause Fever

Transfusion of blood contaminated with bacteria, although rare, can be fatal, resulting in shock, disseminated intravascular coagulation, renal failure, and hemoglobinuria. Most commonly, endotoxin-producing gram-negative bacteria are involved. Treatment with antibiotics should be implemented early, and if clinical suspicion is high, the remaining untransfused blood product should be cultured.

The current risk of transmission of viral hepatitis, human immunodeficiency virus (HIV), and human T-lymphotrophic viruses is low. Advances in testing for viral proteins, antibody responses, and, more recently, viral nucleic acids have significantly reduced the risk.

### Fever Caused by Drugs

Drugs used in cancer patients may cause fever. Bleomycin, daunorubicin, cisplatin, asparaginase, cyclophosphamide, cytarabine, vincristine, 5-fluorouracil, and methotrexate are the commonly used chemotherapeutic agents that have been found to elicit fever. Other drugs used in the cancer setting that commonly cause fever are monoclonal antibodies such as rituximab and alemtuzumab, growth factors such as filgrastim and sargramostim, and biologic agents such as IFN and IL-2.<sup>28</sup> Antibiotics such as amphotericin B, trimethoprim-sulfamethoxazole, ciprofloxacin, and rifampicin can also cause fever. Fever usually disappears after discontinuing the offending drug and may be attenuated with the use of acetaminophen, a nonsteroidal anti-inflammatory drug, and steroid premedication. Meperidine is commonly used as a premedication or for treatment of chills associated with drug fever.

More dramatic reactions occur in patients with neuroleptic malignant syndrome, which manifests with hyperthermia. This rare but potentially fatal syndrome is seen in patients receiving neuroleptic drugs. The manifestation is the presence of hyperthermia, and the pathogenesis of this event is related to an idiosyncratic reaction to antipsychotic agents such as piperazine, butyrophenones, and haloperidol. Neuroleptic malignant syndrome should be differentiated from malignant hyperthermia, characterized by a genetic predisposition that may be manifested after the administration of anesthetic agents such as succinylcholine and halothane. Clinical features include marked hyperthermia, muscle rigidity, hypotension, arrhythmias, and disseminated intravascular coagulation.

### Other Causes of Fever

Radiation-induced fever, adrenal crisis, and central nervous system metastasis should be given consideration when evaluating an oncology patient with fever. Central nervous system metastasis may cause fever from hypothalamic

involvement, meningeal leukemia, or meningeal carcinomatosis. Steroid withdrawal and metastasis or primary tumor involvement of the adrenal gland are possible causes of adrenal insufficiency. Primary adrenal non-Hodgkin's lymphoma is a rare and aggressive disease.<sup>29</sup> The most common cancers that cause metastasis to the adrenal glands are lung, esophageal, gastric, and liver or bile duct carcinomas.<sup>30</sup> Fever owing to radiation should be considered in patients receiving radiation alone, after infection has been ruled out. The fever usually presents hours after the initial treatment. In acute radiation pneumonitis, fever may be part of the syndrome, which includes dyspnea and non-productive cough developing 2 to 3 months after radiation therapy.<sup>31</sup>

Other systemic illnesses that cause fever, such as rheumatoid arthritis and lupus erythematosus, may coexist in cancer patients. Careful review of the patient's symptoms and medical history are invaluable for diagnosing these diseases.<sup>31</sup>

Radiologic imaging services provided to patients with cancer go well beyond the diagnosis, staging, and treatment of the cancer(s) the patient may have. In addition to local relationships, proliferation, and metastasis, cancers affect the human body in many ways. Neoplasms may stimulate or elaborate biologically active substances that cause paraneoplastic syndromes. Solid tumors may create local mass effects on adjacent organs. Complications of tumors and therapy are many and include vascular problems, infection, induced necrosis, and organ failure. Imaging methods are often critical for elucidation of the specific clinical problem and provision of an interventional therapy.

The entire spectrum of imaging methods is required to manage accurate diagnosis and characterization of the problem(s) suffered by the patient with cancer. Conventional radiography is best suited to survey the chest, abdomen, and skeleton. Computed tomography (CT) provides detailed anatomic information about the brain, spine, thorax, abdomen, pelvis, and extremities. With the addition of appropriate contrast agents, CT is effective for assessment of the heart and pulmonary vasculature, as well as intra-abdominal organs and vessels. Magnetic resonance imaging (MRI) with or without gadolinium contrast enhancement is preferred for many central nervous system (CNS), cardiac, abdominal, and musculoskeletal soft tissue conditions. Conventional nuclear medicine methods, including single photon emission computed tomography (SPECT), positron emission tomography (PET), and combined CT-PET, are preferred for physiologic and functional imaging tasks. Scintigraphy provides qualitative answers to questions of whether there is normal or abnormal function of the brain, heart, blood elements, viscera, and vasculature. It answers quantitative questions of how well the organ works or how badly the organ

is damaged. Ultrasonography is employed for imaging solid organs, hollow organs, blood vessels, muscles, and masses of any origin. All of these technologies are available to interventional radiologists, who must perform biopsies and drainages and implant various devices within bronchial, ductular, and vascular structures. The partnership of diagnostic and interventional radiologists with internists, surgeons, pathologists, and other clinicians is required to achieve the most specific diagnosis; the most complete characterization of the problem, anatomy, and function; and the best minimally invasive diagnostic or therapeutic procedure for the individual patient. There is no substitute for teamwork based on reasonable knowledge of the expertise contributed by each member of the team.

Contemporary imaging is wholly digital and therefore able to be distributed in a timely fashion to all involved health care providers in a simultaneous manner, permanently and reliably stored and preserved, and easily duplicated into transferable formats for patients and distant providers.

## Paraneoplastic Syndromes

Paraneoplastic syndromes are nonmetastatic clinical syndromes that accompany tumors but occur at a distance from the tumor. These conditions develop as a result of substances produced by the tumor or stimulated by the tumor but produced by other tissues. Fever is the most common clinical manifestation, but many other endocrine, rheumatologic, neurologic, dermatologic, cardiovascular, gastrointestinal, and renal symptom complexes occur. At times, the paraneoplastic syndrome precedes the discovery of the primary tumor, and recognition of the syndrome leads to a search for the tumor. Many times, the syndrome occurs concomitantly with the tumor. Sometimes

decreased or increased activity in the syndrome complex corresponds to changes in the primary or metastatic tumor burden. Although a complete exposition of paraneoplastic syndromes is outside the scope of this chapter, there are many instances in which imaging plays a role in syndrome verification and quantification.

Oncogenic (tumor-induced) osteomalacia is an example of an endocrine paraneoplastic syndrome.<sup>1</sup> Tumors elaborate a phosphaturic peptide that acts at the proximal renal tubule and causes phosphate wasting, with resultant hypophosphatemia. The serum calcium level is generally normal. The condition is usually caused by benign tumors, such as a hemangiopericytoma. The patient presents with debilitating osteomalacia and insufficiency fractures, both of which are evident on conventional radiographs (Figure 1). Recognition that a tumor is the cause and actual localization of the tumor may take many years. CT, MRI, and nuclear medicine tests are effective for tumor detection. Resection of the tumor commonly leads to reversal of the phosphaturic effect and remineralization of the skeleton, with regained muscle strength. Skeletal remineralization can be monitored by conventional bone surveys and by bone mineral mass (densitometry) tests.

Hypertrophic osteoarthropathy (HOA) is an example of a rheumatologic paraneoplastic syndrome manifested by swollen painful joints, clubbing of the fingers and toes, and symmetric periosteal reactions of the long bones and short tubular bones.<sup>2</sup> Humoral and neurogenic mechanisms have been theorized, but no etiologic agent has been proven. HOA occurs with a variety of conditions of the head and neck, thorax, and abdomen, including malignant and benign tumors, infections, and gastrointestinal inflammatory conditions. The most common association is with lung cancer. The HOA symptom complex may precede diagnosis of the cancer and

**FIGURE 1** Oncogenic (tumor-induced) osteomalacia. An 80-year-old man, originally treated for B-cell lymphoma, presented with severe pain and progressively developed multiple insufficiency fractures of the ribs (A, detail from a radionuclide bone scan shows multiple bilateral rib fractures) and severe osteopenia with thoracic kyphosis owing to vertebral insufficiency fractures (B, detail from a lateral chest radiograph shows demineralized vertebral bodies with wedge deformities). Hypophosphatemic osteomalacia was diagnosed. Four years later, a rib lesion was detected (C, detail from a rib series shows a lytic, expansile lesion in the left tenth rib [arrows]) and shown to be a tumor by magnetic resonance imaging (D, detail from an axial section with contrast enhancement shows a soft tissue tumor [arrow]). After resection of a hemangiopericytoma, the skeleton remineralized, the rib fractures healed, and the pain abated.

be responsible for the search for the cancer. Clinical and radiologic manifestations vary from barely perceptible to severe. Hand involvement may seem like an intense flair of rheumatoid arthritis, with conventional films showing dramatic periarticular osteopenia in addition to thick immature periostitis (Figure 2). Radionuclide scintigraphy may show periostitis of all long bones and confirm generalized synovial joint inflammation. CT and MRI are used to detect and characterize the responsible malignant process in the head and neck, thorax, or abdomen. Sometimes resection of the primary tumor leads to total resolution of the HOA.

Paraneoplastic neurologic disease (PND) refers to central or peripheral nervous system syndromes that result from indirect effects of systemic cancer on the nervous system.<sup>3</sup> These syndromes can precede the detection of the primary cancer, and in the absence of any other cancer symptoms, the neurologic disability caused by the paraneoplastic syndrome is often profound. Treating the primary cancer can improve the

neurologic symptoms. The incidence of PND is less than 1% of patients with systemic cancer; higher incidences are reported when peripheral nerve and neuromuscular disorders are included. The first description, a peripheral neuropathy in a lung cancer patient, by Oppenheimer in 1888 was followed by descriptions of other PND syndromes: myasthenia gravis in association with thymic tumor, sensory neuropathy with lung cancer, subacute cerebellar degeneration associated with ovarian carcinoma and small cell lung carcinoma, myasthenic syndrome with small cell lung carcinoma, and cancer-associated retinopathy. The diagnosis of PND by neurologists is based primarily on the clinical presentation and

**FIGURE 2** Hypertrophic osteoarthropathy. A 20-year-old man with lower extremity osteosarcoma metastatic to the lungs, mediastinum, and pericardium presented with arthritis. Posteroanterior radiograph of the right hand shows thick periostitis (arrows) and periarticular osteopenia.

lack of an alternative diagnosis. MRI is the imaging modality of choice for detection of pathologic processes within the brain and hence is used to detect abnormalities within the brain related to PND. Unfortunately, MRI-detectable brain and spinal cord alterations exist in only a few paraneoplastic neurologic conditions. These include paraneoplastic cerebellar degeneration, limbic encephalitis, brainstem encephalitis, and optic neuritis. PND-related spinal cord lesions detected by MRI include myelitis and necrotizing myelopathy. The discovery of serum autoantibodies that reacted with neurons offered initial insight to the pathogenesis of PND. Several PND autoantibodies and their associated antigens have been characterized.

Paraneoplastic cerebellar degeneration (PCD) was described in 1919. Serum anti-Purkinje cell antibody (anti-Yo) occurs with PCD in women in association with gynecologic malignancies, most commonly adenocarcinoma of the ovary, adnexa, endometrium, and breast. Anti-Yo is a polyclonal immunoglobulin G autoantibody that reacts primarily with Purkinje cell cytoplasm. Patients with Hodgkin's and non-Hodgkin's lymphoma may develop this syndrome but are negative for anti-Purkinje cell antibodies. Most males with PCD have either small cell lung carcinoma or lymphoma. Patients with small cell lung carcinoma or breast cancer may have anti-Hu antibodies. Patients can develop neurologic symptoms before or at the time of discovery of the neoplasm or during remission. Signs and symptoms include gait ataxia, nystagmus, dysarthria, and tremors. Pathologic findings include atrophy of the cerebellum secondary to loss of cerebellar Purkinje neurons and thinning of the granular neuronal layer. MRI can be normal in initial stages of the disease, but when cerebellar atrophy is prominent, MRI can easily detect the extent of vermian or cerebellar atrophy and resultant dilatation of cerebellar sulci.

Limbic encephalitis symptoms precede the discovery of tumor in more than half of patients. Associated tumor types are lung, testicular, and breast. Most patients have antineuronal antibodies: anti-Hu, anti-Ma, or anti-Ma2. Signs and symptoms of limbic encephalitis include personality changes that develop over days or weeks and are associated with severe impairment of recent memory, agitation, confusion, hallucinations, and seizures. Pathologic changes are usually restricted to the limbic and insular cortices, but deep gray matter and surrounding white matter may also be involved. Histologic findings include extensive loss of neurons with reactive gliosis, perivascular lymphocytic cuffing, and microglial proliferation. MRI can detect abnormal findings in one or both temporal lobes, particularly involving the region of the hippocampus and insular cortex. Imaging findings consist of abnormal

hyperintensity on T<sub>2</sub>-weighted sequences with or without abnormal enhancement following administration of a contrast agent.

Brainstem encephalitis can result in loss of cranial nerve function, with resultant diplopia, dysphagia, dysarthria, nystagmus, vertigo, and hearing loss. This condition is usually part of an encephalomyelitis or may present as an isolated finding. Patients with brainstem encephalitis usually have anti-Hu antibodies and small cell lung carcinoma. Pathologic findings include perivascular cuffing of lymphocytes and diffuse proliferation of microglial cells in the lower brainstem, particularly involving the inferior olives of the medulla. MRI can reveal generalized swelling of the brainstem with decreased signal on T<sub>1</sub>-weighted images and increased signal on T<sub>2</sub>-weighted images.

Myelitis, as a paraneoplastic lesion, is usually associated with a diffuse encephalomyelitis pattern. Paraneoplastic myelitis is most common with small cell lung carcinoma and is associated with anti-Hu antibody. Patients present with progressive weakness, lower motoneuron signs including fasciculations, sensory loss, and incontinence. Pathologic findings include inflammatory cells, demyelination, and neuronal loss. MRIs of the spinal cord can demonstrate the abnormality within the spinal cord with low signal intensity on T<sub>1</sub>-weighted images and increased signal intensity on T<sub>2</sub>-weighted images with or without contrast enhancement.

Gastrointestinal and genitourinary paraneoplastic syndromes are infrequently encountered by radiologists.<sup>4,5</sup> Excess prostaglandin production may produce malabsorption syndromes that are evaluated by conventional barium examinations or by abdominal CT. They have the non-specific findings of sprue. Fever not associated with infection can occur in patients with hepatic metastases from gastrointestinal adenocarcinomas. Hepatomas have been associated with hypercalcemia, hypoglycemia, erythrocytosis, hypertension, and porphyria. Hypercalcemia as a paraneoplastic syndrome in gallbladder carcinoma has been reported. Nephrotic syndrome is sometimes encountered with lymphomas and solid tumors of the lung, colon, ovary, or pancreas. When nephrotic syndrome is considered, ultrasonography, CT, and nuclear medicine tests are employed as appropriate to the individual clinical situation. Rarely, paraneoplastic syndromes mimic pregnancy. Ultrasonography is particularly valuable to rule out intrauterine or ectopic pregnancy.

Pancreatic paraneoplastic syndromes are well known. Multiple syndromes are associated with the pancreas. Islet cell tumors can lead to hypoglycemia (insulinoma), Zollinger-Ellison syndrome (gastrinomas), glucagonomas, pancreatic cholera (Verner-Morrison syndrome), hypercalcemia, ectopic adrenocorticotropic

hormone syndrome, syndrome of inappropriate antidiuretic hormone, hyperpigmentation, and systemic nodular panniculitis. Pancreatic cancer is also associated with migratory superficial thrombophlebitis (Trousseau's syndrome). The pancreas is initially imaged by ultrasonography, although the tail of the pancreas is not seen in a significant number of patients. Color Doppler evaluation can be used to assess the adjacent vasculature. Thin-slice multidetector CT scans with dedicated pancreatic protocols provide the best detail of the pancreas, adjacent and regional vasculature, and other solid and hollow viscera in the abdomen. MRI, magnetic resonance cholangiopancreatography, angiography, and nuclear medicine scintigraphy can also be used in the evaluation of pancreatic disease based on the clinical situation.

### Direct Medical Complications of the Cancer

Clinicians and radiologists often encounter problems directly caused by the cancer that require accurate diagnosis, detailed characterization, and appropriate treatment for relief of the symptoms they cause. The local effect of a tumor mass on an adjacent structure is a prime example.

Superior vena cava syndrome (SVCS) is caused by obstruction of the superior vena cava (SVC) and/or brachiocephalic veins and can present with facial and arm swelling, chest pain, cough, proptosis, hoarseness, stridor, dyspnea, cyanosis, and symptoms of increased intracranial pressure, such as somnolence, syncope, convulsions, and visual disturbance. SVCS usually presents with slowly progressive symptoms but can present with an abrupt onset, constituting a true medical emergency. More than 80% of the cases result from malignant etiologies, with bronchogenic carcinoma, lymphoma, and metastatic carcinoma being the most common.<sup>6</sup>

In the most typical presentation of SVCS, the appearance of a large mediastinal mass at conventional chest radiography is usually adequate for the diagnosis of neoplastic obstruction, although infectious masses can also cause obstruction. Smaller masses or masses high in the thoracic inlet may not be visible by conventional radiography and require contrast-enhanced chest CT for adequate evaluation. Patients with radiographically obvious masses may also require CT for radiation therapy planning to relieve the obstruction. In the absence of a mass, SVC stenosis may cause the syndrome and be related to previous radiation therapy or thrombosis from long-term central venous catheter placement.<sup>7</sup> CT can provide excellent delineation of any mediastinal mass or vascular stenosis.

Although medical therapy with elevation of the affected extremities and head, along with

anticoagulation, corticosteroids, and diuretics, may temporize the condition, short- and long-term results are poor. In SVCS caused by malignancy, radiotherapy and/or chemotherapy are considered the current standard for treatment, with resolution rates up to 90%; however, regression of symptoms occurs slowly (2–4 weeks) and may be incomplete. Symptoms recur in 10 to 30% of the patients. Moreover, response rates are highly dependent on tumor histology and radio- or chemosensitivity. Surgical bypass of the obstructed SVC is associated with a high rate of morbidity and mortality and often fails because of thrombosis of the graft.

Imaging-guided percutaneous endovascular techniques, such as transluminal angioplasty, thrombolysis, and stent implantation, used alone or in combination, have shown excellent short-term and midterm success in patients with SVCS secondary to malignancy.<sup>8</sup> Generally, percutaneous techniques have been used after failure of radiotherapy and/or chemotherapy. However, with the refinement of endovascular techniques, percutaneous stenting of the SVC is increasingly used as the primary treatment modality. Balloon angioplasty is used to assist stent deployment; although balloon angioplasty alone can cause immediate improvement in symptoms, short- and long-term vessel patency is poor. Intravascular metallic stent implantation provides significant resolution of symptoms in 70 to 100% of patients. In the majority of cases, a subjective improvement is noticed after a few hours and the soft tissue edema disappears in 24 to 72 hours. In patients with SVCS associated with acute thrombosis, local thrombolytic treatment by direct administration of fibrinolytic substances via an infusion catheter improves the results of stenting. Mechanical thrombectomy devices may be used to remove the thrombus in patients with significant clot burden or in patients who may not receive thrombolysis safely. Complications resulting from thrombolytic treatment or stent placement are infrequent. Stent migration, prosthesis breakage, cardiac arrhythmias, transient phrenic nerve paralysis, and bleeding have been reported.

Symptoms of SVCS recur in 4 to 45% of treated patients and are usually secondary to tumor ingrowth, extrinsic tumor compression, or thrombus formation. Recurrent obstruction can be treated with anticoagulation, angioplasty of the stented area, or repeat stenting. A covered stent may be used to retard tumor ingrowth; however, its efficacy is unproven.

Intrinsic venous stenosis secondary to venous thrombosis or thrombophlebitis owing to long-term central venous catheter placement for chemotherapy is usually asymmetric because the location of the stenosis typically develops before the confluence of brachiocephalic veins.<sup>9</sup> CT and digital venography are diagnostic tests. When the

upper extremity edema is asymmetric, it is important that contrast media be administered through the edematous extremity. If central venous thrombosis is suspected, bilateral arm injection of contrast media can be performed.<sup>10</sup> Venous stenosis caused by long-term catheter placement or radiation therapy typically demonstrates a long segment of venous stenosis or complete obliteration of the involved vein, with no appreciable soft tissue mass. By comparison, thrombosis presents a well-defined filling defect within the vein and thrombophlebitis as a mildly enhancing, poorly defined tubular mass along the expected course of the vein (Figure 3). Flow artifacts from incomplete mixing of the contrast agent with the intravascular blood must be differentiated from true filling defects within the venous system. The continued presence of a central venous catheter can simulate contrast passing through a residual lumen of the occluded vessel, but the presence of extensive collateral venous drainage will confirm the severity of the stenosis. Anticoagulation or thrombolytic therapy is the usual treatment strategy.

Inferior vena cava (IVC) obstruction secondary to primary or secondary liver malignancies or other abdominal tumors presents with debilitating features such as leg edema, scrotal or vulvar edema, venous stasis ulceration, ascites, and anasarca below the diaphragm. CT and MRI are effective for the diagnosis and staging of this complication. Endovascular stent placement can be used to palliate symptoms related to malignant

**FIGURE 3** Subclavian vein thrombophlebitis. A 22-year-old woman with osteosarcoma had a right central venous catheter removed for infection. Computed tomography of the chest at the thoracic inlet demonstrates a poorly defined tubular mass (arrows) in the course of the right subclavian vein behind the right medial clavicular head (C). Note abundant collateral vein enhancement (arrowheads).

IVC obstruction. In a study involving 50 consecutive patients with malignant IVC syndrome who were treated with intrahepatic stent placement, Broutzos and colleagues reported primary and secondary patency rates of 59 and 100%, respectively, at 540 days.<sup>11</sup> All symptoms related to IVC obstruction were significantly improved after stent placement and, with the exception of ascites, remained significantly improved until the last follow-up. Even patients with a very short life expectancy benefited significantly from palliative stent placement.

Dysphagia owing to esophageal stricture in patients with inoperable primary or secondary esophageal malignancies is safely and effectively treated by fluoroscopic placement of self-expandable metal stents, such as the Gianturco Z stent, Wallstent, and Ultraflex stent. These stents successfully relieve esophageal obstruction and yield rapid relief of dysphagia and improved quality of life.<sup>12</sup> Esophageal stents can be inserted endoscopically without fluoroscopic guidance. However, use of fluoroscopic guidance and catheter guidewire technology is essential for crossing tight esophageal stenoses and for accurately positioning the metallic stents. Interventional radiologists are in the ideal position to perform these procedures safely and relatively easily. Stents should never be placed across the superior esophageal sphincter (C5–C6 level), and crossing the gastroesophageal junction with the stent should be avoided if possible. Covered stents appear to be efficacious for sealing malignant esophagorespiratory fistulae.

Other contemporary methods used for palliation of malignant esophageal strictures, such as surgical bypass, laser ablation, radiation therapy, and endoscopic alcohol injection, are associated with substantial morbidity and mortality. Although the complication rate of metallic stent placement is less than that of other palliative methods, complications such as chest pain, stent migration (0–35%), tumor ingrowth or overgrowth (5–50%), hemorrhage (0–10%), perforation or fistulization (0–8%), and food impaction (6%) have been reported.

Bowel obstruction or perforation is first evaluated with a conventional abdominal or obstructive series, although the imaging modality of choice is often a CT scan of the abdomen and pelvis with use of gastrointestinal and intravenous contrast (Figure 4). A CT scan gives a global view of the gastrointestinal tract and the solid viscera, vasculature, and lung bases. Ascites and suspected appendicitis can be evaluated by ultrasonography. A CT scan is a better study in difficult patients and can image the rest of the hollow organs and solid viscera for disease processes mimicking appendicitis.

Gastric outlet and duodenal obstructions in patients with primary or metastatic cancer are

**FIGURE 4** Small bowel perforation. Contrast-enhanced axial computed tomographic image of the upper abdomen shows free fluid and gas (\*) secondary to the perforation. Wisps of extravasated gastrointestinal contrast agent are evident (arrows).

serious conditions causing nausea, vomiting, and abdominal distention that can lead to progressive deterioration in the patient's condition and quality of life. Surgical palliation may be associated with significant morbidity and mortality, with symptomatic improvement in only half of the cases. Laparoscopic gastroenterostomy can provide successful palliation with less morbidity and mortality; however, it still requires general anesthesia and may not be feasible in patients with ascites and/or peritoneal malignant disease. Fluoroscopically guided placement of a gastrostomy tube by an interventional radiologist is a simple, minimally invasive method for symptom palliation in patients with malignant gastroduodenal obstruction. Alternatively, a dual-lumen gastrojejunostomy catheter can be placed; the gastric (proximal) port provides drainage, and the jejunal (distal) port provides a conduit for alimentation. In spite of their effectiveness, these measures do not allow oral intake and the nausea and vomiting are not always resolved.

Self-expanding metal stents are increasingly placed for symptom palliation in patients with inoperable malignant gastroduodenal obstructions.<sup>13</sup> Both uncovered and covered metal stents have been used for this purpose, and both provide effective palliation. A metallic stent allows the patient to eat and improves quality of life. Recurrent obstruction secondary to tumor ingrowth through the openings between the wire filaments of uncovered stents remains a major problem; recurrent stenosis rates of 8 to 46% have been reported. The use of a covered stent decreases the rate of recurrent obstruction by preventing tumor ingrowth. However, because of the smooth surface of the stent covering, there is an increased risk of stent migration, seen in up to 26% of patients 1 to 4 days after placement. Further investigations are still needed to develop an ideal stent design that combines the advantages of

covered (low tumor ingrowth rate) and uncovered (low migration rate) stents. Recently, Lopera and colleagues described the use of a partially covered stent to overcome these limitations; a central covered portion prevents tumor ingrowth, and uncovered flared ends anchor the stent to the bowel mucosa to prevent migration.<sup>14</sup> Another technique involves placement of coaxial placement of an outer uncovered stent and an inner covered stent. Although initial results are promising, a larger group of patients is necessary to determine the effectiveness of these new techniques.

Biliary obstruction frequently complicates primary or secondary abdominal malignancy. Complications associated with obstructive jaundice, such as malabsorption, coagulopathy, hepatocellular dysfunction, disabling pruritus, and cholangitis, greatly interfere with a patient's quality of life. Endoscopic or percutaneous insertion of a biliary stent is a well-established method for palliation of inoperable malignant obstructive jaundice.<sup>15,16</sup> Although endoscopic placement of biliary stents is the preferred method for most biliary obstructions, percutaneous biliary drainage is used in situations when the endoscopic approach fails or when gastric outlet obstruction or partial gastrectomy makes endoscopic placement difficult or impossible. The percutaneous transhepatic approach is also preferred in patients with high obstructions and bilateral or multiple strictures.

Percutaneous biliary drainage can be of three types: external, combined external-internal, or internal (Figure 5). An external drainage catheter ends proximal to the obstruction, and the bile

drains into an external bag. An internal-external catheter extends across the level of obstruction, with the distal tip of the catheter in the duodenum and multiple side holes along the catheter shaft allowing internal drainage. Internal biliary drainage can be accomplished with the use of plastic or metal stents. Self-expanding metallic stents are associated with reduced reintervention rates, lower complication rates, and longer patency rates compared with plastic stents. Long-term patency remains an important problem with uncovered metal stents. Reobstruction rates varying from 5 to 100%, with a weighted mean of 22%. Proximal and distal tumor overgrowth, tumor ingrowth through the wire mesh, and encrustation and sludge formation are common causes of stent occlusion. Several investigators have described use of covered stents in an effort to improve the patency rates. Various prototype covered stents have been used for treatment of malignant biliary obstruction.<sup>17</sup> However, their occlusion rates remain high, varying from 0 to 37%, with a weighted mean of 14.7%. Also, fully or partially covered stents are prone to migration (3–11% of cases); use of anchoring fins at each end of the stent can reduce the risk of migration.

Ureteral obstruction is common in advanced pelvic malignancy, occurs with metastatic disease from nonpelvic malignancy, and may be related to iatrogenic causes, such as surgery and radiation. Ultrasonography is the study of choice to evaluate hydronephrosis, not only for obstruction but also to assess renal echogenicity, location, number, shape, size, calculi, and masses and with color Doppler evaluation to determine the status of the renal vasculature. Some tiny calculi

**FIGURE 5** Biliary drainage. A 71-year-old man with inoperable pancreatic head carcinoma and hilar adenopathy presented with biliary obstruction. A, A spot abdominal radiograph shows percutaneously placed external biliary drainage catheters (short arrows) and internal metal stents in the right and left bile ducts (long arrows) and in the common duct. Note the presence of a duodenal stent (arrowheads), which was placed for duodenal obstruction. B, Contrast administration through the left and right external biliary drainage catheters shows adequate drainage through the biliary and duodenal stents and into the duodenum.

may not be seen by ultrasonography, especially in large patients. The full length of the ureters may not be completely visualized even though a distal obstruction with hydroureter(s) may be present. Dedicated CT urography, which does not require intravenous contrast, is available to evaluate renal colic. Routine CT scans can also evaluate hydronephrosis, masses, and disease within the abdomen and pelvis that can mimic renal colic. CT scans can also help identify the etiology and location of obstruction or source of hematuria. MRI can evaluate the kidneys especially when the patient is in renal failure or is allergic to iodinated intravenous contrast agents. The kidneys and collecting systems can also be evaluated using conventional radiography, intravenous urography, and scintigraphy.

Percutaneous nephrostomy (PCN) is a well-established safe and effective technique for the management of urinary obstruction.<sup>18</sup> In these patients, urinary diversion with PCN helps preserve renal function and allows institution of appropriate anticancer treatment. It is particularly important in patients whose therapeutic regimens will include agents that depend on renal excretion and are potentially nephrotoxic.

Many cancer patients presenting with ureteral obstruction may expect a reasonably good quality of life, and intervention is often warranted. However, the quality of life after palliative urinary diversion must be carefully examined. Patients who present with bilateral obstruction and uremia have a poor performance status and short life expectancy after ureteral decompression if their disease remains untreated. Many authors believe that nephrostomy is of little use in patients with advanced disease if no effective salvage therapy is available. Hence, selection of cancer patients for nephrostomy should take factors such as the stage of cancer, prognosis of primary cancer, prospects of further antineoplastic treatment, and quality of life into consideration before the PCN is created.

Major or minor complications may be seen in 10% of patients who undergo a PCN procedure.<sup>18</sup> Although transient hematuria is common, major hemorrhagic complications that require transfusion or intervention occur in only 1 to 3% of patients. Hydrothorax, hemothorax, and pneumothorax can also occur, and their prevalence increases when renal access is supracostal. The mortality rate for PCN is low (0.046–0.3%). Although initial PCN has a high technical success rate, long-term management of nephrostomy catheters is cumbersome and the presence of an external drainage bag and the need for daily catheter care substantially compromise the patient's quality of life. Also, frequent catheter revisions may be required.

Internal ureteral stenting is an alternative to external nephrostomy catheterization for provision of long-term urinary drainage.<sup>19</sup> Internal stents can be placed from either a retrograde

approach via the bladder by cystoscopy or from the antegrade approach through the kidney following percutaneous access. Internal ureteral stents eliminate the need for external collection devices and improve patient independence. Internal stents need to be exchanged every 6 months; this is in contrast to external nephrostomy tubes, which often require exchange at 3-month intervals. Double-J plastic stents are the most commonly used ureteral stents. Metal stents have also been used in the treatment of malignant ureteral obstructions, with encouraging initial results. However, mid- and long-term outcomes are poor, with a primary patency rate of only 31% at 12 months. Newer stents with a biocompatible covering (stent grafts) may improve patency rates of metal stents.

Pleural effusions are a common consequence of pleural tumor or may result from therapy.<sup>20</sup> Large pleural effusions can cause significant respiratory impairment. Pleural effusion can typically be demonstrated with conventional radiography. For moderate-size effusions, lateral decubitus views may be helpful to demonstrate free flow or layering as distinct from loculation of the effusion. Contralateral decubitus views are helpful in distinguishing between compressive atelectasis and pulmonary consolidation that may be associated with the effusion. For very large effusions, decubitus views are unlikely to add much additional information. If the hemithorax is completely opacified, then CT or ultrasonography is useful in distinguishing effusion from the mass and to direct appropriate drainage therapy. Talc pleurodesis performed to treat chronic pleural effusion can result in abnormal uptake on fluorodeoxyglucose PET. Correlation with CT should allow this uptake to be differentiated from pleural tumor.<sup>21</sup>

Almost half of patients with disseminated cancer develop symptomatic malignant pleural effusion (MPE) during the course of their disease. The most common causative neoplasms are lung cancer, breast cancer, lymphoma, ovarian cancer, and gastric cancer. These patients face a dismal prognosis, with a median survival time of less than 6 to 12 months. MPEs are associated with significant morbidity because of resultant dyspnea, cough, chest discomfort, and diminished quality of life. Repeated thoracentesis can be used for management of MPE; however, it is uncomfortable, carries a 10% risk of pneumothorax, can contaminate the pleural space, and may provide only temporary symptom relief. Although thoracentesis can be performed in the clinic, image guidance may be necessary in patients with loculated fluid or when pleural tumors coexist with the effusion. The use of repeated thoracentesis is typically limited to symptomatic patients with an effusion expected to respond to systemic therapy or for patients with a very limited life expectancy.

Tube thoracostomy followed by chemical pleurodesis is the standard treatment for MPE. Although large surgical chest tubes traditionally are used for this purpose, smaller-caliber tubes placed by interventional radiologists are equally effective.<sup>22</sup> Generally, a 12F or 14F tube is placed under image guidance, and a sclerosing agent is administered when outputs drop to less than 150 to 300 mL/d and when chest imaging shows drainage of the fluid and reexpansion of the lung. The most commonly used sclerosing agents are tetracycline, doxycycline, bleomycin, and talc. Randomized trials have shown no significant differences among various agents.

Chemical pleurodesis may not be effective in patients with (1) persistent high-output effusion that prevents adequate apposition of the pleural layers; (2) the presence of a trapped lung from a pleural peel, endobronchial obstruction, or parenchymal lung disease; or (3) viscous or loculated fluid interfering with drainage. Administration of fibrinolytic agents through the catheter can be used to liquify viscous or loculated fluid. The major drawbacks of chemical pleurodesis are the need for 4 to 7 days of hospitalization, the presence of pain and discomfort associated with the procedure, and the occasional development of multiloculated fluid collections following treatment.

Recently, the use of an indwelling tunneled pleural catheter has been accepted as an effective alternative to chemical pleurodesis in managing MPE.<sup>23</sup> The Denver Pleurx catheter (Denver Biomaterials, Inc., Golden, CO) is a 15.5F soft silicone catheter with multiple distal side holes to enhance drainage, a polyester cuff along the proximal shaft to promote fibrosis in the subcutaneous tunnel, and a valve in its hub that prevents inadvertent entry of air or leakage of fluid. The drainage system consists of a vacuum bottle with a preconnected tube that has a dilator at its end to fit into the hub of the catheter. The system is commonly used in the outpatient setting by a visiting nurse, family members, or the patient. Drainage is performed at least every other day but can be done more frequently if necessary. This treatment achieves safe, long-term, outpatient control of MPE and related symptoms in 80 to 90% of patients. Also, the presence of the tube and intermittent complete aspiration of the fluid can cause pleurodesis in up to 50% of patients. Administration of a sclerosing agent through the tube may enhance the pleurodesis rates. Complications are uncommon but include sequestration of the catheter from the effusion caused by formation of a fibrotic sleeve, catheter occlusion, development of separate loculations, infection, and catheter fracture during removal.

Pericardial effusions owing to tumor or therapy are frequent. Cardiac tamponade is an

uncommon complication of tumor involvement.<sup>24</sup> The relatively slow accumulation of pericardial fluid usually allows the pericardium to enlarge to accommodate the volume. Although conventional radiography may show cardiac silhouette enlargement, echocardiography or CT is needed to accurately distinguish effusion from cardiomegaly and may also demonstrate right atrial and right ventricular collapse resulting from tamponade (Figure 6).

Hemorrhage, occasionally life threatening, is a common problem in oncology patients that may be related to the tumor itself or may be encountered as a complication of thrombocytopenia, surgery, or radiotherapy. Technetium 99m (Tc 99m)-labeled sulfur colloid can localize the hemorrhage, with bleeding rates as low as 0.1 mL per minute.<sup>25</sup> However, because of the prompt trapping of the sulfur colloid by the reticuloendothelial system from the general circulation, Tc 99m sulfur colloid can detect active bleeding only during the first few minutes after injection. For more prolonged periods (several hours) of detection, Tc 99m-labeled red blood cells are preferred because they remain in the blood pool much longer. However, because of the high background circulating radioactivity, Tc 99m red blood cells detect bleeding that occurs only at rates above 1 mL per minute (Figure 7).<sup>26</sup> Angiographic methods may also be used to detect bleeding sites, particularly when interventional procedures are selected to control the hemorrhage.

**FIGURE 6** Malignant pericardial effusion. A 69-year-old man with lung cancer developed fatigue and dyspnea. Computed tomography of the chest at the level of the right atrium (RA) and right ventricle (RV) demonstrates low-attenuation pericardial thickening with enhancement of the parietal pericardium (arrowheads). A partly loculated portion of the effusion (\*) is compressing the right ventricle. A pericardial window was performed to relieve the compression.

**FIGURE 7** Red blood cell scan for gastrointestinal bleeding. A patient with bright red blood per rectum underwent a gastrointestinal bleeding scan using 20 mCi technetium 99m-labeled red blood cells. The scintigraphs were 1 minute apart, and abnormal focal tracer activity accumulated in the left upper quadrant. The activity subsequently localized in the small bowel (arrow).

Intra-arterial administration of embolic agents to induce vascular occlusion is a well-established technique used to arrest hemorrhage. Numerous devices or materials have been used as embolic agents. The choice of the embolic agent for a given case depends on the nature of the bleeding, the desired level and duration of occlusion, the availability of the particular agent, and the experience and preference of the interventional radiologist.

Pelvic bleeding from gynecologic and urologic tumors can present as chronic, intractable bleeding or occasionally as massive and potentially life-threatening hemorrhage. Although surgical ligation of internal iliac arteries has been used for management of pelvic bleeding, surgery may not be appropriate in many patients either because of the poor general condition of the patient or because of deformed, friable pelvic tissues owing to radiotherapy, previous surgery, or tumor recurrence. Percutaneous transcatheter arterial embolization of the anterior division of internal iliac artery results in complete control of bleeding in about 70% of pelvic malignancies.<sup>27</sup>

Endovascular techniques can also be used to manage iatrogenic pelvic bleeding. Hemorrhagic cystitis resulting from chemotherapy or following radiotherapy can present with intractable hematuria. Although simple bladder irrigation; cystodiathermy; oral, parenteral, and intravesical agents; hyperbaric oxygen therapy; or urinary

diversion can help control the bleeding in a majority of patients, bilateral internal iliac embolization has also been successful. Arterioureteral fistulae are uncommon causes of potentially life-threatening hemorrhage and can be seen after pelvic surgery for malignancy, often in association with irradiation and chronic indwelling ureteral stenting. Percutaneous embolization of the iliac artery followed by extra-anatomic arterial bypass has been successfully used to manage these cases. More recently, covered stents have been used to close the fistula while maintaining antegrade flow through the iliac artery.<sup>28</sup>

Head and neck hemorrhage in patients with head and neck cancer can be difficult to control because of postsurgical changes, fistulae, infection, radiation necrosis, or recurrent tumor. In these patients, hemorrhage usually results from erosion of vessels. Conventional noninvasive measures such as nasal packing and balloon tamponade often fail. Transcatheter arterial embolization is a safe and effective alternative treatment of severe epistaxis.<sup>29</sup> Diagnostic internal and external carotid artery angiography is performed to detect the source of bleeding and any possible anastomoses between the two arterial systems that might present a risk of embolization of non-target tissues. Superselective catheterization and embolization are then performed.

Rupture of the extracranial carotid arteries, the so-called carotid blowout, often results in catastrophic hemorrhage. Predisposing factors include radiation therapy, radical resection, flap necrosis, wound infection, pharyngocutaneous fistula, and recurrent or persistent carcinoma. Emergency surgical ligation of the common or internal carotid artery is associated with unacceptable rates of death and stroke. Endovascular occlusion with detachable balloons or coils after a balloon occlusion test to assess cross-circulation yields improved outcome; however, recurrent bleeding and delayed neurologic ischemic events may occur. More recently, covered stents have been used to exclude carotid pseudoaneurysms with parent vessel preservation.

Hemoptysis with bronchogenic carcinoma, pulmonary metastases, and postradiation bronchiectasis can be massive and recurrent. Conservative management of massive hemoptysis has a mortality of 50 to 100%, asphyxiation being the most common cause of death. Because of poor pulmonary reserve and other comorbid conditions, most cancer patients with massive hemoptysis are not surgical candidates. Transcatheter arterial embolization results in control of bleeding in 51 to 85% of patients, but recurrent bleeding requiring repeat embolization is seen in 16% of cases.<sup>30</sup> Major complications such as spinal cord injury related to invisible anastomotic connections between the bronchial circulation and the anterior spinal artery, transient thoracic pain,

and bronchial, esophageal, pulmonary arterial, or aortic wall necrosis are rare.

Gastrointestinal hemorrhage can result from primary bowel neoplasms, direct invasion by adjacent tumors, or bowel metastases. Transcatheter arterial embolization can successfully control malignancy-related gastrointestinal hemorrhage in patients with inoperable cancer or to stabilize the patient prior to definitive surgery. Pseudoaneurysms involving the gastroduodenal artery or pancreaticoduodenal arteries can develop as a complication of pancreaticoduodenectomy for pancreatic cancer and can present with gastrointestinal bleeding. Transcatheter superselective arterial embolization is the preferred technique for control of bleeding in these patients.

### Indirect Medical Complications of the Cancer

Pulmonary embolism (PE) remains a diagnostic challenge because it is often occult and because the results from physical examination, laboratory, and most radiologic tests are commonly nonspecific. The imaging evaluation of dyspnea, the most common presenting symptom, typically begins with a conventional chest radiograph. A number of radiographic signs have been associated with PE. These include a peripherally based, wedge-shaped pulmonary opacity known as a Hampton hump, decreased blood flow in the lung affected by PE known as Westermark's sign, and enlargement of the central pulmonary artery known as Fleischner's sign.<sup>31</sup> However, these signs are infrequently encountered and are neither sensitive nor specific for PE. In fact, the most common radiographic findings of PE include a normal-appearing chest radiograph or nonspecific pulmonary consolidation and pleural effusion.<sup>32</sup>

The traditional imaging test for a more sensitive and specific diagnosis of PE is ventilation-perfusion scintigraphy, which can be effective when there are no significant pulmonary abnormalities demonstrated by chest radiography. Ventilation-perfusion scanning effectively identifies patients with a very high or very low probability of PE, and this determination is sufficient for therapeutic management. However, many patients have intermediate or indeterminate-probability nuclear scans for PE and thus require further evaluation. Conventional pulmonary angiography emerged as the definitive imaging test in cases of indeterminate probability. However, its invasive nature, limited availability, and perceived risks discouraged its use.

More recently, CT pulmonary angiography has matured as a method to image PE (Figure 8).<sup>33</sup> Contemporary CT scanners allow rapid acquisition of thinly collimated images and provide a high-resolution direct assessment of the

**FIGURE 8** Pulmonary embolus by computed tomography (CT). A 73-year-old man with colon cancer developed pleuritic chest pain and a swollen left lower extremity. CT of the chest at the level of the main pulmonary artery (PA) demonstrates pulmonary emboli in the right pulmonary artery and branches of the left pulmonary artery (arrows). Notice how the emboli extend across the bifurcation of the right pulmonary artery and lie centrally in the left pulmonary artery branches.

pulmonary arterial tree. The accuracy of CT angiography has been validated through the demonstration of its negative predictive value. Several studies have shown absence of significant risk for future PE events in patients with a negative CT pulmonary angiographic study.<sup>34–36</sup> Because of its wide availability and confidence in its interpretation, CT pulmonary angiography has largely displaced other methods to detect pulmonary emboli. Additionally, CT pulmonary angiography provides prognostic information for those patients in whom PE is confirmed.<sup>37</sup> Evidence of right ventricular strain, including bowing of the septum toward the left ventricle and an increase in the right ventricle to left ventricle diameter ratio, is predictive of the need for intensive care unit admission.<sup>38</sup> An important feature of CT angiography is its ability to show features that indicate alternative diagnoses in the absence of PE. CT can identify independent causes of dyspnea, including atelectasis, pneumonia, effusion, pneumothorax, and other cardiovascular abnormalities.

The utility of CT pulmonary angiography can be enhanced with preexamination use of a D-dimer assay to exclude patients without evidence of intravascular thrombosis. This strategy reduces the number of negative examinations and prevents unnecessary radiation exposure.<sup>39</sup> However, because of its low specificity, a positive D-dimer assay alone is not justification for performing CT pulmonary angiography.

PE is estimated to result in 150,000 deaths per year in the United States. Standard management consists of anticoagulation with heparin and warfarin to prevent recurrence of PE; however, the 3-month mortality rate still ranges from 10 to 17.5%.<sup>40</sup> Also, anticoagulation alone may constitute sufficient therapy for massive PE. Systemic thrombolytic therapy and interventional procedures, including catheter-directed thrombolysis, percutaneous embolectomy, and percutaneous thrombus fragmentation techniques, are alternative treatment options. These aggressive measures are usually reserved for life-threatening massive PE associated with hemodynamic instability and cardiogenic shock.

There is no consensus regarding the indications for thrombolytic therapy in patients with a PE. Although several randomized controlled trials have shown that thrombolytic agents dissolve clot more rapidly than does heparin, reduced recurrence and mortality rates have been difficult to demonstrate. Nevertheless, since thrombolysis provides a rapid reduction in thrombus burden, allowing restoration of pulmonary blood flow, thrombolytic treatment is strongly recommended and can be lifesaving in patients with an acute massive PE associated with shock. More recently, based on studies showing that right ventricular hypokinesia, as demonstrated on the echocardiogram, is associated with decreased survival in these patients, thrombolytic therapy has been advocated in hemodynamically stable patients with right ventricular dysfunction. The usefulness of thrombolytic therapy in this subset of patients requires large, prospective, randomized, controlled trials. Currently available thrombolytic agents include urokinase, alteplase (tissue plasminogen activator), reteplase, and tenecteplase. There is no significant difference in the efficacy of these agents.

Percutaneous placement of a catheter within the pulmonary artery allows catheter-directed local delivery of a thrombolytic drug into the pulmonary circulation or into the thrombus itself. This strategy has been proposed as an alternative to systemic thrombolysis in patients with acute massive PE. Theoretically, local delivery should accelerate clot lysis and achieve more rapid reperfusion of the pulmonary circulation. In one report, catheter-directed thrombolysis with recombinant tissue plasminogen activator (rt-PA) resulted in rapid clot lysis in 94% of patients.<sup>41</sup> In another report, intrapulmonary infusion of rt-PA did not offer significant benefit compared with intravenous administration.<sup>42</sup> Further research is needed to define the role of catheter-directed thrombolysis in the management of these patients. Improvements in survival and long-term pulmonary perfusion will require consistent demonstration.

Thrombolytic therapy is associated with major bleeding events, the most feared of which is

intracranial hemorrhage. A recent meta-analysis of available data demonstrated that thrombolysis is associated with an increased risk of bleeding (13.7%) compared with heparin (7.7%) in patients with an acute PE.<sup>43</sup> Although it has been suggested that catheter-directed thrombolysis could reduce the risk of hemorrhage, this remains to be proven. Any patient considered for thrombolytic treatment should be evaluated for contraindications such as recent cerebrovascular accident, intracranial surgery (< 2 months), active intracranial abnormality (neoplasm, aneurysm, or vascular malformation), or recent major hemorrhage.

Patients with massive PE and compromised hemodynamic status, in whom thrombolytic therapy is not effective or is contraindicated and who are not candidates for open surgery, can be treated with percutaneous interventional procedures such as embolectomy, clot fragmentation, and thrombectomy.<sup>43</sup> Percutaneous mechanical devices can fragment, macerate, aspirate, or remove clots. They can break the thrombus into smaller fragments that migrate into the peripheral pulmonary artery branches, opening up the central pulmonary arteries and improving perfusion. There is some evidence that redistribution of larger central clots into the peripheral pulmonary arteries may result in an acute reduction in pulmonary pressure and an increase in total pulmonary blood flow. These devices can be used as a complement to thrombolytic therapy. Fragmentation of the clot exposes fresh surfaces for infused thrombolytic drugs. Conversely, softening of the clot by a thrombolytic drug may facilitate debulking and fragmentation of occlusive clots.

Venous thrombosis is a common precursor to PE. Although anticoagulation remains the treatment of choice for venous thrombosis and PE, IVC filters provide a viable and effective alternative for reduction of PE (Figure 9). Absolute indications for IVC filter placement include (1) contraindication to anticoagulation; (2) failure of anticoagulation, such as recurrent PE despite adequate anticoagulation; (3) development of complication from anticoagulation therapy; and (4) inability to anticoagulate to a therapeutic range despite patient compliance with medication. Some relative indications include (1) a large free-floating thrombus in the IVC, (2) chronic untreated PE prior to pulmonary embolectomy, (3) thromboembolic disease with marginal cardiopulmonary reserve, (4) poor compliance with anticoagulant medication, and (5) thrombolysis of deep venous thrombophlebitis. The only absolute contraindications to IVC filter placement are chronic thrombosis of the IVC and a lack of venous access.

Vena cava filters are generally placed in the infrarenal IVC. Suprarenal placement of filters is

**FIGURE 9** Inferior vena cava filter. A patient with lung cancer and brain metastases presented with deep venous thrombosis involving the right femoral vein. A cavogram through a transjugular sheath shows a filter deployed in the infrarenal portion of the inferior vena cava.

indicated in the following situations: infrarenal vena cava thrombosis precluding infrarenal placement, renal vein thrombosis, ovarian vein thrombosis, possible current or future pregnancy, and thrombus proximal to an infrarenal filter.

Most complications of IVC filter placement are minor in nature. The recurrent symptomatic PE rate is similar, with all available filters and ranges from 2 to 5%.<sup>44</sup> IVC thrombosis is seen in 2 to 30% of patients and although usually partial and asymptomatic can rarely become complete and cause phlegmasia cerulea dolens, necessitating thrombolysis. Other complications include recurrent deep venous thrombosis, filter migration and embolization, IVC penetration, filter fracture, venous insufficiency, guidewire entrapment, and access-site thrombosis.

Currently, 10 different filters approved by the Food and Drug Administration are available for use in the United States. Most filters are constructed of nonferromagnetic material and hence are considered safe during MRI and do not cause significant artifact on MRIs. Although safe, the stainless steel Greenfield filter and the Bird's Nest filter produce substantial artifact in MRIs. Even though MRI can be performed safely in patients with all types of IVC filters, a delay of

6 weeks between implantation and imaging is recommended.

### Systemic Complications of Malignancy and Therapy

Neutropenic fever is a diagnostic challenge because the host lacks its usual responses to infection. The imaging evaluation typically begins with a chest radiograph.<sup>45</sup> The findings at chest radiography can be very minimal. In this clinical setting, subtle findings of linear atelectasis or small pleural effusions must be viewed with suspicion as they may be the only evidence of infection. CT can be effective in the evaluation of pulmonary infections in these patients as CT has a greater sensitivity to subtle alveolar filling and interstitial thickening. There is value in characterization of pulmonary infections with CT, although no findings are entirely specific for a particular infectious agent.<sup>46</sup> Because of the overlap in appearance between various infectious etiologies and with other lung diseases, other evaluations, such as bronchoscopy and culture, are usually necessary to direct therapy.

Other sources of infection are found throughout the body. Indium 111–labeled white blood cells (either autologous or from human leukocyte antigen–matched donors) can detect focal infectious sources with great sensitivity.<sup>47</sup> Osteomyelitis can also be detected by the three-phase bone scan in which all three phases will demonstrate abnormally elevated focal tracer distribution.<sup>48</sup> Both the indium 111 white blood cell and three-phase bone scans are partly limited by the use of antibiotics and the chronicity of the infection.

Renal infection and inflammation are initially evaluated by ultrasonography to determine the type of renal echogenicity, renal size, and the presence of focal lesions, which can be either unilateral or bilateral. The most common ultrasound finding in pyelonephritis is a normal scan. Multidetector contrast-enhanced CT scans are also valuable to identify acute pyelonephritis, pyonephrosis, renal abscess, and chronic infection.

Pulmonary infections are usually bacterial and present as single or multifocal areas of pulmonary consolidation and ground-glass opacity.<sup>49</sup> Nodular and cavitory lesions are suggestive of fungal infections or septic emboli (Figure 10).<sup>50</sup> However, bacterial infections can also have nodular or cavitory components. Branching tubular opacities with mucous plugging of the bronchial tree may be due to poor clearance of secretions or to infection, such as bronchopulmonary aspergillosis. Pulmonary nodules associated with invasive pulmonary aspergillosis may have a halo of ground-glass opacity.<sup>51</sup> Pulmonary infections that extend from the lung into the chest wall or into mediastinal structures are uncommon

**FIGURE 10** Septic pulmonary emboli by computed tomography (CT). A 49-year-old woman with breast cancer developed fever and new pulmonary nodules detected by chest radiography. CT of the chest at the level of the main pulmonary artery (PA) demonstrates cavitary nodules in the right upper lobe (arrows). Hemorrhage around the nodules causes the surrounding ground-glass attenuation halo (arrowheads). Blood cultures revealed *Staphylococcus aureus*, and the nodules resolved with antibiotic therapy.

and indicate an aggressive organism such as actinomycosis, nocardia, or mucormycosis.<sup>52</sup>

The pulmonary pattern most characteristic of viral infection is interstitial thickening, but nodules or consolidation is more frequently encountered.<sup>53,54</sup> Interstitial thickening is also seen in a variety of other pulmonary infections and in noninfectious lung disease. Tiny nodules can be seen along peripheral bronchovascular bundles and in the center of secondary pulmonary lobules in many early infections. Most often these are clustered in distribution. Although associated with *Mycobacterium avium* complex (MAC) infections, this pattern can be seen in virtually any early infection.<sup>55</sup> MAC infection frequently has a distribution involving the anterior middle lobe and lingula and often has bronchiectasis associated with the tiny nodules. Similar findings of clustered nodules and bronchiectasis can be seen in chronic aspiration, most often distributed dependently in the lower lobes. Thus, the combination of CT appearance and distribution of findings can be helpful in suggesting an infectious etiology.

Respiratory failure as a consequence of chemotherapy, surgery, or infection can evolve into a diffuse lung injury known as acute respiratory distress syndrome (ARDS).<sup>56,57</sup> The condition is most frequently imaged with portable chest radiography in an intensive care unit as patients are generally too unstable to be transported to the imaging department for a conventional chest

radiograph or CT examination. By portable chest radiography, ARDS presents as heterogeneous opacification throughout both lungs, usually in a relatively symmetric distribution. The distribution can be asymmetric, with areas of sparing. The pulmonary pattern is difficult to distinguish from infection or pulmonary edema. The slowly changing relatively stable appearance can be suggestive of ARDS over the other possibilities.

Pulmonary edema can sometimes be distinguished from ARDS if there are other signs of volume overload, such as cardiomegaly or widening of the vascular pedicle, on serial radiographs.<sup>58</sup> However, the assessment is severely limited on the typical supine portable radiographs obtained in these patients. The supine position causes low lung volumes, which increases the apparent size of the heart and mediastinum. This is accentuated further by the anteroposterior orientation of the patient and short source-to-image distance for the examination. In addition, the low lung volumes cause indistinctness of the pulmonary vessels and redistribution of pulmonary blood flow, two features that are otherwise useful on upright radiography in identifying pulmonary edema. Septal thickening is often not demonstrated in supine patients because gravity causes dependent distribution of the interstitial fluid to the posterior portions of the lungs and away from the lateral portions of the lungs, where septal thickening is normally identified. The time course of changes in the radiographic findings may provide the most useful information as pulmonary edema is likely to respond relatively quickly to manipulations of fluid status.<sup>59</sup>

Metastatic disease in the chest is a concern as a differential possibility in evaluating pulmonary lesions identified on a chest radiograph or CT scan.<sup>50,51</sup> The pulmonary nodules typically seen in metastatic disease are usually more sharply demarcated than nodules of an infectious process. However, neoplasms with associated hemorrhage, such as choriocarcinoma, melanoma, or vascular neoplasms, may have poorly defined margins more typical of infection. Cavitary metastatic disease, in particular, can simulate fungal infection or septic emboli. These entities can most readily be distinguished with clinical information about signs and symptoms of infection and the time course of appearance of lesions.

In these extremely ill patients with multiorgan failure, appropriate assessment is dependent on integration of all medical information and the sequence of recent images.

Hepatic dysfunction is common in oncology patients who are subject to hepatic complications associated with therapy but who may also experience any of the broad spectrum of liver disorders that are independent of cancer. The hepatic parenchyma can be diffusely abnormal with infiltration, cirrhosis, passive congestion, portal

hypertension, and hemochromatosis. Hepatic metastases can lead to hepatic dysfunction and an abnormal liver test profile. Imaging can identify a diffuse parenchymal pattern or a space-occupying lesion, the presence or absence of biliary ductal dilation, and the patency status of the intrahepatic vasculature. Ultrasonography with or without Doppler evaluation should be the initial study of choice. The ultrasound study can be performed at the bedside, is noninvasive and inexpensive, and involves no radiation but is operator dependent. The results are influenced by the patient's body habitus, with large patients and/or patients with fatty infiltrated livers being more difficult to study. Multidetector CT and MRI, with dedicated liver protocols, are alternative imaging modalities that can provide information not rendered by the ultrasound study.

Liver dysfunction is common in bone marrow transplant patients, the common etiologies being graft-versus-host disease; viral, bacterial, and fungal infections; drug- (cytotoxic or immunosuppressive drugs, antimicrobials, total parenteral nutrition) related hepatotoxicity; veno-occlusive disease; and iron overload. When the cause of liver dysfunction cannot be determined by noninvasive means, liver histology may suggest the correct diagnosis. Liver tissue for histologic analysis may be obtained by image-guided percutaneous liver biopsy or transjugular liver biopsy in patients with coagulopathy and thrombocytopenia.

Ultrasonography is the initial imaging modality of choice to evaluate conditions involving the gallbladder and biliary tree. These diseases include cholelithiasis, cholecystitis, choledocholithiasis, gallbladder polyps and masses. Alternative imaging modalities include CT, MRI, magnetic resonance cholangiopancreatography, hepatobiliary nuclear scintigraphy, and percutaneous transhepatic cholangiography.

Renal dysfunction can occur in patients with nonrenal carcinoma. Some of these complications include radiation nephritis, antineoplastic drug-induced toxicities, antibiotic-associated nephropathies, analgesic nephropathy, and contrast-associated nephropathy. Infiltration of the kidneys can occur with leukemia and lymphoma. Hypercalcemia, hypocalcemia, hyponatremia, and tumor lysis syndrome can also occur. Glomerular disease can be produced by membranous glomerulopathy associated with carcinomas of the lung, gastrointestinal tract, and breast; minimal change disease; amyloidosis; and consumptive coagulopathy.

Osteoporosis is a naturally occurring condition in humans that increases in severity with increasing age and therefore is a comorbid process in older persons with cancer. Osteoporosis in cancer patients worsens owing to therapeutic

success in the treatment of cancer (increased longevity leads to increased osteopenia) and to the direct bone-resorptive effects of the cancer therapies themselves.<sup>60</sup> Thus, osteoporosis increases with increased patient age, progressive stage of disease, and duration of specific therapy. With lengthened survival, this comorbid condition emerges as a more important determinant of both morbidity (quality of life) and mortality, primarily owing to fractures. The goal is to control bone mineral density and to effectively treat osteoporosis to reduce its affect on morbidity and mortality. Several bone mineral measurement methods are available for the detection of osteoporosis, for prediction of fracture risk, and for determination of therapeutic success. These tests include quantitative CT of the spine, dual x-ray absorptiometry of the spine and femoral neck, quantitative ultrasonography of the calcaneus, and others. Unfortunately, agreement among the tests is poor.<sup>61</sup>

Chronic back pain diminishes the quality of life for many oncology patients. Imaging is a critical component of the diagnostic assessment. Radionuclide bone scans localize metabolically active lesions. The pattern may indicate the presence of metastatic disease, but often the pattern is nonspecific or nondiagnostic. Conventional radiography of the spine often improves specificity by revealing features diagnostic of metastasis, degenerative disk disease, apophyseal joint osteoarthritis, or osteoporosis. Commonly, some combination of conditions exists or the radiographs do not provide a satisfactory correlate for the symptoms. MRI is more sensitive and specific for detection of metastases, for differentiation of acute and chronic vertebral fractures, and for differentiation of osteoporotic fractures from metastatic fractures.<sup>62</sup>

Percutaneous vertebroplasty may be used for treating refractory vertebrogenic pain from malignant vertebral body fractures in patients with myeloma, lymphoma, leukemia, and metastases and provides rapid pain relief and significantly improved mobility and quality of life. The results in patients with metastatic fractures indicate similar levels of symptom control as in those with osteoporotic fractures. Sixty to 85% of patients with neoplastic vertebral collapse experience a marked reduction in narcotic requirements or complete relief within 72 hours.<sup>63</sup> Vertebroplasty palliates pain through the solidification of the osteolytic lesion and provides structural stability to the spine. Although it has been suggested that a direct cytotoxic effect alone or in combination with a thermal reaction resulting from the cement injection may have a tumoricidal effect, this remains unproven.

Although radiotherapy is widely used for pain control of malignant vertebral lesions, radiotherapy alone may not be effective when the

pain is primarily mechanical, such as with wedge fracture or vertebral collapse. Vertebroplasty is complementary to radiotherapy in these patients. Vertebroplasty is a preferred treatment when immediate pain relief is required; radiotherapy requires around 1 to 2 weeks for pain relief.

Vertebroplasty is generally performed under fluoroscopic guidance, although CT guidance may be used for needle placement for certain cervical or thoracic vertebrae. A large-bore needle is advanced into the anterior portion of the vertebral body, frequently by a transpedicular approach. Once the needle position is confirmed, polymethylmethacrylate, an acrylic polymer noted for its excellent compressive strength, is injected under direct fluoroscopic visualization. Potential complications include bleeding; infection; trauma to the nerve roots or spinal cord; fracture of a lamina, pedicle, or rib; and cement extravasation into the epidural, paravertebral, foraminal, or disk spaces. The incidence of complications is quite low.

CNS malfunction can be a significant issue during the life of oncology patients. Radionuclide tests may provide qualitative information as an aid in these situations. Changes in mental status may result from the use of oncologic drugs, including interferons. Specific patterns of hypoperfusion of the temporal and parietal lobes as confirmed by SPECT or PET (for glucose hypometabolism) can distinguish Alzheimer's dementia from other causes of dementia or delirium.<sup>64</sup> Other cancer-related CNS diseases, such as cerebrospinal fluid (CSF) block or iatrogenic CSF leakage, can be confirmed with scintigraphy using indium 111-labeled diethylenetriaminepentaacetic acid (DTPA). Fast clearance or abnormal appearance of indium 111 DTPA after intrathecal injection indicates extrathecal activities or CSF leakage.<sup>65</sup> Slow clearance of indium 111 DTPA from the CSF or abrupt cessation of flow indicates CSF block, which in cases of leptomeningeal metastasis may show flow improvement and symptomatic relief on focal external beam irradiation.<sup>66</sup>

One of the most crucial questions of patient care is whether the patient is alive. Even though the consensus from the president's commission and the Harvard criteria is that the final diagnosis of brain death must be made by specialty-trained physicians, including a neurologist, an anesthesiologist, or a neurosurgeon, radionuclide cerebral blood flow determination remains the most important ancillary and objective test for that assessment.<sup>67,68</sup>

### Chemotherapy-Induced Toxicity

Chemotherapy-induced toxicity of the brain is relatively uncommon and presents in a nonspecific fashion with seizures, altered mental status, and motor deficit.

Methotrexate toxicity results when this common chemotherapeutic agent is used for the treatment of leptomeningeal metastases (involvement of pia and arachnoid mater that envelops the brain and spinal cord) from lymphoma, leukemia, and lung and breast cancers. Common CNS tumors that invade the leptomeninges are glioblastoma, medulloblastoma, ependymoma, and primitive neuroectodermal tumors. Methotrexate does not penetrate the blood CSF barrier in systemic therapeutic doses given orally or parenterally. To provide more uniform distribution of the drug through CSF and better penetration into brain parenchyma and perivascular spaces, methotrexate is used as a high-dose chemotherapeutic agent. In the treatment and prevention of leptomeningeal metastasis secondary to leukemia or lymphoma, methotrexate is commonly administered via lumbar puncture into the lumbar subarachnoid space. Intraventricular injection of methotrexate through an Ommaya reservoir is performed to treat leptomeningeal metastasis secondary to primary CNS solid tumors because intrathecal chemotherapy via the lumbar route is less effective and also circumvents the problems of local subdural or epidural injection of the chemotherapeutic agent when a lumbar route is employed. Methotrexate-induced leukoencephalopathy is a chronic, progressive demyelinating encephalopathy that can appear months to years after treatment. The encephalopathy gives rise to headaches, seizures, drowsiness, blurred vision, and dysarthria and can even lead to dementia. MRI readily demonstrates the toxic effects of methotrexate on the white matter as large areas of T<sub>2</sub>-weighted hyperintensity, particularly involving the periventricular white matter and the region of the centrum semiovale. Periventricular white matter is preferentially involved. Because of local concentration differences, methotrexate-induced leukoencephalopathy is more common with intraventricular and intrathecal chemotherapy than with systemic therapy. MRI can also detect methotrexate-induced necrosis of the brain occurring as a result of accidental leakage of methotrexate into the brain substance during intraventricular chemotherapy installation, a rare complication. MRI findings of necrotizing leukoencephalopathy of the brain owing to a chemotherapeutic agent consist of a focal area of abnormal contrast enhancement with surrounding edema and can be mistaken for a metastatic lesion. The area of abnormal enhancement occurring along the path of the ventricular catheter particularly close to the entrance of the catheter into the ventricle should suggest the current diagnosis of chemotherapy-induced necrosis (Figure 11).

Tacrolimus (Prograf) toxicity results when this potent immunosuppressive agent is used for the prophylaxis of organ rejection in kidney, liver,

**FIGURE 11** Cytarabine-induced necrotizing leukoencephalopathy after intraventricular therapy for acute myelogenous leukemia. *A*, Axial postcontrast  $T_1$ -weighted magnetic resonance image (MRI) demonstrates abnormal contrast enhancement involving the lateral ventricular walls (arrows). *B*, Adjacent MRI shows abnormally enhanced supraventricular white matter (arrowheads) surrounding the catheter (arrow).

heart, and bone marrow transplants. It is associated with a posterior reversible encephalopathy syndrome (PRES) in about 2% of treated patients.<sup>69</sup> The diagnosis is made by characteristic clinical findings consisting of headache, a change in mental status, seizures, visual abnormalities, and/or focal neurologic deficits. The median patient age is about 35 years, and the median time to the onset of PRES is about 60 days from institution of tacrolimus. Imaging findings in PRES consist of parieto-occipital hypodensity on CT images, an area of low signal intensity on  $T_1$ -weighted MRIs, and hyperintensity on fluid attenuated inversion recovery (FLAIR)  $T_2$ -weighted MRIs. The abnormality involves the subcortical white matter and adjacent cortex, with a predilection for areas supplied by the posterior circulation, namely the occipital, parietal, and temporal lobes and cerebellum.

In 1996, Hinchey and colleagues described a clinicoradiologic condition named posterior reversible leukoencephalopathy syndrome, which is characterized by visual disorders, seizures, and altered mental status, with changes in the subcortical white matter of the temporoparieto-occipital lobes detected in neurologic images.<sup>70</sup> These clinical manifestations were associated with arterial hypertension. Although the precise pathogenesis is not known, the striking similarities of the symptoms and the imaging findings among patients with tacrolimus toxicity and those with hypertensive encephalopathy, cyclosporine toxicity, and eclampsia of pregnancy suggest a common mechanism. Tacrolimus and cyclosporine both

cause inhibition of neuronal and endothelial nitric oxide synthase activity. Inhibition of nitric oxide results in vasodilatation, and fluid extravasation has been suggested as the cause of eclamptic encephalopathy. The loss of autoregulation presumed to occur in PRES results in blood barrier disruption and leads to interstitial fluid accumulation in the subcortical white matter and the cortex. This vasogenic edema accounts for the abnormal findings seen in brain imaging. Magnetic resonance FLAIR imaging is particularly sensitive for detection of early edema seen with this syndrome.

Clinical symptomatology and MRI findings of PRES can be mistaken for acute infarction. MRI findings of acute infarction consist of cortical swelling, gyral enhancement, abnormal hyperintensity on FLAIR images, and restricted diffusion, producing bright signal intensity on diffusion-weighted images. Diffusion-weighted imaging improves acute stroke detection by 95%. PRES can be differentiated from acute stroke with an appropriate clinical history and recognition of MRI findings of bilateral vasogenic edema primarily involving the subcortical white matter and with no evidence of restricted diffusion. Drug-induced encephalopathy is usually reversible when the drug is discontinued or the dose is reduced (Figure 12). Drug toxicity can lead to acute infarction with or without hemorrhage if early signs are not recognized.

Cardiac toxicity results in decreased cardiac function manifest as decreased ejection fraction and stroke volume.<sup>71</sup> These changes can be

demonstrated at radionuclide ventriculography, echocardiography, or cardiac MRI. The multi-gated cardiac radionuclide ventriculogram radionuclide test using Tc 99m-labeled red blood cells remains the most reliable method to measure cardiac function before and after chemotherapy. In general, left ventricular ejection fraction below 45% or an interval decrease of more than 15% implies impending cardiotoxicity.<sup>72</sup> In compensation for decreased contractility, the ventricles become dilated. This dilation may be apparent at conventional radiography or may be demonstrated at CT or echocardiography.<sup>73</sup> Eventually, the heart can no longer compensate for the decreased contractility, and cardiac failure results.

Acute cardiac failure is best demonstrated with conventional chest radiography, the typical findings of which include bilateral perihilar opacity, indistinct pulmonary vessels, and peripheral interlobular septal thickening.<sup>59</sup> Pleural effusions may also be present. Widening of the vascular pedicle, the mediastinal structures above the aortic arch, to more than 74 mm indicates volume overload or congestive heart failure.<sup>74</sup> At CT, dilated cardiac chambers and increased pulmonary attenuation owing to fluid filling the interstitium and alveoli are seen in cardiac failure. There may be an increase in the prominence and attenuation of mediastinal soft tissues.<sup>75</sup> Contrast material administered through the upper extremity venous system may reflux into the IVC and hepatic veins owing to poor cardiac function. A congestive pattern may also be seen in the liver as patchy increased attenuation centered on the hepatic veins. Cardiac failure can also result in enlargement of mediastinal lymph nodes, simulating adenopathy.<sup>76</sup> Enlarged nodes that develop in this setting should be reevaluated after resolution of cardiac failure rather than be accepted as recurrent or metastatic tumor.

Pulmonary toxicity secondary to chemotherapeutic agents typically presents as diffuse pneumonitis or bronchiolitis obliterans organizing pneumonia.<sup>77</sup> The radiographic appearance can range from air trapping, demonstrated as mosaic attenuation in the lungs that is accentuated on expiratory imaging, to nodular or patchy areas of consolidation or poorly defined ground-glass opacities (Figure 13).<sup>78</sup> Although the pattern of involvement is usually diffuse throughout the lungs, it may be asymmetric or even unilateral. This appearance may be very difficult to distinguish from pulmonary infection. Pulmonary fibrosis that results from chemotherapy-induced pulmonary toxicity is a less common presentation. It has the typical appearance of fibrosis, with basilar distribution of interstitial thickening, a subpleural honeycomb pattern, and decreased total lung volume. PE may also be seen as a consequence of chemotherapy, particularly with thalidomide.

**FIGURE 12** Cyclosporine-induced posterior reversible encephalopathy syndrome. A, A T<sub>2</sub>-weighted image shows bilateral abnormally increased signal intensity involving the cortex/subcortical white matter of the occipital lobes (arrows). B, A follow-up magnetic resonance examination 8 months later reveals complete resolution of the abnormal findings after cessation of cyclosporine therapy.

**FIGURE 13** Pulmonary toxicity owing to carmustine. A 66-year-old woman with glioblastoma multiforme developed dyspnea after carmustine chemotherapy. Computed tomography of the chest at the level of the left ventricle (LV) demonstrates symmetric distribution of patchy areas of consolidation (arrows) and ground-glass attenuation (arrowheads). No infectious etiology was demonstrated at bronchoscopy. The patient's symptoms improved after withholding further carmustine treatments.

### Radiation-Induced Toxicity

Radiation-induced neurotoxicity is postulated to derive from the combined effects of vascular injury, glial and white matter damage, and alterations in the fibrinolytic enzyme system. Vascular injury consists of endothelial damage, vascular ectasia, and telangiectasia, all of which result in increased capillary permeability, with resultant cytotoxic and vasogenic edema. Progressive vascular changes include vessel wall thickening

caused by hyalinization, with consequent thrombosis, infarction, and necrosis. Oligodendrocytes are extremely sensitive to radiation, and their destruction is associated with demyelination. Metabolic changes in irradiated cells reduce glycolysis and glucose consumption and result in decreased glucose and oxygen use observed on PET scans. Necrotic brain tissue shows absent tissue plasminogen activator and excess urokinase plasminogen activator, a combination that contributes to cytotoxic edema and tissue necrosis. Radiation necrosis most commonly develops around blood vessels within the white matter and is manifested as fibrinoid necrosis of the blood vessel wall with surrounding perivascular parenchymal coagulative necrosis. Confluence of multifocal perivascular necrotic zones results in larger zones of parenchymal necrosis. Clusters of abnormally dilated thin-walled telangiectasias are common. Late vascular changes include vessel wall thickening caused by hyalinization, with resultant luminal narrowing. White matter changes include focal and diffuse demyelination.

Radiation necrosis may develop months to years after completion of radiation therapy and is frequently irreversible and often progressive. Radiation necrosis most commonly occurs at the site of maximum radiation delivery, typically in the immediate vicinity of a surgical cavity following partial or total resection of tumor. It is important to recognize the spectrum of MRI features of radiation necrosis because the tissue damage can mimic other pathologic processes.<sup>79</sup> The typical MRI finding in radiation necrosis is an enhancing mass with central necrosis (Figure 14). Other, less common patterns may be observed, including (1)

**FIGURE 14** Radiation necrosis involving the right temporal lobe 2 years after receiving radiation therapy for nasopharyngeal carcinoma. Axial postcontrast T<sub>1</sub>-weighted magnetic resonance image shows focal enhancement (arrowheads) with central necrosis.

multiple lesions, (2) lesions in the contralateral hemisphere, and (3) lesions arising remotely from a primary cerebral site, such as in the cerebellum or brainstem. Each pattern can be mistaken for a different pathologic process. For example, radiation necrosis occurring at the site of the resected primary tumor easily can be mistaken for recurrent tumor. Necrosis occurring distant from the site of the primary tumor may mimic multifocal glioma. Contralateral hemisphere involvement can be diagnosed as multicentric glioma. Multiple foci can resemble multiple metastases. Periventricular white matter involvement may mimic tumefactive multiple sclerosis. Radiation-induced necrotic lesions can also spread subependymally and mimic subependymal tumor spread.

The incidence of radiation necrosis after conventional radiation therapy ranges from 5 to 24%, with higher rates at autopsy. The interval from completion of radiation therapy to histopathologic confirmation varies from 3 to 48 months, mostly occurring between 7 and 24 months. The use of platinum-based chemotherapy drugs, such as cisplatin and carboplatin, combined with radiation therapy may contribute to the development of radiation-induced necrosis. It is important to recognize that radiation-induced necrosis is a dynamic pathophysiologic process with several possible clinical outcomes. Although continued growth with attendant cytolytic edema and mass effect is commonly seen, lethal progression is not inevitable in all cases. Some lesions will stabilize, whereas others will regress. Surgery may be required to reduce the mass effect and edema. Despite advancements in special imaging

techniques, biopsy may be needed to establish an accurate histopathologic diagnosis.

Radiation-induced cranial neuropathy is relatively rare. Radiation-induced optic neuropathy can occur when focused radiation is delivered to tumors in the perioptic regions. The pathologic process of this neuropathy consists of optic pathway vasculopathy with secondary hemorrhage, reactive gliosis, necrosis, and atrophy.

Radiation-induced brain atrophy can also occur, with shrinkage of the white matter and cortex.

Radiation-induced pneumonitis and pulmonary fibrosis can be a significant cause of respiratory compromise and can present a diagnostic challenge. Conventional radiography and CT demonstrate areas of consolidation that correspond to the radiation ports used for therapy.<sup>80</sup> The acute phase of pneumonitis presents as focal consolidation with obscuration of the underlying pulmonary vessels and bronchi at CT. As the process progresses to fibrosis, the air space consolidation may clear or may become more sharply demarcated. Typically, the involved area decreases in volume, with resulting traction on adjacent mediastinal and pulmonary structures. Within the area of involvement, the bronchi become distorted and ectatic. The process often stabilizes within 9 to 12 months but rarely may continue to evolve over more than 2 years. In cases with slower evolution, new areas of involvement do not emerge after about 1 year, but consolidation and volume loss progress in the involved area. The fibrotic process does not cause filling of the bronchi. Bronchial filling that develops after radiation fibrosis has begun to mature should be regarded as evidence of recurrent tumor or superimposed infection.<sup>81</sup>

Radiation-induced pleural and pericardial effusions most often emerge about 3 to 9 months after therapy. Radiation therapy to involved mediastinal lymph nodes typically reduces the size of the nodes and may induce calcification within the nodes. In addition, radiation can cause increased attenuation of the mediastinal fat and blurring of soft tissue borders within the mediastinum. In radiation-induced esophagitis, the esophageal walls become thickened and the borders of the esophagus become poorly defined. As with radiation pneumonitis, radiation-induced esophagitis may cause increased metabolic activity on PET scans.<sup>82</sup> This metabolic activity limits the value of early follow-up with PET. Pleural scarring related to radiation fibrosis or radiation-induced pleural effusion can result in traction on the underlying lung causing focal areas of rounded atelectasis, which can simulate infection or a mass lesion. Because the scarring may be related to the resolution of the effusion rather than being directly due to radiation therapy, it can occur outside the original radiation field.

The important feature for identification of radiation-induced pneumonitis and fibrosis is detection of the limits of the radiation port. The port borders are typically linear and do not correspond to normal anatomic boundaries. Commonly observed radiation injury patterns include involvement of the anterior subpleural lung from tangential breast radiation, involvement of the lung apices from cervical lymph node radiation, and paramediastinal involvement from mediastinal lymph node radiation (Figure 15).<sup>83</sup>

Radiation therapy to the primary lung tumor is also common. When conventional radiation therapy is used, a significant portion of lung may be irradiated. Ensuing radiation fibrosis will have the linear, nonanatomic borders seen with mediastinal and tangential radiation. The use of three-dimensional conformal radiation therapy can complicate the identification of radiation fibrosis. Because multiple exposure ports are used, the pattern of lung injury is more complex (Figure 16). Consolidation can develop outside the usual anteroposterior and posteroanterior ports used for conventional radiation therapy. Conformal radiation therapy also results in a less linear appearance to the boundaries of radiation fibrosis.<sup>84</sup>

Intensity-modulated radiation therapy (IMRT) is a method of delivering conformal radiation therapy with nonuniform beams of radiation energy and also induces radiation injury in a pattern different from conventional radiation therapy. For example, in IMRT treatment of mesothelioma, the therapeutic dose contour is matched to the pleural surface and chest wall. The radiation injury therefore involves less of the underlying pulmonary parenchyma. Because the

**FIGURE 15** Pulmonary radiation fibrosis from conventional radiotherapy. A 40-year-old man with lymphoma received conventional mantle radiation therapy. Computed tomography of the chest at the level of the pulmonary artery (PA) 2 months after the completion of therapy reveals bilateral paramediastinal consolidation (arrowheads) with linear lateral margins confined to the radiation ports.

**FIGURE 16** Pulmonary radiation effect from conformal radiotherapy. A 75-year-old man with stage I lung cancer was not a surgical candidate owing to poor cardiac function. Computed tomography of the chest at the level of the aortic arch (Ao) 8 months after the completion of therapy demonstrates bronchiectasis (arrows) and surrounding consolidation and ground-glass attenuation. The area of involvement has poorly defined borders and does not have the typical linear margins seen with conventional radiation therapy, as seen in Figure 13-15.

radiation ports include the upper aspect of the liver, low attenuation can be induced in the periphery of the liver and should not be confused with recurrent tumor or infection.

Radiation-induced skeletal changes include growth disturbances, focal osteopenia, osteoradionecrosis, and induced benign or malignant neoplasms.<sup>85</sup> Growing bone is sensitive to radiation, and the growing physis is most sensitive, with damage roughly proportional to the amount of radiation absorbed. Radiography shows metaphyseal sclerosis and fraying with physal plate widening. A transient dense metaphyseal band may develop as healing commences, giving way to normal bone remodeling. Scoliosis may develop secondary to asymmetric irradiation of the spine. Mature bone and cartilage are very radioresistant. However, focal osteopenia and cortical thinning may follow long bone irradiation. Osteoradionecrosis is the result of vascular damage and osteoblast death. It is most prevalent in the mandible but also occurs in the clavicle, shoulders, ribs, pelvis, sacrum, and knees. The typical radiographic features begin with subtle osteopenia or osteosclerosis, eventually leading to fragmentation or disintegration of the irradiated bone. The involved bone segments are subject to fracture and infection. Conventional radiography is usually sufficient for diagnosis of the condition and for assessment of complications. CT and MRI

are effective in areas of complex anatomy or in difficult diagnostic situations.

Osteocartilaginous exostoses are the most frequent benign radiation-induced tumors of bone. They typically develop in growing bones and may occur in any location in any irradiated bone. Osteosarcoma is the most common radiation-induced malignant tumor of bone. Radiation-induced bone sarcomas have an imaging appearance similar to those that spontaneously occur. Radiographic features are generally sufficient for diagnosis, and CT and MRI are effective for characterization and staging.

### Surgically Induced Conditions in Patients with Cancer

Postoperative alterations of the thorax can cause diagnostic dilemmas in subsequent evaluation of thoracic disease. Small pneumothoraces are routinely present after pulmonary and esophageal resections. These are usually satisfactorily managed with drainage catheters placed at the time of surgery. Pneumothoraces that persist or enlarge despite catheter drainage suggest air leak and may need surgical management. Postoperative pleural infections typically require catheter drainage and may also require surgical débridement.<sup>86</sup> After pneumonectomy, there is a shift of mediastinal structures into the pneumonectomy space, and the space slowly fills fluid over about 3 to 4 weeks. The absence of any mediastinal shift over the first few postoperative days could indicate the presence of tension pneumothorax. If the pleura fills with fluid much more rapidly than expected, hemothorax and empyema are considerations. In the setting of extrapleural pneumonectomy, the pneumonectomy space will fill with fluid more rapidly than with simple pneumonectomy. As with many major surgical procedures, PE is a concern after lung resection. The postpneumonectomy syndrome is a late complication owing to chronic tracheobronchial narrowing resulting from marked shift of mediastinal structures.<sup>87</sup>

Anastomotic leaks are a concern following several types of surgery. After esophagectomy with gastric pull-up or bowel interposition, leaks present as a collection of fluid alongside the anastomotic site, sometimes separated from the anastomosis by a short distance.<sup>88</sup> Communication of the fluid collection with the bowel lumen can be demonstrated with use of oral contrast agents either at fluoroscopy or with CT. To prevent bronchopleural fistula formation after lung resection and in the treatment of known bronchopleural fistula or an anastomotic leak from esophageal resection, a variety of vascular flaps are used to provide additional soft tissue coverage.<sup>89</sup> These can alter the radiographic appearance and simulate recurrent tumor or infection. Many flaps are predominantly fat and therefore easy to identify,

but muscular flaps are more difficult to assess. Muscular flaps should have some linear areas of fat attenuation on CT, even shortly after operation. They also may have linear calcifications. These features allow muscular flaps to be distinguished from soft tissue masses of more concern.

Abscess formation following surgery remains a serious and potentially fatal complication, with mortality rates up to 30%. Image-guided percutaneous catheter drainage (PCD) of abscesses offers a less invasive alternative to open surgical drainage and has become the procedure of choice in this group of patients.<sup>90</sup> Postoperative abscesses in various locations, such as the peritoneal space, retroperitoneum, viscera, pelvis, mediastinum, and extremities, are amenable to PCD. PCD is most effective in patients with unilocular abscesses, with cure rates up to 95%. Several recent studies have shown that PCD is also very successful (80–90% cure) with complex postoperative abscesses (ie, loculated, poorly defined collections, abscesses communicating with enteric fistulae, and interloop abscesses). In patients with abscesses associated with enteric fistulae, PCD, along with concomitant enteric decompression and diversion of bowel contents with nasoenteric tubes, allows spontaneous closure of the fistulae in 57 to 88% of cases.

Either ultrasonography or CT may be used for guidance during the PCD procedure. The main advantages of ultrasound guidance include real-time imaging and portability, allowing a bedside procedure in critically ill patients. Combining fluoroscopy with ultrasonography allows for precise positioning of the catheter. Ultrasonography is commonly used for superficial and unilocular abscesses. Endocavitary ultrasonography is also used for transrectal or transvaginal drainage of deep pelvic abscesses. However, ultrasonography is of limited use in obese patients, in the presence of intra-abdominal free air, when bowel gas interferes with sonographic visualization, and in patients with open surgical wounds or dressings overlying the abscess. Because of the deep location of many abscesses and the frequent presence of free air in postoperative tissues, CT is commonly the imaging modality of choice for PCD guidance.

Lymphoceles of the pelvis or abdomen are a complication of radical lymphadenectomy performed for prostatic or gynecologic malignancy and are believed to result from surgical transection or inadequate ligation of lymphatic vessels during lymph node dissection. Most lymphoceles are small and asymptomatic and eventually resolve spontaneously. Large lymphoceles can cause abdominal distention, hydronephrosis, bladder dysfunction, constipation, and thrombosis of iliac vessels, or they may become infected and present with fever, chills, and sepsis. Large or infected lymphoceles require treatment. Surgical

treatment is successful in up to 90% of cases but is associated with mortality and morbidity and requires hospitalization. Simple needle aspiration is safer than surgery, but repeated procedures are necessary in 80 to 90% of patients. PCD is a safe and effective treatment for symptomatic lymphoceles, with success rates ranging from 50 to 87% in most series.<sup>91</sup> In patients with pronged drainage, transcatheter sclerotherapy with tetracycline, doxycycline, povidone-iodine, or alcohol results in improved success rates of 79 to 93%.

Urinoma may be secondary to iatrogenic ureteral injury following genitourinary, retroperitoneal, or gynecologic surgeries or following manipulation during endourologic procedures, or it may be due to an anastomotic leak following ureteral diversion procedures. Interventional management of ureteral injuries requires combined use of PCD of the urinoma along with a PCN to divert the urine away from the leak. Placement of a J stent or a nephroureteral stent across the site of ureteral injury for 4 to 8 weeks permits regrowth of uroepithelium over the site of injury.

Biloma formation may complicate hepatobiliary and pancreatic surgery. PCD of the biloma in conjunction with percutaneous biliary drainage is a safe and effective minimally invasive technique for management of this complication. Placement of a percutaneous transhepatic biliary catheter extending across the site of leak prevents further leakage of bile and allows the anastomosis to heal.

### Summary

Patients with cancer typically have comorbidity that complicates their general medical care and the care of their specific cancers.<sup>92</sup> In fact, the comorbid conditions increase in number and severity, with increased number and intensity of the therapies the patients undergo in the treatment of their cancers. Thus, the bulk of imaging resources consumed by patients with cancer are not used for diagnosis and staging but rather are expended in the management of comorbid conditions.

## Cancer Center Laboratory

Laboratory support for the oncology patient typically encompasses two discreet yet interdependent functions. Being subject to the same non-cancer-related conditions prevalent in the general population of similar demographic makeup, in addition to those that are directly or indirectly cancer related, patients require a range of testing services that sufficiently meet both needs. Reflecting these dual functions, the organization of a cancer center laboratory optimally includes clinical chemistry, hematology, microbiology, and transfusion services that offer expanded testing options to support the diagnosis, staging, and monitoring of malignancies, cancer-related conditions, and cancer therapy-associated conditions. Included are bone marrow evaluation, hematology, and flow cytometry functions for diagnosis and monitoring, along with extended transfusion medicine and apheresis services to support bone marrow and peripheral blood stem cell transplantation. Tumor-related or treatment-related blood component deficiencies must also be addressed. A full range of microbiology laboratory services is also needed to address the needs of the immunosuppressed patient, as well as a clinical chemistry laboratory that offers tumor marker and other biochemical testing required for the confirmation of a diagnosis of a malignancy, monitoring of treatment response, and detection of cancer-related or therapy-associated conditions. Additional services are also commonly available, such as those provided by molecular diagnostic and human leukocyte antigen laboratories.

In general, a substantial volume of testing typically reflects the diagnostic and follow-up needs of a patient population receiving somewhat longer-term or chronic care, with a lesser volume devoted to acute, short-term, emergency services. In this population, several types of aberrant laboratory results are encountered frequently and often necessitate further investigation. Some of these are discussed in this chapter.

## Laboratory Issues in the Oncology Patient Population

### Test Result Validity

A substantial portion of the testing performed in the cancer center clinical laboratory typically

involves the use of immunoassays. These provide relatively sensitive, accurate assays that are well adapted for high-volume testing and serial monitoring. Interferences in these methodologies, however, can occur. These can be patient independent, such as those that are caused by the use of inappropriate anticoagulant or specimen tube type, medications, hemolysis, hyperlipidemia, and other factors that either degrade specimen integrity or interfere with the test methodology, and are seen in any clinical laboratory. A common example is the background interference found with hyperlipidemic sera when immunoglobulins or other protein concentrations are measured using nephelometry-based testing. These are generally predictable and are avoided by adhering to published specimen collection requirements. Others are patient specific and are caused by either unexpected antibodies within the sample that effectively interfere with the activity of test kit reagent antibodies or are due to ectopic production of the substance of interest, such as a hormone by tumor. Patients with malignancies are at particular risk of having human antimouse antibodies (HAMAs),<sup>1</sup> autoantibodies,<sup>2-7</sup> and ectopic hormone production. Consequently, laboratories serving a cancer patient population frequently have protocols in place to evaluate suspect samples when it appears that patient-specific factors are impacting test results. Expedient resolution is usually required to avoid unnecessary delays in treatment. For example, elevated serum or urine  $\beta$ -human chorionic gonadotropin (hCG) concentrations can be seen owing to ectopic production by nontrophoblastic tumors. This can be found with a diverse variety of cancers, including carcinomas of the breast, liver, and gastrointestinal tract; melanoma; and multiple myeloma,<sup>8-13</sup> and can serve as a source of confusion when performing routine pregnancy testing prior to administration of chemotherapy or radiation treatment. It has been estimated that up to 30% of cancers in general can be associated with increased serum  $\beta$ -hCG levels.<sup>2</sup> Similarly, the production of HAMAs is known to be an occasional consequence of exposure to mouse monoclonal antibodies used in cancer treatment or imaging studies.<sup>1,14</sup> Their presence or absence, however, cannot be predicted in individual patients.<sup>15</sup> Consequently, in this setting, requests for the

laboratory to review results can be helpful when they appear to be inconsistent with previous results or when they are incompatible with observed clinical findings. The laboratory's role involves a step-by-step process to rule out or identify potential sources of interference. This typically includes comparing results from analyzers that use different methodologies, assessing the reproducibility of results at differing concentrations, using antibody-blocking reagents, and assessing the ability to obtain expected results from known quantities of the substance in question.<sup>16</sup> Given the large volume of testing performed in the typical cancer center laboratory, detectable interference from HAMAs, heterophiles, or other antibodies appears to be relatively infrequent, although it can potentially affect virtually any immunoassay. Table 1, although not all-inclusive, illustrates that a broad range of routine testing is commonly performed using immunoassays. Other patient-specific factors can also affect non-immunoassay-based testing. These include pseudohyperkalemia owing to marked leukocytosis or thrombocytosis,<sup>17</sup> artifactually abnormal cell counts owing to large amounts of white blood cell fragmentation found with some leukemias,<sup>18</sup> platelet satellitism or clumping, or the presence of cold agglutinins,<sup>18-21</sup> among others. Laboratory review, again, is usually helpful in clinically suspicious cases.

The clinical laboratory also serves a role as a direct source of information on specific test performance characteristics. For those providing service to cancer centers, questions not uncommonly arise concerning the optimum use of tumor markers and other assays performed for serial monitoring, in particular. Interpretation of temporal changes in laboratory values is dependent on the ability to discriminate clinically relevant changes from those that are due to biologic or

**Table 1** Tests that Are Frequently Performed by Immunoassay

Tumor marker measurement

random variation. Knowledge of physiologic factors, such as diurnal variation and method of clearance, that specifically affect the substance of interest and the individual test kit characteristics are both key to an accurate interpretation of both baseline values and serial changes. Some of these are listed in Table 2.

### Serum Proteins

Confirmation of and/or establishing a diagnosis of malignancy and monitoring for treatment response, disease recurrence, or treatment side effects together encompass a substantial portion of the chemistry testing.

Serum protein concentration abnormalities are not uncommon, whether they consist of a relatively mild, moderate, or severe hypogammaglobulinemia or, alternately, an increased total protein of varying proportions. Hypogammaglobulinemia, with its extensive list of potential causes, some of which work in concert, can require additional evaluation. A consequence of deficient immunoglobulin production, enhanced loss, or both, treatment, when necessary, will focus on amelioration of the underlying cause.<sup>22</sup> In the setting of cancer, etiologies can include gastrointestinal or renal protein loss but also frequently involve immunologic mechanisms that are as yet poorly understood and do not appear to be readily reversible.<sup>23–25</sup> Infectious complications can be a significant cause of morbidity and mortality, particularly for patients with hematologic malignancies, and not uncommonly, these are associated with a hypogammaglobulinemia.<sup>23,26–28</sup> When it is the presenting feature, serum immunoglobulin quantitation, serum immunofixation, serum free light chain assessment, and Bence Jones protein studies with urine immunofixation are helpful in ruling out the presence of a monoclonal protein as the cause. Determining prealbumin concentrations along with those of albumin can be useful adjuncts to the clinical history and physical examination in the assessment of nutritional status; however, levels of both can be unreliable in the presence of acute inflammation.<sup>29–31</sup>

Because an increased serum total protein in the absence of a known infectious, inflammatory,

or other benign etiology, like a hypogammaglobulinemia, may also herald an underlying malignancy, serum protein electrophoretic studies and quantitation of immunoglobulins are usually helpful initial aids in distinguishing polyclonal from monoclonal immunoglobulin production. If the results are indicative of or the clinical suspicion remains high for the presence of a monoclonal gammopathy, further laboratory investigation includes immunofixation, Bence Jones protein studies, and serum free light chain concentration assessments, as were discussed previously for the evaluation of patients with low gammaglobulin levels. In addition, when the constellation of clinical findings includes the cerebral, cardiovascular, pulmonary, renal, or bleeding abnormalities suggestive of microcirculatory insufficiency, this may raise a suspicion that hyperviscosity syndrome is present and prompt the measurement of serum viscosity.<sup>32,33</sup> Onset of symptoms can occur acutely or manifest slowly over prolonged periods of time and can consist of headache, altered mental status, disturbance of gait, mucosal bleeding including the gastrointestinal or the urinary tract, cardiac failure, visual changes, papilledema, or retinal hemorrhage.<sup>34–36</sup> The presence or absence of symptoms cannot be readily predicted by serum protein concentrations alone as other factors influence blood protein–protein interactions, such as polymerization tendency, the effects of pH and temperature, and protein size and shape.<sup>32</sup> As a result, patients with relatively modest levels of a monoclonal protein component may present with a severity of symptoms that are seemingly out of proportion to its concentration, whereas others with high levels can appear to be surprisingly unaffected.<sup>32,35</sup> Table 3 lists conditions that have been associated with hyperviscosity syndrome. Most commonly, it occurs as a complication of hematologic malignancies, which

have resulted in excessive immunoglobulin or blood component production, although it can occasionally be found with benign conditions or, even rarely, with malignancies that are nonhematopoietic in origin.<sup>33–35,37–50</sup> Cryoglobulinemia, in particular, is one disorder commonly associated with increased viscosity that can be considered in a symptomatic patient with a monoclonal gammopathy. Consisting of cold precipitable proteins, which are most often immunoglobulins, they are estimated to be present in up to 20% of patients with Waldenström's macroglobulinemia and up to 10% of patients with multiple myeloma.<sup>51</sup> Generally categorized into three types, type 1 is due to an isolated monoclonal immunoglobulin, type 2 (mixed) involves a monoclonal immunoglobulin (frequently IgM) with activity against polyclonal immunoglobulins (often IgG), and type 3 involves polyclonal proteins (frequently IgM and IgG).<sup>51,52</sup> Type 1 is characteristically found in patients with multiple myeloma, Waldenström's macroglobulinemia, or other lymphoproliferative disorders, whereas type 2 can be found in lymphoproliferative disorders, autoimmune diseases, and infections (especially with hepatitis C virus).<sup>51,53</sup> Although often asymptomatic, patients can present with a variety of manifestations, including skin changes (purpura, urticaria, Raynaud's phenomenon), arthralgias, peripheral neuropathy, and organ dysfunction (hepatic, pulmonary, renal).<sup>51,53</sup> Symptoms are the result of either the occlusion of small blood vessels or vasculitis associated with immune complex deposition.<sup>51,53</sup> When the clinical suspicion is high that a cryoglobulin may be present, it is helpful to maintain close communication with the clinical laboratory as special specimen handling (maintenance at 37°C) is necessary for accurate diagnosis,<sup>54</sup> as well as the fact that the presence of a cryoglobulin in a blood sample can interfere with the results of other laboratory tests.

### Electrolytes

Electrolytes are routinely monitored closely as cancer patients have an increased risk of experiencing fluid or electrolyte imbalances during the course of their disease, either directly as a tumor-related effect or secondarily as a side effect of treatment.<sup>55,56</sup> Some can be anticipated based on tumor type or a known treatment complication, whereas others appear to be patient dependent. Although abnormalities of sodium, potassium, and phosphate, among others, are not uncommon, assessment for possible hypomagnesemia or hypercalcemia is of particular interest in patients with malignancies.

It has been suggested that hypomagnesemia may be present in a substantial portion of patients seen in general clinical practice but often goes unrecognized.<sup>57</sup> It has been estimated to occur in

**Table 2** Factors Important in the Evaluation of Baseline and Serial Values

Clearance rate: How is it influenced by hepatic, renal, or other diseases?
Specificity of test: What other substances or conditions can give positive results?
Sensitivity of test: What is the smallest amount that can be reliably measured?
Potential interferences in test method
Physiologic variability: How much variation can occur with no real change in disease status?
Analytic variability: How much variability is inherent in the laboratory measurement?

**Table 3** Conditions that Have Been Associated with Hyperviscosity Syndrome

Monoclonal hematopoietic disorders
Waldenström's macroglobulinemia
Multiple myeloma (most often immunoglobulin A or G)
Leukemias
Polycythemia vera
Nonhematopoietic malignancies
Ovarian carcinoma
Metastatic breast carcinoma
Polyclonal gammopathies
Rheumatoid arthritis
Sjögren's syndrome
Systemic lupus erythematosus
Human immunodeficiency virus (HIV) infection
Other conditions
Cryoglobulinemia
Iatrogenic

approximately 10% of patients hospitalized for various reasons<sup>58</sup> and over 17% of patients hospitalized for cancer.<sup>59</sup> Causes include insufficient dietary intake, losses through the kidneys or gastrointestinal tract or as a secondary effect of treatment, particularly with cisplatin-containing regimens.<sup>57,60,61</sup> Obvious signs and symptoms are usually absent or are nonspecific and are attributed to either depression or the primary disease, leading to underrecognition.<sup>62,63</sup> These vary from subtle to clinically acute. They range from headache, general apathy, or other seemingly psychiatric-based behavioral changes or other associated electrolyte deficiencies to neuromuscular hyperexcitability, cardiac arrhythmias, and even coma.<sup>63,64</sup> Measurement of serum total, ionized, intracellular, and urinary magnesium concentrations have all been employed, in addition to the use of the magnesium loading test in the evaluation of patients with magnesium abnormalities. Optimum test selection, at this time, appears to be situation dependent.<sup>65,66</sup>

In clinical practice, hypercalcemia is most often caused by either primary hyperparathyroidism or malignancy.<sup>67</sup> It has been estimated to be found in up to 20% of patients with malignant neoplasms overall, although the actual prevalence varies by tumor type.<sup>56,68–70</sup> Known mechanisms include tumor cell cytokine production promoting local osteolysis and the activity of parathyroid hormone–related protein and other humoral factors that promote skeletal resorption and renal tubular calcium reabsorption.<sup>56,71</sup> Similar to patients with hypomagnesemia, the presentation can consist of only vague or essentially nonspecific complaints. Depending on the rapidity of onset and the severity of the abnormality, symptoms range from general feelings of fatigue, lethargy, or anorexia through muscular, gastrointestinal, cardiovascular, renal, and neurologic manifestations.<sup>56,72</sup> Given the common occurrence of this electrolyte disturbance in the cancer patient population and its diverse clinical presentation, serum calcium levels are routinely measured to confirm the presence of normocalcemia.

## Organ Systems

### Central Nervous System

Although cerebrospinal fluid (CSF) is obtained in general, for several well-established clinical indications, including the diagnosis of demyelinating disorders, central nervous system (CNS) infections, and subarachnoid hemorrhage,<sup>73,74</sup> in the cancer center, it is often obtained to evaluate for CNS involvement by either primary or metastatic tumor. Neurologic symptoms range from relatively subtle to overt and include headache, cranial nerve palsy, seizures, and coma.<sup>75</sup> Findings of CNS involvement can occasionally be the initial

evidence that a patient has a malignancy.<sup>75,76</sup> Macroscopically observable and chemically measurable CSF characteristics can be associated with the presence of tumor, including xanthochromia,<sup>73</sup> increased cell counts,<sup>73</sup> abnormal total protein concentrations,<sup>73,75</sup> and decreased glucose concentrations.<sup>73</sup> The diagnosis, however, is dependent on the cytologic identification of malignant cells. A positive cytology confirms tumor involvement of the leptomeninges or the ventricles.<sup>77</sup> Evidence suggests that the test performance is enhanced by the use of immunocytochemistry<sup>77,78</sup> and, if necessary, repeat sampling.<sup>78</sup> Electrophoresis with immunofixation to detect the presence of an M-protein within the CSF can also be helpful if a plasma cell–derived malignancy is suspected. Several specimen collection–related factors have been identified that help minimize the occurrence of false-negative results.<sup>79</sup> These consist of immediate sample processing, collecting the specimen from a known area of leptomeningeal involvement, ensuring an adequate sample volume, and, again, obtaining a repeat sample if the first result was negative despite a high level of clinical suspicion.<sup>79</sup>

### Cardiac

In addition to the degree of risk for cardiovascular disease prevalent in individuals of similar background, patients with malignancies can be exposed to tumor or treatment-related effects that negatively impact cardiac function.<sup>80</sup> Tumor-associated conditions include compression of the heart or large blood vessels by masses, the presence of pericardial effusions, and the production of substances such as catecholamines by the malignant cells that either have cardiotoxic properties or promote arrhythmias.<sup>80</sup> Among the treatment side effects are chemotherapy-associated cardiac failure, myocarditis, pericarditis, and coronary artery spasms.<sup>80</sup> Measurement of either brain natriuretic peptide or pro–brain natriuretic peptide serves as a fast, easily performed, and economical blood test to assist in the assessment of suspected heart failure or, when appropriate, the clinical evaluation of patients prior to surgery or administration of cardiotoxic chemotherapy. Cardiac marker tests such as cardiac troponin I or T, creatine kinase MB, and myoglobin are useful adjuncts to the electrocardiogram in the assessment of chest pain. Because the predictive value of these tests varies by time since onset of the cardiac event, measurement of an “early” marker, such as myoglobin, is frequently combined with that of a “late” marker, such as cardiac troponin I or T. Serial measurements (typically three or four) are obtained over a 24-hour period to detect the expected changes in values over time characteristic of cardiac injury. Increased cardiac marker values can also be found in conditions other than acute myocardial infarction that are commonly

seen in patients hospitalized with cancer. These include renal failure, pulmonary emboli, myocarditis, pericarditis, sepsis, and heart failure.<sup>81</sup> As a result, clinical correlation is important, especially when evaluating the clinically ill, hospitalized patient to ensure the accurate interpretation of results.

### Gastrointestinal Tract

*Clostridium difficile* is a common cause of hospital-acquired diarrhea in patients treated with antibiotics and, consequently, is a source of treatment-related complications in the oncology patient as treatment with antibiotics usually occurs sometime during the course of the disease.<sup>82</sup> Although a cytotoxin-mediated diarrhea is frequently the only overt symptom, an increase in the white blood cell count, an elevated temperature, or even toxic megacolon can also be present.<sup>82</sup> Rarely, the organism can be associated with other findings, such as abscess formation, peritonitis, and other infections.<sup>83</sup> A pseudomembranous colitis is the classic finding, although the diagnosis is often made clinically when cytotoxin is detected in individuals who are also symptomatic.<sup>82</sup> It should be noted, however, that asymptomatic colonization is estimated to occur in approximately 3% of healthy adults,<sup>83</sup> and these do not require treatment.<sup>82</sup>

### Skin

Ancillary laboratory studies can be useful in the evaluation of skin lesions when malignancy is suspected and the diagnosis will be aided by additional confirmatory evidence. Such studies are most often helpful when tumors are hematopoietic in origin. An example is the assessment of patients for a possible diagnosis of mycosis fungoides. Biopsy of the skin typically shows an atypical dermal lymphoid infiltrate. Additional complementary studies include immunohistochemical stains that provide evidence of T-cell lineage (CD3<sup>+</sup>, CD4<sup>+</sup>) while simultaneously ruling out the presence of B-cell, myeloid, or other tumor cell types. T-cell receptor gene rearrangement studies are useful to confirm the presence of monoclonality, whereas flow cytometry analysis performed on a blood sample can evaluate for the presence of an aberrant T-cell population within the patient’s peripheral blood. Use of immunohistochemistry, flow cytometry, and molecular analysis can particularly enhance the ability to discriminate benign, inflammatory skin lesions from true clonal expansions, as well as to identify the specific cell type of origin in malignant skin tumors that are hematopoietic in nature. As such, these studies can provide invaluable confirmatory information in these types of cases.

### Hematology

Cancer has a well-recognized association with the presence of coagulopathies, although the

underlying mechanisms are still under investigation. It is estimated that thrombosis may be the most common complication experienced by cancer patients and the second most common cause of mortality.<sup>84</sup> Symptoms associated with cancer-related hypercoagulability range from ischemic strokes<sup>85</sup> to recurrent episodes of thromboembolism.<sup>85</sup> Symptoms and laboratory evidence of a coagulation disorder, including thrombocytopenia and increased D-dimer levels,<sup>86,87</sup> can be the first manifestation of a previously undetected malignancy.<sup>86</sup>

## Summary

Patients with cancer are at risk of both disease-related and treatment-related complications. These include electrolyte disturbances, serum protein abnormalities, coagulation disorders, cardiac manifestations, and infection. A broad range of testing services are necessary to provide the needed level of support for diagnosis and treatment.

# Risk Assessment and the Management of Neutropenia and Fever

Kenneth V. I. Rolston, MD

The relationship between neutropenia and the frequency and severity of infection was first described by Bodey and colleagues four decades ago.<sup>1</sup> Febrile neutropenic patients can develop rapidly progressive infections and serious medical comorbidity, necessitating aggressive antimicrobial therapy and supportive care, including close monitoring in the hospital.<sup>2</sup> It has long been recognized, however, that not all neutropenic patients have the same risk of developing serious infections and/or complications. Our ability to reliably identify such patients early in the course of a febrile episode was quite limited until very recently, leading to the uniform policy of administering hospital-based empiric antibiotic therapy to all febrile neutropenic patients.<sup>3</sup> As our understanding of the syndrome of “febrile neutropenia” has grown, it has become possible to identify low-risk patients with reasonable accuracy at the onset of a febrile episode.<sup>4</sup> Several risk assessment schemes are available, including statistically derived and validated risk prediction rules and clinical criteria developed primarily at The University of Texas M. D. Anderson Cancer Center (MDACC).<sup>4-8</sup> Improvements in supportive care, including drug development and delivery systems and the ability to manage substantial numbers of patients in an ambulatory setting, have enabled clinicians to consider not only the nature of empiric antibiotic therapy in febrile neutropenic patients (eg, combination regimens vs monotherapy) but the route of administration (parenteral, sequential, or oral), and the treatment setting (hospital, ambulatory treatment center, home) as well. This chapter focuses on risk assessment in neutropenic patients, the various choices available to treat low-risk patients, and the infrastructure necessary to develop and maintain a successful program of outpatient therapy. Many of the principles that are discussed were developed at MDACC, where outpatient antibiotic therapy in low-risk febrile neutropenic patients has been practiced safely since the late 1980s.

## Historical Perspective

The development of chemotherapy represented a significant step in the fight against cancer. Most chemotherapeutic regimens caused some degree of myelosuppression, leading to the two most common complications associated with chemotherapy: bleeding owing to thrombocytopenia and infection secondary to neutropenia. In neutropenic patients, fever is almost always the result of an infection and is often the only manifestation of infection, although, occasionally, noninfectious causes, such as tumor fever or drug fever, might be present.<sup>9</sup> Approximately 15 to 50% of patients with a solid tumor and > 80% of patients with hematologic malignancies will develop at least one episode of fever.<sup>10</sup> Early autopsy studies demonstrated that, particularly in patients with hematologic malignancies, infections were among the most frequent causes of death.<sup>11,12</sup> Often these infections were unrecognized and untreated, negating the potential benefit of antineoplastic therapy on the underlying neoplastic disorder. These data led to the concept of administering “empiric” antimicrobial therapy to neutropenic patients before documenting a specific infection.<sup>13</sup>

Early empiric therapy consisted of agents such as oxacillin, nafcillin, and vancomycin for gram-positive coverage and aminoglycosides such as gentamicin for gram-negative coverage.<sup>13</sup> These regimens had a significant impact on gram-positive infections, but aminoglycosides were associated with treatment failures despite *in vitro* susceptibility of gram-negative bacilli, such as *Escherichia coli* and *Pseudomonas aeruginosa*, to them.<sup>14</sup> The first major advance in the treatment of gram-negative infections was the development of the antipseudomonal agent penicillin-carbenicillin, which, when combined with an aminoglycoside or used as a single agent in high doses, was successful in treating many gram-negative bacteremic infections.<sup>15,16</sup> Further refinements, such as the addition of a cephalosporin to the empiric regimen to cover *Klebsiella* species and to enhance gram-positive coverage, led to

regimens that were associated with response rates of 60 to 75%.<sup>17-20</sup>

All early empiric regimens were administered parenterally. The first experience with oral antibiotic therapy in hospitalized patients was the use of trimethoprim-sulfamethoxazole (TMP-SMX) for infections that were refractory to other antibiotic regimens.<sup>21</sup> With the subsequent development of the fluoroquinolones, particularly ciprofloxacin (which had potent activity against most gram-negative organisms, including *P. aeruginosa*), sequential (ie, intravenous → oral) or oral antibiotic therapy for the entire febrile episode became a viable option.<sup>22,23,24</sup> Economic pressures led to the development of home health care agencies, which shifted the focus away from hospital-based care. Many institutions invested in the infrastructure necessary to maintain ambulatory or home health care programs as part of a comprehensive health care plan. All of these developments have had an impact on the management of febrile neutropenic patients.

## Risk Assessment Strategies

Several investigators have attempted to devise risk prediction rules since the late 1980s. Talcott and colleagues at the Dana-Farber Cancer Institute identified four subsets among febrile neutropenic patients in a deviation study.<sup>5</sup> Group 1 consisted of patients primarily with hematologic malignancies and substantial medical comorbidities, who were already in hospital when they developed their febrile episode (Table 1). This group had a complication rate of 34% and a mortality rate of 23%. The three remaining groups were not hospitalized when their febrile episodes developed. Group 2 consisted of outpatients with concurrent medical comorbidity (eg, volume depletion, nausea or vomiting, pain). Of the patients in group 2, serious complications occurred in 55% and 14% died. Group 3 contained outpatients without concurrent comorbidity but whose cancer was uncontrolled. Major complications occurred in 31% of these patients and 15% died. None of these three groups were

**Table 1** Outcomes Related to Risk Groups among Febrile Neutropenic Patients\*

Risk Group	Number of Patients (%)	Serious Complications (%)	Deaths (%)
Group 1 (inpatients)	369 (52)	128 (37)	48 (13)
Group 2 (outpatients with concurrent comorbidity)	65 (9)	26 (40)	8 (12)
Group 3 (outpatients with uncontrolled cancer)	55 (8)	14 (25)	8 (15)
Group 4 (low-risk outpatients)	216 (31)	7 (3)	0 (0)
All patients	705 (100)	175 (25)	64 (9)

\*Combined data from Talcott and colleagues' derivation and validation studies.<sup>5,6</sup>

considered to be low risk. Group 4 consisted of patients with no comorbidity and responsive tumors, that is, uncomplicated fever and neutropenia. The complication rate in this group was 3%, and there were no deaths. These patients were considered to be low risk. These findings were later validated in a two-center validation study and formed the basis for some initial studies of early discharge or outpatient treatment of low-risk febrile neutropenic patients.<sup>6,25</sup> Interestingly, the presence of a hematology malignancy or a bloodstream infection did not appear to portend a poor outcome in the analysis.

Several years later, an international collaborative study conducted through the Multinational Association for Supportive Care in Cancer (MASCC) established and validated a scoring system to identify low-risk febrile neutropenic patients at the time of presentation.<sup>7</sup> Integer weights were assigned to seven different characteristics to develop a risk index score (Table 2). These characteristics included the extent of illness, hypotension, lung disease, solid tumor or absence of fungal infection, no dehydration, outpatient status, and age < 60 years (children were excluded). A score of 21 or greater identified low-risk patients with a positive predictive value of 91%. This MASCC risk index has been internationally accepted and endorsed by societies such as the Infectious Diseases Society of America

**Table 2** MASCC Risk Index Scoring System for Identification of Low-Risk Neutropenic Patients\*

Characteristic	Score
Burden of illness (no symptoms or mild symptoms)	5
No hypotension	5
No COPD	4
Solid tumor or no previous fungal infection	4
No dehydration	3
Burden of illness (moderate symptoms)	3
Outpatient status at onset of fever	3
Age < 60 yr	2

COPD = chronic obstructive pulmonary disease; MASCC = Multinational Association for Supportive Care in Cancer.  
\*Highest score possible is 26. A score of  $\geq 21$  indicates strong likelihood of low-risk status.<sup>7</sup>

(IDSA) and the National Comprehensive Cancer Network (NCCN).<sup>26,27</sup>

Before the development and validation of these risk assessment rules, several institutions, including the National Cancer Institute (NCI), the European Organisation for Research and Treatment of Cancer (EORTC), and MDACC, used clinical criteria to identify low-risk patients for clinical trials.<sup>8,28,29</sup> These criteria included hemodynamic stability, outpatient status, expected duration of neutropenia  $\leq 7$  to 10 days, and absence of a significant medical comorbidity, such as abdominal pain, bleeding, mental status changes, suspected serious catheter-related infection, or a new pulmonary infiltrate. Some centers do not consider patients with hematologic malignancies to be low risk, regardless of other clinical characteristics.<sup>8,30</sup> These clinical criteria might be more practical to use in busy clinical practices, whereas the MASCC risk index is recommended when conducting clinical trials to ensure uniformity in patient selection and interpretation of study data.<sup>31</sup>

Most risk assessment rules have been derived and validated in adult oncology patients. One study from the Memorial Sloan-Kettering Cancer Center evaluated 161 pediatric oncology patients with 509 episodes of fever and neutropenia and determined that children who initially lack signs of sepsis, are afebrile, and have an absolute neutrophil count (ANC) of 100 or higher after 48 hours are at low risk of complications and could be selectively discharged on antimicrobial agents after a 48-hour period of hospitalization.<sup>32</sup> These and other criteria are now being used to identify low-risk pediatric oncology patients for outpatient antibiotic therapy from the onset of a febrile episode.<sup>33</sup>

## Epidemiology of Infection

The epidemiology of infection in neutropenic patients undergoes periodic change and is often subject to geographic and institutional factors. Nevertheless, certain general trends are consistently observed. Approximately half the number of patients with fever and neutropenia will have episodes of “unexplained fever,” that is, a clinical course consistent with infection but with no

clinical microbiologic or serologic documentation of infection.<sup>9</sup> Approximately 20 to 30% will have “clinically documented infections,” that is, a clinical site such as cellulitis or pneumonia, but negative cultures. Only 25 to 30% will have a “microbiologically documented infection,” that is, positive cultures from a normally sterile site, such as blood or urine (Figure 1). A very small proportion of patients, generally less than 5%, will have noninfectious causes of fever, such as tumor fever or drug fever.

Among patients with documented infections, the most common sites are the bloodstream, urinary tract, respiratory tract, skin and skin structure, and gastrointestinal tract.<sup>9</sup> Approximately 50% of microbiologically documented infections are caused by gram-positive organisms, predominantly *Staphylococcus* species, various streptococci, and *Enterococcus* species (Table 3).<sup>34,35</sup> If only bloodstream infections are considered, the proportion of gram-positive infections is even higher (70–75%).<sup>36</sup> Gram-negative organisms cause 20 to 25% of microbiologically documented infections, and a similar number are polymicrobial.<sup>37</sup> Anaerobes are isolated very infrequently. Fungal and viral infections occur much later in the course of a neutropenic episode, and some viral infections are seasonal (eg, community respiratory viruses). These infections are dealt with in Viral Infections (Chapter 17) and Fungal Infections (Chapter 18). The frequency of infection in low-risk patients is approximately 20 to 30%. The spectrum is different from that seen in high-risk patients, with very few infections caused by viridans group streptococci, *Enterococcus* species, *P. aeruginosa*, *Stenotrophomonas maltophilia*, and other multidrug-resistant bacteria being seen in this patient subset.<sup>38</sup>

## Risk-Based Therapy

There is uniform agreement that patients who are not classified to be low risk should receive hospital-based, parenteral, broad-spectrum empiric antibiotic therapy.<sup>39</sup> The various benefits of this approach and the many treatment options (including combination regimens and monotherapy) are discussed in detail in Chapter 19. In

**FIGURE 1** Nature of febrile episodes in neutropenic patients.

general, empiric therapy should take into consideration local epidemiology and susceptibility or resistance patterns. It is probably not advisable to have one standard regimen for use in such patients since this hastens the development of resistance.<sup>40</sup> Using various options based on patient type and the nature and site of infection (termed antibiotic heterogeneity) is probably a better approach, although there are no randomized trials comparing these two approaches. The remainder of this discussion focuses on the various options available to treat low-risk, febrile neutropenic patients.

### Antibiotic Therapy in Low-Risk Patients

The various treatment options for low-risk febrile neutropenic patients are listed in Tables 4 and 5. Each option is discussed separately with appropriate background information.

### Hospital-Based Oral Antibiotic Therapy

Despite the development of reasonably accurate risk prediction rules, the availability of oral antimicrobial agents (eg, the fluoroquinolones)

**Table 4** Treatment Options for Low-Risk Febrile Neutropenic Patients

Hospital-based oral antibiotic therapy
Initial parenteral therapy in hospital, followed by early discharge on outpatient parenteral or oral antibiotics, when stable
Outpatient parenteral, sequential (intravenous → oral), or oral antibiotic therapy for the entire febrile episode

with a broad spectrum of activity, including potent gram-negative activity, and the emergence of home health care agencies, many clinicians and investigators did not feel comfortable with the concept of oral outpatient antibiotic therapy for low-risk febrile neutropenic patients. Consequently, they chose to evaluate oral therapy in hospitalized low-risk patients, making the assumption that the hospital was the safest place to treat such patients. Two large prospective randomized trials compared oral antibiotics with standard parenteral regimens in hospitalized low-risk patients. The International Antimicrobial Therapy Cooperative Group of EORTC compared intravenous ceftriaxone plus amikacin with oral ciprofloxacin plus amoxicillin-clavulanate and found these two regimens to be equivalent (84% vs 86% success rate). The frequency of adverse events, including death (related or unrelated to infection), was also found to be similar for both regimens.<sup>28</sup>

**Table 5** Common Therapeutic Regimens in Low-Risk Febrile Neutropenic Patients

<b>Parenteral regimens</b>	
Aztreonam + clindamycin

<b>Oral regimens</b>	
Ciprofloxacin + clindamycin	
Ciprofloxacin + amoxicillin-clavulanate	
Gatifloxacin or moxifloxacin*	
Ofloxacin, levofloxacin†	
*Only pilot data are available. No randomized studies yet. (Gatifloxacin not available in U.S.)	
†Not recommended as monotherapy.	

Investigators from the NCI and allied institutions compared oral ciprofloxacin plus amoxicillin-clavulanate with intravenous ceftazidime monotherapy.<sup>29</sup> Although both regimens were again found to be equivalent (success rates of 71% and 67%, respectively), the response rates achieved with both regimens were lower than expected. Also, there was a high rate of intolerance of the oral regimen (16%) in comparison with the intravenous regimen (1%). Nevertheless, there were no deaths in either regimen, and more than 90% of patients were afebrile by day 5 of therapy.

The success of oral antibiotic regimens demonstrated in these and other smaller trials may have significant implications for the management of neutropenic patients with fever, particularly in countries with limited resources.<sup>41</sup> In the United States and other nations with similar reimbursement and legal systems, hospital-based oral antibiotic therapy will probably not enjoy widespread use. In reality, most low-risk patients who are able to tolerate oral therapy can probably be discharged from the hospital and treated as outpatients. A small number may need to be hospitalized for reasons not related to their febrile episode or might live alone and be unable to adequately care for themselves. Such patients might benefit from hospital-based oral therapy.

### Early Discharge on Parenteral or Oral Antibiotics

Another approach in low-risk febrile neutropenic patients is initial treatment in hospital, followed by early discharge (after approximately 48 hours of hospitalization) on oral or parenteral antibiotics. Several trials have evaluated this approach. Shortly after developing their risk prediction rule, Talcott and colleagues conducted a pilot study to test the feasibility of this approach.<sup>25</sup> Low-risk patients who had evidence of a significant source of infection, including an infiltrate on a chest radiograph or bacterial growth from initial blood cultures, and those who were 65 years or older were excluded to reduce the risk to patients further. All patients received “standard” parenteral regimens for 48 hours in a hospital and were then discharged on the same regimen for home antibiotic therapy. The regimens included ceftazidime as monotherapy or mezlocillin + gentamicin as a combination regimen.

The results of this trial were disappointing. Of the 30 patients treated on this trial, 9 (30%) required readmission to the hospital. Four of these had medical complications (hypotension, renal failure, persistent fever, development of new infections, including mucormycosis), and five required changes to their antibiotic regimen after discharge. It was notable that 75% of serious complications occurred in patients with > 7 days of neutropenia. These results brought into

question Talcott and colleagues' criteria for the identification of low-risk patients, particularly the inclusion of patients with leukemia with the potential to develop prolonged neutropenia.

Better results were achieved by investigators from the United Kingdom, who modified Talcott and colleagues' criteria for patient selection (excluding patients with documented infections and only enrolling patients with solid tumors or lymphomas and an anticipated duration of neutropenia of 7 days or less).<sup>42</sup> Early discharge on oral ciprofloxacin and amoxicillin-clavulanate was associated with a much lower readmission rate (7.6%), the regimen was well tolerated, and there were no deaths associated with this approach.<sup>43</sup>

In a similar study, children presenting with fever and neutropenia at six hospitals in Santiago, Chile, were randomly assigned to receive ambulatory antibiotic treatment after 24 to 36 hours of hospital-based therapy if categorized to be low risk.<sup>33</sup> Initial parenteral therapy consisted of intravenous teicoplanin and ceftriaxone followed by oral cefuroxime on early discharge. Seventy-four (95%) of 78 patients treated in this manner had a positive response. Three recovered completely after therapeutic modifications. One developed fulminant infection owing to *P. aeruginosa* and died within 96 hours. Although the results of this trial are encouraging, they do highlight the fact that, occasionally, fulminant infections do occur even in patients considered to be low risk. Notably, neither regimens used in this study (intravenous or oral) had adequate antipseudomonal coverage.

### Ambulatory Management of the Entire Febrile Episode

A significant proportion of patients cared for at MDACC come from other countries, are uninsured, and/or pay out of pocket. In the early 1980s, approximately 50 patients with solid tumors who developed fever and neutropenia while receiving outpatient chemotherapy refused hospital admission and were treated with oral antibiotic regimens (primarily TMP-SMX + rifampin or clindamycin) without hospitalization. Most of these patients responded to oral, outpatient therapy, with no serious complications and no deaths (K. Rolston, 1988). This experience served as pilot data for formal trials of outpatient antibiotic treatment of febrile neutropenic patients at this institution. To date, three randomized trials have evaluated this approach at MDACC, and a few other trials have been conducted at other institutions as well. A recently published meta-analysis of these trials concluded that "oral antibiotics may be safely offered to neutropenic patients with fever who are at low risk for mortality."<sup>44</sup> The results of four trials (and outcomes of patients treated on MDACC

institutional outpatient pathways) conducted at MDACC are summarized in Table 6. These results demonstrate that both parenteral and oral regimens are safe and effective in low-risk febrile neutropenic patients. The response rates associated with these regimens ranged from 80 to 95%. Many patients not responding to the initial regimen responded to alternative outpatient regimens. Among the few patients requiring hospital admission, none had serious complications, none required care in the intensive care unit, and there were no infection-related deaths.<sup>8,45-48</sup>

All of the therapeutic approaches discussed above for the treatment of low-risk febrile neutropenic patients have now been accepted and endorsed by the IDSA and the NCCN as the standard of care.<sup>26,27,39</sup> Some important issues regarding risk-based therapy are discussed below.

### Risk-Based Therapy: General Issues

The above discussion has summarized progress that has been made over several decades but particularly during the past 15 years. This progress is the result of several factors, including

- Increased understanding of the syndrome of "febrile neutropenia"

- Technological advances in vascular access, infusion therapy, and outpatient monitoring
- The availability of potent oral antimicrobial agents that are easy to administer and are associated with very few adverse events
- Improved microbiologic techniques
- The current climate of the health care industry, which has provided much of the impetus for evaluating nontraditional methods and sites of care
- The "team approach" to management, which includes the patients and their families

It must be remembered that most of the strategies discussed above have been developed and tested in large tertiary care hospitals and/or comprehensive cancer centers, with a particular interest and substantial experience and expertise in caring for cancer patients. The ability to create and maintain an infrastructure that can handle these strategies and the complicated logistics involved in large numbers of patients is critical to the success of such programs, and may not be available at many institutions. This infrastructure includes health care providers from various disciplines—physicians, nurses, pharmacists, vascular access and infusion therapy teams, home health care personnel, and patients and their caregivers—all acting in concert to ensure that

**Table 6** Results of Trials of Outpatient Antibiotic Therapy in Low-Risk Patients with Fever and Neutropenia Conducted at The University of Texas M. D. Anderson Cancer Center

Author	Reference	Type of Study and Patient Population	Antibiotic Regimen(s)	% Response to Initial Regimen
Rubenstein et al	8	Randomized trial of outpatient regimens, all adults, 83 episodes	IV, aztreonam 2 g q8h + clindamycin 600 mg q8h vs PO, ciprofloxacin 750 mg q8h + clindamycin 600 mg q8h	95 88

the best supportive care is delivered as efficiently and safely as possible (Table 7). At institutions in which such an infrastructure does not exist, standard hospital-based care should continue to be provided to low-risk patients.

### Risk-Based Therapy: Advantages and Disadvantages

Standard, hospital-based antibiotic treatment of the febrile neutropenic patient has been extremely successful in reducing the mortality and improving the overall outcome of such patients, particularly high-risk patients prone to developing serious complications.<sup>39</sup> It is, however, not necessary or even beneficial in all febrile neutropenic patients. Risk-based therapy is associated with several benefits, which are outlined in Table 8.

Data presented at the Fourth Decennial International Conference on Nosocomial and Healthcare-Associated Infections (Atlanta, GA, 2002) documented that each year approximately

2 million patients in the United States develop infections while hospitalized for other conditions.<sup>51</sup> These infections cost 4.6 billion dollars to treat and result in 88,000 deaths. Additionally, more than 70% of these infections are caused by organisms resistant to at least one antibiotic (many are multidrug resistant) generally used to treat such infections. Such infections are much more common in a hospital or long-term care setting than in a home care setting. Studies done in the 1960s demonstrated that patients acquired “hospital flora” 5 to 7 days after hospitalization. Consequently, early discharge from hospital to a home health care setting or total ambulatory care substantially reduces the frequency of resistant nosocomially acquired infections, particularly in patients who are otherwise at very low risk of developing serious complications or mortality.

As mentioned previously, many clinicians assumed that the hospital is the safest place to deliver health care and that care delivered at other sites must be shown to be “as safe as” hospital-based care. This assumption was brought into serious question in a disturbing report entitled “To Err Is Human,” produced by the Institute of Medicine.<sup>50</sup> This report focuses on several studies conducted across the United States and points out that the frequency of adverse events in US hospitals ranges between 2.9 and 3.7% of hospitalizations. Furthermore, between 8.8 and 13.6% of these events lead to death, and over half of these adverse events are due to medical errors that are considered to be preventable. When extrapolated to the 37 million annual admissions to US hospitals, these studies imply that between 44,000 and 98,000 patients die each year as a result of medical errors. Although medical errors (preventable or otherwise) occur in all health care settings, this report also points out that four of five such events occur in the hospital. These data strongly suggest that the hospital may not be the safest place to deliver health care. The low complication and death rates associated with outpatient therapy seem to support the findings of this important report. Governmental and nongovernmental organizations responsible for developing policies for the delivery of health care need to take these outcomes into consideration.

Several studies have demonstrated the positive economic benefits of early discharge and/or outpatient antibiotic therapy compared with hospital-based therapy.<sup>8,25,33,47</sup> Studies have also documented significant improvements in the quality of life of patients receiving risk-based therapy (particularly outpatient therapy) and increased convenience for their families or other caregivers as well.<sup>8,25,44</sup> This aspect does not receive much mention in today’s “outcomes” and financially focused health care environment. It is, however, an extremely important consideration

in the overall care of the cancer patient and should not be ignored.

There are some potential disadvantages of risk-based (particularly oral, outpatient) therapy. Low risk does not mean “no risk,” and the potential for developing serious complications, such as septic shock, severe bleeding, or seizures, in a relatively unsupervised environment does exist. Careful patient selection and close monitoring of patients generally prevent but do not eliminate the occurrence of such events or enable one to manage them promptly should they occur. The potential for litigation might be a bit higher since hospital-based mishaps appear to be better accepted than those that occur outside the hospital. Additionally, some patients, particularly those on oral therapy, might not be fully compliant. Maintaining adequate vascular access can also occasionally become a problem that might be difficult to deal with immediately in an ambulatory or home care setting. Finally, patients might develop a false sense of security regarding their febrile episode since it did not require hospitalization and may ignore early signs or symptoms of progressive infection or other complications. It is imperative that patients be given very specific, written instructions regarding follow-up and monitoring. Some institutions might be unwilling or unable to invest in the infrastructure necessary to maintain these standards and requirements.

### Future Considerations

Current risk assessment strategies are reasonably accurate. However, misclassification of patients does occur. This can have serious consequences when high-risk patients are misclassified as low risk. Further refinements in risk prediction rules that increase sensitivity and specificity and reduce the misclassification rate might increase the safety of this approach and perhaps make it applicable even in institutions that lack the infrastructure required currently.

The duration of neutropenia following the development of an episode of neutropenic fever is a critical determinant of low risk. Our ability to predict the duration of neutropenia has improved, but studies are under way to develop prediction rules that are more accurate. The impact of hematopoietic growth factors (granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor) on the risk and duration of neutropenia also needs to be fully investigated.

As the epidemiology of infection and susceptibility or resistance patterns change (eg, the startling increase in community-acquired methicillin-resistant *Staphylococcus aureus*) and as newer antimicrobial agents become available, newer treatment and preventive regimens and strategies will need to be developed.

---

## Summary

The use of empiric antibiotic therapy in neutropenic patients with fever has been a very successful strategy that has dramatically improved the overall survival of such patients. The recent recognition of distinct risk groups among febrile neutropenic patients has led to the development of newer treatment strategies for low-risk patients instead of the uniform strategy of hospital-based parenteral antibiotic therapy for all patients. Newer options include hospital-based oral antibiotic therapy for a selected group of patients, early discharge on parenteral or oral regimens after initial hospitalization, and ambulatory (clinic, office, home) management of the entire febrile episode. The advantages of risk-based therapy currently far outweigh the potential disadvantages. Newer challenges and newer opportunities will undoubtedly arise as future changes occur in the treatment of cancer patients.

# Bacterial Infectious Disease Issues: Catheter-Related Infections

Issam I. Raad, MD  
Hend Hanna, MD, MPH  
Dennis G. Maki, MD

The management and care of patients with cancer and critically ill patients have, no doubt, been revolutionized by the technologic advances in medical devices, including the availability of central venous catheters (CVCs). Patients with cancer often need these devices, particularly long-term Silastic catheters, to receive chemotherapy, antibiotics, blood products, and intravenous hyperalimentation. CVCs are vascular access devices that are made of soft flexible biocompatible polymers. After being inserted into a large vein of the vascular system, such as the subclavian or internal jugular vein, they are advanced until the tip of the catheter is resting in the superior vena cava.

Prior to the advent of central catheterization, patients with cancer received intravenous chemotherapeutic agents, including vesicant agents through small peripheral venous catheters. This process was often complicated by extravasation and thrombosis of peripheral veins, which often interfered with anticancer chemotherapy administration. CVCs allowed for the safe and extended use of anticancer agents and the appropriate use of total parenteral nutrition, such as for patients with short bowel syndrome, as well as blood products and intravenous therapeutic agents. Similarly, patients requiring hemodialysis are in need of CVC as either an interim access during maturation of a graft or fistula or as a permanent vascular access for patients who may have failing arteriovenous fistulae or shunts. Therefore, it is no surprise that health care organizations purchase millions of intravascular catheters annually.

CVCs are not, however, without risk, and their use puts patients at potential risk of infections, both local and systemic. Infectious complications associated with the use of CVCs include local site infection, catheter-related bloodstream infection (CRBSI), septic thrombophlebitis, and other metastatic infections, such as endocarditis,

osteomyelitis, endophthalmitis, and occasional organ abscesses.

## Epidemiology and Impact

Hospitals and clinics in the United States purchase annually more than 150 million intravascular devices to administer various intravenous medications, blood products, and parenteral nutrition fluids; to provide hemodialysis; and to monitor hemodynamic status.<sup>1</sup> Although the majority of these devices are peripheral catheters, still, each year, over 5 million CVCs are inserted. More than 200,000 health care-related bloodstream infections (BSIs) occur in the United States per year, where most of these infections are associated with the use of CVCs, with the rates of BSIs being higher among patients with CVCs than among those without these devices.<sup>1</sup> The incidence of CRBSIs depends on the type, material, and site of the catheter; how often the catheter is manipulated and accessed; the patient's underlying disease; the acuity of the illness; and the type of drug injected through the catheter. According to recommendations from the Centers for Disease Control and Prevention (CDC) and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), the rates of CRBSIs are better expressed as the number of BSIs per 1,000 catheter-days.<sup>2,3</sup> Reporting the rate of infection in such a manner accounts for the BSI over time, adjusting the risk of the infection to the number of days the catheter is in use, and, hence, is at risk of infection.

Since the 1970s, the CDC established a National Nosocomial Infection Surveillance (NNIS) system to collect data on hospital-acquired infections and their etiology and incidence, including BSIs associated with the use of CVCs. The NNIS data are collected from more than 300 participating hospitals in the United States, and the rates of CRBSI vary, depending on

the size of the hospital, the particular service or unit at the hospital, the type of intensive care unit (ICU), and the type of catheter used.<sup>3</sup> According to NNIS data, from January 1995 through June 2003, the rates of CRBSI, ranged from 2.9 (in cardiothoracic ICU) to 10.6 (in a neonatal nursery for infants weighing  $\leq 1,000$  g) BSIs per 1,000 catheter-days.<sup>3</sup>

The problem of CVC-associated infections creates an undeniable substantial burden, both to the patient, in terms of morbidity and mortality, and to the economy, in terms of cost of care. It is estimated that about 80,000 CRBSIs occur annually in ICUs in the United States.<sup>4</sup> The magnitude of this problem among these patients was estimated with the aid of a computer model that was based on American Hospital Association data. According to this model, Mermel estimated that an average of 5.3 CRBSIs per 1,000 catheter-days occur annually, which accounts for around 80,000 CRBSIs per year and approximately 2,400 to 20,000 deaths owing to CRBSIs.<sup>5,6</sup> The model also helped estimate that the annual management of these ICU patients with CRBSIs could cost from \$296 million to \$2.3 billion.<sup>5,6</sup> In addition to these critically ill and hospitalized patients, many patients are discharged with central venous lines in place while they continue their intravenous therapy on an outpatient basis. This patient group is also at risk of acquiring catheter-related infections. When the entire health care-related services (not only ICUs) are considered, it is estimated that about 250,000 cases of CRBSIs occur annually. These infections are associated with prolongation of hospital stay and attributable mortality that range from 12 to 25%, with a cost of care that is estimated to be from \$34,508 to \$56,000 per each episode of infection, and the yearly cost of managing and caring for patients with CRBSIs was found to range from \$296 million to \$2.3 billion.<sup>1,3,6-10</sup>

## Pathophysiology and Risk Factors

A thorough understanding of the pathogenesis of catheter-related infections is an important prerequisite for accurate diagnosis, effective prevention, and successful management of these infections. Catheter-related infections are often caused by organisms that are resistant to many available antimicrobial agents and hence are difficult to treat. For the CVC to be inserted into the blood vessel, the integrity of the skin has to be broken to allow for the introduction and advancement of the device into the vascular system. Indwelling catheters connect a sterile environment, namely, the interior of the blood vessel, with the nonsterile skin surface at the catheter insertion site, allowing organisms, commonly colonizing the skin surface, to migrate along the catheter surface.

## Sources of Infections and Microbiologic Characteristics

Once the catheter is inserted, it becomes at risk of being colonized with microorganisms that eventually may lead to catheter-related infections. Microorganisms that are able to colonize the surface of the catheter may originate from different sources through any of the following mechanisms (Figure 1):

Organisms colonizing the skin are able to invade the percutaneous tract around the catheter insertion site, colonizing the catheter surface, particularly the extraluminal. This can occur either at the time of catheter insertion, especially when maximal sterile barrier precautions are not

being thoroughly practiced, as during an emergent insertion of a catheter, or afterward during the catheter dwelling.<sup>11</sup> Short-term, nontunneled, and noncuffed catheters are often colonized through this route, whereby organisms migrate along the external surface of the catheter, colonizing the catheter tip, which may eventually lead to BSI.<sup>12–14</sup>

As the catheter hub is accessed and manipulated during the catheter use (such as for blood drawing, intermittent medication administration, or flushing), microorganisms from the hands of health care personnel may contaminate the catheter hub and lumen, causing intraluminal colonization of the catheter. This route of contamination is more relevant for long-term tunneled silicone catheters, such as Hickman or Broviac, or long-term totally implantable catheters, such as ports, where the lumen of the hub or the bell of the port, as they are accessed for use, becomes the major source of colonization, which may eventually lead to infection.<sup>15,16</sup>

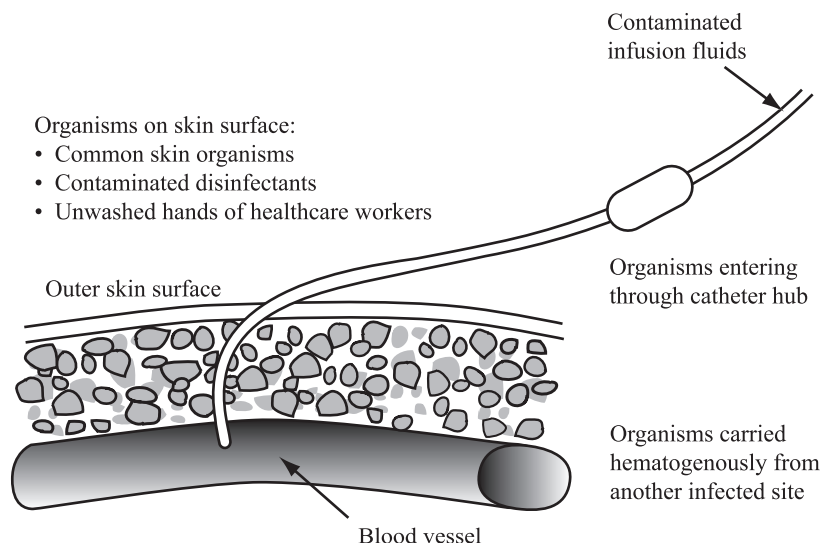

Catheters can also be colonized during the flow of contaminated infusate, as shown by reports of several epidemics of infusion-related bacteremia; however, this mechanism for catheter-related pathogenesis is not very common.<sup>17,18</sup> Whereas *Staphylococcus* and *Candida* are responsible for most other CRBSIs, infusion-related sepsis is often caused by gram-negative bacilli, with *Enterobacter*, *Pseudomonas*, *Citrobacter*, and *Serratia* species being the most commonly seen. In addition, it is known that parenteral nutrition solutions and lipid emulsions promote the growth of certain bacteria and fungi, such as *Candida parapsilosis* and *Malassezia furfur*.<sup>19–21</sup>

Microorganisms originating from an infected site elsewhere in the body, such as pneumonia, urinary tract infection, or gastrointestinal infection, may be carried through the blood, hematogenously, and ultimately adhere to the surface of the inserted catheter, colonizing it (Figure 1). Although hematogenous seeding of the CVC has been suggested,<sup>22,23</sup> its role in catheter colonization and subsequent infection is rarely demonstrated. A study that used electron microscopy in studying catheters that were removed from patients with gram-negative or fungal BSI failed to show evidence of catheter seeding with organisms responsible for the bacteremias that preceded the removal of the catheters.<sup>24</sup>

Because the skin of the patient and the hands of health care workers are the main sources of the contamination of the indwelling catheter, the organisms that are commonly found to be colonizing the CVCs are the ones found to be skin colonizers. Staphylococci, particularly coagulase-negative staphylococci (such as *Staphylococcus epidermidis*) and *Staphylococcus aureus*, are the leading causes of CRBSIs.<sup>14,25–28</sup> Catheters may also become colonized by gram-negative bacilli, mostly nonenteric, originating from the hospital's environment, such as *Pseudomonas*, *Stenotrophomonas*, and *Acinetobacter* species.<sup>25–31</sup> In addition, the hands of medical personnel could also be colonized by yeast, such as *Candida albicans* and *C. parapsilosis*,<sup>32</sup> which are also known to be associated with the use of total parenteral nutrition and infusions containing glucose and, hence, could be responsible for CRBSIs.<sup>24,25</sup> Less commonly, gram-positive bacilli, such as *Corynebacterium* species, although rarely do they colonize the skin or the catheter hub, can sometimes cause catheter-related infections.<sup>25–28,33,34</sup>

## Pathogenesis and Biofilm Formation

The interaction between microorganisms, the medical device itself, and the patient as a host results in the occurrence of catheter-related infections. Microorganisms are able to colonize the catheter because of their ability to attach themselves to the surface of the polymer and synthesize or produce a hydrated extracellular polymeric exopolysaccharide, creating a complex matrix in which they aggregate, forming a biofilm.<sup>35</sup> Virtually all indwelling CVCs become colonized by microorganisms that become embedded in the biofilm matrix, as was shown by scanning and transmission electron microscopy.<sup>36</sup> On catheter insertion, platelets, plasma, and a variety of host tissue proteins, such as fibronectin, fibrinogen, fibrin, collagen, thrombospondin, and laminin, act as mediators of bacterial adherence to the surface of the catheter.<sup>36–41</sup> Different organisms adhere differently to these host tissue proteins; for example, coagulase-negative staphylococci, as well as *C. albicans*, have the ability to adhere to fibrin,<sup>42</sup> whereas *S. aureus* is able to strongly adhere to fibronectin and laminin.<sup>38,39</sup>

**FIGURE 1** Pathogenesis of catheter-related bloodstream infections and possible sources of infection.

The presence of platelets, even in small numbers, was found to greatly enhance the adherence of both streptococci and staphylococci to the fibrin matrix.<sup>37</sup> Raad and colleagues showed that although the biofilm formation on CVC surfaces was universal, its extent and its location depended on the duration of catheterization.<sup>14</sup> Raad and colleagues found that biofilm formation was greater on the external surface of the catheter for short-term catheters that remained in place > 10 days, whereas long-term catheters, with at least 30 days of dwell time, had more biofilm formation on the inner lumen of the catheter. Furthermore, the type of fluid being infused through the CVC may also influence microbial growth; for example, gram-negative organisms, such as *Pseudomonas aeruginosa*, *Klebsiella*, *Enterobacter*, *Pantoea*, and *Serratia* species, grew well in intravenous fluids, whereas gram-positive *S. epidermidis* and *S. aureus* did not.<sup>1,43,44</sup>

During the process of catheter colonization, staphylococci produce significant amounts of extracellular slime, in which these organisms are embedded and covered (Figure 2). This slimy material acts to protect the microorganisms against the host defense mechanisms and antimicrobial agents.<sup>45</sup> Microorganisms within the biofilm are known to behave differently from free-floating or suspended organisms, also known as planktonic organisms. Anwar and colleagues showed that organisms in biofilm are more resistant to antimicrobial treatment, where the cell count of *P. aeruginosa* in biofilm was reduced by about two logs, after treatment with levels of piperacillin plus tobramycin that far exceeded its minimum inhibitory concentration, whereas the same dosage of the antibiotics produced more than an eight-log decrease in the planktonic *P. aeruginosa*.<sup>46</sup> Their study suggested that young biofilm cells of mucoid *P. aeruginosa* could be effectively eradicated with the combination of piperacillin and tobramycin, whereas old biofilm cells were very resistant to these antibiotics and eradication of old biofilm cells was not achievable.

### Risk Factors

The risk of catheter-related infections varies according to several factors (Table 1). Prolonged

Type of Vascular Device	Exit Site	Length (cm)	Rate of CRBSI per 1,000 Catheter-Days, Pooled Mean (95% CI)*	Estimated Cost of Insertion at MDACC (\$)
Peripheral venous catheter	Peripheral veins of forearm or hand	< 7	0.6 (0.3–1.2)	< 1,000
Arterial catheter	Major artery: radial, femoral, axillary, dorsalis, pedis, or brachial	< 7 cm	2.9 (1.8–4.5)	≈ 1,300
Nontunneled CVC	Subclavian, internal jugular, or femoral	25–40	2.3 (2.0–2.4)	≈ 1,300
Pulmonary artery catheter	Swan-Ganz: subclavian, internal jugular, or femoral	Up to 110	5.5 (3.2–12.4)	≈ 1,300
Peripherally inserted central catheter	Basilic, cephalic, or brachial veins into superior vena cava	40–60	0.4 (0.2–0.7)	≈ 1,000
Tunneled venous catheter	Surgically implanted into subclavian, internal jugular, or femoral vein	> 8	1.2 (1.0–1.3)	≈ 6,500
Hemodialysis catheter				
Noncuffed	Surgically implanted into subclavian, internal jugular, or femoral vein	> 8	2.8 (2.3–3.1)	
Cuffed				
Port, implanted	Surgically implanted subclavian or internal jugular	> 8	1.1 (0.7–1.6) 0.2 (0.1–0.2)	≈ 6,500 ≈ 7,000

Adapted from Crnich CJ and Maki DG<sup>103</sup> and Schinabeck MK and Ghannoum MA.<sup>104</sup>  
 CI = confidence interval; CRBSI = catheter-related bloodstream infection; CVC = central venous catheter; MDACC = M. D. Anderson Cancer Center.  
 \*Based on 206 published prospective studies.

duration of catheterization has been found, by several studies, to be a major risk factor for infections associated with the use of venous and arterial vascular catheters.<sup>13,47–50</sup> Because catheter colonization involves microbial adherence to the catheter surface, the polymer material that catheters are made of may also play an important role in promoting thrombogenesis and adherence of organisms. Linder and colleagues demonstrated that catheters made of polyurethane and flexible silicone were less thrombogenic than catheters made of polyvinyl chloride and hence

are associated with fewer infections.<sup>51</sup> Furthermore, staphylococci and fungi adhere better to polyvinyl chloride surfaces than to Teflon.<sup>52,53</sup> Numerous studies, mostly nonrandomized and retrospective in nature, suggest that the risk of infection seems to be higher among catheters with triple lumens than among those with a single lumen.<sup>54–59</sup> Triple-lumen catheters are more likely to be manipulated and accessed more often than single-lumen ones. However, triple-lumen catheters tend to be used more frequently in sicker patients than single-lumen catheters. Prospective randomized trials that included sicker patients at higher risk of developing catheter-related infections failed to show a difference in infection rates, based on the number of lumens.<sup>60–62</sup> The location of the catheter could also influence the risk of catheter-related infection. CVCs have been found to be associated with higher infection rates than arterial catheters or short peripheral catheters. In a review by Hampton and Sherertz, in which they evaluated 30 prospective studies, the daily risk of infection per day of catheterization was found to be 1.3% per day for peripheral venous catheters, 1.9% per day for peripheral arterial catheters, and 3.3% per day for CVCs.<sup>63</sup>

FIGURE 2 Biofilm formation on catheter surface.

Catheters inserted into internal jugular veins were found to be at higher risk of infection than those inserted into subclavian veins, as in the study by Mermel and colleagues, in which catheters inserted into an internal jugular vein were associated with a higher risk of infection (relative risk 4.3,  $p < .01$ ).<sup>13</sup> On the other hand, Senagore and colleagues did not find such an association, and they concluded that using a standard, sterile-insertion technique and a catheter maintenance protocol yielded a low risk of insertion and infectious complications at either the internal jugular or the subclavian site.<sup>64</sup> In a prospective randomized trial, patients in the ICU were randomized to receive either femoral or subclavian CVCs. Femoral catheterization was found to be associated with a higher incidence rate of overall infectious complications (20% vs %,  $p < .001$ ) and thrombotic complications (22% vs 2%,  $p < .001$ ). Femoral catheterization was the only factor associated with infectious complications in that study (hazard ratio 4.8, 95% confidence interval [CI] 1.96–11.93,  $p < .001$ ).<sup>65</sup>

The type of dressing applied to the catheter insertion site has also been studied in terms of its impact on the risk of catheter-related infection. In one prospective randomized study, patients with CVCs for 3 or more days were prospectively randomized to receive an occlusive transparent or gauze dressing and the incidences of insertion-site colonization, local catheter-related infection, and CRBSI were compared.<sup>66</sup> After 48 hours, transparent dressings were associated with significantly increased rates of insertion-site colonization ( $p \leq .009$ ), local catheter-related infection ( $p = .002$ ), and CRBSI ( $p = .015$ ) in patients with long-term CVCs.<sup>66</sup> Occlusive dressing tends to create a warm, moist atmosphere at the insertion site, where microbial growth would be favorable, and, hence, the risk of catheter colonization and infection. Craven and colleagues confirmed these findings in a study in which, by multiple logistic regression analysis, catheter-tip colonization was found to be associated with the summer season (odds ratio 3.0, 95% CI 1.4–6.2) and transparent polyurethane dressings (odds ratio 1.8, 95% CI 1.1–3.2).<sup>67</sup> In addition, Hoffmann and colleagues performed a meta-analysis of all studies published in the English literature, including abstracts, letters, and reports that examined the infection risks associated with transparent compared with gauze dressings for use on central and peripheral venous catheters.<sup>68</sup> The results demonstrated a significantly increased risk of catheter-tip colonization with the use of transparent compared with gauze dressings when used with either central or peripheral catheters. An increased risk of CRBSI associated with the use of transparent compared with gauze dressings was also suggested by the findings of the study, although not confirmed.

Other risk factors that have been observed by investigators include multiple catheter manipulations, the inexperience of some inserters, and violations of aseptic techniques.<sup>63</sup>

### Types of Intravascular Devices

A number of different CVCs are available with varying insertion techniques, sizes, and catheter materials. CVCs may be single-lumen or multilumen, double or triple (Table 1).

### Nontunneled Percutaneously Inserted Catheters

These may be made of silicone or polyurethane materials, and they are inserted into either the peripheral venous system (subclavian vein) or in the neck (jugular vein), through a percutaneous stick, where the catheter tip is advanced until it rests into the superior vena cava. These catheters can be placed in outpatient nonsurgical settings and can be exchanged over a guidewire, at the onset of catheter-related infection. An example of these catheters is the Hohn catheter.

### Tunneled Catheters

These catheters are tunneled surgically under the skin for several inches to the cannulated vein. In 1973, Dr. John W. Broviac designed an intravenous catheter that provided access for patients who required prolonged parenteral alimentation.<sup>69</sup>

Dr. Robert Hickman altered Broviac's prototype in 1979 for patients with leukemia who required chemotherapy.<sup>70</sup> His modified catheter had a larger lumen that facilitated the drawing of blood and the infusion of chemotherapeutic agents, blood, and intravenous fluids. After the catheter is inserted, its distal tip is advanced to just above the right atrium. The proximal end exits via a subcutaneous tunnel from the lower anterior chest wall. A felt Dacron cuff is used to anchor the catheter in place subcutaneously, where eventually it becomes enmeshed with fibrous tissues, allowing the catheter to become securely anchored and, hence, rendering it more stable and less likely to be pulled out accidentally. The cuff also creates a tissue interface that acts as a barrier against the migration of microorganisms. A further modification of these tunneled catheters led to the Groshong catheter, which, unlike the traditional open-ended catheters, has a rounded closed tip, with an adjacent two-slit valve that remains closed unless the catheter is in use. Because the valve remains closed when not in use, it literally seals the fluid inside the catheter, preventing it from getting in contact with the patient's blood and hence reducing the risk of intraluminal blood clotting or infusion of air when the catheter is not in use. The valve also eliminates the need for routine clamping of the catheter.

### Implantable Ports

Ports are totally implantable vascular access devices that are made of plastic or titanium material and are inserted completely beneath the skin, connected to the catheter tube.<sup>71</sup> Ports are surgically placed as either a central subclavian port, which is placed in the subcutaneous pocket of the upper chest wall, or as a peripheral port, which is placed in the antecubital fossa of the arm. Ports are available as single- or double-lumen catheters, with or without the Groshong valve.

### Peripherally Inserted Central Venous Catheters

The use of peripherally inserted central venous catheters (PICCs) has gained acceptance as a method for long-term venous access. A PICC is a catheter made of silicone or polyurethane material and may or may not have the Groshong valve. It is inserted peripherally at or above the antecubital space into the cephalic, basilic, medial cephalic, or medial basilic vein, after which it is advanced into the superior vena cava above the right atrium. These catheters are usually placed in a nonsurgical outpatient setting, under local anesthesia, and may be placed by a skilled and trained infusion therapy nurse. At The University of Texas M. D. Anderson Cancer Center, PICCs were shown to be safe, with a mean duration of dwell of 87 days, and associated with a low rate of infection and a low cost of insertion.<sup>72</sup>

### Manifestations and Definitions

#### Local Catheter Infection

Local signs and symptoms of infection may indicate catheter-related infections. Local infection may exist alone, in the absence of BSI, at the catheter exit site, tunnel, or port pocket. It may be manifested by clinical signs of inflammation and/or infection, such as erythema, swelling, pain, or purulent exudates in the immediate proximity of the catheter insertion site. However, this local inflammatory reaction may be absent, especially in immunocompromised neutropenic patients who lack those inflammatory cells. Clinical evidence of local infection at an exit site, tunnel, or port pocket may suggest that the catheter is the source of a BSI. However, this is not always the case. For example, PICC lines may be associated with local aseptic catheter-site inflammation, secondary to local mechanical irritation of the vein owing to the insertion of a large catheter in the relatively small cephalic or basilic veins.<sup>72</sup> Therefore, it is important to define local catheter-related infections, not only in terms of clinical manifestations but also microbiologic evidence implicating the catheter as the source of the infection. The guidelines from the Infectious Diseases Society of America (IDSA) proposed the following definitions of local catheter infections<sup>73</sup>:

- *Exit-site infection.* Clinically, it could be manifested by erythema, induration, and/or tenderness within 2 cm of the catheter exit site. These manifestations may be associated with other signs and symptoms of infection, such as fever or purulent discharge oozing from the exit site, in the presence or absence of concomitant BSI. Microbiologically, a culture of the exudate or purulent discharge at the catheter exit site may yield a microorganism, with or without concomitant BSI.
- *Pocket infection.* Purulent exudates in the subcutaneous pocket of a totally implantable intravascular device, containing the reservoir of the port, often in the presence of local tenderness, erythema, and/or induration over the pocket, usually indicate pocket infection. Necrosis of the overlying skin or spontaneous rupture and drainage may also occur, with or without concomitant BSI.
- *Tunnel infection.* Clinical signs and symptoms of infection, such as tenderness, erythema, and induration more than 2 cm from the catheter exit site or along the subcutaneous tract of tunneled catheters, such as Broviac or Hickman catheters, in the presence or absence of BSI.<sup>74,75</sup>

### Systemic Catheter Infection

Probable CRBSI consists of bacteremia or fungemia in a patient with a CVC and one or more positive cultures of blood samples (preferably from the peripheral vein) in the presence of signs and symptoms of infection, such as fever, chills, and hypotension, and no apparent source for the BSI, other than the catheter. In addition, documented or definite CRBSI requires further confirmation through one of the following:

1. Positive result of semiquantitative ( $\geq 15$  colony-forming units [CFU]/catheter segment) or quantitative ( $\geq 10^2$  CFU/catheter segment) catheter culture, whereby the culture yields the same organism (identical species and antibiogram) isolated from the peripheral blood sample
2. Quantitative cultures of blood samples, drawn simultaneously through the CVC and via a peripheral vein, with a ratio of  $\geq 5:1$  (CVC vs peripheral)
3. Differential time to positivity, whereby the culture of blood drawn through the CVC becomes positive and yields the same microorganism, at least 2 hours before the culture of blood drawn simultaneously from a peripheral vein

Most CRBSIs are uncomplicated. However, some virulent microorganisms, such as *S. aureus*, *C. albicans*, and *P. aeruginosa*, may be associated with complicated deep-seated infections, including catheter-related septic thrombosis, whereby

the CRBSI is associated with an infected thrombus.<sup>76–78</sup> Septic thrombosis is characterized by occasional swelling above the site of the thrombotic vein and persistent BSI in spite of appropriate antimicrobial therapy and the removal of the catheter. CRBSI may also become disseminated to another anatomic site, causing deep-seated infections, such as endocarditis, osteomyelitis, organ abscesses, and retinitis.<sup>76,77</sup> Signs and symptoms of such deep-seated infections depend on the site affected by the infection.

### Diagnosis

Catheter-related infections are often misdiagnosed, resulting in wasteful removal of catheters and unnecessary administration of antimicrobial agents. Clinical manifestations of sepsis, with no obvious cause other than the presence of a CVC, usually lead to suspecting CRBSI; however, signs and symptoms of sepsis, such as fever, chills, or hypotension, are nonspecific and may be caused by a myriad of etiologic factors, other than an infected catheter. Catheter-related BSIs are occasionally associated with local signs and symptoms at the catheter exit site, such as erythema, tenderness, warmth, and lymphangitis. However, these clinical manifestations of local inflammatory signs have poor correlation with catheter-related infections because although their presence has a highly predictive value for infection, their absence has a very poor negative value.<sup>79</sup> Safdar and Maki recently evaluated short-term catheters for CRBSIs, using insertion-site inflammation as the diagnostic indicator.<sup>80</sup> Their study yielded sensitivity  $\leq 3\%$ , indicating that insertion-site inflammation is not predictive of CRBSI. Therefore, signs of local infection should be evaluated carefully when diagnosing CRBSI, and it is important to use microbiologic techniques to identify catheter colonization or infection.

Furthermore, as infections in immunocompromised patients increase in number and complexity, laboratory diagnosis of catheter-related infections in this patient population presents the following challenges: (1) clinical presentation of the infection is often muted or delayed and nonspecific, (2) frequent blood drawing for cultures should be done judiciously, especially for pancytopenic patients, and (3) careful consideration should be given to the decision of catheter removal and insertion of new catheter at a different site, especially in thrombocytopenic patients with poor vascular access, and, hence, the critical need for diagnosing catheter-related infections before removing the catheter.

It is important to accurately diagnose CRBSIs based not only on clinical findings but also on reliable microbiologic results. In the following section, we review two major diagnostic approaches based on whether the diagnosis of

catheter-related infection is achieved while the suspected catheter is still in place or after the catheter is removal.

### Diagnostic Techniques without Catheter Removal

Ideally, diagnosing CRBSIs needs to be done before removing the catheter, to avoid the needless removal of catheters not responsible for the infection. A good diagnostic method would accomplish this early diagnosis without compromising its accuracy.

#### Cultures of Blood Drawn Percutaneously or through the Catheter

According to this method, patients with suspected CRBSI have two sets of blood cultures done, in which at least one set is drawn through a peripheral venipuncture. Single blood cultures, quantitative or qualitative, according to which blood is drawn only through the CVC, have low positive predictive values as they do not compare the results of these cultures with the results of peripheral blood cultures and hence are not reliable. In a study of hospitalized hematology-oncology patients, culture of blood drawn through either the central catheter or peripheral vein showed excellent negative predictive value (99% and 98%, respectively), whereas culture of blood drawn through an indwelling CVC had low positive predictive value (63%), apparently less than from a peripheral venipuncture (73%).<sup>81</sup> The study suggested that the use of a catheter to obtain blood for culture may be an acceptable method for ruling out BSIs. However, a positive culture of blood drawn through a catheter would require further clinical interpretation.

#### Partial Simultaneous Quantitative Cultures of Peripheral and Catheter Blood Samples

This technique relies on the results of quantitative cultures of simultaneously drawn blood samples, in which one is drawn via a peripheral vein and the other through the CVC. Studies suggest that when quantitative cultures of blood drawn through the CVC yield at least fivefold the colony count (CFU) of blood drawn simultaneously through the peripheral vein, this finding is predictive of CRBSI.<sup>82–85</sup> However, studies differ in regard to the exact cutoff point for this ratio, where it was found to be between  $\geq 4:1$ <sup>84</sup> and  $10:1$ .<sup>85</sup> Nonetheless, this test was shown to be 94% sensitive and 100% specific.<sup>84</sup> Recently, Franklin and colleagues suggested a method for diagnosing CRBSI when a peripheral culture is unavailable.<sup>86</sup> They defined CRBSI as a fivefold or greater difference in CFU/mL between the two catheter lumens in pediatric patients, with sensitivity, specificity, a positive predictive value, and a likelihood ratio of 62%, 93%, 92%, and 9.2, respectively.

### Endoluminal Brush Technique

This technique involves introducing a nylon brush through the catheter hub and into the lumen, brushing its interior wall. The brush is withdrawn and immediately placed into a buffered container that is sonicated, and the solution is cultured onto a blood agar plate, with counts > 100 CFU/mL considered positive. This technique was found to have sensitivity of 95% and specificity of 84% by Kite and colleagues, who found the technique to be easy, with no adverse effects,<sup>87</sup> contrary to another study in which it was associated with arrhythmia and embolization.<sup>79</sup> The method is also criticized for being impractical and unreliable and may result in subsequent bacteremia owing to the brush's entry into the lumen, which may introduce microorganisms into the catheter or may lodge them further. The brush may even disrupt any existent biofilm, releasing organisms into the bloodstream.

### Skin and Hub Cultures

There is no standard method for culturing the skin around the insertion site and no agreed on criteria for positive quantitative cultures. Basically, the area chosen for culture, either the skin at the catheter exit site or the interior of the catheter hub, is swabbed and then the swab is streaked onto an agar plate to be cultured semiquantitatively.<sup>88</sup> Skin culturing, as a diagnostic test for CRBSI, was found to have ≤ 61% sensitivity, 72% specificity, and 62% positive predictive value.<sup>89</sup> However, when infection is suspected, sensitivity rises to 75%, specificity to > 90%, and the positive predictive value to 100%.<sup>90</sup> Skin culturing at the catheter exit site has been studied, with varied results, which may be attributed to surface contamination.

Cultures of the hub alone still have a low sensitivity of 61%.<sup>89</sup> However, when both the skin and the hub were cultured together, sensitivity improved to 86%, although specificity and the positive predictive value remain low. An alternative combination of superficial cultures is taking a culture of the hub and subcutaneous catheter segment, which slightly boosts the specificity to 82% and the positive predictive value to 78%, whereas the sensitivity remains at 84%.

### Differential Time to Positivity

In the presence of CRBSI, blood drawn through the catheter hub would turn positive much more quickly than blood drawn through a peripheral vein. This method relies on the availability of an automated blood culture system that records the time at which a culture turns positive. Recent studies suggest that if the difference in the time it takes for the culture of blood drawn through the CVC and a culture drawn simultaneously from a peripheral vein to become positive is at least 120 minutes, then it is highly suggestive of a CRBSI.<sup>91,92</sup>

This has been shown in a study involving 235 neutropenic patients with febrile neutropenia, in which the differential time to positivity had 82% sensitivity and 88% specificity in diagnosing CRBSI.<sup>93</sup> Although the differential time to positivity could not be verified as a diagnostic method among intensive care patients,<sup>94</sup> recently, Raad and colleagues found it to be diagnostic in 191 cases of BSI.<sup>95</sup> The patient pool was subanalyzed for short-term catheterization (< 30 days) and long-term catheterization (≥ 30 days), and the study reported 81% sensitivity with 92% specificity and 93% sensitivity with 75% specificity, respectively. Furthermore, receiver operating characteristic curve analysis showed that the ≥ 120-minute cutoff optimizes sensitivity and specificity. However, interpretation of this diagnostic method could become complicated when antibiotics are given intraluminally at the time of drawing blood cultures through the catheter, in which case, colonized catheters may become falsely negative and sensitivity can be compromised.<sup>95</sup> The technique is also limited in that it does not evaluate cases with negative peripheral blood cultures in the presence of positive central blood cultures, a combination indicative of possible CRBSI catheter colonization.

## Diagnostic Techniques Requiring Catheter Removal

### Quantitative Catheter Culture

According to this technique, the removed catheter tip is immersed in broth, which is then cultured, and any growth is considered significant.<sup>96</sup> This method lacks sufficient quantitation, and at the present time, its use is limited owing to its low specificity and high frequency of contamination.

### Semiquantitative Roll Plate Catheter Culture

After the catheter is removed, its intravascular tip is cut and rolled four times, back and forth, on an agar plate. The microorganisms are retrieved only from the external surface of the catheter, and after being cultured on the agar plate, the colonies are counted. Catheters are considered to be colonized if at least 15 CFU/catheter-tip segment are grown.<sup>97</sup> If the same microorganism is isolated from both the catheter tip, at the quantitative level that defines colonization, and the bloodstream, the diagnosis of CRBSI is established. This method is limited in that it retrieves free-floating (nonbiofilm) microorganisms only from the external surface of the catheter and therefore misses culturing organisms colonizing the intraluminal surface of the catheter, such as with long-term catheters.

### Quantitative Catheter Culture

Several methods, such as centrifugation, vortexing, and sonication, are used to retrieve

microorganisms from both the external and the internal surfaces of the catheter. The catheter is said to be colonized when at least 1,000 CFU/catheter-tip segment are retrieved. If the same organism colonizing the catheter tip also grows from a peripheral blood culture, in the presence of signs and symptoms of infection and in the absence of other sources for the infection, the diagnosis of CRBSI is established.<sup>98</sup> A recent meta-analysis showed that quantitative catheter culture was a more sensitive diagnostic method than the semiquantitative catheter culture method.<sup>99</sup>

### Stain and Microscopy Rapid Diagnostic Techniques

Staining of the removed catheter segments and subsequent microscopy have been suggested as a simple and immediate diagnostic method. Cooper and Hopkins explored the use of direct Gram staining of the catheters for diagnosis.<sup>100</sup> After being cultured, the catheters were immediately stained, and extraluminal organisms were identified under the oil immersion objective. The cutoff value of one organism per 20 oil immersion fields indicates that the catheter is colonized. Cooper and Hopkins reported 100% sensitivity, 97% specificity, a positive predictive value of 84%, and a negative predictive value of 100%, but the results were not reproduced in another study.<sup>101</sup> In a similar technique, acridine orange staining has been used for diagnosis, in which fluorescence is indicative of positivity.<sup>102</sup> In addition to achieving a sensitivity of 84% and a specificity of 99%, acridine orange staining perhaps may be more easily performed than Gram staining, although microscopic techniques as a whole are labor intensive.

## Preventive Strategies

Because CRBSIs are associated with serious morbidity and mortality and because of the difficulty and complexity of its diagnosis and its management, particularly in immunocompromised patients, major effort should be exerted in trying to prevent these infections (Table 2).<sup>103,104</sup>

Successful preventive strategies should aim at carefully controlling all factors that could lead to the colonization of the CVC by microorganisms. Evidence-based guidelines and preventive measures have been published to provide health care practitioners with background information and specific recommendations aimed at reducing the incidence of intravascular CRBSIs (Table 2). The published guidelines represent the recommendations of the Healthcare Infection Control Practices Advisory Committee (HICPAC) and other professional organizations, including the IDSA, Society for Healthcare Epidemiology of America (SHEA), and American Society of Critical Care Anesthesiologists (ASCCA), among others.<sup>105</sup> In the next section, we review major

**Table 2 Strategies for the Prevention of Catheter-Related Bloodstream Infection**

Strategies during CVC insertion
Maximal sterile barrier precautions <sup>11</sup>
Using an expert infusion therapy team <sup>108,109</sup>
Use of antiseptics at CVC exit site <sup>27,127</sup>
Device-related strategies
Select the least number of lumens needed <sup>24–59</sup>
Antimicrobial coating of CVC <sup>117–122</sup>
CVCs with silver cuff <sup>28–30</sup>
Tunneled CVC <sup>26</sup>
Implantable port <sup>70</sup>
Strategies during CVC dwell period
Avoid needless manipulation of CVC <sup>63</sup>
Use of nonocclusive dressing <sup>66</sup>
Topical antiseptics or antibiotics <sup>27,126,127</sup>
Anticoagulant and antimicrobial flush solution <sup>123–125</sup>

CVC = central venous catheter.

strategies for prevention of catheter-related infections.

### Specialized Infusion Therapy Team

Well-organized programs that help health care workers provide, monitor, and evaluate care given to patients and that facilitate patient education and continuous education to physicians, fellows, and medical students are critical for a successful preventive strategy. Risk of infection is known to decline following standardization of aseptic care.<sup>106–108</sup> When medical centers used the services of experienced infusion therapy teams, for the insertion and maintenance of catheters, including dressing changes, catheter-associated infection rates decreased five- to eightfold.<sup>109,110</sup> At M. D. Anderson Cancer Center, where an experienced infusion therapy team is available, the infection rates of nontunneled, noncuffed, Silastic catheters were found to be 0.13 infections per 100 catheter-days, comparable to the low rates of the tunneled Hickman catheters.<sup>72</sup>

### Maximal Sterile Barriers

The insertion of some types of catheters, such as implantable ports and tunneled catheters, requires involved surgical procedures; therefore, these types are usually inserted in the operating room. On the other hand, nontunneled catheters and PICCs are usually inserted elsewhere; hence, their insertion may not be subject to the same stringently sterile atmosphere of an operating room. However, a prospective randomized clinical trial succeeded in proving that the use of maximal sterile barrier precautions during the insertion of nontunneled long-term silicone catheters in the subclavian vein and PICCs resulted in a significant reduction in infections associated with these devices.<sup>11</sup> The devices had a mean dwell time of 70 days, and the rate of CRBSI dropped from

0.5/1,000 catheter-days to 0.02/1,000 catheter-days. Maximal sterile barrier precautions involved wearing a sterile gown, gloves, and a cap and using a large drape, during the insertion of catheters, similar to the drapes used in operating rooms.

### Tunneling

These catheters are buried under the skin in a subcutaneous tunnel and a felt Dacron cuff is used to anchor the catheter subcutaneously in place. The cuff eventually becomes enmeshed with fibrous tissues, allowing the catheter to become securely anchored, and it also creates a tissue interface that acts as a barrier against the migration of microorganisms. A prospective randomized study found that CRBSI occurred more frequently and more rapidly in the nontunneled than in the tunneled group, in which catheters were tunneled into the internal jugular vein ( $p = .02$ , log rank test), with an infection rate of 1.9 per 100 catheter-days in the nontunneled group and 0.7 per 100 catheter-days in the tunneled group.<sup>26</sup> The study demonstrated that subcutaneous tunneling of internal jugular CVCs reduced by at least fourfold the risk of CRBSI in critically ill patients. However, another prospective randomized study of tunneled silicone catheters inserted in the subclavian vein in immunocompromised patients failed to demonstrate the efficacy of subcutaneous tunneling, in which the infection rate among the patients with tunneled catheters was 0.22/100 catheter-days and among the nontunneled catheters was 0.20/100 catheter-days.<sup>111</sup> Nonetheless, the main issue here is whether tunneling is cost effective since the surgery required for the procedure may cost an additional \$2,500, and other, more cost-effective alternatives could be as efficacious in reducing the rate of catheter-related infections.

### Antimicrobial Coating of Catheters

A newer approach to prevention of CRBSI is the coating of the catheter surface with antimicrobial agents to prevent the initial biofilm formation. This method allows sustained and slow release of the antimicrobial agents, with virtually undetectable serum levels. First-generation catheters impregnated with chlorhexidine and silver sulfadiazine (CHX-SSD) lowered the rate of CRBSIs from 7.6 per 1,000 catheter-days to 1.6 per 1,000 catheter-days ( $p = .03$ ).<sup>12</sup> A cost-effectiveness analysis concluded that using these catheters in patients at high risk of catheter-related infections reduces the incidence of CRBSI and death and provides significant saving in costs estimated to be \$196 per catheter inserted.<sup>112</sup> These first-generation CHX-SSD catheters were coated only on the external surface, and the catheters in the study were cultured by the roll plate technique, retrieving microorganisms only from the outer surface of the catheter. This may explain the failure

of three subsequent studies to reproduce the results of Maki and colleagues,<sup>12</sup> especially when both catheter surfaces were cultured by sonication.<sup>113–115</sup> Mermel estimated the effect of this device on CRBSI and showed that the CHX-SSD catheter reduces the risk of infection in short-term catheterization but is not effective for catheters placed for an average of 3 weeks, probably owing to the reduction in its antimicrobial activity over time.<sup>4</sup> Mermel also attributed the lack of long-term efficacy to the fact that only the outer surface of the catheter was impregnated; therefore, there was no protection against luminal colonization. A second-generation CHX-SSD catheters impregnated on both surfaces is now available. However, the zones of inhibition produced by this second-generation catheters were shown to decrease to less than 10 mm in only 3 days.<sup>116</sup> This second-generation CHX-SSD catheters were tested in a prospective randomized study in patients from 14 ICUs of university hospitals in France. Although the use of the CHX-SSD catheters decreased the catheter colonization significantly from 11/1,000 catheter-days (13%) to 3.6/1,000 catheter-days (3.7%),  $p = .01$ , they failed to decrease the rate of CRBSI.<sup>117</sup>

Raad and colleagues and Darouiche and colleagues developed commercially available polyurethane catheters impregnated intraluminally and extraluminally with minocycline and rifampin, and they were more efficacious when compared, in prospective, randomized, double-blind, controlled studies, with uncoated catheters and with catheters impregnated with CHX-SSD.<sup>118,119</sup> In comparison with first-generation CHX-SSD catheters, the catheters impregnated with minocycline and rifampin were 12-fold less likely to be associated with CRBSI (relative risk 0.1, 95% CI 0.0–0.6) and 3-fold less likely to be colonized. In a review for the CDC, Wenzel and Edmond estimated that 4,745 to 9,450 lives would be saved with the use of catheters impregnated with minocycline and rifampin according to varying attributable mortality rate estimates.<sup>120</sup> The use of minocycline and rifampin catheters, in medical and surgical intensive care units, was associated with a significant decrease in nosocomial BSIs, including vancomycin-resistant enterococci (VRE) bacteremia, catheter-related infections, and lengths of hospital and ICU stay.<sup>121</sup> The risk of developing resistance after prolonged use of these antimicrobially coated catheters was investigated in a retrospective evaluation of 4-year clinical use of minocycline and rifampin-impregnated catheters in bone marrow transplantation patients. The study found no evidence of development of staphylococcal resistance to the antibiotics coating the catheters.<sup>122</sup> A recent prospective randomized study evaluated long-term nontunneled silicone CVCs impregnated with minocycline and rifampin and found

them to also be significantly more efficacious than control uncoated catheters in reducing CRBSIs in cancer patients.<sup>123</sup>

### Anticoagulant and Antimicrobial Lock Solutions

This technique is particularly useful for long-term catheters, in which hub contamination is the main source of catheter colonization and, ultimately, CRBSI.<sup>15</sup> According to this method, the catheter lumen is flushed and then filled with 2 to 3 mL of anticoagulant in combination with an antimicrobial agent. Heparin as an anticoagulant, alone or in combination with vancomycin, has been used to lock the catheter lumen. Heparin interferes with the thrombin sheath formation on the catheter surface and was shown, alone and combined with vancomycin, to reduce catheter-tip colonization.<sup>124,125</sup> However, using vancomycin prophylactically should be avoided to minimize the risk of emergence of vancomycin-resistant organisms. Also, there is a potential for a superinfection with gram-negative bacilli and *Candida* because vancomycin has an antimicrobial spectrum limited to gram-positive bacteria. Raad and colleagues prevented recurrent CRBSI by using a lock solution of 3 mg minocycline and 30 mg ethylenediaminetetraacetic (EDTA) as prophylaxis in three patients.<sup>126</sup> The combination of minocycline and EDTA showed synergistic activity against methicillin-resistant staphylococci, gram-negative bacilli, and *C. albicans* and a cidal effect on bacteria in the biofilm.<sup>127–129</sup>

### Topical Antiseptics or Antibiotics

Topical antibiotics, such as polymixin-neomycin-bacitracin, significantly decrease the risk of catheter-related infections but may increase the risk of fungal colonization and infection.<sup>130</sup> Maki and colleagues compared the effectiveness of 70% alcohol, 10% povidone-iodine, and 2% chlorhexidine gluconate and the rate of CRBSI was almost fourfold lower in the chlorhexidine arm than in the other two arms.<sup>27</sup> A meta-analysis evaluated the efficacy of skin disinfection with chlorhexidine gluconate compared with povidone-iodine solution in preventing CRBSI and found that chlorhexidine gluconate reduced the risk of CRBSI by 49%.<sup>131</sup>

### Silver Cuff

A collagen cuff impregnated with silver and connected to the catheter is placed subcutaneously to act as a mechanical barrier against migrating organisms. The device failed to reduce the rates of CRBSI when used with long-term catheters,<sup>132,133</sup> possibly owing to the biodegradable nature of the collagen since it degrades within a week. However, in critically ill patients with short-term catheters, it was shown to reduce infections.<sup>134</sup> The silver cuff is rarely used in the United States.

## Management

The management of CRBSI involves making decisions related to (1) whether the CVC should be removed, (2) the type of antimicrobial therapy, based on the type of organism and its resistance pattern, and (3) the duration of antimicrobial therapy. Such decisions depend on two factors. The first is the type of organism and whether this organism has a high tendency to be associated with deep-seated complications and a high rate of relapse. Second is whether there are clinical manifestations suggestive of a complicated source, such as the persistence of fever and bacteremia or fungemia after catheter removal and initiation of appropriate antimicrobial therapy.

Given that the CVC is an identifiable, removable source of the infection, there is a tendency to consider all patients with a CVC and an associated BSI to represent a catheter-related infection. Indiscriminate removal of the CVC in this situation would result in an unnecessary, wasteful, and highly expensive practice. Therefore, it is important for the clinician to carefully determine whether the catheter is the source of the BSI prior to making management decisions as to the need for CVC removal and the duration of antimicrobial therapy. Hence, simultaneous blood cultures need to be drawn at the time of presentation of the patient, and the internist should make determinations on the diagnosis of CRBSI based on the differential time to positivity<sup>91–95</sup> or the differential quantitative blood cultures,<sup>82–86</sup> as outlined in the Diagnosis section of this chapter (Figure 3). Because management decisions as to whether the CVC should be removed and the duration and type of therapy depend on the type of organism causing CRBSI, we discuss such organisms below.

### Coagulase-Negative *Staphylococcus*

These organisms are considered to be the most likely cause of CRBSI.<sup>26–28</sup> Since these organisms, which include *S. epidermidis*, are usually skin organisms, they are often the cause of contaminated blood cultures. Therefore, a single blood culture drawn from the CVC and subsequently found to be positive for coagulase-negative staphylococci could reflect hub or intraluminal colonization of the catheter rather than a true bacteremia.<sup>135</sup> To ascertain the diagnosis of bacteremia, at least two blood cultures, including a positive blood culture drawn from a peripheral vein, are necessary. When quantitative blood cultures are used, a colony count of > 15 CFU of coagulase-negative staphylococci isolated from a blood sample drawn through the CVC is highly suggestive of true bacteremia.<sup>136</sup>

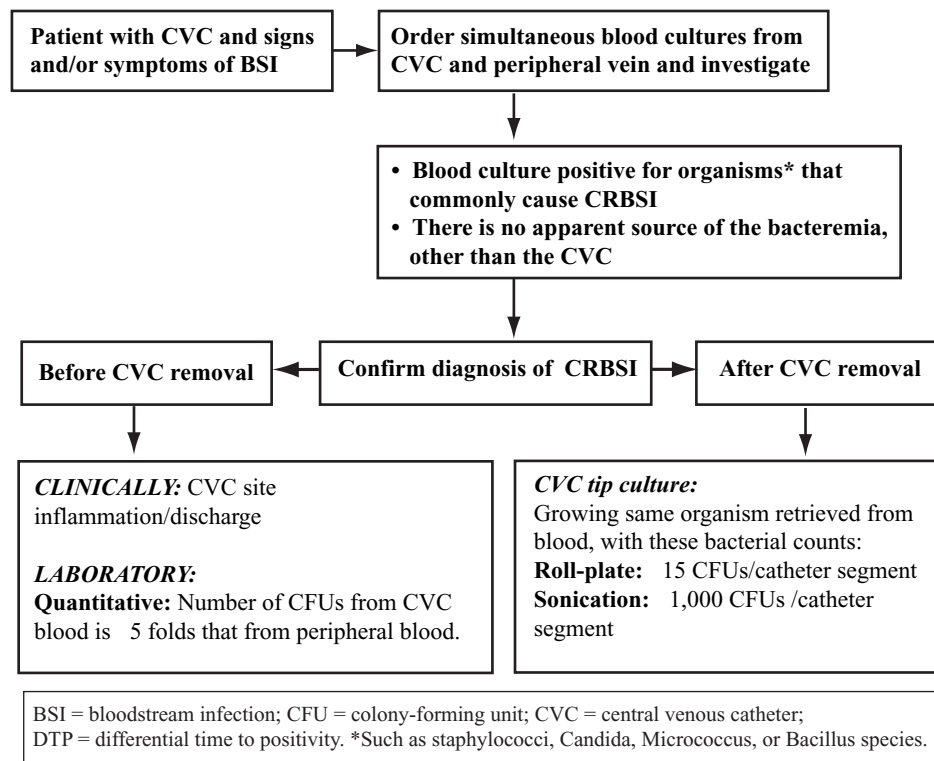

Although catheter removal was once thought to be necessary, most (almost 80%) of the CRBSI caused by coagulase-negative staphylococci could

be treated with glycopeptide antibiotics, such as vancomycin, without catheter removal. However, if the CVC is not removed, there is a 20% chance that the bacteremia will recur.<sup>137</sup> This is compared with only a 3% risk of recurrence if the catheter is removed ( $p < .005$ ). Because this organism is associated with low virulence and a low tendency for metastatic deep-seated infections (such as endocarditis), the IDSA guidelines on management suggested that the catheter associated with CRBSI caused by coagulase-negative staphylococci could be salvaged through antibiotic lock therapy.<sup>73</sup> Hence, if the CVC is to be retained, a longer duration of therapy consisting of 10 to 14 days (rather than 5 to 7 days if the CVC is removed) is to be considered with antibiotic lock therapy. Alternatives to vancomycin are available for the treatment of coagulase-negative staphylococcal bacteremia. These include dalbavancin, which is a long-acting glycopeptide given once per week. Dalbavancin was recently shown to be superior to vancomycin in the treatment of CRBSI caused by coagulase-negative staphylococci and *S. aureus*.<sup>138</sup> The high frequency of infections caused by methicillin-resistant *S. aureus*, including coagulase-negative staphylococci, has been the driving force for the wide use of glycopeptide antibiotics, which, in turn, has resulted in higher rates of VRE. Other alternative antibiotics with an activity against VRE are also available. These include linezolid and daptomycin.<sup>139,140</sup>

### *S. aureus*

The CVC is the leading source of *S. aureus* bacteremia in the cancer patient.<sup>141</sup> *S. aureus* is associated with a high rate of deep-seated metastatic infections, including endocarditis, particularly in the nonthrombocytopenic solid tumor patient. Deep-seated infections, including septic thrombosis and endocarditis, have been reported in 33 to 35% of non-neutropenic, nonthrombocytopenic patients with solid tumor.<sup>76,141</sup> The associated overall mortality was reported as 38%.<sup>141</sup> In contrast, thrombocytopenic and neutropenic patients with underlying hematologic malignancy and *S. aureus* bacteremia have a very low rate of metastatic infection (< 3%), with an overall mortality of 11%.<sup>142</sup> This difference could be attributed to several factors. First, nonthrombocytopenic cancer patients with a solid tumor have a high prevalence of cardiac valve lesions and non-bacterial thrombotic vegetations of the valve associated with thromboembolism.<sup>143</sup> This serves as a substrate for a higher rate of infective bacterial endocarditis in the setting of *S. aureus* bacteremia.

Second, an important factor in the development of infective endocarditis is the formation of platelet bacterial thrombi on the surface of the valve.<sup>144,145</sup> *S. aureus* cells have been shown to form

**FIGURE 3** Algorithm for the diagnosis of catheter-related bloodstream infection (CRBSI). BSI = bloodstream infection; CFU = colony-forming unit; CVC = central venous catheter; DTP = differential time to positivity. \*Such as staphylococci, *Candida*, *Micrococcus*, or *Bacillus* species.

platelet aggregations through fibronectin-binding proteins, leading to platelet bacterial valvular thrombi and vegetation formation.<sup>145</sup> Hence, the thrombocytopenia could be a protective factor against the formation of the platelet bacterial valvular thrombi.

Three observational prospective studies have demonstrated that removal of the CVC in *S. aureus* CRBSI (including the uncomplicated cases) has been associated with a more rapid response to therapy and a lower relapse rate.<sup>146–148</sup> In a subset of thrombocytopenic patients with hematologic malignancy and a surgically implantable catheter with no other available vascular access, consideration should be given to catheter salvage and antibiotic lock therapy.<sup>73,126</sup> This consists of filling the lumen of the catheter with 2 mL of an antibiotic combination, often mixed with an anticoagulant. Vancomycin in combination with heparin or minocycline and vancomycin in combination with EDTA are some of the options to be considered.<sup>125–127</sup> Combinations could be alcohol based, consisting of 25% ethanol solution.<sup>149</sup>

The type of antibiotics used should be based on the susceptibility of *S. aureus*. For methicillin-sensitive *S. aureus*, a semisynthetic antistaphylococcal penicillin or first-generation cephalosporin is the first choice.<sup>73</sup> For methicillin-resistant *S. aureus*, several options can be considered, including vancomycin, linezolid, daptomycin, or even

dalbavancin.<sup>138–140</sup> The duration of therapy should be based on the likelihood of deep-seated complications. For uncomplicated *S. aureus* CRBSI, a 10-day to 2-week course is acceptable if the CVC is removed.<sup>73</sup> Raad and colleagues showed in several studies including patients with underlying cancer that the persistence of fever and bacteremia for more than 72 hours after antibiotic initiation and catheter removal is highly suggestive of a complicated course associated with deep-seated infections, including septic thrombosis and endocarditis.<sup>76,150</sup> These findings were further supported by a large prospective observational study that included 720 consecutive adults with *S. aureus* bacteremia.<sup>151</sup> The strongest predictor of *S. aureus* bacteremia was the persistence of fever and/or bacteremia for more than 72 hours. In this subpopulation of *S. aureus* CRBSI with persisting fever and bacteremia, strong consideration should be given to transesophageal echocardiography to rule out endocarditis and the treatment duration should be expanded to at least 4 weeks.<sup>73</sup> In uncomplicated cases of *S. aureus* CRBSI, consideration should be given to the use of an oral antibiotic combination beyond 7 days of parenteral antibiotic treatment. Recent studies have suggested that a combination of quinolones plus rifampin active against *S. aureus* could be useful in patients who are allergic to  $\beta$ -lactam antibiotics, including those patients with staphylococcal CRBSI.<sup>152</sup>

## Gram-Negative Bacilli

Gram-negative bacillary bacteremia usually emerges from a non-catheter-related source, such as nosocomial urinary tract infection, nosocomial pneumonia, or intra-abdominal infection. However, gram-negative bacillary CRBSI caused by organisms such as *Klebsiella pneumoniae*, *Enterobacter* species, *Pseudomonas* species, *Acinetobacter* species, and *Stenotrophomonas maltophilia* have been reported.<sup>29,30,78</sup> Elting and Bodey reported on 149 episodes of bacteremias caused by *S. maltophilia* and other non-aeruginosa *Pseudomonas* species in which the CVC was the most common source of the BSI.<sup>30</sup> Failure to remove the catheter in this cancer patient population was associated with a significantly higher rate of treatment failure and bacteremia recurrence. In another study involving cancer patients from Memorial Sloan-Kettering Cancer Center, catheter-related infections caused by *Pseudomonas* species were associated with a higher rate of treatment failure unless the catheter was removed.<sup>78</sup> A more recent study by Hanna and colleagues demonstrated that documented CRBSIs caused by gram-negative bacilli were associated with a high frequency of relapse if the CVC was retained, whereas CVC removal was associated with only a 1% risk of relapse ( $p < .001$ ).<sup>153</sup> Therefore, if the gram-negative bacillary bacteremia is judged to be CRBSI, then it is prudent to remove the CVC in cancer patients and treat with a 1-week course of appropriate broad-spectrum anti-bacillary antibiotics (Figure 3).<sup>73</sup>

## *Candida* Species

Catheter-related candidemia may be associated with serious complications, such as septic thrombosis and endocarditis.<sup>154,155</sup> In a multivariate analysis of nosocomial BSIs, *Candida* species were the only organisms independently predictive of a poor outcome.<sup>156–170</sup> Fourteen studies evaluated the impact of CVC removal on the outcome of candidemia. All five prospective studies have demonstrated that CVC removal was associated with improved outcome.<sup>157–161</sup> These included large studies in which multivariate analysis showed that catheter retention proved to be a significant independent risk factor for the persistence of candidemia and was associated with higher mortality.<sup>157</sup> Of the nine retrospective studies, eight have demonstrated an improved outcome with CVC removal.<sup>162–169</sup> In cancer patients, catheter removal improved outcome independent of persistent neutropenia and vascular catheter retention proved to be an independent risk factor for the persistence of candidemia.<sup>158,162,169</sup> Nucci and colleagues prospectively analyzed the risk factors for death among 145 patients with nosocomial candidemia.<sup>158</sup> Catheter retention was found to be an independent variable for increased risk of death in multivariate

analysis independent of persistent neutropenia. In a retrospective study, Anaissie and colleagues reviewed 416 patients with cancer and underlying candidemia and showed that the catheter retention was associated with poor outcome, death, and persistence of the infection compared with the outcome of patients who underwent guide-wire exchange or removal of the catheter ( $p = .002$ ), independent of the severity of the illness and the persistence of the neutropenia.<sup>162</sup> In a recent retrospective study involving 404 cancer patients with candidemia and an indwelling CVC, Raad and colleagues determined by multivariate analysis that CVC retention for more than 72 hours is associated with a poor outcome (decreased response to antifungal agents, morbidity, and mortality) in patients with *Candida* CRBSI.<sup>169</sup> In that study, CVC removal did not have any impact on improving outcome in patients with non-catheter-related secondary candidemia. Therefore, in cancer patients, the CVC should be removed early within 72 hours in patients with suspected or documented catheter-related candidemia. According to the study by Raad and colleagues, patients with previous chemotherapy or high-dose steroids are more prone to have their candidemia emerging from a noncatheter source and, hence, may not benefit from the early CVC removal.<sup>169</sup>

Rex and colleagues demonstrated that fluconazole has comparable efficacy to amphotericin B in the treatment of candidemia (71% of the cases were considered to be catheter related), with a significantly better safety profile in favor of fluconazole.<sup>171</sup> Echinocandins (caspofungin and micafungin) were demonstrated through prospective randomized trials to be equivalent to amphotericin B or liposomal amphotericin B respectively in the treatment of candidemia with an improved safety profile. A recent multicenter study showed that anidulafungin (another echinocandins) is equivalent to and possibly superior to fluconazole in the treatment of invasive candidiasis. Therefore, in patients with catheter-related candidemia, fluconazole or echinocandins should be considered efficacious and safer alternatives to amphotericin B. In a center in which there are higher rates of fluconazole-resistant *Candida glabrata* and *Candida krusei*, echinocandins should serve as a better alternative to fluconazole.<sup>173,174</sup> The duration of therapy for uncomplicated catheter-related candidemia has been suggested to be 2 weeks from the last positive blood culture, according to the IDSA guidelines.<sup>73</sup>

# Viral Infections

Harrys A. Torres, MD  
Michael Boeckh, MD  
Roy F. Chemaly, MD, MPH

Viruses have been implicated in the pathogenesis of several malignancies. In addition, viral infections are common complications among cancer patients and are associated with considerable morbidity and mortality, especially in those with hematologic malignancies and those who have undergone hematopoietic stem cell transplantation (HSCT). For example, herpes viruses are common pathogens in these patient populations, especially herpes simplex virus, varicella-zoster virus, and cytomegalovirus (CMV) and, to a lesser extent, Epstein-Barr virus (EBV), and human herpesvirus (HHV)-6. Other common viruses in these immunocompromised patients are community-acquired respiratory viruses (CRVs), including respiratory syncytial virus (RSV), influenza virus, and parainfluenza virus (PIV), which produce upper respiratory tract infections (URIs) that can potentially progress to severe lower respiratory tract infections (LRIs). Other, less common viruses that can cause serious illness in cancer patients and HSCT recipients include hepatitis viruses, polyomaviruses, picornaviruses, rhinoviruses, coronaviruses, enteroviruses, adenoviruses, and metapneumoviruses. In this chapter, we review the potential role of viruses as causative agents of cancer and cover relevant issues on viral infections affecting both patients with cancer and HSCT recipients.

## Viral Infections as Causes of Cancer

Several viruses, including herpesviruses, hepatitis viruses, retroviruses, and polyomaviruses, have been implicated in the pathogenesis of various malignancies (Table 1).<sup>1–7</sup> Such an association has been supported by the oncogenic properties of these viruses in animal models or cell cultures, and epidemiologic evidence is mounting. Tumor viruses might drive the malignant growth or modify the tumor phenotype. Viral carcinogenicity is cell type specific, multifactorial, and influenced by cofactors; the interaction between viral and chemical carcinogens may explain the cause of several cancers (see Table 1). For example, cervical cancer, hepatocellular carcinoma (HCC),

and Kaposi's sarcoma (KS) may be the result of the virus-chemical interaction.

EBV was the first human virus associated with carcinogenesis, specifically to the origin of B-cell lymphomas.<sup>8</sup> To date, a variety of EBV-related tumors, such as Hodgkin's disease and nasopharyngeal cancer, have been described (see Table 1).

HHV-8 has been suggested as the etiologic agent for KS, with deoxyribonucleic acid (DNA) sequences of this herpesvirus isolated in KS tissues.<sup>9</sup> Hence, this virus is also termed Kaposi's sarcoma-associated herpesvirus (KSHV).<sup>10</sup> The pathogenesis of human immunodeficiency virus (HIV)-associated KS appears to be multifactorial. For instance, the use of nitrite inhalants and exposure to wet clay soils or other environmental sources appear to be linked to the unique epidemiology of HIV-associated KS.<sup>11,12</sup>

Hepatitis B (HBV) and C (HCV) viruses have also been associated with the development of HCC, and their interaction with chemical carcinogens such as aflatoxin exposure, heavy alcohol consumption, inorganic arsenic ingestion, radioactive thorium dioxide exposure, iron overload, oral contraceptive use, and anabolic steroid use appears to be important in the pathogenesis of HCC.<sup>6,13,14</sup> HCV might also have a role as an etiologic agent in non-Hodgkin's B-cell lymphoma,<sup>15,16</sup> although this association may have some geographic variations.<sup>17</sup>

Human papillomavirus (HPV) has been associated with a variety of cancers, and its interaction with cofactors (eg, smoking, oral contraceptives, high parity) may play a carcinogenic role.<sup>18</sup> Virtually all cases of cervical cancer are due to a subset of HPV types, of which the most important are HPV-16, HPV-18, and HPV-45.<sup>1</sup> HPV has also been associated with the development of penile, anal, or vulvar cancers, as well as with pulmonary adenocarcinoma, head and neck squamous cell carcinoma, laryngeal squamous cell carcinoma, and ovarian cancer.<sup>1,5,19–22</sup> Polyomaviruses such as JC virus and simian virus 40 (SV40) could also contribute to the pathogenesis of cancer, especially those affecting the central nervous system and the skin.<sup>3,23</sup>

Human T-cell leukemia virus type 1 has been identified as the causative agent of T-cell leukemia or lymphoma.<sup>1</sup> Unlike other retroviruses that have direct oncogenic properties, HIV is thought to facilitate—through the suppression of the immune system—the occurrence of several cancer types caused by other infectious agents,<sup>24</sup> although recent data indicate that HIV-1 infection may actively promote cancer growth, based on the evidence that the HIV-1–encoded Tat protein can directly induce tumor angiogenesis and enhance transmission of KSHV to target cells.<sup>10</sup>

The importance of detecting viruses as causes of cancer has enormous implications for public health. Such infectious agents constitute an identifiable and possibly preventable cause of cancer, and treatment options to prevent infection with or to eradicate these viruses could diminish the incidence of cancer. For example, HBV's association with HCC and HPV's association with cervical cancer have led to trials of vaccines for preventing cancer; encouraging results have been reported.<sup>25,26</sup>

## Viral Hepatitis

The existence of more than 400 million people chronically infected with HBV and another 170 million individuals chronically infected with HCV makes these two infections a serious global public health problem.<sup>27–29</sup> More than 25% of people with chronic hepatitis B infection will die of liver disease, and more than 1 million deaths result from this infection annually.<sup>28</sup> Likewise, chronic hepatitis C is a major cause of chronic liver disease and death throughout the world, with approximately 280,000 deaths attributable to this infection annually.<sup>29</sup>

## HBV Infection

### Clinical Manifestations

For adults, the risk of the HBV infection becoming chronic (ie, carriage of HBV surface antigen [HBsAg] for at least 6 months) is less than 5%.<sup>30</sup> Chronic HBV infection can cause hepatic cirrhosis and cancer.<sup>28</sup>

Table 1 Association between Viruses and Various Cancers

Virus Family	Type of Association and Cancer	Other Factors Associated with These Cancers
Herpesviridae		
EBV	Proven: Burkitt's lymphoma, Hodgkin's disease, non-Hodgkin's lymphoma, AIDS-associated lymphomas, nasopharyngeal cancer, post-transplantation lymphoproliferative disorders Controversial: breast cancer, gastric cancer, leiomyosarcomas	Burkitt's lymphoma: malaria, nitrosamines Non-Hodgkin's lymphoma: polychlorinated biphenyls, pesticides, hair dyes
HHV-8 (KSHV)	Proven: Kaposi's sarcoma, primary effusion lymphoma	HIV, nitrite inhalants, immunosuppressants, water and/or volcanic soils, nitrosamines
Hepadnaviridae		
HBV	Proven: hepatocellular carcinoma	Dietary aflatoxins, alcohol
Flaviviridae		
HCV	Proven: hepatocellular carcinoma Potential: non-Hodgkin's lymphoma	Alcohol
Papovaviridae		
Polyomaviruses		
JC virus	Potential: human brain tumors and non-neural tumors	No data
Simian virus 40	Potential: mesothelioma, brain tumors	Mesothelioma: asbestos, tobacco
Papillomaviruses		
HPV	Proven: cervical cancer, oropharyngeal cancer Potential: penile cancer, squamous cell skin cancer, pulmonary adenocarcinoma, laryngeal squamous cell carcinoma, esophageal squamous cell carcinoma Controversial: colorectal tumors	Cervical cancer: HSV-2 coinfection, tar-based vaginal douches, tobacco, wood smoke, oral contraceptives, high parity, tobacco Oropharyngeal cancer: alcohol, tobacco
Retroviridae		
HTLV-1	Proven: adult T-cell leukemia	No data
EBV = Epstein-Barr virus; HBV = hepatitis B virus; HCV = hepatitis C virus; HHV-8 = human herpesvirus 8; HIV = human immunodeficiency virus; KSHV = Kaposi's sarcoma-associated herpesvirus; HPV = human papillomavirus; HSV-2 = herpes simplex virus type 2; HTLV-1 = human T-cell leukemia virus type 1.		

HBV infection can produce a high incidence of hepatic complications during therapy for cancer.<sup>31</sup> Acute hepatitis owing to HBV reactivation is a complication observed in up to 67% of HBsAg-positive patients undergoing chemotherapy.<sup>32–34</sup> In most cases, the reactivation of HBV is asymptomatic, with mild and transient elevations of alanine aminotransferase levels. Some patients may have more severe flare-ups; massive necrosis and liver failure are associated with a mortality rate of 5 to 40%.<sup>31,35,36</sup> Therefore, the possibility of HBV reactivation should be considered in patients with a history of HBV infection who develop liver dysfunction following chemotherapy.

#### Pathophysiologic Mechanisms

In reactivation of HBV or HCV, chemotherapy depresses the immune system, leading to enhanced viral replication and an increase in the number of infected hepatocytes.<sup>34,35</sup> In both infections, hepatocellular damage appears to be mediated primarily by host cellular immune responses, and the clinical signs of acute hepatitis are usually

manifested at reconstitution of circulating lymphocytes. After discontinuation of chemotherapy and restoration of the individual's immune system, T cells directed at HBV or HCV antigens press on hepatocytes, potentiate inflammation, and can initiate hepatocyte lysis and progression to fibrosis.<sup>32,35,37,38</sup>

#### Diagnosis

HBV reactivation in cancer patients appears to be more common in male subjects, of young age, who have a diagnosis of lymphoma or breast cancer, positive results for hepatitis B early antigen (HBeAg), a high prechemotherapy HBV viral load, and previous exposure to anthracyclines and/or corticosteroids.<sup>31,33,39,40</sup> The presence of corticosteroids in the chemotherapy regimens is considered one of the most important risk factors for chemotherapy-induced HBV reactivation.<sup>34,39</sup> HBV contains a corticosteroid-responsive element that is an HBV enhancer.<sup>38</sup> Other chemotherapeutic agents or immunosuppressive drugs, apart from anthracyclines or corticosteroids,

that have been linked to the reactivation of HBV include vincristine, bleomycin, etoposide, methotrexate, actinomycin D, mercaptopurine, azauridine, chlorambucil, cytosine arabinoside, leukovorin, cisplatin, and gemcitabine<sup>39</sup> and the newer chemotherapeutic drugs fludarabine<sup>32</sup> and rituximab.<sup>41</sup>

Patients previously infected with HBV and undergoing HSCT are also at higher risk of hepatitis-related morbidity and mortality.<sup>27,40</sup> Nevertheless, the presence of chronic hepatitis B or C infection before transplantation should not be an absolute contraindication to HSCT, particularly in patients with normal serum aminotransferases and patients without marked hepatic fibrosis or cirrhosis.<sup>27,40</sup>

Patients should be screened routinely for HBsAg in endemic areas of chronic HBV infection before they undergo cytotoxic treatment.<sup>36</sup> Enzyme-linked immunosorbent assays are used to test for the presence of HBsAg, HBeAg, and antibodies against HBeAg. Patients who have positive results and are suspected to be having an HBV reactivation should have HBV-DNA levels measured for confirmation.<sup>32,36</sup> In addition, during chemotherapy and immunosuppressive therapy, serologic antibody markers of hepatitis may be negative, thus making HBV-DNA monitoring by polymerase chain reaction (PCR) useful.<sup>42</sup> Reactivation of HBV infection can occur with either HBeAg-positive or HBeAg-negative/anti-HBe-positive cancer patients.<sup>34,39</sup> Similarly, reactivation can occur despite the presence of HBV surface antibody following HSCT.<sup>43</sup> Pretransplantation liver biopsy to assess for the presence of fibrosis or cirrhosis is recommended in patients with abnormal serum aminotransferases or clinical manifestations of chronic liver disease.<sup>37</sup>

Chemotherapy regimens in individuals with HBV reactivation are usually discontinued and restarted several months after the acute event, when liver function test results normalize and HBV-DNA levels become undetectable.<sup>38</sup> Reactivation-related acute hepatitis can also cause delays and necessitate reductions in chemotherapy, reducing the chance of cancer remission and increasing the mortality rate.<sup>34,44</sup>

#### Treatment

The two modes of treatment for hepatitis B infection are viral suppression (eg, with nucleoside analogues such as lamivudine or adefovir dipivoxil) and immunomodulation (eg, with interferon- $\alpha$ ) (Table 2).<sup>28,45–50</sup> Lamivudine has been successfully used for the treatment of acute HBV reactivation in cancer patients undergoing chemotherapy.<sup>38,51</sup> In these patients, treatment of HBV infection may be indicated when a high risk of hepatic disease progression is documented during or at the end of chemotherapy.<sup>27</sup> In cancer

Table 2 Antiviral Agents Used for Treating Hepatitis B and C Viral Infections

Antiviral Agent	Mechanism of Action	FDA-Approved Indication	Reported Adverse Effects
Lamivudine	Inhibition of reverse transcriptase and incorporation into viral DNA, which halts the DNA synthesis of HBV	Chronic hepatitis B infection	Fatigue, headache, rashes, insomnia, myalgias, arthralgias, decreased appetite, diarrhea, nausea, vomiting, hepatomegaly with steatosis, pancreatitis, fat redistribution, lactic acidosis, death
Adefovir dipivoxil (oral prodrug of adefovir)	Inhibition of DNA synthesis of HBV through competitive inhibition of reverse transcriptase and incorporation into viral DNA	Chronic hepatitis B infection	Headache, asthenia, abdominal pain, diarrhea, dyspepsia, flatulence, nausea, pruritus, rash, renal failure
Interferon- $\alpha$	The precise mechanism of action has not been determined; thought to be related to altered synthesis of RNA and DNA, enhanced phagocytic activity of macrophages, and augmented specific cytotoxicity of lymphocytes for target cells	Chronic viral hepatitis caused by either HBV (interferon- $\alpha$ -2a and $\alpha$ -2b) or HCV (interferon- $\alpha$ -2a or -2b or alphacon 1, peginterferon $\alpha$ -2a and $\alpha$ -2b)	Influenza-like symptoms (eg, fever, chills, fatigue, headache, malaise, myalgia, and arthralgia), alopecia, anorexia, nausea, vomiting, diarrhea, dizziness, hypersensitivity, pruritus, aplastic anemia, hepatotoxicity, liver enzyme elevations, nephrotic syndrome, neutropenia, thrombocytopenia, pancreatitis, impaired concentration, severe somnolence, depression, suicidal ideation, anxiety, psychosis, pneumonitis, renal insufficiency/failure, retinal hemorrhages, cotton-wool spots, retinal artery/vein obstruction, thyroid and liver function test abnormalities
Ribavirin	Still unclear; may act at several sites, including cellular enzymes, to interfere with viral nucleic acid synthesis	Chronic hepatitis C infection with compensated liver disease (in combination with interferon- $\alpha$ -2b, peginterferon $\alpha$ -2a and $\alpha$ -2b)	Fatigue, headache, anorexia, dyspepsia, nausea, rash, lethargy, increased concentrations of serum bilirubin, pruritus, conjunctivitis, headache, hemolytic anemia, pancreatitis, bronchospasm, worsening respiratory status, cardiac arrest, hypotension, bradycardia, death

DNA = deoxyribonucleic acid; FDA = US Food and Drug Administration; HBV = hepatitis B virus; HCV = hepatitis C virus; RNA = ribonucleic acid.

and HSCT patients, nucleoside analogues are preferable because they do not cause substantial myelosuppression, a possible complication of interferon- $\alpha$  therapy.<sup>35,40</sup> Liver transplantation is also effective and should be considered in patients with end-stage disease that does not respond to medical therapy.<sup>28</sup> In children undergoing chemotherapy or HSCT, the criteria to start treatment must be the same as those used in children with chronic hepatitis, such as disease lasting for at least 6 months with abnormal transaminase levels and HBV-DNA positivity.<sup>27</sup>

Primary prophylactic therapy using lamivudine is well tolerated and effective in reducing the incidence of HBV reactivation in chronic HBsAg carriers undergoing chemotherapy.<sup>34,38,52</sup> Lamivudine treatment should continue for 6 to 12 months following the last dose of immunosuppressive treatment.<sup>38</sup> Prophylactic use of nucleoside analogues such as lamivudine or famciclovir may also result in a significant decrease in the incidence and severity of HBV reactivation after HSCT.<sup>40,53</sup> However, limiting the use of prophylactic antiviral agents to patients who are at the highest risk of developing HBV reactivation may reduce the potential complication of emergence of mutant viruses.<sup>39</sup>

Besides the prophylactic use of nucleoside analogues in HBsAg-positive patients, other strategies to reduce the risk of reactivation of HBV in patients with HBV infection and cancer who

receive cytotoxic chemotherapy include the use of less aggressive and less immunosuppressive chemotherapy protocols in HBsAg-positive patients, close monitoring every 1 to 3 weeks throughout the course of chemotherapy, and early intervention during reactivation.<sup>34,44</sup> To date, insufficient information exists to allow recommendation of antiviral prophylaxis for the population that has been exposed to HBV but tests negative for HBsAg.<sup>35</sup>

### HCV Infection

#### Clinical Manifestations

Acute HCV infection is generally benign in less than one-third of patients and tends to become chronic in more than 70% of them, at which stage it can induce cirrhosis, end-stage disease, liver failure, and liver cancer.<sup>29,54</sup> Several factors are clearly associated with the rate of fibrosis progression, including a low CD4 count.<sup>29</sup>

#### Pathophysiologic Mechanisms

These are described in the section on HBV infection.

#### Diagnosis

HCV infection may be diagnosed using serologic assays for antibodies and molecular tests for viral particles. Antibodies against HCV are detected by enzyme immunoassays that are very sensitive

and very specific. However, cancer patients, especially those with hematologic malignancies, can have false-negative results. In these patients, the conventional detection of anti-HCV antibodies is not sufficient for diagnosis, thus necessitating PCR determination of HCV-ribonucleic acid (RNA).<sup>27,29,55,56</sup> Knowledge of the viral load is also helpful for predicting treatment response and relapse.<sup>29</sup> Liver biopsy should be considered in patients with clinical manifestations of cirrhosis, patients with chronic HCV infection and elevated serum aminotransferase levels, and patients with HCV who have a history of excessive alcohol intake. Patients with marked hepatic fibrosis or cirrhosis should not proceed to high-dose myeloablative therapy and HSCT because of the high risk of complications and death from HCV infection.<sup>37</sup>

It seems that HCV has a lower reactivation rate than HBV has following chemotherapy, but when it occurs, it can be fatal.<sup>32,34</sup>

#### Treatment

The combination of pegylated interferon and ribavirin can eradicate HCV in more than 50% of patients (see Table 2). Combination antiviral therapy has been more effective than monotherapy with either agent and has a higher rate of sustained response.<sup>48</sup> Combination therapy should be considered for patients with decompensated but stable chronic HCV liver disease.<sup>57</sup>

These antiviral treatments reduce the progression of liver fibrosis and can reverse cirrhosis.<sup>29</sup> Liver transplantation is the primary treatment option for patients with decompensated cirrhosis.<sup>29</sup> A high viral load degree and the presence of genotype 1 are predictors of poor outcome in the general population.<sup>27</sup>

Ribavirin, administered during conditioning and after transplantation in HCV-infected patients requiring HSCT, appears to be safe and can result in clearance of HCV-RNA.<sup>58</sup>

High alcohol consumption must be avoided<sup>59</sup> and metabolic disorders (eg, diabetes, overweight) improved.<sup>60</sup> Superinfection with hepatitis A virus in patients with chronic HCV infection can result in severe acute or even fulminant hepatitis. Therefore, hepatitis A vaccine should be recommended for individuals with HCV infection and evidence of chronic liver disease.<sup>61</sup> Based on limited data, hepatitis A vaccination can be used among HSCT recipients 24 months or older at least 12 months after HSCT.<sup>62</sup>

## Cytomegalovirus

CMV is a ubiquitous herpesvirus that infects 40 to 100% of adults.<sup>63</sup> CMV infection is a considerable problem in patients who have undergone allogeneic or autologous HSCT,<sup>64,65</sup> and it is an emerging infection with significant morbidity and mortality among patients with leukemia<sup>66</sup> and lymphoma.<sup>67,68</sup>

## Clinical Manifestations

The most common forms of infection in patients with hematologic malignancies and in HSCT recipients are CMV infection (antigenemia) and CMV disease (end-organ disease). Pneumonia and gastrointestinal disease are the most common manifestations of CMV disease in these patient populations; other manifestations, such as myocarditis, hepatitis, adrenalitis, thyroiditis, pancreatitis, nephritis, and encephalitis, are less common.<sup>64,66,67,69,70</sup> Retinitis, a common manifestation of CMV disease in acquired immune deficiency syndrome (AIDS) patients,<sup>71</sup> is rare in cancer patients and those who have undergone HSCT.<sup>63,67,72,73</sup>

The mortality rate from CMV pneumonia varies according to the underlying malignancy, reported as 30% in patients with lymphoma, 57% in those with leukemia, and up to 90% in those who have undergone HSCT.<sup>64,66,74,75</sup> With current treatment regimens consisting of ganciclovir and intravenous immunoglobulin (IVIG), the mortality rate is approximately 60% for pneumonia.<sup>74</sup> In patients with CMV pneumonia, the presence of lymphopenia in leukemia patients<sup>66</sup> and a high APACHE II score and development of antiviral toxicity in lymphoma patients are predictors of poor outcome.<sup>67</sup>

Development of either CMV infection or CMV disease in cancer patients has been associated with the use of corticosteroids<sup>68,70</sup> and new chemotherapeutic agents such as, alemtuzumab, and fludarabine.<sup>66,76,77</sup> Potential risk factors for the development of CMV disease in HSCT recipients include pretransplantation CMV seropositivity, transplantation of hematopoietic stem cells from a matched unrelated donor or a mismatched related donor, use of T cell-depleted marrow, severe graft-versus-host disease, previous use of tacrolimus, and administration of prophylactic ganciclovir only three times per week.<sup>63–65,78,79</sup>

## Pathophysiologic Mechanisms

CMV remains latent in tissues after a patient's recovery from the initial infection.<sup>63</sup> Lymphocytes, particularly cytotoxic T cells, play a crucial role in maintaining CMV in the latent stages and in controlling CMV infection<sup>80</sup>; thus, their impairment may contribute to the development of CMV infection or CMV disease in cancer patients or those who have undergone HSCT.<sup>67,81</sup> CMV also exerts an immunomodulatory role, which predisposes patients to fungal infections.<sup>82</sup> For instance, patients with hematologic malignancies and HSCT who develop either CMV infection or CMV pneumonia commonly have concomitant *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia and an increased risk of subsequent development of invasive pulmonary aspergillosis.<sup>83,84</sup>

## Diagnosis

Early detection of CMV infection is critical to its optimal management.<sup>66</sup> Conventional viral culturing has been the gold standard for diagnosing CMV to date but is limited by its poor predictive value, lack of quantitation, false-negative results, and up to 6 weeks' turnaround time.<sup>85–88</sup> Rapid viral culturing using the shell vial method, a modification of conventional culturing, has reduced the diagnosis time to approximately 2 days and has a sensitivity of 68 to 100% compared with conventional culturing.<sup>85,87,89</sup> The CMV pp65 antigenemia assay using peripheral blood leukocytes is another reliable, rapid, and sensitive test. Similarly, the CMV pp67–messenger RNA assay appears to be a promising diagnostic tool with high specificity for the diagnosis of CMV infection, comparable to that of the quantitative pp65-antigenemia assay.<sup>90,91</sup> In patients who have undergone HSCT, the presence of antigenemia is a predictor of the development of CMV pneumonia,<sup>79,85,92</sup> although no correlation between CMV antigenemia and the development of CMV pneumonia has been observed in patients with lymphoma.<sup>67</sup> Real-time PCR for detection of CMV-DNA in the blood is an alternative that is also rapid and sensitive for diagnosing active

disease and monitoring the response to therapy; additionally, it appears to be more sensitive than the identification of antigenemia in detecting CMV reactivation in patients with lymphoid malignancies and after HSCT.<sup>93,94</sup> Virus quantitation can be used to risk-stratify patients and to monitor treatment.<sup>94</sup> CMV in tissue and bronchoalveolar lavage specimens may also be identified by cytology, histopathologic examination for viral inclusions, or immunohistochemical staining.<sup>67,85,89</sup>

A definitive diagnosis of CMV pneumonia depends on the detection of the virus in lung tissue.<sup>85</sup> However, lung biopsies are rarely performed in patients with cancer because of the morbidity (eg, bleeding) associated with this procedure.<sup>85</sup> Detection of CMV in bronchoalveolar lavage samples correlates highly with detection in lung biopsies<sup>95</sup> and is therefore presently the preferred method of diagnosis. Therefore, most cases of CMV pneumonia in cancer patients are diagnosed by the presence of both clinical and radiographic evidence of pneumonia and the isolation of CMV in respiratory samples obtained by noninvasive procedures (eg, bronchoalveolar lavage samples or sputum). The clinical manifestations and radiologic appearances of CMV pneumonia are indistinguishable from those of other causes of pneumonia in patients with cancer and after HSCT (Figure 1). Consequently, establishing the diagnosis by bronchoalveolar lavage samples is critical in these patients.

The second most common presentation of CMV disease in cancer patients is gastrointestinal infection (Figure 2).<sup>69</sup> Gastrointestinal CMV disease mainly involves the stomach (41%) and

**FIGURE 1** Cytomegalovirus pneumonia in a patient with lymphoma. Chest radiograph shows bilateral interstitial and alveolar infiltrates along with right pleural effusion.

**FIGURE 2** Gastrointestinal cytomegalovirus disease in a patient with cancer. Esophagogastroduodenoscopy showing cytomegaloviral infection associated with ulcer, granulation tissue, and edema.

colon (28%) and may be associated with a high attributable mortality rate (42%) among patients with cancer, particularly those with disseminated CMV disease or AIDS.<sup>69</sup> We previously reported that the presentation of gastrointestinal CMV disease varies according to the type of cancer and is influenced by the HIV serostatus.<sup>69</sup> More specifically, upper gastrointestinal tract CMV disease is more common in patients with hematologic malignancies than in those with solid tumors. Even more, cancer patients with AIDS are more likely than those without AIDS to have colonic involvement, whereas cancer patients without AIDS are more likely than those with AIDS to have gastric involvement.<sup>69</sup> Thus, gastrointestinal CMV disease should be suspected even in non-HSCT patients to initiate treatment before dissemination occurs.

### Therapy

The use of antiviral agents affects the outcome of cancer patients with CMV infection or CMV disease (Table 3).<sup>46,48,49,66–69,96–98</sup> Therapy for CMV infection consists of intravenous administration of ganciclovir with or without IVIG for CMV

pneumonia. The use of ganciclovir is limited by the associated development of neutropenia, however, which can increase the risk of superinfections, and the emergence of ganciclovir-resistant CMV infection.<sup>99</sup> Foscarnet is used in patients who experience severe myelosuppression during ganciclovir therapy. This agent does not cause neutropenia but is associated with nephrotoxicity and electrolyte imbalances. Valganciclovir is an oral prodrug of ganciclovir with a 10-fold greater bioavailability than oral ganciclovir's and has the potential to replace intravenous drug treatment in cancer patients who can take oral medication.<sup>96</sup> Cidofovir can also be used for treatment, but like foscarnet, it causes nephrotoxicity and occasionally neutropenia.<sup>97</sup> CMV infections refractory to sequential therapy with foscarnet and cidofovir have been reported.<sup>99</sup>

Combinations of antiviral agents against CMV disease have not been systematically evaluated in cancer patients. Although combination therapy with ganciclovir and high-dose IVIG appears to be more effective than therapy with ganciclovir alone in the treatment of CMV pneumonia in patients who have undergone HSCT,<sup>75</sup> no randomized trials have been done comparing these two treatment modalities.

Thus, to date, therapy for CMV disease in cancer or HSCT patients is suboptimal, and more effective and less toxic antiviral agents are urgently needed. However, preventing CMV infection has been more successful. It can be prevented in CMV-negative HSCT recipients by using bone marrow and screened blood products from donors who are also seronegative for CMV. Because of the high risk of CMV infection in seropositive HSCT recipients or those whose donors are seropositive, instituting measures to prevent CMV disease is important. Two strategies are used to prevent CMV infection in seropositive patients who are at risk of reactivation. One is the prophylactic administration of ganciclovir (foscarnet can be used as an alternative); valganciclovir may be useful in some high-risk patients. The second strategy involves early or preemptive therapy for subclinical CMV infection, based on positive surveillance testing (ie, antigenemia or PCR) for CMV from blood or the fluid obtained during bronchoalveolar lavage.<sup>88</sup> Each of these strategies has limitations, but both prophylactic and preemptive therapies are effective for preventing CMV disease.<sup>65,78</sup> Novel strategies include the use of donor-derived CMV-specific T cells.<sup>62,100,101</sup>

### HIV/AIDS-Related Cancers

Immunodeficiency, whether congenital or acquired (eg, HIV infection, drug or transplant related), increases the risk of certain types of cancers.<sup>102,103</sup> Patients with AIDS have an increased

incidence of certain cancers, some of them with unusual spectra and manifestations.<sup>24,103–105</sup> AIDS patients have a definite increased incidence of five cancers: KS; non-Hodgkin's lymphoma (NHL), including primary central nervous system lymphoma (PCNSL); squamous cell carcinoma of the conjunctiva; Hodgkin's disease; and childhood leiomyosarcoma.<sup>102</sup> Most of these cancers are known to be associated with specific herpesviruses and HPV coinfections.<sup>10,102,103</sup>

### Kaposi's Sarcoma

HHV-8, also known as KSHV, has been suggested as the causative agent of KS.<sup>9,10</sup> The distribution of KS appears to have geographic variations, at least partially related to the effect of the use of highly active antiretroviral therapy (HAART). For example, KS is relatively common in parts of Africa,<sup>24</sup> whereas it is rare in the United Kingdom.<sup>102</sup> In Africa, a steady increase in the incidence of KS has been observed over the last several years, and its occurrence in women has increased.<sup>104,106</sup> An increase in childhood KS has also been noted.<sup>106</sup> In developed countries, the incidence of KS has declined since the introduction of HAART, but this cancer is still a problem for AIDS patients in these countries.<sup>107,108</sup> This is probably because KS manifests less aggressively in patients receiving HAART, although the natural history and outcome do not appear to be influenced by the use of this therapy.<sup>109</sup>

The skin is the most common site of KS, with painless, slightly raised nodular tumors or plaque-like lesions, although, rarely, it can manifest in skeletal muscle and bone.<sup>108</sup> HIV-associated KS often manifests as multiple lesions affecting both the skin and internal organs.<sup>102</sup> HIV-infected patients with KS should be treated with HAART.<sup>108</sup> Identification of the optimal chemotherapy or immunotherapy against KS as well as antiviral therapy is the subject of continuous investigations.

### Non-Hodgkin's Lymphoma

NHL is a relatively late complication of HIV infection, and the incidence increases with the duration of infection.<sup>105</sup> The effect of HAART in HIV-associated NHL is mixed. For example, the incidence of systemic NHL has decreased<sup>110,111</sup> but to a lesser extent than the incidence of other AIDS-defining malignancies, such as KS and PCNSL.<sup>107,111</sup> Moreover, the prognosis of NHL has improved,<sup>110,112</sup> but it is still the most frequent cause of death among AIDS patients,<sup>111,112</sup> even in the era of HAART.<sup>111</sup> Roughly half of all cases of systemic NHL related to AIDS are linked to EBV infection.<sup>103</sup>

HIV-associated systemic NHL exhibits pleomorphic features, has a range of subtypes, and can have an aggressive clinical course.<sup>102</sup> The vast

Table 3 Systemic Antiviral Agents Used for Treating Cytomegalovirus Infection or Disease

Antiviral Agent	Mechanism of Action	Indication	Reported Adverse Effects
Ganciclovir	Guanosine analogue; inhibits DNA synthesis by suppressing DNA chain elongation	CMV prophylaxis and treatment*; CMV infections, particularly CMV retinitis in immunocompromised (eg, AIDS) patients (treatment and prophylaxis)	Anemia, neutropenia, thrombocytopenia, hypersensitivity (eg, fever, skin rash), phlebitis, anorexia, nausea or vomiting, eosinophilia, increased levels of creatinine or blood urea nitrogen, central nervous system effects (eg, mood or other mental changes, nervousness, tremor, seizures, confusion, encephalopathy), increased liver function test results
Foscarnet	Pyrophosphate analogue that acts by inhibiting DNA polymerase during the DNA polymerization process	CMV retinitis,* CMV prophylaxis and treatment	Anemia, fever, headache, diarrhea, nausea, vomiting, nephrotoxicity, seizures, electrolyte disturbances (eg, hypocalcemia, hypophosphatemia, hyperphosphatemia, hypomagnesemia, hypokalemia)
Valganciclovir	Prodrug of ganciclovir, then acts as described for ganciclovir	CMV retinitis in AIDS patients* and CMV disease prophylaxis (heart, kidney, kidney-pancreas transplantation)*; therapy and prophylaxis of CMV infection	Headache, insomnia, pyrexia, anemia, neutropenia, thrombocytopenia, abdominal pain, diarrhea, nausea, vomiting
Cidofovir	Inhibition of viral DNA polymerase by its diphosphorylated metabolite	CMV retinitis in patients with AIDS*; may be effective in the treatment and prophylaxis of CMV infection	Nausea, vomiting, headache, rash, severe nephrotoxicity, metabolic acidosis, ocular hypotony, anterior uveitis, iritis, neutropenia, thrombocytopenia

AIDS = acquired immune deficiency syndrome; CMV = cytomegalovirus; DNA = deoxyribonucleic acid.  
\*Indication approved by the US Food and Drug Administration.

majority of systemic AIDS-related NHLs belong to the three high-grade B-cell lymphomas: Burkitt's lymphoma, immunoblastic lymphoma, and large cell lymphoma. Among the less common types are primary effusion lymphoma and multicentric Castleman's disease-associated NHLs.<sup>10</sup> Most NHLs are of nodal origin (71%),<sup>106</sup> but HIV-associated NHL is characterized by widespread disease involving extranodal sites such as the bone marrow, gastrointestinal tract, central nervous system, ovary, and skin.<sup>102,106,113</sup> In Africa, a significant increase in the incidence of NHLs in women has been reported.<sup>104</sup> The response to HAART remains an important prognostic factor in patients with NHL.<sup>112</sup> Standard chemotherapies similar to those used for systemic NHL in non-HIV-infected patients have also been used for those infected with HIV.<sup>112</sup>

### Primary Central Nervous System Lymphoma

PCNSL is an aggressive cancer in AIDS patients. More than 95% of cases are of B-cell origin, with microscopic and immunologic features similar to those of systemic NHL, including its association with EBV infection.<sup>110,114</sup> However, PCNSL is rarely accompanied by lymphoma outside the central nervous system. PCNSL occurs most often in the advanced stages of AIDS, typically observed in HIV-infected patients who have CD4<sup>+</sup> cell counts below 50/mm<sup>3</sup>.<sup>110,114</sup> The incidence of PCNSL has dropped since the introduction of HAART.<sup>112,114</sup>

These patients have constitutional symptoms, altered mental status, seizures, and multiple irregular or ring-shaped enhancing lesions on magnetic resonance images.<sup>114</sup> PCNSL must be differentiated from a more common AIDS-defining illness, cerebral toxoplasmosis. In the absence of a response to a trial of antitoxoplasmosis therapy, cytologic examination of the cerebrospinal fluid and EBV-DNA detection or a stereotactic biopsy are required to confirm the diagnosis of PCNSL. The median survival rate is poor, and the optimal therapy against PCNSL is not well defined. Local radiotherapy is favored over chemotherapy, and the combination of radiotherapy and HAART improves patients' survival rate.<sup>110</sup>

### Hodgkin's Disease

The risk of developing Hodgkin's disease is high after the onset of AIDS.<sup>103</sup> Like systemic NHL and PCNSL, most HIV-associated Hodgkin's disease tumors are also linked to EBV infection.<sup>103</sup> Among HIV-infected individuals, Hodgkin's disease is clinically unusual, generally presenting at a late stage with extranodal dissemination and an atypical, aggressive clinical course.<sup>102,113</sup> The predominant histologic subtypes are mixed cellularity and lymphocyte depletion, which are relatively rare in HIV-negative patients.<sup>102</sup> The effect of HAART on the epidemiology of HIV-associated Hodgkin's disease remains unclear.<sup>107</sup>

### Other Cancers

A dramatic increase in the incidence of eye tumors, particularly of squamous cell tumors of the conjunctiva, has been observed in Africa, one of the regions most affected by the AIDS epidemic.<sup>104,106</sup> Similarly, HIV-infected children have been observed to have a high risk of developing leiomyosarcoma.<sup>115</sup> Increases in oral, testicular, skin, brain, lung, breast, and thyroid cancers have been linked to HIV infection, although further research is needed to clarify such associations.<sup>102</sup>

The incidence of cervical cancer remains very high, and it is the most common cancer among women with AIDS.<sup>104</sup> However, there has been no suggestion that the natural history of cervical cancer has been affected by HIV.<sup>104,106</sup> HIV infection appears to increase the risk of low-grade cervical lesions but not the risk of invasive cervical cancer.<sup>102</sup> Furthermore, there is no evidence that the oncogenic role of HPV is different in HIV-infected women than it is in HIV-noninfected women.<sup>10</sup> Similarly, in no study has an increase in the relative risk of HCC been observed in HIV-seropositive subjects.<sup>102</sup>

### Community-Acquired Respiratory Viruses

CRVs can produce severe infections in both community and hospital settings.<sup>116-118</sup> These viruses frequently cause respiratory illnesses that are

associated with high morbidity and mortality rates among cancer patients and HSCT recipients.<sup>116–125</sup> For instance, among adult HSCT recipients in 1997 at The University of Texas M. D. Anderson Cancer Center, CRV infection was the major cause of death, second only to *Aspergillus* infection.<sup>126</sup> However, there are seasonal differences in the intensity and virulence of the epidemics in the communities and between regions; thus, the impact of CRV infections in HSCT recipients varies between centers.

The CRVs include some virulent and highly contagious viruses, the most common of which include RSV, the influenza viruses, and PIV<sup>122,127–129</sup>; there are two subtypes of RSV (A and B), three types of influenza viruses (A, B, and C), and four types of PIV (1 through 4, with serotype 3 the most common). Picornavirus, rhinovirus, coronavirus, adenovirus, and enterovirus are less common respiratory viruses.<sup>116,121,129–131</sup>

CRV infections in HSCT recipients have been extensively studied, and their characteristics are summarized in Table 4.<sup>117,119–121,126–129,132–135</sup> Overall, they occur in up to 36% of all adult HSCT recipients.<sup>120,126,127</sup> The risk from CRV infection is higher in allogeneic HSCT recipients than in autologous HSCT recipients.<sup>119,126,127</sup>

In the case of hematologic malignancies, especially leukemia, CRV infections occur in up to 33% of affected patients; the characteristics of those infections in this subset of patients are summarized in Table 5.<sup>123–125,130,131,136,137</sup>

Of note is that the incidence of RSV, influenza, or PIV infection varies between different series of HSCT recipients and patients with hematologic malignancies. These differences might result from the CRV infection rates in the community and/or differences in the diagnostic methods and infection control measures used in the different centers.

## Clinical Manifestations

RSV and influenza infections are observed in seasonal patterns. In the United States, most RSV infections occur during November and May,<sup>116</sup> although, rarely, cases have been reported at different times throughout the year, including the summer months.<sup>138</sup> The start of influenza season typically follows that of the RSV season, and most cases are reported during the winter months. The seasonal prevalence of influenza infections in patients with hematologic malignancies and in HSCT recipients parallels their prevalence in the general community.<sup>117,118</sup> On the other hand, PIVs, rhinoviruses, and adenoviruses are prevalent throughout the year.<sup>128–131</sup>

Immunocompromised patients with CRV infections usually display a more prolonged duration of infection and viral shedding and have more varied initial manifestations of symptoms than normal CRV hosts do.<sup>116</sup> Cancer patients may present with mild to moderate URIs, such as pharyngitis or laryngitis, or with potentially lethal LRIs, such as tracheobronchitis, bronchiolitis, or pneumonia.<sup>116</sup> The most common signs and symptoms of CRV infections are cough, fever, sputum, rhinorrhea, sinus congestion, sore throat, rales, or rhonchi.<sup>133,134</sup> It is interesting that in HSCT recipients with CRV infection, alveolar condensation is the most common abnormality, followed by the presence of an interstitial infiltrate.<sup>133</sup> An association of CRV infections with late airflow obstruction has recently been described.<sup>139</sup>

Up to 80% of CRV-associated URIs in HSCT recipients and patients with hematologic malignancies may progress to LRIs; however, in the majority of studies, progression occurs in 30 to 50% for RSV and 25 to 30% for PIV.<sup>117,118,124,126,133</sup> Progression usually occurs within 2 weeks of the diagnosis of a URI (median 7 days), with

certain variations observed according to the virus involved, and it appears to be more commonly produced by RSV than by an influenza virus or PIV (see Table 4 and Figure 3). Allogeneic HSCT recipients appear to have a higher risk of developing LRIs than autologous HSCT recipients do.<sup>127</sup> Progression from influenza URI to pneumonia has been reported in HSCT recipients given amantadine or rimatadine but not in those given oseltamivir or zanamivir.<sup>117</sup> Influenza in patients treated with corticosteroids, antiviral agents, or both is less likely to progress to an LRI than it is in untreated HSCT patients.<sup>117</sup> The strongest risk factors for progression to LRIs in HSCT recipients are older age, lymphopenia in patients with RSV infection, and use of systemic corticosteroids and lymphopenia in patients with PIV infection.<sup>128</sup>

**FIGURE 3** Respiratory syncytial virus pneumonia in a patient with chronic myeloid leukemia. Chest radiograph shows airspace disease in the right lower lobe.

**Table 4** Characteristics of the Most Common Community-Acquired Respiratory Virus Infections in Hematopoietic Stem Cell Transplant Recipients

Virus	Incidence (%)	Risk Factors for Infection	Progression from URI to LRI (%)	Risk Factors for Progression to LRI	Median Days (range) to Progression to LRI	Shedding Duration, d (range)	Treatment	Mortality Rate* (%)
RSV	5–10	Male sex	27–80	Older age, stem cells from mismatched or unrelated donor, pre-engraftment period, lymphopenia	4–7 (0–7)	10–16 (1–30)	RSV-IVIG plus aerosolized ribavirin	7–100
Influenza	1	Female sex, advanced disease	7–32	Lymphopenia, less exposure to corticosteroids, autologous HSCT	11 (4–14)	7 (2–37)	Oseltamivir appears to be more effective than rimantadine	10–57
PIV	2–7	Use of unrelated stem cell donor	0–27	Use of high-dose corticosteroids	3 (0–30)	No data	Aerosolized ribavirin with or without IVIG	0–75

HSCT = hematopoietic stem cell transplantation; IVIG = intravenous immunoglobulin; LRI = lower respiratory tract infection; PIV = parainfluenza virus; RSV = respiratory syncytial virus; URI = upper respiratory tract infection.

\*Mainly due to LRI.

Risk factors for progression of CRV-associated URIs to LRIs in patients with hematologic malignancies include inpatient status at the onset of infection, lymphopenia, and CRV infection caused by RSV.<sup>118</sup>

In HSCT recipients, prolonged shedding of CRVs may occur for all species (see Table 4). Influenza virus shedding has a longer duration in allogeneic recipients, those given higher doses of corticosteroids, or those who have not received antiviral therapy.<sup>117</sup>

The most common periods during which CRV infections occur are in the first 30 days and 90 days after HSCT.<sup>119,133</sup> Patients who develop CRV pneumonia before engraftment are at the greatest risk of death, with a reported mortality rate of up to 80%.<sup>116,121</sup> However, the outcome of infection in such a patient population varies with the type of infection and the virus involved (see Table 4), and the results from recent studies suggest that outcome is improved with early institution of therapy.<sup>140</sup>

Notable geographic and probably center-to-center differences occur in the outcome of CRV infections in HSCT recipients. For example, in the United States, the highest mortality rate observed in this patient population appears to occur in those with RSV infection,<sup>117</sup> whereas in Brazil, influenza A infection accounts for most fatal cases.<sup>133</sup> Furthermore, in Europe, the mortality rate associated with RSV infection appears to be higher in allogeneic than in autologous recipients, whereas the mortality rate associated with influenza infection seems to be similar in the two groups of HSCT recipients.<sup>127</sup> Overall, the mortality rates associated with CRV-associated pneumonia are between 7 and 100% in HSCT recipients<sup>118,123,124,126</sup> and 5 and 83% in patients with leukemia (see Tables 4 and 5).<sup>118,123</sup> These differences are likely due to differences in the definition of LRIs, underlying immunosuppression, the presence of copathogens, and the timing and type of treatment regimens.

### Pathophysiologic Mechanisms

In immunocompromised patients, URIs caused by CRVs can spread to the lower respiratory tract. For example, RSV, influenza viruses, and PIV may predispose cancer patients and HSCT recipients to serious secondary bacterial or fungal infections.<sup>116–118,123,127,129,133</sup> Additionally, coinfection with more than one of these CRVs has been reported in 3 to 7% of HSCT recipients and in 12 to 50% of patients with hematologic malignancies.<sup>118,119,125,127,137</sup> It is interesting that RSV infections were also associated with delayed engraftment following transplantation in one study.<sup>141</sup>

### Diagnosis

Prompt and accurate diagnosis of CRV infections allows early treatment, possibly delays the

**Table 5** Characteristics of the Most Common Community-Acquired Respiratory Virus Infections in Patients with Leukemia

Virus	Incidence (%)	Predominant Leukemia	Frequency of LRI (%)	Treatment	Mortality Rate* (%)
RSV	10	Acute and chronic myeloid	59–67	Aerosolized ribavirin plus RSV-IVIG	53–83
Influenza	33	Acute and chronic lymphoid	35–80	Oseltamivir, zanamivir, amantadine, rimantadine, aerosolized ribavirin	5–43
PIV	3	Acute and chronic lymphoid	55–67	Aerosolized ribavirin	15–66

IVIG = intravenous immunoglobulin; LRI = lower respiratory tract infection; PIV = parainfluenza virus; RSV = respiratory syncytial virus.  
\*Mainly due to LRI.

necessity for chemotherapy and transplantation, and permits rapid initiation of infection control measures.<sup>120,126,128,133</sup> Methods used for diagnosing CRVs include viral culture, enzyme-linked immunosorbent assays for antigen detection, direct or indirect immunofluorescence assays with monoclonal antibodies, PCR amplification, and chemical reactions for enzyme detection.<sup>116,122,129,133</sup> PCR testing also allows virus quantitation. Histopathologic examination of lung tissue with immunohistochemical staining has also been used for diagnosing CRV infections.<sup>125,134</sup>

In patients who have rhinorrhea, nasal or sinus congestion, otitis media, pharyngitis, and/or cough without hypoxemia or infiltrates on chest radiography, CRV-associated URIs are usually diagnosed when a CRV is microbiologically isolated in a specimen from the upper respiratory tract. However, CRV-associated LRIs are diagnosed when a CRV is either microbiologically isolated from a lower respiratory tract sample or identified during histopathologic examination of lung tissue in the presence of symptoms and radiographic findings compatible with a diagnosis of a viral LRI.<sup>117,130,134,142</sup>

### Therapy

Without treatment, the mortality rate associated with RSV LRIs may be as high as 100%,<sup>116,120,127</sup> although recent reports also suggest that some RSV-infected patients may have a good outcome without treatment.<sup>141</sup> The results with the use of antiviral therapy against RSV URIs in HSCT recipients (mainly autologous recipients) and patients with multiple myeloma have been conflicting.<sup>127,138,141</sup> The reasons for these differences are poorly understood but are likely due to the immunosuppressive state of the patient.

The experience from several transplantation centers suggests that the patients at highest risk of severe RSV disease are those whose transplants have not yet fully engrafted; therefore, treatment should be initiated early in the pre-engraftment period.<sup>126,134,135</sup> At M. D. Anderson Cancer Center

and the Fred Hutchinson Cancer Research Center, our current practice is to individualize care for HSCT recipients with a postengraftment RSV-associated URI based on the presence of risk factors for progression to severe disease, such as the presence of lymphopenia.<sup>134,135</sup>

To date, the only available antiviral therapy for RSV infection is aerosolized ribavirin.<sup>49,116</sup> RSV-IVIG is derived from pooled adult plasma containing high titers of neutralizing antibodies against RSV. Monotherapy with RSV-IVIG may modify RSV infections.<sup>126</sup> In recent years, the use of aerosolized ribavirin plus RSV-IVIG has been associated with better outcomes than available previously in patients with RSV LRIs, especially when treatment is initiated early during the infection; however, these results were not obtained in randomized trials.<sup>116,120,126,134,135</sup> For HSCT recipients, the prompt use of this combination approach resulted in a dramatic decrease in the overall mortality rate from 100% to less than 40%.<sup>116,126,143</sup> However, the benefit of combining aerosolized ribavirin with IVIG in HSCT recipients remains to be elucidated in prospective controlled clinical trials, as does the benefit of using standard IVIG preparations rather than antibody preparations containing high titers of RSV-neutralizing antibody or RSV-specific monoclonal antibody.<sup>135,140</sup>

Initial treatment options for uncomplicated influenza A viral infection include amantadine, rimantadine, oseltamivir, and zanamivir. Amantadine and rimantadine are chemically related antiviral drugs with the same target (M2) and are effective in the treatment of influenza A infection.<sup>96,116</sup> Oseltamivir and zanamivir belong to a new class of antiviral agents, the neuraminidase inhibitors, which are active against both influenza A and B viruses and are approved for the treatment of influenza infections.<sup>96,116</sup> Treatment options for uncomplicated influenza B viral infections include oseltamivir and zanamivir. The results of noncontrolled studies have shown that oseltamivir might be more effective than

rimantadine for the treatment of influenza virus-associated URIs and LRIs.<sup>117</sup> Ribavirin is a broad-spectrum antiviral agent with activity against RNA and DNA viruses, including influenza A and B viruses, PIV, and RSV.<sup>48</sup> Few clinical studies exist on ribavirin in treating influenza infection.

The idea of combination antiviral therapy for treatment of severe influenza infections has not been explored in controlled trials.<sup>116</sup> Combination therapy of M2 and neuraminidase inhibitors can be considered for severe disease; however, published data are limited.<sup>117</sup> Compared with single agents, combinations of ribavirin with amantadine or rimantadine have shown enhanced antiviral activity in vitro and in animal models of influenza A infection.<sup>144</sup> Ribavirin could be used in combination with neuraminidase inhibitors for life-threatening influenza B infections. Antiviral therapy against influenza virus infections should be administered for at least 5 days in patients with hematologic malignancies because a shorter duration of therapy might be associated with progression to an LRI in high-risk patients.<sup>142</sup>

Currently, no licensed antiviral therapy is available for treating severe PIV infections. Ribavirin is active against PIV in vitro but possesses only marginal activity in vivo.<sup>116,124</sup> Several investigators have reported that successful outcomes with ribavirin depended on early initiation of therapy, that is, when the virus was confined to the upper respiratory tract.<sup>116,145</sup> However, PIV infections appear to be less responsive than RSV infections to treatment with aerosolized ribavirin.<sup>128</sup> Ribavirin has also failed to shorten the time for PIV shedding in HSCT recipients.<sup>129</sup> Although the combination of IVIG and ribavirin has also been used to treat PIV-associated LRIs, the results have been inconclusive.<sup>116,129</sup>

In the absence of optimal therapy against CRV infections in HSCT recipients and cancer patients, preventing such infections is of the utmost importance. RSV-IVIG has been used for prevention of severe RSV-associated LRIs in children with chronic lung disease or a history of premature birth.<sup>116</sup> The development of palivizumab, a monoclonal antibody directed against RSV, has provided another option for preventing RSV infection.<sup>116</sup> The mainstay of influenza prophylaxis in the general population is the inactivated influenza vaccine.<sup>116</sup> Prophylactic oral antiviral therapy against influenza viruses may be warranted for patients in high-risk groups if vaccination is contraindicated or if supplies of vaccine are insufficient.<sup>116</sup> Antiviral drugs currently approved for influenza chemoprophylaxis include amantadine, rimantadine, and oseltamivir.<sup>116</sup> Amantadine and rimantadine are equally effective in preventing influenza A infection, with efficacy rates of 70 to 90% in controlled

trials.<sup>116</sup> Neuraminidase inhibitors are highly effective in prophylaxis<sup>146</sup>; the side-effect profile appears to be more favorable than that of M2 inhibitors. Surveillance, vaccination of contacts, and preemptive antiviral therapy might also minimize the effect of influenza infection in HSCT recipients.<sup>62,117</sup>

Finally, the use of infection control measures is important and has dramatically reduced the incidence of CRV infections.<sup>126</sup> At M. D. Anderson Cancer Center and the Fred Hutchinson Cancer Research Center, patients are screened for CRV infections before they undergo stem cell transplantation if they are symptomatic, and transplantation is delayed if a URI is present.<sup>62,147</sup> Whether all transplants must be delayed (including autologous transplants for multiple myeloma) remains controversial,<sup>138</sup> and more research is needed to identify patients who can safely be transplanted. PCR testing might prove useful in this regard in future. Meanwhile, we favor delaying transplantation in patients with URI. Patients are encouraged to wash their hands frequently, visits to patients are limited, and both visitors and staff must wear masks and gloves when entering the rooms of patients with URI symptoms.<sup>126</sup> Whether a general mask policy (even during contact with uninfected patients) is effective remains controversial. Contact of family members, visitors, and staff with uncontrolled respiratory secretions should be minimized. In addition, patients should be placed in respiratory isolation conditions until they are symptom free and respiratory samples yield negative microbiologic results.<sup>117,126</sup>

## Summary

Clinical and epidemiologic studies have suggested that many viruses may be associated with carcinogenesis. In addition, viral infections are important causes of morbidity and mortality in HSCT recipients and patients with hematologic malignancies. Less is known about the effect of these infections on other subsets of cancer patients. The risk factors for developing a severe viral infection need better definition to permit identification of high-risk patients who may benefit from preventive measures and/or early diagnosis and therapy. Because of the suboptimal response of these infections to the currently available antiviral therapies, new antiviral agents are needed. Finally, prevention remains the most important approach in this patient population, and infection control measures are of paramount importance.

# Fungal Infections in Immunocompromised Hosts with Cancer

Dimitrios P. Kontoyiannis, MD, ScD

Russell E. Lewis, Pharm D

T. J. Walsh, MD

For many years, the major focus of attention in the study of infectious complications of cancer was on bacterial infections. In recent years, however, with the use of more aggressive therapies, widespread use of human stem cell transplantation, and the ability to control most bacterial infections, fungal infections have emerged as serious and frequently fatal complications in patients with cancer, especially those with acute leukemia and recipients of human stem cell transplants (HSCTs).<sup>1-4</sup> This chapter provides an overview of modern antifungal agents and the current issues regarding the most important mycoses that inter- nists encounter in patients with cancer.

## Overview of Antifungal Agents

Until the early 1990s, treatment of life-threatening invasive fungal infections was essentially limited to the use of only one antifungal agent, amphotericin B (AMB) deoxycholate (AMB-d).<sup>5</sup> The introduction of several new antifungal agents with activity against opportunistic yeasts and molds has provided new treatment options, however.<sup>2,6,7</sup> Currently, 13 antifungals are licensed for the treatment of invasive mycoses. These drugs belong principally to four classes: polyenes, pyrimidines, azoles, and echinocandins (Table 1). No ideal antifungals for the treatment of deep mycoses have been identified, and the drug of choice is influenced by many factors, such as the specific type of fungal infection, its site, and the presence of comorbidities (Table 2). Consequently, selection of antifungal therapy should be an individualized process with careful consideration of the disease severity, potential for organ toxicity, and drug interactions.

## Amphotericin B

For decades, conventional AMB has been considered the gold standard for the treatment of deeply invasive fungal infections.<sup>5</sup> However, the

significant toxic effects of the conventional AMB formulation, which include infusion-related fever, rigors, headache, dose-limiting nephrotoxicity, and anemia, often limit the effectiveness of this agent in severely ill patients.<sup>5</sup> Consequently, lipid-based formulations of AMB (eg, AmBisome, Abelcet, Amphotec) that offer the advantages of fewer infusion-related side effects and reduced nephrotoxicity were developed.<sup>6,8</sup> The dose equivalency of these formulations differs from that of conventional AMB-d, with the requirement of lipid formulation doses three- to five-fold higher (in mg/kg) for similar efficacy.<sup>6,8</sup> When AMB is incorporated into a lipid carrier, the pharmacokinetics of the drug change depending on the particle size of the formulation. The larger-particle formulations (Abelcet and Amphotec) are rapidly removed from the bloodstream by macrophages and other cells of the reticuloendothelial system and deposited into deep tissue sites such as the liver, spleen, and lung, resulting in more rapid clearance from the bloodstream relative to the standard AMB formulation.<sup>6</sup> In contrast, the smaller-particle liposomal AMB formulation (AmBisome) circulates in the bloodstream for longer periods before being sequestered into deep tissue sites.<sup>6</sup> Therefore, clearance of this formulation and the volume of its distribution are lower than those of AMB.<sup>6</sup> The clinical impact of these pharmacokinetic differences between different AMB formulations is unclear.<sup>8</sup> All three lipid formulations accumulate to a lesser degree in the kidneys when compared with the standard AMB formulation, however, which accounts for their reduced rates of nephrotoxicity.

Despite the improved therapeutic index of these lipid formulations of AMB, there are still relatively few data from prospective clinical trials suggesting that these considerably more expensive formulations are more effective than conventional AMB. Moreover, the 10- to 20-fold higher acquisition cost of the lipid formulations has

required many institutions to restrict their use to patients with preexisting renal failure or those at high risk of nephrotoxicity while receiving AMB (eg, patients receiving concomitant nephrotoxic drugs). Currently, there is no consensus regarding the clinical or pharmacoeconomic threshold for using lipid AMB formulations as first-line therapy for most invasive mycoses in patients with cancer. Cost-effective use of these formulations relies on institution-specific factors, including their acquisition (primary) costs and secondary costs (eg, increased length of stay; use of a pharmacy, blood bank, laboratory, and radiology services) associated with managing the additional toxic effects of the standard AMB formulation.

The most common acute toxic effects of all AMB formulations are infusion-related reactions, which are characterized by fever, chills, rigors, anorexia, nausea, vomiting, myalgia, arthralgia, and headache.<sup>5</sup> Hypotension, flushing, and dizziness are less common, but bronchospasm and true anaphylactic reactions have been reported with both the conventional and lipid formulations of AMB. Severe hypokalemia and cardiac arrhythmia have also been reported in patients with a central venous catheter in place who received a rapid infusion or excessive dose of the conventional AMB formulation.<sup>5</sup> Therefore, slower infusion rates (more than 4–6 hours) and electrocardiogram monitoring should be considered for patients with underlying cardiac conduction abnormalities. Because thrombophlebitis is a common local side effect with infusion into a peripheral vein, use of a central venous catheter is required if AMB will be administered for more than 1 week.<sup>5</sup> Slower infusion rates, rotation of infusion sites, application of hot packs, use of low-dose heparin, and avoidance of AMB concentrations greater than 1 g/L can minimize thrombophlebitis.

Table 1 Systemic Antifungal Therapies

Antifungals	Trade Name(s)	Usual Adult Dose	Mechanism of Action	Toxic Effects	Spectrum/Comments
<b>Polyenes</b>					
AMB	Fungizone	0.25–1.50 mg/kg IV q24h	Binds to ergosterol and intercalates the fungal cell membrane, resulting in increased membrane permeability to univalent and divalent cations	Acute: fever, chills, rigor, arthralgia with infusion Thrombophlebitis, dyspnea (rare), arrhythmia (rare)	Drug of choice for severe infections caused by endemic dimorphic fungi, most <i>Candida</i> spp, and common $\alpha$ -hylophomycetes ( <i>Aspergillus</i> , <i>Zygomycetes</i> )
Lipid formulations of AMB	AmBisome, Abelcet, Amphotec	3–10 mg/kg/q24h 5 mg/kg/q24h 3–4 mg/kg/q24h	Delayed: azotemia (26%), tubular acidosis, hypokalemia, hypomagnesemia, anemia		Nephrotoxicity is the dose-limiting side effect, which is reduced with lipid AMB formulations and saline before and after hydration Infusion-related reactions: AmBisome < Abelcet < Amphotec AmBisome is considered the preferred formulation for central nervous system mycoses
<b>Liposomal AMB</b>					
ABL					
BCD					
<b>Fluoropyrimidines</b>					
Flucytosine (5-FC)	Ancobon	100 mg/kg/d PO divided q6h Dosage adjustment required in renal impairment	Drug is transported into susceptible fungi by cytosine permease and then deaminated to active form (5-fluorouracil) by cytosine deaminase where the drug interferes with DNA/RNA synthesis	Increase in serum transaminase levels (7%); nausea and vomiting (5%); diarrhea, abdominal pain, rash, enterocolitis (rare) Less common: leukopenia, thrombocytopenia, anemia	Narrow spectrum for deep mycoses: <i>Candida</i> and <i>C. neoformans</i> only. Resistance is common when used as monotherapy. Typically administered in combination with AMB for cryptococcal meningitis. Risk of bone marrow suppression is increased with persistent flucytosine levels > 100 $\mu$ g/mL. Careful dosage adjustment is required for patients with renal dysfunction.
<b>Azoles</b>					
Ketoconazole	Nizoral	200–800 mg PO q24h Divided doses recommended at doses of 400 mg/d or greater	Inhibition of cytochrome P-450 14- $\alpha$ -demethylase decreased production of ergosterol, accumulation of lanosterol leading to perturbation of fungal cell membrane, fungistasis	Gastrointestinal (20–50%) including nausea and vomiting, anorexia, rash (2%), transient increases in hepatic enzyme levels, severe hepatotoxicity (rare), alopecia, inhibition of adrenal steroid synthesis (especially at dosages > 600 mg/d)	Oral formulation only. Inconsistencies in oral absorption/poor gastrointestinal tolerance limits use for treatment of deep mycoses Potent inhibition of mammalian cytochrome P-450 can lead to potentially severe drug interactions when administered concomitantly with other P-450-metabolized drugs

Table 1 Continued

Antifungals	Trade Name(s)	Usual Adult Dose	Mechanism of Action	Toxic Effects	Spectrum/Comments
Itraconazole	Sporanox	200–400 mg PO q24h, IV 200–400 mg q12h, and then q24h Divided doses recommended at $\geq$ 400 mg/d	Similar to ketoconazole but more selective for fungal P-450 demethylase	Gastrointestinal (20%) including nausea and vomiting, diarrhea, rash (2%), taste disturbance (oral solution), transient increases in hepatic enzymes, severe hepatotoxicity (rare), alopecia, inhibition of adrenal steroid synthesis (especially at dosages > 600 mg/d) Accumulation of hydroxypropyl- $\beta$ - cyclodextran vehicle in patients with creatinine clearance < 30 mL/min (intravenous formulation); consider switch to oral therapy if possible Congestive heart failure (rare)	Spectrum similar to fluconazole with enhanced activity against <i>C. krusei</i> and <i>Aspergillus</i> . Not active against <i>Fusarium</i> or <i>Zygomycetes</i> . Drug of choice for mild to moderate infections caused by endemic dimorphic fungi. Bioavailability of oral solution is improved over capsules by 30% under fed conditions and 60% under fasting conditions. Potent inhibitor of mammalian cytochrome P-450 enzymes. Serum level monitoring is occasionally recommended; trough levels measured by high- performance liquid chromatography should exceed 0.5 $\mu$ g/mL.
Fluconazole	Diflucan	100–800 mg PO/IV q24h Dosage adjustment required for renal impairment	Similar to ketoconazole but a more selective inhibitor of cytochrome P-450 enzyme 14- $\beta$ -demethylase	Gastrointestinal (5–10%), rash, headache, transient increases in hepatic enzyme levels, hepatotoxicity (rare), alopecia	Spectrum includes most <i>Candida</i> spp, <i>C. neoformans</i> , and endemic dimorphic fungi. Less active against <i>C. glabrata</i> . <i>C.</i> <i>krusei</i> is intrinsically resistant. Not clinically active for deep mycoses caused by invasive molds. Best tolerated of the azoles. Higher daily dosages are recommended (eg, 12 mg/kg/d) for critically ill patients or in institutions where <i>C. glabrata</i> infection is common (> 10% of all <i>Candida</i> spp). Inhibitor of mammalian cytochrome P-450 enzymes Spectrum similar to itraconazole with enhanced activity against <i>Aspergillus</i> , <i>Fusarium</i> , and <i>Scedosporium apiospermum</i> . Retains activity against some fluconazole-resistant <i>C. glabrata</i> , but cross-resistance is possible. Considered by many experts as the initial drug of choice for invasive aspergillosis Inhibitor of mammalian cytochrome P-450 enzymes
Voriconazole	Vfend	6 mg/kg IV q12h for two doses and then 4 mg/kg q12h 200 mg PO q12h if $\geq$ 40 kg, 100 mg PO q12h if < 40 kg	Similar to fluconazole but with greater affinity for fungal cytochrome P-450 enzyme 14- $\alpha$ -demethylase	Transient visual disturbances (reported up to 30%), rash, hallucinations (2%), transient increases in hepatic enzyme levels, severe hepatotoxicity (rare) Accumulation of sulfobutyl ester cyclodextran vehicle may occur in patients with CrCl < 50 mL/min receiving intravenous formulation	

Table 1 Continued

Antifungals	Trade Name(s)	Usual Adult Dose	Mechanism of Action	Toxic Effects	Spectrum/Comments
Posaconazole	Noxafil	200 mg PO q6h for 7 d and then 400 mg q12h Dose-proportional saturable oral absorption	Similar to voriconazole	Gastrointestinal (5–15%), fever, headache, musculoskeletal pain (5%)	Spectrum similar to voriconazole with enhanced activity against <i>Fusarium</i> , <i>Zygomycetes</i> , and black molds (phaeohyphomycetes) Inhibitor of mammalian cytochrome P-450 3A4
Echinocandins Caspofungin	Cancidas	70 mg IV on day 1 and then 50 mg q24h	Inhibition of cell wall glucan synthesis leading to osmotic instability of fungal cell	Fever, chills, phlebitis/thrombophlebitis (peripheral line), rash; drug concentrations decrease with P-450 3A4 inducers; decreases tacrolimus blood levels by 25%; increases liver toxicity with cyclosporine?	Spectrum includes most <i>Candida</i> spp, including fluconazole-resistant <i>C. krusei</i> and <i>C. glabrata</i> . Higher dosages may be required for <i>C. parapsilosis</i> . Active against <i>Aspergillus</i> spp. Not active against <i>C. neoformans</i> , <i>Fusarium</i> , <i>Zygomycetes</i> , or black molds (phaeohyphomycetes)
Micafungin Anidulafungin	Mycamine Eraxis	50–100 mg IV q24h 200 mg IV on day 1 and then 100 mg/d	Similar to caspofungin Similar to caspofungin	Similar to caspofungin Similar to caspofungin	Similar to caspofungin Similar to caspofungin

ABCD = amphotericin B cholesterol dispersion; ABLC = amphotericin B lipid complex; AMB = amphotericin B; DNA = deoxyribonucleic acid; IV = intravenously; PO = orally; q6h = every 6 hours; q12h = every 12 hours; q24h = every 24 hours; RNA = ribonucleic acid.

Table 2 Common Mycoses and Treatment

Mycoses	Recommended Therapy*	Alternative Therapies	Comment
Primary mycoses Histoplasmosis* Mild to moderate	Observation or itraconazole 200 mg PO daily for 6–12 wk	Itraconazole 200 mg PO daily for 6–12 weeks or IV 200 mg q12h for 1 d and then 200 mg q24h (non-CNS disease only) or fluconazole 800 mg PO daily for 6–12 wk	Itraconazole is not effective for CNS infections Fluconazole is less effective but better tolerated than itraconazole
Severe, including CNS disease or immunocompromised host	AMB 0.7 mg/kg/d IV or L-AMB 3 mg/kg/d for 12 wk or until clinically stable	AMB 0.7 mg/kg/d IV or L-AMB 3 mg/kg/d until clinically stable	Lipid formulations may be more effective than conventional formulations, especially for CNS disease. Once the patient is clinically stable, he or she can be transitioned to itraconazole or fluconazole. Corticosteroid therapy should be considered for hypoxic patients with acute pulmonary infection
Blastomycosis* Mild to moderate Severe, including CNS or immunocompromised host	Itraconazole 200 mg PO daily × 6 mo AMB 0.7 mg/kg/d IV until patient is clinically stable and then itraconazole (non-CNS) or fluconazole 800 mg PO daily for 6 mo	Ketoconazole 400–800 mg PO daily or fluconazole 400–800 mg PO daily; L-AMB formulations	Relapses are common in immunocompromised hosts. Suppressive therapy with itraconazole 200 mg PO/d or fluconazole 800 mg PO/d is recommended.

Table 2. Continued	Recommended Therapy*	Alternative Therapies	Comment
Mycoses			
Coccidioidomycosis*			
Mild to moderate Diffuse pneumonia or disseminated infection	Observation or itraconazole 200 mg PO twice daily for 6–8 mo AMB 1.0–1.5 mg/kg/d with dose and frequency decreased as improvement occurs	Fluconazole 400–800 mg PO daily or L-AMB formulations	Itraconazole demonstrated a trend toward superiority over fluconazole in a randomized controlled trial for progressive, nonmeningeal coccidioidomycosis; however, fluconazole is better tolerated than itraconazole Fluconazole 800–1,000 mg/d may be preferred for meningitis
Opportunistic mycoses			
Candidiasis*			
Catheter related and acute hematogenous	Two weeks of antifungal therapy: AMB 0.7 mg/kg/d IV or fluconazole 400–800 mg IV q24h or caspofungin 70 mg IV for 1 and then 50 mg q24h or AMB plus fluconazole Fluconazole 400–800 mg/d (low risk) or AMB 0.7 mg/kg/d IV or itraconazole 200 mg q12h for 2 d and then 200 mg IV q24h or L-AMB 3 mg/kg q24h	L-AMB formulations or AMB 0.5–0.7 mg/kg/d plus flucytosine 100 mg/kg/d PO divided q6h or voriconazole 6 mg/kg q12h for 1 d and then 3–4 mg/kg q12h; itraconazole 200 mg q12h for 2 d and then 200 mg IV q24h Caspofungin 70 mg IV for 1 d and then 50 mg q24h or voriconazole 6 mg/kg q12h for 1 d and then 3–4 mg/kg q12h AMB 0.3 mg/kg/d IV for 1–7 d; AMB bladder irrigation effective only for infection in the bladder	Patients can be switched to oral fluconazole when clinically stable if isolate is susceptible Caspofungin and AMB are the preferred agents for fluconazole-resistant species. Voriconazole appears to be effective against fluconazole-resistant <i>Candida Krusei</i> .
Urinary candidiasis			Antifungals with coverage of <i>Aspergillus</i> should be used in higher-risk patients and those with prolonged neutropenia (> 2 wk)
Fluconazole 200 mg IV or PO for 7–14 d			Asymptomatic candiduria does not require therapy. However, treatment is recommended for neutropenic, low birth weight infants and patients undergoing urologic manipulation or with renal allografts.
Cryptococcosis*			
Pulmonary, isolated Severe or disseminated disease, including CNS	Fluconazole 200–400 mg/d IV or PO for 6–12 mo Induction: AMB 0.7–1.0 mg/kg/d plus flucytosine 100 mg/kg/d PO divided q6h for 2 wk Consolidation: fluconazole 400–800 mg/d for 10 wk Voriconazole 6 mg/kg q12h for 1 d and then 4 mg/kg q12h	AMB 0.7–1.0 mg/kg/d plus flucytosine 100 mg/kg/d PO divided for 6–10 wk AMB 0.7–1.0 mg/kg/d for 6–10 wk L-AMB 5 mg/kg/d for 6–10 wk	L-AMB was shown to produce faster sterilization of CSF when compared with conventional AMB-d and was less nephrotoxic
Invasive aspergillosis†			
		L-AMB or AMB 1.0–1.5 mg/kg/d or caspofungin 70 mg IV for one dose and then 50 mg IV q12h or posaconazole <sup>§</sup> 200 mg PO QID × 14 d and then 200 mg PO q12h or combination therapy	Voriconazole can be administered as oral therapy in patients taking oral medications Because of the high dosages and prolonged treatment courses, lipid formulations are preferred for AMB-based therapy Preclinical studies suggest mold-active azoles plus echinocandins have enhanced activity against <i>Aspergillus</i>
Invasive fusariosis†			
	L-AMB or voriconazole 6 mg/kg q12h for 1 d and then 4 mg/kg q12h	Posaconazole <sup>§</sup> 200 mg PO QID for 14 d and then 200 mg PO q12h or combination therapy	Activity of AMB and voriconazole is decreased versus <i>Aspergillus</i> spp. Higher doses or combination therapy may be indicated for more refractory cases.
Invasive zygomycosis‡			
	High-dose L-AMB (eg, 7.5–10.0 mg/kg/d)	Posaconazole <sup>§</sup> 200 mg PO QID for 14 d and then 200 mg PO q12h or combination therapy	Prompt diagnosis and surgical débridement are essential for successful outcome. High dosages of L-AMB are required. Posaconazole is the only azole with activity against zygomycoses.

AMB = amphotericin B; AMB-d = amphotericin B deoxycholate; CNS = central nervous system; CSF = cerebrospinal fluid; IV = intravenously; L-AMB = lipid formulation of amphotericin B; PO = orally; q6h = every 6 hours; q12 = every 12 hours; q24 = every 24 hours.

\*Based on guidelines published by the Infectious Diseases Society of America.

†Not part of the guidelines of the Infectious Diseases Society of America.

‡Lipid formulations of AMB (L-AMB, 3–5 mg/kg IV q24h; AMB lipid complex, 5 mg/kg IV q24h; or AMB cholesterol dispersion, 3–4 mg/kg IV q24h).

§Investigational.

Acute reactions to AMB generally subside over time and with subsequent infusions of it. Use of lipid formulations reduces, to varying degrees, the incidence of infusion-related reactions. Interestingly, the concentration of each AMB formulation (% weight/volume) may play a role in the incidence of infusion reactions. Ambisome (10% w/v) has the lowest incidence of reactions, followed by Abelcet (34% w/v) and conventional AMB-d (35% w/v). The cholesterol dispersion lipid formulation of AMB (Amphotec) has both the highest concentration of AMB (50% w/v) and the highest reported rates of infusion-related reactions. Lipid AMB formulations have also been associated with a unique triad of acute infusion-related reactions, including dyspnea; severe abdominal, flank, and/or leg pain; and flushing and urticaria. Most of these reactions can be effectively managed by administration of diphenhydramine and interruption of the lipid AMB infusion. In the past, administration of a test dose of AMB-d (eg, 1–5 mg) was recommended prior to initiating therapy, but this is no longer considered useful for screening patients for hypersensitivity reactions. Premedication with agents such as low-dose hydrocortisone (1 mg/kg), diphenhydramine, meperidine (0.5 mg/kg), and nonsteroidal anti-inflammatory agents may be performed prior to AMB infusions to blunt symptoms of acute reactions, although the data from organized clinical trails supporting their routine use are limited. Premedication should also be considered with the use of lipid AMB formulations, even though their infusion reactions are somewhat less severe (formulation dependent) when compared with those of the conventional AMB formulation.

Nephrotoxicity is the most significant delayed toxic effect of AMB and can be classified by glomerular and tubular mechanisms.<sup>5</sup> AMB directly constricts the afferent arteriole, resulting in a decrease in both renal blood flow and glomerular filtration (increased serum creatinine), eventually leading to azotemia (increased blood urea nitrogen). AMB-induced azotemia can be delayed by ensuring that patients are well hydrated prior to starting therapy and sodium loading (intravenously administering 0.5–1.0 L of normal saline before and after infusing AMB) to maintain renal blood flow and adequate glomerular filtration pressure. Although the exact amount of sodium needed to reduce nephrotoxicity is unknown, studies in human adults receiving AMB-d have examined the use of 85 to 600 mg/d of sodium before AMB administration.<sup>5</sup> Although several recent uncontrolled studies have suggested that administration of AMB-d by continuous infusion can delay glomerular toxic effects, this dosing approach is not widely recommended. Azotemia with AMB administration is generally reversible, although 5 to 10% of patients may have persistent renal impairment after discontinuation of therapy.

Distal tubular membrane damage caused by AMB leads to Fanconi-like syndrome with impaired urinary acidification, defective urinary concentrating ability, and potassium and magnesium wasting.<sup>5</sup> Hypokalemia in particular is common in patients receiving either conventional or lipid formulations of AMB and may require the administration of up to 15 mEq of supplemental potassium per hour. Hypokalemia and hypomagnesemia frequently precede decreases in glomerular filtration (increased serum creatinine level), especially in patients who are adequately hydrated or receiving lipid formulations of AMB. However, continued tubular damage eventually results in decreases in renal blood flow and glomerular filtration through tubuloglomerular feedback mechanisms that constrict the afferent arteriole. Therefore, renal protective measures, such as sodium loading, should still be considered for patients receiving lipid AMB formulations.

Prolonged courses of treatment with AMB may result in normochromic, normocytic anemia owing to the inhibitory effects of AMB on renal erythropoietin synthesis.<sup>1,2</sup> Patients with diseases other than cancer may experience decreases in hemoglobin of 15 to 35% below baseline that will return to normal within several months of discontinuation of the drug; these decreases may be even more severe in patients with cancer. Administration of recombinant erythropoietin has been suggested for patients with symptomatic anemia during AMB administration.

### 5-Flucytosine

Flucytosine is the fluoropyrimidine approved for the treatment of invasive fungal infections and is available only as an oral capsule formulation.<sup>6</sup> The usefulness of flucytosine in treating invasive mycoses is hampered by its relatively narrow spectrum, high rates of acquired resistance in common pathogens (ie, *Candida* spp), and significant potential for toxic effects. Thus, flucytosine is not used as monotherapy and has a narrowly defined role in the treatment of most mycoses. Because flucytosine is widely distributed throughout the body, including the cerebrospinal fluid (CSF), after oral administration, it is a useful adjuvant to antifungals with slow or minimal distribution into anatomically privileged sites, such as the meninges.

Flucytosine was originally developed as an antitumor chemotherapeutic agent before it was discovered to have antifungal activity against common yeast.<sup>6</sup> Not surprisingly, its most common side effects are nausea and vomiting, increases in serum transaminase levels, and bone marrow suppression.<sup>6</sup> The risk of bone marrow suppression can be reduced if serum levels are maintained at less than 100 µg/mL. Because flucytosine is eliminated unchanged through the kidneys, serum level monitoring and dosage

adjustment are required for patients receiving flucytosine in combination with AMB or other nephrotoxic agents.

### Azole Antifungals

The availability of azole antifungals, particularly the oral triazoles itraconazole, fluconazole, and, most recently, voriconazole, fulfills a critical need for effective and better tolerated alternatives to AMB.<sup>2,6,7</sup> Fluconazole, itraconazole, and voriconazole have proven to be valuable agents in the prevention and treatment of both primary and opportunistic mycoses. All three triazoles are available in tablet or capsule form, oral solution or suspension, and intravenous formulations, providing clinicians with added flexibility in therapy selection. Because all azoles are potentially teratogenic, their use should be avoided in pregnant women.

#### Fluconazole

Of the triazoles, fluconazole (Diflucan) is clearly the best tolerated and has the most desirable pharmacologic properties, including high bioavailability, high water solubility, a low degree of protein binding, linear pharmacokinetics, and a wide volume of distribution, including the CSF, eye, and urine.<sup>6,7</sup> Fluconazole has a more limited spectrum of activity than itraconazole does, including most *Candida* spp (except *Candida krusei* and, in certain cases, *Candida glabrata*) and *Cryptococcus neoformans*, and it is a second-line agent for *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*. Fluconazole<sup>6,7</sup> does not have clinically useful activity against molds such as *Aspergillus*. Unlike other azoles, fluconazole is eliminated primarily unchanged through the kidneys and is less susceptible to clinically significant drug interactions through mammalian cytochrome P-450 enzymes at standard dosages used to treat superficial (100–200 mg/d) or systemic (400–800 mg/d) infections. However, administration of higher dosages of fluconazole (eg, 800 mg/d) may result in more pronounced cytochrome P-450 inhibition.

#### Itraconazole

Itraconazole (Sporanox) was introduced in the early 1990s as a capsule formulation that was effective against superficial fungal infections and mild to moderately severe endemic mycoses. However, its erratic absorption in critically ill patients limited its effectiveness against opportunistic mycoses. The subsequent reformulation of itraconazole into an oral and intravenous solution with hydroxy-β-propyl cyclodextran significantly improved the blood levels of the agent that could be obtained in critically ill and immunocompromised patients. Specifically, administration of the oral liquid formulation

results in a 30% higher area under the curve (AUC) over 24 hours under fed conditions and 60% higher AUC under fasting conditions. Itraconazole is a relatively broad-spectrum triazole with activity against many common fungal pathogens, including most *Candida* spp, *Cryptococcus*, endemic dimorphic fungi (*H. capsulatum*, *B. dermatitidis*, and *C. immitis*), and *Aspergillus* spp.<sup>6,7</sup> This drug is lipophilic and highly protein bound and has a long half-life, nonlinear pharmacokinetics, and limited distribution into some body fluids, including the CSF and urine. Itraconazole is metabolized in the liver and, to a lesser extent, the gut into more hydrophilic metabolites, one of which (hydroxyitraconazole) retains potent antifungal activity.

The most common adverse effects of oral itraconazole therapy are gastrointestinal effects, rash, and asymptomatic increases in hepatic transaminase levels. Cases of severe idiosyncratic hepatitis have been reported infrequently in patients receiving itraconazole therapy. Prolonged therapy with itraconazole can be associated with metabolic disturbances (suppression of adrenal steroid synthesis) and increased risk of congestive heart failure. Itraconazole is a substrate and potent inhibitor of mammalian cytochrome P-450 enzymes and is therefore susceptible to a number of clinically significant drug interactions (see Azole Drug Interactions). When administered as an oral solution, the cyclodextran vehicle used to dissolve itraconazole is passed through the gastrointestinal tract with minimal metabolism.<sup>7</sup> In the intravenous formulation, however, cyclodextran must be cleared through the kidneys. This vehicle may accumulate in patients with moderate to severe renal dysfunction (eg, estimated creatinine clearance of < 30 mL/min), which in animal studies has been associated with toxic effects in the bladder epithelium.<sup>7</sup> Although these effects have not been observed in humans, patients with poor renal function who are candidates for itraconazole should be preferentially given the oral formulation of itraconazole unless the potential benefits of the intravenous formulation (high blood levels) outweigh the theoretical risk.

#### Voriconazole

Voriconazole (Vfend) is a methylated analogue of fluconazole with enhanced activity against yeast and important opportunistic molds, including *Aspergillus* and *Fusarium* spp.<sup>6,7</sup> Voriconazole is not active, however, against *Zygomycetes*. In terms of its clinical pharmacology, voriconazole has characteristics of both fluconazole and itraconazole. Like fluconazole, voriconazole is well absorbed orally, has limited protein binding, and is distributed widely throughout the body, including the CSF. Like itraconazole, intravenous voriconazole is formulated in a cyclodextran

solution (sulfobutylether cyclodextran) and has nonlinear pharmacokinetics and similar precautions for its use in patients with marked renal dysfunction. Voriconazole is metabolized into inactive metabolites through the liver and is an inhibitor of mammalian cytochrome P-450 enzymes. In addition to the common adverse effects seen with other triazoles (gastrointestinal effects, rash, increases in hepatic enzyme levels), voriconazole causes transient visual disturbances in 15 to 30% of patients, manifesting as photophobia, perception of blinking or flashing lights (even with the eyes closed), and, occasionally, hazy or blurred vision. These side effects tend to occur during the first week of therapy and disappear with continued therapy in most patients. Occasionally, visual disturbances are intensified by hallucinations, a separate side effect seen in 2 to 8% of patients receiving voriconazole (often with concomitant benzodiazepines and narcotic analgesic therapy). These visual disturbances are thought to result from temporary alterations in electrical conduction of photoreceptors in the rods and cones of the retina, which revert to normal once therapy is stopped. No permanent damage to the retina has been noted in human or animal studies of voriconazole.

The dose-limiting toxicity of voriconazole, like that of most azole antifungals, is hepatic toxicity that initially presents with asymptomatic increases in serum transaminase levels. Generally, these increases are reversible and transient and do not require discontinuation of therapy. However, serious hepatic reactions during treatment with voriconazole and other azoles have been reported, including clinical hepatitis, cholestasis, and fulminant hepatic failure. These reactions often occur when an azole is administered concomitantly with other hepatotoxic drugs. Liver function tests should be evaluated at the start of and during the course of azole therapy. Abnormal elevations in liver function should be routinely monitored, and azole therapy should be discontinued if severe hepatic impairment develops.

#### Posaconazole

Posaconazole (Noxafil) is a recently approved oral triazole for the treatment and prevention of invasive fungal infections. This agent has a very broad spectrum of activity against yeasts and molds, including the *Zygomycetes*.<sup>7</sup> Posaconazole is given orally 2–4 times a day. It is widely distributed in the body, metabolized by the liver, and well tolerated, even in long-term.

#### Azole Drug Interactions

An inherent limitation of azole pharmacology is that the target of their antifungal activity, the cytochrome P-450 enzyme 14- $\alpha$ -demethylase, shares considerable homology with mammalian cytochrome P-450 enzymes involved in drug metabolism.<sup>5</sup> Thus, azole antifungals are both substrates and inhibitors of cytochrome P-450

systems in humans. Not surprisingly, these drugs have many interactions with the metabolism of other drugs; many of these interactions have the potential to result in severe clinical outcomes if not detected early. Cytochrome P-450 3A4 inducers increase the metabolism of all azoles to varying degrees depending on their lipophilicity. Coadministration of rifampin, for example, can reduce fluconazole serum concentrations by approximately 50% and itraconazole, voriconazole, and posaconazole concentrations by up to 90%. When possible, azole antifungal therapy should be avoided during high-dose conditioning chemotherapy prior to hematopoietic cell transplantation owing to an increased risk of acute hepatotoxicity and accumulation of toxic chemotherapy metabolites.

#### Echinocandins

With the introduction of caspofungin (Cancidas) in 2001, the echinocandins became the first truly novel class of antifungal agents to be introduced in more than 40 years.<sup>6</sup> Echinocandins disrupt the integrity of the fungal cell wall by disturbing the synthesis of  $\beta$ -(1,3)-glucan polymers, which are critical cross-linking structural components in the cell wall of *Candida* and *Aspergillus* spp and the mycelial forms of some endemic fungi. Although echinocandin resistance appears to be rare, some *Candida* spp (*C. parapsilosis* and *C. guilliermondii*) may be inherently less susceptible to lower echinocandin concentrations than other species of *Candida* due to subtle differences in their  $\beta$ -(1,3)-D-glucan synthase structure. Also, echinocandins have no clinically effective activity against *C. neoformans*. They also appear to have suboptimal in vitro activity against endemic fungi. In most cases, differences in fungal cell wall construction appear to define the spectrum of these agents. For example, the cell walls of *Zygomycetes* spp are constructed primarily of chitin and chitosan polymers, with relatively fewer  $\beta$ -(1,3)-D-glucan synthases, glucuronomannoproteins, and matrix components. Not surprisingly, echinocandins are not effective against *Zygomycetes*.<sup>6</sup>

One echinocandin, caspofungin, has been approved for the treatment of infections by *Candida* and *Aspergillus* spp. Two other echinocandins, micafungin and anidulafungin, were recently approved. Despite some modest differences in pharmacokinetics and potency, the echinocandins are pharmacologically similar and probably interchangeable. All three of these agents are available only as intravenous formulations, have predominantly linear pharmacokinetics, have relatively high tissue concentrations (except in the CSF, eyes, and urine), have a prolonged elimination half-life, and are metabolized mostly through chemical degradation followed by secondary hepatic metabolism (caspofungin and micafungin). Caspofungin dosage adjustment is

recommended for patients with severe hepatic dysfunction (Child-Pugh score 7–9). All three echinocandins were well tolerated in phase II and III clinical trials, with the most common adverse effects being phlebitis or venous irritation, headache, fever, and rash. Infusion-related reactions analogous to the ones seen with vancomycin have been described with caspofungin because of its potential to cause histamine release from mast cells. The most common adverse effects reported with echinocandin therapy in the laboratory are transient elevations in serum transaminase and alkaline phosphatase levels. The echinocandins are neither substrates nor inhibitors of cytochrome P-450 enzymes of P-glycoprotein enzymes. For reasons not completely understood, coadministration of echinocandins with inducers of cytochrome P-450 3A4 (eg, rifampin, phenytoin) results in modest (25–50%) decreases in the AUC of these antifungals, which can be overcome with increased dosages. Furthermore, caspofungin modestly (20%) decreases the AUC of concomitant tacrolimus therapy. Coadministration of caspofungin and cyclosporine in early phase I and II trials resulted in increased cyclosporine levels and elevated serum transaminase levels. Although this interaction was not observed in subsequent clinical trials or with other echinocandins, current caspofungin labeling does not recommend coadministration of the drug with cyclosporine unless the benefits outweigh the potential risk of increased hepatotoxicity.

### Pathogenesis of Fungal Infections

Multiple, frequently interrelated factors impact the susceptibility of patients with cancer to a variety of fungal infections (Table 3).<sup>3,9,10</sup> *Candida* spp are often part of the patient's endogenous flora,<sup>9</sup> whereas opportunistic molds (eg, *Aspergillus* and *Fusarium* spp) are ubiquitous in the environment.<sup>1,10,11</sup> Although symptoms of infection with these organisms usually develop while the patient is in the hospital, except during periods of

hospital construction or faulty air handling, most infections are community acquired.<sup>11</sup> Most serious fungal infections occur in patients with cancer who have prolonged, severe neutropenia.<sup>3,9–11</sup> This is not surprising as neutrophils are capable of ingesting and killing *Candida* spp, and neutrophils were found to be the primary defense against the hyphae of *Aspergillus* spp in animal studies.<sup>3,9–11</sup> Administration of high doses of adrenal corticosteroids, especially for protracted periods, predisposes patients to mycoses, especially to aspergillosis and other mold infections.<sup>12</sup> The alveolar macrophages ingest and kill *Aspergillus* spores, and corticosteroids interfere with the fungicidal activity of macrophages.<sup>12</sup> In addition, disruption of mucocutaneous barriers predisposes patients to fungal infections. Furthermore, candidemia<sup>3</sup> and, rarely, *Fusarium* fungemia<sup>13</sup> are associated with the use of intravascular catheters. Local *Aspergillus*<sup>11</sup> and *Zygomycetes* infections<sup>14</sup> have occurred at catheter insertion sites, often leading to disseminated infection. Disseminated fusariosis<sup>13,15</sup> occasionally arises from paronychia caused by skin trauma adjacent to sites of onychomycosis.<sup>13,15</sup> Other sites of tissue damage may also facilitate fungal infections. For example, leukemic infiltrates and chemotherapy-induced ulcerations of the oropharynx and gastrointestinal tract may be sites of origin for disseminated candidiasis.<sup>3,9</sup> Different types of defects in cellular immunity, such as decreased numbers of CD4 T lymphocytes and defects in T-cell signaling, play an important role in predisposing patients to certain fungal infections, such as oropharyngeal candidiasis,<sup>3</sup> cryptococcosis, reactivation of histoplasmosis, and coccidioidomycosis.

Broad-spectrum antibiotic therapy has been associated with fungal infections, especially candidiasis.<sup>3,9</sup> This may be due to suppression of the normal flora, allowing for fungal overgrowth, as has been shown with *Candida* spp in the oropharynx and gastrointestinal tract. Antibacterial and antifungal prophylaxis also may be associated with fungal infections, the latter of which facilitates acquisition of fungi resistant to antifungal agents. For example, fluconazole prophylaxis has been associated with increased colonization and, in some studies, infection with fluconazole-resistant non-*albicans Candida* spp, such as *C. krusei* and *C. glabrata*.<sup>16–20</sup>

### Candidiasis

Candidiasis is the most common mycosis in patients with cancer, although its frequency has decreased in recent years because of the widespread use of antifungal prophylaxis, especially with fluconazole, in highly susceptible populations.<sup>16,21</sup> Multiple risk factors predispose patients with cancer to candidiasis (see Table 3). The spectrum of infections caused by *Candida* spp in

cancer patients is broad. Hence, *Candida* spp can cause a range from mild yet uncomfortable superficial infections to major organ and widely disseminated infections.<sup>3</sup>

Although *C. albicans* has accounted for more than 50% of systemic infections for some time, other *Candida* spp that are frequently resistant to fluconazole have emerged as relatively common pathogens in patients with cancer.<sup>16–20</sup> For example, *Candida tropicalis* mimics acute bacterial sepsis in neutropenic patients with leukemia,<sup>22</sup> is more likely to cause the characteristic skin lesions associated with disseminated candidiasis, and occasionally causes a syndrome of skin lesions and painful myositis. *C. glabrata* has variable susceptibility to fluconazole, and increased colonization and infection with this species have been associated with fluconazole prophylaxis.<sup>23</sup> Also, *C. parapsilosis* has been associated with parenteral alimentation and use of intravascular catheters.<sup>3</sup> Finally, *C. krusei* is inherently resistant to fluconazole and has been isolated with increasing frequency of colonization and infection in institutions that use fluconazole prophylactically.<sup>17–19</sup>

### Oral Candidiasis

The most common superficial *Candida* infection in patients with cancer who are not receiving prophylaxis is acute pseudomembranous candidiasis of the oropharynx (thrush).<sup>3</sup> This infection occurs following mucosal damage by chemotherapy or radiotherapy, such as patients with head and neck cancer who undergo chemoradiation. The lesions associated with it are creamy, whitish, curd-like plaques or pseudomembranes on the buccal mucosa, palate, or tongue, the exposed base of which is erythematous and painful and may bleed. These lesions may be associated with fissures in the angles of the mouth. Rarely, patients with cancer who have clinically significant thrush also have esophageal involvement manifesting with only mild or moderate odynophagia.

Diagnosis of oral candidiasis is confirmed by the presence of yeasts and pseudohyphae on scraping of an infected area and in culture analysis.<sup>3</sup> Recovery of *Candida* spp from a culture alone is insufficient evidence because these fungi are commonly found as colonies in the oropharyngeal mucosal surfaces, especially in patients who are receiving antibiotics. The most effective therapy for oral candidiasis has been fluconazole, which is well absorbed from the gastrointestinal tract, easy to take, and well tolerated. Some patients have a response to topical agents; however, these agents are not palatable (eg, nystatin, clotrimazole).

### *Candida* Esophagitis

Patients with cancer are also susceptible to esophageal candidiasis.<sup>3</sup> Symptoms of esophageal

**Table 3** Overview of Risk Factors for Candidiasis in Patients with Cancer

Nosocomial factors
Broad-spectrum antibiotics
Chemotherapy-induced mucositis
Central venous catheters
Systemic corticosteroids
Major surgery, especially intra-abdominal
Length of intensive care unit stay
Total parenteral nutrition
Underlying conditions/comorbidities
Neutropenia
Hematologic malignancy
Diabetes mellitus
Solid tumors with necrosis
Pancreatitis
Chronic renal failure

candidiasis include dysphasia, retrosternal pain, and odynophagia. This infection, if left undetected, can have serious complications, including chronic esophageal strictures, bronchoesophageal fistulae, and mediastinitis. Approximately 70% of patients with *Candida* esophagitis also have thrush; hence, the diagnosis is usually easy to suspect. A barium contrast roentgenogram may show peristaltic abnormalities, spasm, shaggy ulcerations, and a moth-eaten appearance of the mucosa. It is important to recognize, however, that esophagitis in cancer patients has other causes, such as herpes simplex virus and cytomegalovirus. Thus, esophagoscopy with brushing, biopsy, and culture analysis is the only way to confirm the diagnosis of *Candida* esophagitis.<sup>3</sup> Because *Candida* spp are the most common causes of infectious esophagitis, it is usually appropriate to initiate therapy empirically with an antifungal agent and reserve esophagoscopy for patients who do not have a response after several days of therapy. However, esophagitis in cancer patients who have been receiving antifungal prophylaxis should lower the threshold for early esophagoscopy. Fluconazole is the optimal agent for most cases of esophageal candidiasis because it can be initially administered intravenously if necessary and then be administered orally. Caspofungin has been shown to be as effective as fluconazole in acquired immune deficiency syndrome (AIDS) patients, but its use results in slightly higher rates of relapse. Furthermore, caspofungin is available only as an intravenous formulation. Oral itraconazole and intravenous AMB are occasionally indicated for these infections.

### Urinary Candidiasis

Primary infections of the urinary tract can develop in patients with cancer if they have a urinary obstruction or a urinary catheter in place.<sup>3</sup> Discriminating between colonization and infection on the basis of quantitative cultures is difficult as no culture density suggests infection. *Candida* casts in the urine are diagnostic but are found infrequently. In addition to cystitis, a *Candida* sp may migrate through the urethra to the renal pelvis in some patients (especially those with diabetes mellitus) and cause a urinary obstruction owing to fungus ball formation or necrotizing papillitis. Candiduria in a febrile neutropenic patient may be a manifestation of a disseminated infection. Fluconazole is the most appropriate agent for this infection.

### Disseminated Candidiasis

Disseminated candidiasis usually originates from lesions of the oropharynx or gastrointestinal tract or from intravenous catheters.<sup>3</sup> Sites usually involved include the kidney, heart, muscle, gas-

trointestinal tract, lung, liver, and spleen. Most patients with cancer who have disseminated candidiasis have no unique signs or symptoms that would differentiate it from other infections. Patients usually are debilitated, have experienced a previous or concomitant bacterial infection, and have persistent or recurrent fever that may be associated with pulmonary infiltrates or deteriorating liver or renal function. Some patients present with acute onset of fever and hypotension, which is suggestive of endotoxic shock.

Eye lesions suggestive of disseminated candidiasis may develop. Therefore, a careful ophthalmologic examination should be performed when this infection is suspected.<sup>3</sup> Typical eye lesions are single or multiple whitish, fluffy exudates with indistinct margins that are sometimes associated with hemorrhaging and borders covered by a vitreous haze. Patients often have no symptoms, although some complain of ocular pain, blurred vision, scotoma, or photophobia. These lesions are rarely found in neutropenic patients because these patients are unable to mount an adequate inflammatory reaction.

Characteristic skin lesions have been described in about 10% of patients with disseminated candidiasis. These lesions may be generalized or localized to the extremities and may be numerous or few.<sup>3</sup> They are nontender, firm, raised nodules that are pink to red in color and do not blanch under pressure. Some patients with these lesions have myositis (usually associated with *C. tropicalis* infection) that manifests as diffuse severe muscle tenderness, which is most pronounced in the legs. *Candida* spp can be identified in the dermis and cultured from about half of biopsy specimens.

Diagnosis of disseminated candidiasis may be difficult as the organism was not isolated from multiple blood culture specimens obtained from up to 40% of patients with widespread infection demonstrated at autopsy examination in previous studies.<sup>3,24</sup> The use of lysis centrifugation and high-volume sensitive culture systems (eg, the BacT/ALERT system, which monitors CO<sub>2</sub> production via infrared detection) has improved the yield of positive blood cultures. A variety of methodologies have been developed to detect circulating *Candida* antigens or metabolites (eg, mannan), including polymerase chain reaction, but none have been entirely satisfactory. Also, the ability to culture *Candida* spp from multiple nonsterile sites (eg, sputum, urine, feces) does not establish the diagnosis of candidiasis. Because the diagnosis may be difficult to establish, empiric administration of antifungal therapy is often appropriate for colonized neutropenic patients who do not have a response to broad-spectrum antibacterial agents, especially if they have not received antifungal prophylaxis.

### Chronic Disseminated Candidiasis

A distinct syndrome known as chronic disseminated candidiasis has been described almost exclusively in patients with acute leukemia.<sup>3,25</sup> Typically, these patients have fever that is unresponsive to broad-spectrum antibacterial agents after prolonged periods of neutropenia. After neutropenia is resolved, the patient remains febrile; experiences anorexia, progressive debilitation, and weight loss; and may have hepatosplenomegaly or pain in the right upper quadrant. Also, the patient's alkaline phosphatase level is usually greatly elevated, whereas transaminases and total bilirubin are only mildly elevated. Multiple small lesions can be detected in the liver and spleen by magnetic resonance imaging (MRI), computed tomography (CT), or ultrasonography. The disease can persist for several months despite therapy and interfere with subsequent administration of cytotoxic chemotherapy. The diagnosis of chronic disseminated candidiasis can be confirmed by visualizing hyphae on liver biopsy specimens, but the organism is cultured from only 50% of biopsy specimens. Occasionally, patients may have hypersplenism. This form of candidiasis is rarely seen in leukemic patients receiving treatment at institutions where fluconazole prophylaxis is used routinely.

### *Candida* Pneumonia

Although the lung is usually involved in disseminated *Candida* infections, primary *Candida* pneumonia occurs infrequently in patients with cancer.<sup>3,26</sup> However, aspiration of *Candida*-containing oral secretions and pneumonia may develop in some patients. Isolation of *Candida* spp in clinical specimens from a patient with a pulmonary infiltrate does not establish the diagnosis of *Candida* pneumonia, however. A recent autopsy study of patients with cancer demonstrated that whereas many patients with pneumonia had *Candida* spp cultured from sputum and bronchoalveolar lavage specimens, the specificity and positive predictive value of the cultures were low.<sup>26</sup> Only histopathologic evidence is confirmatory, although it is often impossible to obtain for many patients. Empiric antifungal therapy may be indicated for high-risk patients with cancer who have *Candida*-positive sputum cultures and/or cytology and progressive pulmonary infiltrates despite undergoing broad-spectrum antibacterial therapy.

### *Candida* Meningitis

Multiple small abscesses may be present in the brain in patients with disseminated candidiasis; however, they usually do not have any symptoms.<sup>3</sup> *Candida* meningitis occurs infrequently and is associated with disseminated infection in the majority of cases or the use of ventricular shunts.

There are no specific clinical signs or symptoms that discriminate *Candida* meningitis from bacterial meningitis. Examination of CSF specimens from patients with *Candida* meningitis reveals decreased glucose and elevated protein concentrations and lymphocytosis. *Candida* spp are rarely visualized by direct microscopic examination of CSF, however.

### Treatment and Supportive Care

Mortality rates for candidemia and disseminated candidiasis are especially high in patients with cancer and recipients of HSCTs.<sup>27,28</sup> The mortality rates approach 70% in patients who receive AMB-d. Few neutropenic patients survive their infection unless their neutrophil counts recover. AMB-d has been compared with fluconazole in several prospective randomized trials, most of which have excluded neutropenic patients.<sup>29,30</sup> All of these studies showed these two drugs to be essentially equally efficacious, although fluconazole was substantially less toxic. In one study that included patients with neutropenia at the onset of their infection, the response rate for fluconazole was significantly higher, although the number of patients was not large. Whether fluconazole is superior to AMB-d in patients with persistent neutropenia is not certain, but it is unlikely to be worse as few of these patients have a response to AMB-d. Lipid formulations of AMB are less nephrotoxic than AMB-d, but there is no convincing evidence that they are more effective for invasive candidiasis. Because prolonged antifungal therapy is not required for most cases of acute candidiasis, however, the use of these more expensive lipid preparations might not be justified. Finally, the value of routine in vitro susceptibility testing as a guide for selecting antifungal therapy for invasive candidiasis has not been convincingly demonstrated in this population.<sup>31,32</sup>

Given the broad-spectrum activity of caspofungin against *Candida* spp, it would appear to be an ideal agent for treatment of severe *Candida* infections, particularly in patients with preexisting risk factors or underlying renal dysfunction owing to treatment with AMB.<sup>5</sup> Caspofungin, an echinocandin with broad-spectrum fungicidal activity against *Candida* spp,<sup>6</sup> has been compared with AMB-d in therapy for systemic *Candida* infections, 90% of which were candidemia; few neutropenic patients were included in this trial. Caspofungin was found to be at least as effective as AMB-d and considerably less toxic; thus, it has promise in the treatment of candidiasis.<sup>33,34</sup>

Therapy for chronic disseminated candidiasis is often difficult to perform, and the response to it has often been unsatisfactory.<sup>3,25</sup> However, one small study showed that a lipid formulation of AMB was effective against it.<sup>21</sup> A larger study indicated that fluconazole was effective, even in patients who did not have a response to treatment

with AMB-d.<sup>25</sup> Evidence of response may require several weeks of therapy. The duration of therapy should be determined according to the rapidity of clinical improvement and resolution of lesions in roentgenographic examinations, ideally, 2 to 6 months.<sup>25</sup> Patients may have residual lesions in the liver and spleen because of scarring.

A controversial issue is whether indwelling intravascular catheters should be removed routinely from patients with candidemia.<sup>35–38</sup> Use of these catheters is often vital to the management of seriously ill patients, and there is considerable expense in removing and replacing surgically implanted catheters. Nevertheless, some but not all studies have shown that catheter removal shortens the duration of candidemia and improves the rate of response to antifungal therapy.<sup>35–38</sup> This is especially true if the infecting organism is *C. parapsilosis*; in such cases, fungemia can persist for more than a week despite the use of appropriate therapy if the catheter is not removed. In vitro studies have shown that caspofungin is more active than azoles or AMB against *Candida* spp growing in biofilm, which characteristically forms on catheters.<sup>39</sup> The clinical significance of this is unclear, however. Figure 1 outlines the general principles of management of acute candidiasis in patients with cancer.

### Aspergillosis

Invasive aspergillosis has emerged as an important and significant infection, accounting for 20 to 40% of systemic fungal infections in patients

with acute leukemia, 10 to 20% in recipients of bone marrow transplants (BMTs), and 5 to 15% in recipients of solid organ transplants.<sup>1,11,40</sup> On the other hand, this infection is rare in patients with solid tumors.<sup>41</sup> In view of the decreased incidence of candidiasis in the era of azole prophylaxis, this mycosis has emerged as a leading cause of death in patients with leukemia and/or recipients of BMTs.<sup>16,42</sup> Most cases of invasive aspergillosis occur in patients with neutropenia or who are receiving adrenal corticosteroids, which interfere with macrophage function. *Aspergillus fumigatus* is responsible for most of these infections,<sup>1,11</sup> although the frequency of aspergillosis caused by more resistant *Aspergillus* spp, such as *Aspergillus terreus*, may be increasing.<sup>43</sup> In most cases, the infection is acquired by inhalation of spores, and epidemics have occurred in hospitals undergoing construction within the facility itself or in adjacent areas. *Aspergillus* spp invade blood vessels, causing thrombosis and infarction, and can erode through facial planes, cartilage, and bone.

Over 70% of *Aspergillus* infections involve the lung, and some patients may present with symptoms suggestive of pulmonary embolism, such as sudden onset of pleuritic pain, fever, hemoptysis, and a pleural friction rub.<sup>1,11,42</sup> Other patients may present with fever unresponsive to antibacterial agents and may not initially have any abnormalities on chest roentgenograms. A few patients have acute pulmonary hemorrhage that is fatal.

The earliest-appearing abnormality on chest roentgenograms in patients with aspergillosis is

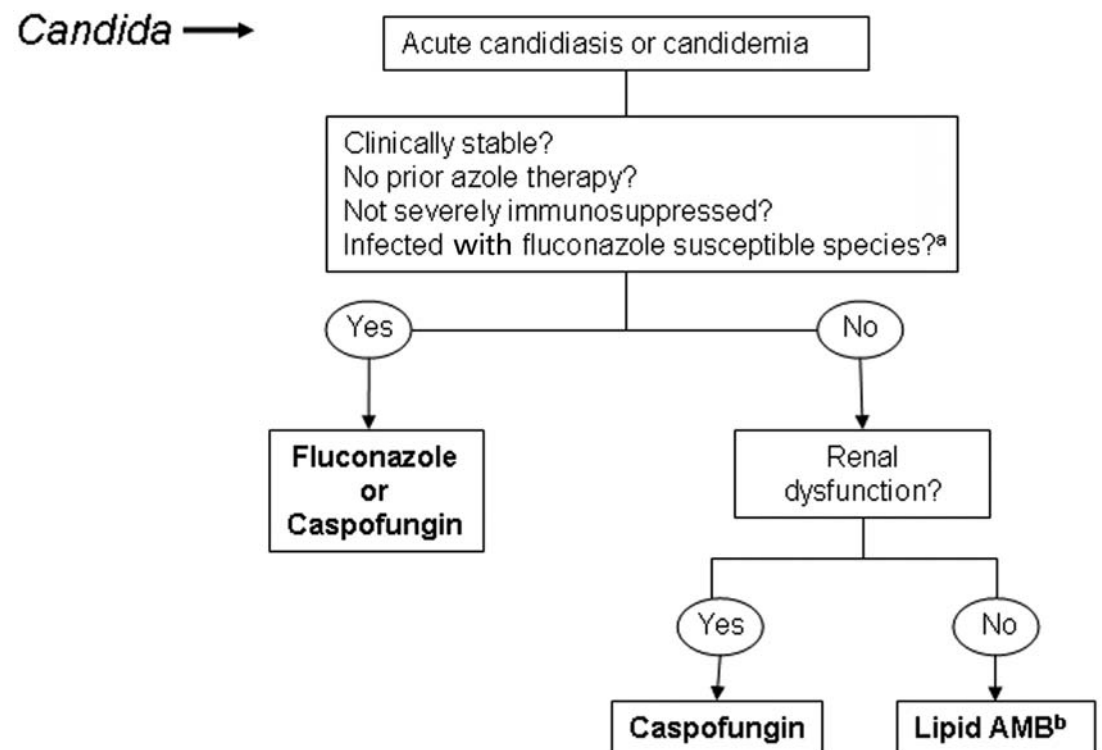

FIGURE 1 Approach to the management of hematogenous candidiasis in the high risk cancer patient.

a single or multiple nodular lesions.<sup>1,11,42</sup> As the infection progresses, wedge-shaped infarcts, necrotizing bronchopneumonia, lobar consolidation, or diffuse infiltrates may be found. Patients with normal roentgenograms should undergo a CT scan, which will usually reveal a nodular infiltrate surrounded by a halo of low attenuation. If the infection is controlled, one or several cavitations usually develop, which often contain a fungus ball.

Approximately 15 to 20% of *Aspergillus* infections in neutropenic patients involve the sinuses.<sup>1</sup> Signs and symptoms include fever, headache, retro-orbital erythema, swelling, and rhinorrhea. Usually, a necrotic lesion can be found on the nose or palate. A CT scan or MRI will show opacification of the sinuses and bony obstructions. As the infection progresses, it causes proptosis, ophthalmoplegia, endophthalmitis, and cerebral infarction. Invasive oral infections involving the gingiva and spreading to facial muscle and bone have been described in patients with leukemia.

Primary invasive cutaneous *Aspergillus* infections have been observed, usually associated with venous access devices.<sup>11</sup> Deposition of *Aspergillus* spores may occur during catheter insertion or subsequent dressing with contaminated materials. The lesions in these cases begin as erythematous or violaceous plaques that progress to necrotic ulcers covered by black eschars.

Hematogenous dissemination occurs in 30 to 40% of *Aspergillus* infections.<sup>1,4,21</sup> The central nervous system is a common site of involvement, resulting in cerebral infarction, which causes neurologic defects, seizures, stupor, or coma. The gastrointestinal tract is involved in 40% of these cases, especially the esophagus and large bowel, which may lead to perforation or massive hemorrhaging. Skin lesions are found in 5 to 10% of patients and evolve into well-circumscribed ulcers that are covered by black eschars.

One major impediment to successful management of invasive aspergillosis is difficulty in establishing an early diagnosis. Thus, most patients receive antifungal therapy with a presumed rather than proven diagnosis of aspergillosis. Tissue biopsy specimens can be obtained from infected sinuses or skin that reveal fungal hyphae, although the organism may not grow on culture media. Unfortunately, the fungus is seldom isolated from blood cultures of patients with a disseminated infection.<sup>44</sup> *Aspergillus* spp are also seldom cultured from the sputum of patients with a pulmonary infection, and bronchoscopy with bronchoalveolar lavage may fail to establish the diagnosis. In a recent study at our institution, *Aspergillus*-positive sputum cultures were obtained antemortem, only 30% of which contained histopathologically proven aspergillosis.<sup>45</sup> Whenever *Aspergillus* spp are cultured from respiratory secretions of susceptible patients, they

are either already infected or likely to become infected in the near future.

A variety of noncultural methods have been used to improve early diagnosis of invasive aspergillosis, but most of them have not been entirely satisfactory.<sup>46-49</sup> Serologic methods designed to detect circulating free antigens or immune complexes have been developed by using enzyme-linked immunosorbent assay and radioimmunoassay techniques.<sup>46-51</sup> These procedures have focused on detecting galactomannan and  $\beta$ -(1,3)-D-glucan.<sup>46-52</sup> These tests might underperform in the setting of *Aspergillus*-active antifungal prophylaxis<sup>52</sup> and false-positive reactions with too commonly used antibiotics, such as piperacillin-tazobactam, in patients with cancer.<sup>53</sup> Despite these limitations, attempts have been made to select patients for preemptive therapy who are at high risk of invasive aspergillosis based on antigen detection and imaging techniques. Molecular approaches such as polymerase chain reaction are also promising as diagnostic tools.<sup>46-49,54,55</sup> The role of these newer, non-culture-based methods for therapeutic monitoring in aspergillosis is not clear at present.

Interpreting the results of therapy for aspergillosis is difficult.<sup>56-58</sup> Many patients do not receive treatment until they have advanced disease, whereas others receive treatment for probable or possible but not proven infection. The status of the patient's host defenses is critical to his or her therapeutic response.<sup>58</sup> Neutropenic patients do not have a response unless their neutrophil count recovers during therapy, a factor that is not often reported in the clinical literature. Some patients have residual lesions that may cause relapse of their infection. Even with the availability of new antifungal therapies, the majority of heavily immunocompromised cancer patients still do not survive an invasive infection with an *Aspergillus* spp.

There is a paucity of well-conducted, controlled clinical studies of the treatment of aspergillosis.<sup>56-58</sup> However, the recent introduction of uniform diagnostic criteria for proven, probable, and possible aspergillosis by the European Organization for Research and Treatment of Cancer Invasive Fungal Infections Cooperative Group/Mycoses Study Group consortium was an advance in this area of clinical research.<sup>59</sup> These criteria consist of host-risk, mycologic, clinical, and radiologic criteria. Standardization of the definitions for diagnosing and assessing the effectiveness of antifungal therapy holds promise for addressing the many controversial issues in the management of aspergillosis. Some of these issues are discussed below.

The lipid formulations of AMB have been shown in uncontrolled studies to have an efficacy rate of about 40 to 60% in patients with aspergillosis whose infection was refractory to AMB-d or who could not tolerate it.<sup>8,60</sup> There is a consensus

that use of the lipid formulations of AMB decreases nephrotoxicity and infusion-related toxicity,<sup>5</sup> but the daily acquisition prices of these products are much higher than those of AMB-d.<sup>8</sup> The nephrotoxicity in these cases frequently appears to be clinically significant, especially in the most heavily immunosuppressed patients.<sup>61</sup> An even more controversial issue is whether there are clinically meaningful differences in the various lipid formulations of AMB.<sup>8,56</sup> Most of the available data on this have been derived from indirect comparisons and suggest that all of the lipid formulations of AMB, when given at the standard dosage of 5 mg/kg/d, appear to have comparable efficacy.

Although itraconazole has been approved for the treatment of aspergillosis, its role in primary therapy remains to be clarified. In most of the published reports of the efficacy of oral itraconazole, it was administered only to less heavily immunosuppressed patients with aspergillosis<sup>62</sup> as the use of intravenous itraconazole was only recently approved. Therapeutic serum levels of itraconazole can be achieved rapidly and reliably by using the intravenous preparation of the drug. Recent encouraging data from a small open-label multicentered study of aspergillosis indicate that administration of intravenous itraconazole followed by oral itraconazole is safe and reliably results in therapeutic levels of the drug and good response rates.<sup>63</sup> Intravenous itraconazole could be a viable option for primary therapy for aspergillosis, especially in slightly immunosuppressed cancer patients who have a stable clinical picture. However, if there is concern about the bioavailability of itraconazole because of interactions with other concomitantly administered medications, another agent should be used, even in stable patients, unless the itraconazole serum level<sup>5</sup> can be routinely monitored in a timely fashion.

A major advance in the treatment of aspergillosis has been the arrival of new antifungals with improved activity against *Aspergillus* spp, such as voriconazole and caspofungin.<sup>64-67</sup> The new triazoles show impressive in vitro activity in animal models of aspergillosis, and their availability in oral form allows their use in long-term therapy.<sup>6,7</sup> Early clinical experience suggested that they are also active in humans in both salvage therapy and primary therapy for aspergillosis.<sup>64-66</sup> Recently, a large randomized multicenter study comparing treatment with voriconazole and AMB-d followed by other licensed antifungal therapy showed a survival advantage in patients randomized to receive voriconazole.<sup>64</sup> The superiority of voriconazole over the other agents tested was consistent in all of the subgroups studied. Voriconazole likely will become the preferred agent for the majority of cases of documented aspergillosis. Echinocandins are static drugs in vitro against *Aspergillus* spp, but their activity in animal models and selected groups of patients

with aspergillosis refractory to or intolerant of other antifungals appears to be promising.<sup>67</sup>

The lack of effective treatment of aspergillosis and availability of new antifungal agents has made the concept of combination therapy for aspergillosis theoretically appealing.<sup>68</sup> To date, no clinical studies have convincingly determined whether therapy with antifungal combinations is more beneficial than that of monotherapy in aspergillosis. For instance, our recent experience suggests that combinations of itraconazole<sup>69</sup> or caspofungin<sup>70</sup> with lipid formulations of AMB are not beneficial. In contrast, a recent small study suggested that the combination of caspofungin and voriconazole is beneficial as salvage therapy for refractory aspergillosis.<sup>71</sup>

The optimal duration of therapy for aspergillosis is uncertain.<sup>56</sup> Such therapy should be highly individualized with respect to resolution of all of the symptoms and signs of the infection, radiologic near-normalization, *Aspergillus*-negative cultures, and, ideally, restoration of the impaired immune defenses.

Pulmonary infarcts and tissue sequestration are common causes of antifungal therapy failure and fatal hemorrhage. Also, the role of adjunctive surgery in the management of aspergillosis has not been addressed in a conclusive way. Early detection of *Aspergillus* lesions by chest CT combined with aggressive combined antifungal and surgical treatment appears to confer a survival advantage,<sup>72</sup> and resection of infected pulmonary tissue has been shown to be beneficial in some patients.<sup>73</sup> After successful antifungal therapy, the presence of residual cavitory lesions, especially those containing fungus balls, may cause late exsanguinating hemorrhage or reactivation of the infection during subsequent myelosuppressive chemotherapy. Removal of these lesions when surgically feasible should be considered and may provide a survival benefit.<sup>73</sup> Surgical intervention may be lifesaving for patients with acute pulmonary hemorrhage, even when performed early in the disease process.

Finally, the role of immunomodulators in the management of aspergillosis remains unresolved.<sup>1,56</sup> As is the case with the other refractory opportunistic mycoses, the beneficial adjunctive role of immunomodulation with cytokines or infusion of immune effector cells in various combinations (eg, granulocyte-macrophage colony-stimulating factor [GM-CSF], granulocyte colony-stimulating factor, interferon- $\alpha$ , GM-CSF-primed white cell transfusions) in cases of refractory or recurrent aspergillosis has been suggestive only in anecdotal clinical reports. However, substantial preclinical evidence supports the role of immunomodulation in the control of *Aspergillus* spp. Further studies are needed in this important area of clinical investigation. Figure 2 outlines the general principles of the management of acute aspergillosis in patients with cancer.

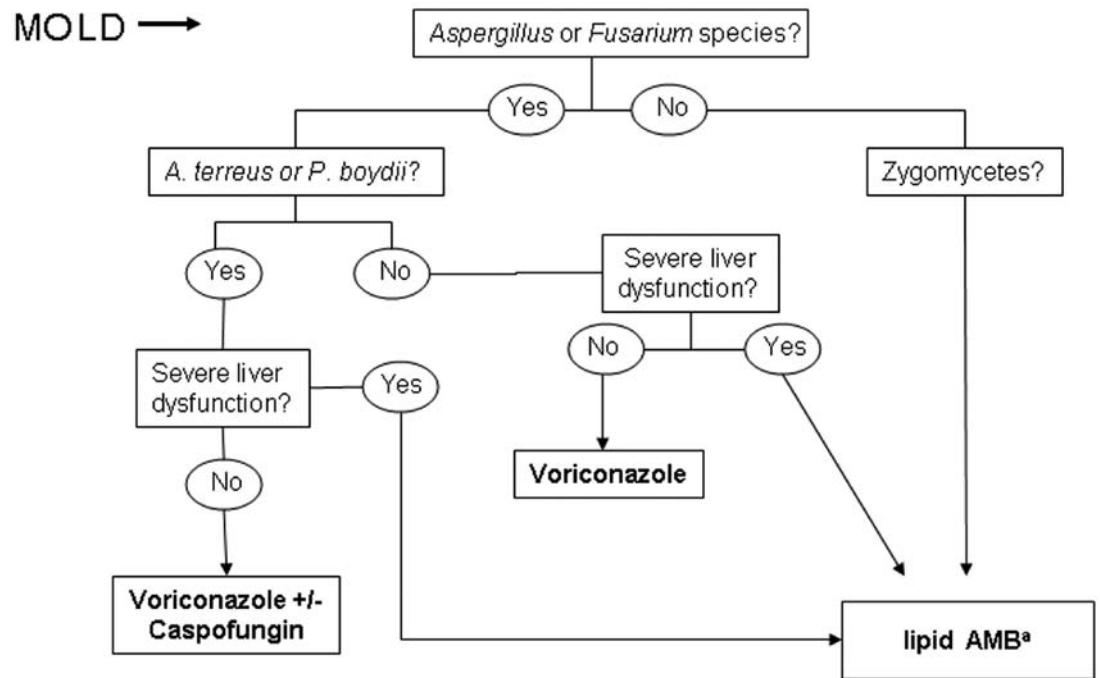

FIGURE 2 Approach to the management of invasive mold infection in the high risk cancer patient.

### Zygomycosis

Zygomycosis refers to infections caused by a variety of molds of the order *Mucorales*. These molds are widely distributed in the environment and are usually acquired by inhalation of spores but occasionally are acquired by contamination of open skin lesions or ingestion.<sup>14</sup> Like *Aspergillus* spp, these fungi invade blood vessels, causing thrombosis and infarcts. The types of zygomycosis are rhinocerebral, pulmonary, sinusitis, gastrointestinal cutaneous, and disseminated.<sup>14,74</sup> Sinopulmonary is the most common type of zygomycosis in cancer patients.<sup>74</sup>

Pulmonary macrophages and neutrophils are important host defenses against these infections. Cancer patients susceptible to zygomycosis include recipients of BMTs; patients with acute leukemia, malnutrition, or diabetes mellitus; and patients receiving treatment with adrenal corticosteroids or undergoing hemodialysis and receiving deferoxamine. The presentations of zygomycosis are similar to those of aspergillosis. Although it occurs less frequently than aspergillosis does, zygomycosis appears to be on the rise in patients with cancer.<sup>74,75</sup> Importantly, the increasing use of agents with good activity against *Aspergillus* but no activity against *Zygomycetes* (eg, voriconazole, echinocandins) may increase the incidence of zygomycosis as a breakthrough infection.<sup>76</sup>

The mortality rate of zygomycosis is high in patients with hematologic malignancies. More specifically, the 3-month mortality rate was 71% in a recent unselected cohort of 24 patients with cancer who had definite or probable zygomycosis at The University of Texas M. D. Anderson Cancer

Center.<sup>74</sup> The attributable mortality rate in these patients was 92%, and 75% of those who died did so within 4 weeks from the onset of their symptoms. Finally, the outcome of disseminated zygomycosis in the setting of continuous immunosuppression, such as in patients with refractory neutropenia, has been almost uniformly fatal despite the use of aggressive antifungal therapy.

The optimal management of zygomycosis has not been well defined as no prospective studies have evaluated the management of this uncommon infection. The introduction of the lipid formulations of AMB, which have improved the therapeutic index and allow for the delivery of higher daily dosages of the agent,<sup>60</sup> as well as posaconazole, a broad-spectrum triazole with promising preclinical activity against the *Zygomycetes*,<sup>77</sup> has renewed interest in studying new therapeutic strategies for this devastating mycosis. Proper management of ketoacidosis in diabetic patients and use of “radical” surgery with extensive débridement of all necrotic areas is important to recovery from zygomycosis.

The widespread use of voriconazole, a triazole with no inherent activity against the *Zygomycetes* has been recently associated with a rise in incidence of Zygomycosis in high risk hematology patients.

### Fusariosis

*Fusarium* spp are found in the air and soil throughout the world and are common plant pathogens.<sup>13,15,78</sup> Several of these species have been recognized as human pathogens, including *Fusarium solani*, *Fusarium moniliforme*, *Fusarium oxysporum*, and *Fusarium dimerum*. Some species

produce mycotoxins.<sup>13,15</sup> Because *Fusarium* spores are recovered from environmental air samples, most systemic infections involve the lung or sinuses. Chronic superficial infection of the skin or nails may be the portal of entry for some systemic *Fusarium* infections. Most systemic infections occur in severely immunocompromised patients, such as recipients of HSCTs and patients with acute leukemia.<sup>13,15,78</sup> The most important risk factors for fusariosis are severe neutropenia and use of high-dose adrenal corticosteroid therapy.<sup>13,15,78,79</sup>

Like *Aspergillus* spp, *Fusarium* spp have a propensity for invading blood vessels, causing thrombosis and infarcts.<sup>13,15</sup> Pulmonary fusariosis may present with symptoms suggesting an acute pulmonary embolism. Approximately 75% of infections in neutropenic patients disseminate, and the organism can be isolated from blood culture specimens in about 70% of patients.<sup>13,15</sup> Multiple skin lesions are common in patients with disseminated fusariosis.<sup>13,15</sup> A variety of these lesions may be found simultaneously, including red or gray macules, papules (some with central necrosis or an eschar), and pustules.<sup>80</sup> Some patients experience significant myalgia or painful subcutaneous lesions.<sup>15</sup> Occasionally, patients with less severely compromised host defenses may have only localized infections of the skin, such as paronychia, erythematous nodules, hemorrhagic bullae, and tender, progressive necrotic lesions at sites of previous trauma.

The susceptibility of *Fusarium* spp to antifungal agents in vitro has been variable, but, overall, it has been mediocre.<sup>15</sup> Some *Fusarium* isolates are susceptible to new triazoles, such as voriconazole and posaconazole.<sup>6,7</sup> In fact, voriconazole was shown to be active as salvage therapy in a small series of patients with fusariosis.<sup>66</sup> At the present time, no antifungal agent is reliably effective in neutropenic patients with fusariosis, and most patients receive high doses ( $\geq 5$  mg/kg/d) of a lipid formulation of AMB with or without voriconazole. However, in neutropenic patients, recovery of neutrophil production is the most critical factor for a successful outcome.

### Trichosporonosis

*Trichosporon asahii* (*beigelii*) and the related yeast *Blastoschizomyces capitatus* are widely distributed in air, soil, and decaying fruit.<sup>81,82</sup> Infections with these fungi occur predominantly in patients with acute leukemia and recipients of HSCTs. These infections can cause endophthalmitis, meningitis, pneumonia, and osteomyelitis, but more than 80% of the infections are disseminated.<sup>81,82</sup> The organisms can be isolated from blood culture specimens obtained from about 80% of patients with a disseminated infection. The mortality rate in patients with disseminated trichosporonosis who have persistent neutropenia has been

reported to be as high as 80%. The liver and spleen are frequently infected, and some patients have chronic infections similar to chronic disseminated candidiasis. About 30% of patients with disseminated trichosporonosis have skin lesions, which may begin as small maculopapular or nodular lesions and become necrotizing ulcerations. However, the presentation of trichosporonosis might be changing. A recent study at our institution indicated that 70% of *Trichosporon* infections were cases of catheter-related fungemia without evidence of disseminated disease.<sup>83</sup> Because fluconazole is active against *Trichosporon* spp,<sup>5</sup> widespread use of this drug in antifungal prophylaxis likely prevents the development of disseminated infection.

Fluconazole appears to be active against trichosporonosis and more effective than AMB based on animal and human studies.<sup>5,81,82,84</sup> The clinical experience with voriconazole is limited,<sup>85</sup> but laboratory studies have suggested that it is the most active available triazole for trichosporonosis. Animal studies have suggested that combination therapy with AMB plus an azole is the optimal therapy for disseminated trichosporonosis.<sup>84</sup>

### Overview of Endemic Mycoses and Cryptococcosis

Endemic mycoses and cryptococcosis are relatively less common causes of morbidity and mortality in patients with cancer, particularly those with chronic deficits in cell-mediated immunity. There is a significant spectrum of manifestations and severity of these infections, ranging from asymptomatic lung nodules to fulminant disseminated infection. Most of these infections occur in patients with hematologic malignancies, especially those with severely suppressed T-cell function.<sup>86–89</sup> These patients are also susceptible to reactivation of latent infections acquired prior to the development of their malignancy. The therapeutic options for endemic mycoses include AMB-d, lipid formulations of AMB (3–5 mg/kg/d),<sup>90–92</sup> and intravenous itraconazole (200 mg given twice daily for 2 days and then once daily). Caspofungin has limited activity, and the experience with voriconazole is very limited at present. AMB-based therapy is preferred for severely ill patients with systemic mycoses who have pneumonia, meningitis, or disseminated infection. Once the patient has improved substantially and is clinically stable, liquid itraconazole (200 mg/d)<sup>89</sup> may be given orally. Therapy should be administered for at least 3 to 6 months or until immunosuppression abates.

### Histoplasmosis

Most cases of histoplasmosis in patients with hematologic malignancies are disseminated

infections.<sup>87</sup> Physical findings may include hepatosplenomegaly, mucocutaneous ulcerations (especially in the oral cavity), and signs of central nervous system involvement.<sup>87</sup> *Histoplasma* is visualized or cultured from infected tissues, respiratory secretions, or blood specimens.<sup>87</sup>

### Coccidioidomycosis

*C. immitis* may cause fulminant pneumonia in immunocompromised hosts with high fever, hypoxemia, and diffuse pulmonary infiltrates.<sup>86</sup> Often these patients have a disseminated infection that may involve the skin, bones, and meninges. Skin lesions in cases of coccidioidomycosis may be papular, pustular, nodular, or ulcerative. Although serologic tests are often positive for coccidioidomycosis, the fulminant nature of the infection usually requires a more aggressive diagnostic approach with examination and culture of tissue specimens, sputum, or CSF.

### Cryptococcosis

*C. neoformans* has tropism toward the central nervous system and is a well-known cause of meningitis and disseminated infection in patients with AIDS.<sup>93</sup> Patients with cancer who have a lymphoid malignancy or T-cell dysfunction secondary to systemic corticosteroid use are at high risk of cryptococcosis.<sup>88</sup> However, recent studies have increasingly identified this infection in patients with solid tumors as routine fluconazole prophylaxis is performed less often in these patients.<sup>88</sup> Pulmonary cryptococcosis is the most common presentation of this infection, which often is asymptomatic and could mimic pulmonary malignancy.<sup>88</sup> AMB-d and lipid formulations of AMB (with or without 5-flucytosine) and fluconazole have clinical activity against cryptococcosis.<sup>5,88,93</sup>

### Empiric Antifungal Treatment

In autopsy studies of neutropenic patients with cancer who had prolonged fever, 40 to 69% had evidence of an invasive fungal infection.<sup>4</sup> This high incidence, along with the high mortality rate associated with fungal infections (approaching 90% in selected patient groups); difficulties in reliable, timely diagnosis; and a lack of clinical signs and symptoms at the initial stages of the infection in neutropenic patients, led to the introduction of empiric antifungal therapy in the 1980s. Most experts recommend introducing an antifungal drug for patients who remain febrile for 5 or more days despite undergoing an appropriate initial regimen and in whom resolution of neutropenia is not imminent. Some authors prefer to institute antifungal therapy earlier (day 3) or even include antifungals up-front for high-risk patients because of the poor prognosis for infections when treatment is delayed.<sup>94,95</sup>

Regardless, physicians should make individualized decisions about the perceived risk of fungal sepsis and timing and type of antifungals to be administered.<sup>94</sup> For example, for a patient with leukemia and a history of invasive pulmonary aspergillosis, the threshold for initiating antifungal therapy should be very low early on in the setting of febrile neutropenia.<sup>94</sup>

The optimal duration of empiric antifungal treatment in patients with no clinical or microbiologic documentation of an invasive fungal infection has not been established.<sup>94</sup> Again, the key factor is resolution of neutropenia. If neutropenia has resolved and the patient is clinically well, antifungal administration can be discontinued. If neutropenia persists despite defervescence and repeated workup shows no suspicious lesions, antifungal administration can be stopped after 2 weeks. In unstable patients with persistent fever and neutropenia, antifungal treatment should be continued for the entire febrile episode, probably at a more intense level.

For some time, AMB has been the only drug available for antifungal therapy, but its efficacy has been limited by significant nephrotoxicity and infusion-related toxic effects. Thus, efforts have been made to develop new, effective, less toxic antifungal drugs. Lipid formulations of AMB have been introduced and proven to be as effective as AMB, with fewer renal and infusion-related toxic effects in empiric antifungal therapy.<sup>96</sup> However, these formulations are far more expensive than the parent drug, making the pharmacoeconomic threshold for their use unclear in neutropenic patients with persistent fever.

Second- and third-generation triazoles, such as fluconazole,<sup>97</sup> itraconazole,<sup>98</sup> and voriconazole,<sup>99</sup> are frequently used as empiric antifungal treatment regimens. Fluconazole has proven to be an acceptable alternative to AMB provided that the probability of infection with *Aspergillus* or resistant *Candida* spp is low. Patients in this group include those without high-risk leukemia and/or any BMTs, sinusitis, pneumonia, or previous prophylactic or empiric use of fluconazole.<sup>97</sup> Additionally, itraconazole and voriconazole have been found to have similar efficacy but lower toxicity when compared with AMB. In a recently completed large, multi-institutional, prospective, randomized study, caspofungin was compared with liposomal AMB in persistently febrile neutropenic patients. Caspofungin was found to be more efficacious and less toxic than liposomal AMB.<sup>100</sup>

Given the growing number of treatment options for fungal infections, the question is which agent is best for empiric antifungal therapy? In the future, with the introduction of non-culture-based diagnostic methods, such as polymerase chain reaction and antigen detection, empiric antifungal therapy will likely evolve to preemptive antifungal therapy.

## Conclusions

Despite the major progress that has been made in the management of mycoses in patients with cancer over the past decade, major challenges remain. The goals for future research include the development of new effective antifungals to overcome the emerging resistant fungal pathogens, refinement of the existing models for risk stratification to reliably identify best therapeutic strategies, and introduction of new non-culture-based modalities for early detection of fungal infection, which will lead to the replacement of empiric therapy with pathogen-specific preemptive therapy.

# Parasitic Disease Issues in Cancer Patients

Javier A. Adachi, MD  
Herbert L. DuPont, MD

Parasitic diseases in patients with underlying malignancies are uncommon infectious problems in the United States, a direct reflect of the very low prevalence of parasitic infections in the general population in this country.<sup>1,2</sup> In contrast, parasitic infections are relatively more frequent in cancer patients in other areas of the world, especially in those with higher prevalence of gastrointestinal parasitic infections (such as cryptosporidiosis, strongyloidiasis), blood-borne parasitic infections (malaria) and central nervous system parasitic infections (toxoplasmosis, cysticercosis).

The objective of this chapter is to review the epidemiology, clinical presentation, diagnosis, treatment and prevention of *Pneumocystis jiroveci* pneumonia (formerly known as *Pneumocystis carinii* pneumonia [PCP]) and *Toxoplasma gondii* infections in cancer patients, follow by a short review of other miscellaneous parasitic infections.

## ***Pneumocystis jiroveci* Infection**

### **Introduction**

*P. carinii* was first identified in 1909–1910 by Chagas and by Carini<sup>3,4</sup> and was recently renamed *P. jiroveci*.<sup>1,5</sup> The first description of PCP was in 1952.<sup>6</sup> Although, initially classified as a protozoan, more recent molecular genetic studies have demonstrated that *P. jiroveci* may be considered an atypical fungus,<sup>2,5,7,8</sup> consisting in multiple strains, each one restricted to infecting a single host species.<sup>5,7</sup> The life cycle and the origin of infection (de novo or reactivation) are still unknown.<sup>2,5</sup>

In 1976, Hughes and colleagues<sup>9</sup> found an incidence of 22 to 45% of PCP in children with acute lymphoblastic leukemia, depending on the stage and the chemotherapy used. Later on, the same author demonstrated that trimethoprim-sulfamethoxazole (TMP-SMX) was an effective prophylaxis,<sup>10</sup> and its routine use has resulted in a decrease of the incidence to 0%.<sup>5,11–13</sup> Since the

1980s, PCP is a well-known life-threatening opportunistic infection in patients with impaired cellular immunity, such as patients with AIDS, hematological malignancies, recipients of transplant, severe malnutrition, congenital T-cell deficiencies, or those receiving high-dose systemic steroids or other immunosuppressive agents.<sup>2,5,14</sup>

### **Epidemiology**

The incidence of PCP without TMP-SMX prophylaxis varies by the type of cancer and the use of immunosuppressive therapy. Patients with hematologic malignancies (leukemia and lymphoma) have a higher incidence (between 22% and 67%)<sup>2,5,9,14,15</sup> than the incidence among patients with solid tumors, usually taking immunosuppressive therapy (1.3 to 34%)<sup>2,5,16,17</sup>. Recipients of hematopoietic stem cell transplantation (HSCT) or solid organ transplantation (especially those post-lung transplant, who also have a high incidence of PCP [from 5% to more than 25%]).<sup>2,5</sup> The majority of patients was found to have lymphopenia (< 1,000 lymphocytes/mL) at the onset of infection.<sup>15</sup>

### **Clinical Presentation**

The clinical presentation of PCP in cancer patients is characterized by the presence of fever (86%), dyspnea (75 to 78%) and non-productive cough (70%).<sup>2,5,15</sup> Compared to HIV-positive patients,<sup>18</sup> cancer patients with PCP have shorter median duration of symptoms (28 vs. 5 days, respectively) and lower median arterial oxygen tension at room air (69 vs. 55 mm Hg, respectively), with a high rate of admission to the intensive care unit (41 to 60%) and of use of mechanical ventilation (30 to 41%).<sup>14,15,18,19</sup> Coinfection with other opportunistic infections is also commonly found.<sup>15</sup>

### **Diagnosis**

The diagnosis of PCP is based on the detection of the organism in a clinical specimen using colorimetric (Gomori's methanemine silver stain

or Giemsa stain) or immunofluorescent stain (using monoclonal antibody 2G2), the latter being more sensitive and specific.<sup>5</sup> Bronchoalveolar lavage specimens from cancer patients have a higher yield for PCP, compared to lung tissue or induced sputum specimens.<sup>2,5,15</sup> It has been reported in the literature that the *P. jiroveci* load seen on microscopic examination of respiratory specimens is lower in cancer patients.<sup>5</sup> PCP shows an acellular intra-alveolar eosinophilic exudate in histopathologic studies.<sup>5</sup>

Recent studies using molecular-based methods have been shown to be more sensitive than the stains for detection of PCP and have also demonstrated the presence of asymptomatic colonization.<sup>5,20,21</sup>

The characteristic radiographic findings of PCP are bilateral interstitial infiltrates, which progress to alveolar infiltrates. However, up to 10% of patients may have normal chest radiograph.<sup>5,15,18,22</sup> The computed tomography of the chest usually demonstrates a characteristic ground glass opacity pattern.<sup>5</sup>

### **Treatment and Clinical Outcome**

The treatment of PCP has remained basically the same since the 1970s. TMP-SMX is the first-line therapy against PCP in any kind of patient, including cancer patients.<sup>2,5</sup> Patients intolerant of TMP-SMX could be treated with one of the alternative therapies summarized in Table 1. Although in-vitro-resistant mutations have been demonstrated, there is no correlation between these mutations and clinical resistance to TMP-SMX.<sup>23</sup>

The duration of therapy for cancer patients with PCP was established to be 2 weeks, unless the PCP is severe, the clinical response is not optimal, or further immunosuppressive therapy is given.<sup>2,5</sup>

Although no adequate clinical trials have been done testing the possible benefit of adjuvant steroids therapy in HIV-negative patients with PCP, it is recommended to follow the same indications for adding steroids to the regimen as

**Table 1** Treatment Regimens of *Pneumocystis Jiroveci* Pneumonia

Drug	Dose
TMP-SMX *	2 tablets double-strength oral every 8h
TMP-SMX	5 mg/kg of TMP every 8h
<i>Alternatives</i>	
TMP + Dapsone	320 mg oral q8h + 100 mg daily
Atovaquone	750 mg oral twice daily
Clindamycin + primaquine	300 to 450 mg oral/IV every 6h + 15 to 30 mg oral daily
Pentamidine	4 mg/kg IV daily
Trimetrexate + leucovorin	45 mg/m <sup>2</sup> IV daily + 20 mg/m <sup>2</sup> oral/IV every 6h
<i>Adjunctive Therapy</i>	
Prednisone	(if PaO <sub>2</sub> at room air < 70 mm Hg)
IV = intravenous; SMX = sulfamethoxazole; TMP = trimethoprim	

were established for patients with AIDS and PCP.<sup>24</sup>

Survival rates vary based on the population at risk, with cancer patients showing the worst rates.<sup>2,5,15,25</sup> Recent data have shown that the survival rate associated with PCP in AIDS patients has declined noticeably during the last decade, in contrast to the little improvement of survival of HIV-negative patients with PCP.<sup>2,5</sup>

Reported poor prognostic factors in cancer patients with PCP were prolonged steroid therapy (> 15 days), diffuse lung involvement, mechanical ventilation, an elevated serum lactate dehydrogenase level and elevated C-reactive protein.<sup>14,15,25</sup>

### Prevention

Since TMP-SMX prophylaxis was demonstrated to be effective prophylactic therapy by Hughes and colleagues,<sup>10</sup> this antimicrobial is the preferred prophylactic agent in any patient population. However, its associated adverse effects, mainly myelotoxicity, have been the driving force behind the use of alternative prophylactic agents, as shown in Table 2. The optimal duration of prophylaxis remains to be determined.

### Summary

In conclusion, PCP is still an uncommon, but life-threatening pulmonary infection in cancer patients. The type of cancer, history of transplant and the use of immunosuppressive therapy influence the clinical presentation and outcome of this infection. In contrast to PCP in HIV-positive patients, there have not been any improvements

**Table 2** Prophylactic Regimens of *Pneumocystis Jiroveci* Pneumonia

Drug	Dose
TMP-SMX *	1 tablet double-strength oral daily 1 tablet single-strength oral daily
<i>Alternatives</i>	
TMP-SMX	1 tablet double-strength oral 3 times/week
Dapsone	100 mg oral daily
Aerosolized Pentamidine	300 mg via nebulizer monthly
Atovaquone	1,500 mg oral daily
SMX = sulfamethoxazole; TMP = trimethoprim	

in mortality rate for PCP in HIV-negative patients. Early diagnosis, identification of risk factors and prompt and better therapy of this infection among cancer patients should improve the clinical outcome.

## Toxoplasma gondii Infection

### Introduction

*T. gondii* is an intracellular protozoan parasite that infects humans and animals. Seroprevalence of toxoplasmosis in the general population varies between geographic areas, from 14 to 40% in the United States to 50 to 90% in continental Europe and Latin America, and increases with age.<sup>26–29</sup> Most infections are asymptomatic, but symptomatic infection may present with a mononucleosis-like picture, chronic infection with chorioretinitis, acute disseminated infection, and single-organ disease (encephalitis or pneumonitis).<sup>26,27,29</sup> Transmission may occur transplacentally, by ingestion of undercooked infested meat or by exposure to oocysts in contaminated soil.

Most of the epidemiology, clinical manifestations, and the outcome, treatment, and prevention of toxoplasmosis in immunosuppressed cancer patients comes from the studies of toxoplasmosis in patients with AIDS.<sup>27</sup> A first-class study contrasting the characteristics of toxoplasmosis in HIV-infected patients with HIV-negative patients is still waiting to be done.

### Epidemiology

Toxoplasmosis occurs frequently in severe immunosuppressed patients—mainly patients with AIDS. It is a rare, but important and often devastating parasitic infection in patients undergoing hematopoietic stem cell transplantation.<sup>27,30,31</sup> Disseminated toxoplasmosis apparently results from reactivation of a latent infection associated with cellular immunodeficiency.<sup>26,27</sup> One recent

European study reported 41 cases of toxoplasmosis after HSCT. Most patients (94%) were seropositive for *T. gondii* before the HSCT, and 73% developed moderate to severe graft-versus-host disease prior to developing the infection.<sup>28</sup>

### Clinical Presentation

Encephalitis is the most common type of infection in cancer patients post-HSCT with toxoplasmosis (60 to 80%), followed by pulmonary involvement in up to 41% of the cases reported.<sup>28,30,31</sup> These patients, like any other immunosuppressed patients, may present with non-specific clinical manifestations (fever, headaches, lymphadenopathy, myalgia, or anorexia) or with more specific ones (confusion, drowsiness, meningism or seizures)<sup>28</sup>

### Diagnosis

The presumptive diagnosis of toxoplasmosis in immunocompromised patients is based on the detection of IgG to *Toxoplasma* in serum and radiologic findings compatible. Diagnosis of acute infection could be established by the simultaneous detection of serum IgG and IgM to *Toxoplasma*.<sup>26–28</sup> Determination of IgG titers in cerebral-spinal fluid (CSF) may be useful to help identify the infection.<sup>27</sup>

Immunohistochemistry or conventional histology examination with identification of parasites in tissue samples are definitive diagnostic tests but are not convenient daily clinical practice.<sup>26,27</sup>

The identification of genetic material of the parasite is under investigation in HSCT recipients, testing blood samples or CSF samples,<sup>27,32</sup> with controversial results.

Imaging studies (computed tomography of the head or magnetic resonance imaging of the brain) could demonstrate focal or multifocal abnormalities in the central nervous system (CNS). However, these findings are not pathognomonic. Radiologic studies are important in order to assess the response to therapy.<sup>26–28</sup>

### Treatment and Clinical Outcome

Table 3 shows the treatment regimens available for acute toxoplasmosis in immunocompromised patients. Combination therapy with pyrimethamine and sulfadiazine, complemented with leucovorin is the first choice.<sup>26,27</sup>

The mortality rate of toxoplasmosis in post-HSCT patients is around 60 to 70%, apparently higher than for AIDS patients, with an elevated number of cases diagnosed post-mortem.<sup>26–28</sup>

In contrast to toxoplasmosis in AIDS, which could be a subacute medical problem, this parasitic infection could be rapidly fatal in patients post-HSCT if they are not treated without delay. Appropriate antimicrobial therapy was identified

**Table 3** Treatment Regimens Of Toxoplasmosis

Drug	Dose
Pyrimethamine	200 mg oral follow by 75 to 100 mg oral daily
+ sulfadiazine	+ 1 to 1.5 gm oral every 6h
+ leucovorin	+ 10 to 15 mg oral daily
TMP-SMX *	5 mg/kg of TMP every 12h
<b>Alternatives</b>	
Pyrimethamine	(As above)
+ leucovorin	+ 600 mg oral/IV every 6h
+ clindamycin	or + 1.0 gm oral daily
or + clarithromycin	or + 1.2 to 1.5 gm oral daily
or + azithromycin	or + 100 mg oral daily
or + dapsone	or + 100 mg oral daily
IV = intravenous; SMX = sulfamethoxazole; TMP = trimethoprim	

as the most important survival factor.<sup>28,29</sup> Therefore, a presumptive diagnosis of CNS toxoplasmosis should prompt the immediate treatment. The optimal duration and role of suppressive therapy needs to be studied.

### Prevention

In AIDS patients, the prophylaxis for PCP is also effective for toxoplasmosis (Table 4). In cancer patients, the use of prophylaxis in seropositive patients after HSCT is apparently justified.<sup>26,33</sup> However, further studies are necessary to confirm this postulate, to determine the role of secondary prophylaxis, and to define the optimal duration of prophylactic regimen.

### Summary

In conclusion, toxoplasmosis is an uncommon, but life-threatening infection in immunocompromised patients with cancer, especially to those post-HSCT. Additional studies should be done to determine the importance of the type of cancer, history of transplant, and the use of immunosuppressive therapy in the clinical presentation and outcome of this infection. Early diagnosis, identification of risk factors, and prompt and better therapy of this infection among cancer patients should improve the clinical outcome.

### Miscellaneous Parasitic Infections

#### *Strongyloides stercoralis*

*Strongyloides* is an uncommon helminth that can produce a wide variety of clinical syndromes in cancer patients, based on the immunologic status of the host. It could remain localized in patients with solid tumors, or develop a hyperinfection syndrome with gastrointestinal manifestations, diffuse pneumonitis and respiratory failure, usually together with gram-negative sepsis, described most often in patients with hematological

**Table 4** Prophylactic Regimens Of Toxoplasmosis

Drug	Dose
TMP-SMX *	1 tablet double-strength oral daily
	1 tablet single-strength oral daily
<b>Alternatives</b>	
Dapsone	50 mg oral daily
+ pyrimethamine	+ 50 mg oral weekly
+ leucovorin	+ 25 mg oral weekly
Atovaquone	1,500 mg oral daily
TMP = trimethoprim; SMX = sulfamethoxazole	

malignancies or post-HSCT.<sup>30,34,35</sup> Apparently, the patients with the disseminated disease do not have a good response to any antimicrobial therapy (thiabendazole or ivermectin), unless there is a recovery of the immune status.

#### *Schistosoma* species

Infection by this trematode is associated with development of cystitis, intestinal and vesical ulcerations, hepatic fibrosis, portal hypertension and bladder cancer. This parasite infection is endemic in tropical and subtropical countries, but there have not been any native reported cases in the United States.<sup>36,37</sup>

#### Intestinal Protozoan Infections

Although *Giardia*, *Cryptosporidium*, *Isospora*, *Cyclospora*, *Microsporida* and *Entamoeba histolytica*, have been associated with chronic infectious diarrhea in AIDS patients, there are very low incidences in infectious enterocolitis in patients with an underlying malignancy in the United States.<sup>38,39,40</sup> Routine microbiology tests for these enteric parasites, as well as for all "classic" enteropathogenic bacteria (*Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, *Aeromonas*, *Plesiomonas* and *Vibrio*) should not be recommended as routine tests in cancer patient with acute uncomplicated diarrhea or without a identified epidemiological risk factor.<sup>38,39</sup> The detection of *Clostridium difficile* toxin in stools of cancer patients with acute diarrhea is the only exception, because of the high prevalence of this infection in cancer patients, especially those with hematological malignancies.<sup>41,42</sup>

# Mycobacterial Infections in Patients with Cancer

Amar Safdar, MD  
Donald Armstrong, MD

Tuberculosis has a substantial impact on global public health; nearly 8 million new cases of *Mycobacterium tuberculosis* are estimated to occur yearly, adding to the existing burden of 1,700 million cases worldwide.<sup>1,2</sup> In 1993, the World Health Organization declared tuberculosis a public health emergency because 3 million patients were expected to die annually owing to complications arising from tuberculosis, making it the most frequent cause of death due to an infectious organism.<sup>3</sup> Humans are the only known reservoir of *M. tuberculosis*, and nearly one-third of the world's population is now estimated to be infected with this potentially devastating infection. Public health measures, including bacilli Calmette-Guérin vaccination, improved living standards, especially among the inhabitants of inner cities has resulted in marked reduction in the infection rates in populations of the developed regions of the world, although the tuberculosis attack rate remains undeterred in underdeveloped and developing countries.

In the United States, reported cases of tuberculosis consistently declined during the 20th century until 1985. The unanticipated sudden increase in the newly diagnosed cases of tuberculosis between 1985 and 1992 in United States were attributed to the epidemic of human immunodeficiency virus (HIV), acquired immunodeficiency syndrome (AIDS), illicit drug use, homelessness, and ineffective tuberculosis control programs in large urban centers.<sup>4,5</sup> The decline in tuberculosis since 1992 was attributed to re-implementation of effective tuberculosis control programs with emphasis on early diagnosis to interrupt spread in the community, directly observed therapy that ensured compliance of adequate anti-tuberculosis therapy, and a number of other preventive measures. They were all credited with establishing in 1997 the lowest ever number of new recorded cases.<sup>6</sup>

Most *M. tuberculosis* infections occur in patients with no known immune defects, although inadequate adaptive cellular immune response

substantially increases the risk of both new infection and reactivation of remotely acquired disease. The host factors that promote tuberculosis include protein-calorie malnutrition and residing in communities with inadequate sanitation, poor ventilation, and overcrowding. In developed regions of the world, homelessness, illicit drug use, incarceration in correctional facilities, prolonged use of systemic corticosteroids and tumor necrosis factor inhibitor therapy has been associated with increased risk of tuberculosis.<sup>7,8</sup> Since the introduction of effective antiretroviral therapy (ART) and ART-related cellular immune reconstitution, patients with HIV-AIDS are less susceptible to developing active tuberculosis.<sup>9</sup>

Patients with an underlying malignancy, Hodgkin's diseases, gastric, head and neck cancers were considered a susceptible population.<sup>10,11</sup> One report said most cases of active tuberculosis in HIV-negative cancer patients receiving care at a comprehensive cancer center in the United States were noted in patients with hematologic malignancies, including acute and chronic myelogenous leukemia, and non-Hodgkin's lymphoma.<sup>12</sup> Tuberculosis has also been reported in the recipients of hematopoietic stem cells, although the infection rate (despite severe cellular immune dysfunction) has remained low in the residents of North America and Europe.<sup>13</sup> Recipients of organ transplantation, however, appear to have a higher rate of developing active tuberculosis.<sup>14</sup> This discrepancy is less obvious in patients undergoing hematopoietic stem cell transplantation in the areas of high *M. tuberculosis* endemicity.<sup>15-17</sup> In the United States, reactivation of *M. tuberculosis* remains a concern in foreign-born cancer patients who have increased risk of infection reactivation during antineoplastic-therapy-induced severe immune suppression.<sup>12,18,19</sup>

In this chapter, we provide a brief introduction of hosts' immune resistance against mycobacterial pathogens and immune defects that promote systemic disease due to mycobacteria. The clinical spectrum of disease and antituberculous therapies are discussed under

two sections: Tuberculosis and Nontuberculous Mycobacteriosis.

## Antimycobacterial Immune Defense

Intact reticuloendothelial systems provide the bases of innate immune defense against the invading virulent *M. tuberculosis* as well as most non-virulent environmental mycobacterial species other than *M. tuberculosis*. However, it is the adaptive cellular immune response that provides effective containment and elimination of intracellular mycobacteria residing within the mononuclear cells.<sup>20</sup> All components of T-lymphocytes including  $\gamma \delta$  cells play a role, although CD4 cells are the dominant  $\alpha \beta$  lymphocytes that provide the backbone of a host's immune response against mycobacterial infections.<sup>21,22</sup> Interferon- $\gamma$  (IFN- $\gamma$ ) is the most important proinflammatory cytokine secreted by primed T-helper type-1 ( $T_H1$ ) lymphocytes, which activates fixed tissue macrophages, recruits peripheral mononuclear cells to the site of infection and sets the stage for granuloma formation.<sup>23</sup> The granuloma 1) serves as a physical barrier for mycobacterial propagation, 2) promotes unfavorable oxygen and micronutrient-deficient environments and 3) most importantly, creates a milieu in which various components of the immune cells and extracellular cytokines and chemokines interact to enhance effector-cell-mediated mycobacterial cell death.<sup>24,25</sup>

The delayed-type hypersensitivity reaction against the invading mycobacterial infection on one hand is critical in effective containment of infection, and on the other hand, via calcification of granulomas, large quantities of caseation necrosis and formation of pulmonary cavities paradoxically enable the intracellular mycobacteria to evade the host's immune surveillance.<sup>26</sup> The cytokines that play an important role in antimycobacterial immune defense cascade other than IFN- $\gamma$  include interleukin 12, T-cell-derived tumor necrosis factor alpha (TFN- $\alpha$ ) and the

expanding family of TNF-related immuno-active peptides.<sup>27–29</sup>

### Immune Defects

The host's immune defects, in the light of earlier discussion, mostly involve dysregulation of cellular adaptive immune response. A complicated cascade of events are set into effect following exposure to mycobacterial antigens, and organism-specific antigen-primed T-cells at the infection site orchestrate events leading to cell death of these intracellular pathogens.

Defects in the protagonist  $T_H1$  cytokine,  $IFN-\gamma$  may present as a deficiency in cytokine production. Dysfunctional cytokine specific receptors ( $IFN-\gamma$ ) have been shown to increase difficult-to-treat systemic mycobacteriosis.<sup>30–33</sup> Furthermore, defects in post-receptor cytoplasmic signaling pathways such as signal transducer and activator of transcription 1 (STAT1), signal transducing molecule, nuclear factor (NF) $_{\kappa}$  $\beta$  essential modulator (NEMO), or ancillary cytokines including interleukin-12, interleukin-18, and  $TNF-\alpha$  can also lead to enhanced risk of severe disseminated infection due to otherwise non-virulent mycobacteria.<sup>20,23,27</sup>

At present, the consensus to undertake an immunologic work is warranted in only HIV-negative patients who present with refractory mycobacterial infections or those with recurring pulmonary nontuberculous mycobacteriosis with no known underlying predisposing conditions. Most patients with *M. tuberculosis* do not have a known immune defect, and for most patients, appropriate antimycobacterial therapy alone results in good sustained response. Nontuberculous mycobacteriosis, even due to organisms with low disease-causing potential, are often in the setting of immunologically intact host, and an extensive immunologic workup at present may not yield clinically relevant information. In a select group of patients with unresponsive mycobacterial infection, immunologic investigation may be undertaken in consultation with Infectious Diseases.

### Tuberculosis

Among the four species of *M. tuberculosis* complex, *M. tuberculosis* and *M. bovis* are associated with the most cases of tuberculosis in humans. Of infections due to the other two species, *M. africanum* causes rare tuberculosis-like illness in Africa and *M. microti*, an agent associated with devastating infection among rodents, leads to rare, accidental infection in humans.

### Acute Infection and Risk of Disease

As humans are the only reservoir of *M. tuberculosis*, infection is spread from person to person, and the most common method of transmission is via

inhalation of aerosolized respiratory secretions from an infected individual. Exposure to patients with acid-fast bacilli (AFB) positive sputum smear have a 25 to 50% risk of acquiring infection. In certain situations such as close, prolonged exposure (especially in overcrowded situations), the attack rate may be as high as 80%.<sup>34</sup> Interestingly, in patients with smear-negative active pulmonary infection, risk of transmission to a non-infected person is not significantly higher than the risk of infection acquisition in the community at large.<sup>35</sup> Nursing home residents are at a higher risk of infection, which may present several predisposing risks, including prolonged close exposures to other individuals compounded by age-associated senescence of adaptive cellular immune response.<sup>36</sup> Other settings that may increase the risk of spreading tuberculosis include shelters for the homeless and correctional facilities. However, it is important to state that only a fraction of patients, after *M. tuberculosis* infection, will go on to develop clinical tuberculosis, and the lifetime risk in the general population varies from 5% to 15%. In contrast, individuals with severe immune suppression have a very high risk of developing active disease following acute infection. Patients with renal failure, alcoholism, malnutrition, underlying malignancy, prolonged systemic corticosteroid use, stem cell and organ transplantation, and especially AIDS, have a nearly 8% to 10% per year lifetime risk of developing tuberculosis after acute infection.<sup>37</sup>

### Pulmonary Tuberculosis

This by far is the most common presentation of tuberculosis. Most pulmonary infections present as reactivation of remotely acquired infection, although in the developed countries, a substantial proportion of pulmonary infection represents recently acquired infection, especially in the non-immigrant native population.

#### Primary Pulmonary Tuberculosis

In contrast to young individuals, adults are immunologically better equipped to handle acute *M. tuberculosis* infection; most infections remains localized to lungs; systemic dissemination seldom occurs; regional lymphadenopathy, if present, is modest, and erythema nodosum or phlyctenular (vesicular) keratoconjunctivitis are not often seen. Pulmonary infiltrates remain localized, with minimal clinical signs and symptoms, especially in patients with ineffective immune defenses, which leads to delay in diagnosis and institution of appropriate therapy, and potentially increases the community- and hospital-based risk of spread of infection to other susceptible individuals.

#### Post-primary Pulmonary Tuberculosis

This is the prevalent form of disease worldwide. Infection is often asymmetrical and involves

apices of lungs and/or the apex of the lower lobes. Focal pneumonitis leads to caseous necrosis that drains in the bronchial tree to form a cavity and which remains patent due to fibrosis and inelasticity of the infected non-necrotic surrounding lung tissue. The caseous drainage in the bronchial tree leads to bronchogenic spread of tuberculosis to other patients with unaffected lungs, and also extends to the trachea, larynx and oropharynx. Along with bronchogenic spread, the organism-rich caseous drainage (via aerosolized respiratory droplets) plays a central role in person-to-person transmission of infection. Infections in this setting are often limited to lungs, and hematogenous spread is kept in check for the most part due to hypersensitivity-induced thrombosis of the involved pulmonary parenchyma. In contrast to primary pulmonary tuberculosis, lymphadenopathy and calcification of paratracheal and mediastinal lymph nodes is not present.

The pulmonary cavities, especially those with thick walls, remain patent for extended periods after completion of effective anti-tuberculosis therapy. These patent cavities provide favorable milieu for secondary superinfections due to *Aspergillus* spp and other nontuberculous mycobacteria. Patients may present with new-onset hemoptysis without the evidence of recurrent tuberculosis. In most cases, this represents locally angioinvasive *Aspergillus* superinfection. This clinical presentation should be considered in the background of more ominous *M. tuberculosis*-associated erosion of pulmonary artery (Rasmussen's aneurysm), which may result in serious hemoptysis, exsanguinations, and death.

In elderly patients, post-primary tuberculosis of the lung may present as a chronic infection that spears upper lobes and that is difficult to distinguish from other infectious causes of chronic pneumonia. A high level of suspicion is needed to attempt an early diagnostic intervention in elderly patients in whom what appears to be bacterial pneumonia fails to respond to appropriate broad-spectrum antimicrobial therapy.

Constitutional symptoms such as loss of appetite, low-grade late-afternoon fever, night sweats, and weight loss are classically described in patients with post-primary tuberculosis, although in patients with cancer or recipients of transplantation, these symptoms do not help in diagnosis of tuberculosis. Cough is invariably present, although in chronic cases, cough may be well compensated. Occasional hemoptysis is also suggestive of tuberculosis, although in cancer patients with severe thrombocytopenia, this important feature becomes subdued as a cardinal sign of advancing pulmonary tuberculosis. Sero-fibrinous pleural effusion may accompany a long-standing untreated infection, and true plural tuberculous empyema are seldom seen in the post-anti-tuberculous chemotherapy era.

In patients with advancing pulmonary tuberculosis, the upper respiratory tract may be involved, including the well-described (although now seldom seen) laryngeal disease. Most laryngeal infection now represents hematogenous seeding rather than what used to be an extension of pulmonary tuberculosis via bronchogenic spread. Nevertheless, patients with untreated laryngeal tuberculosis pose a serious public health risk, as they are able to aerosolize a large number of viable infectious organisms leading to high rate of disease transmission. Laryngeal infections are often pleomorphic, and ulcerative or exophytic lesions may be mistaken for cancer.

### Diagnosis

A high level of suspicion is central in the early diagnosis of tuberculosis. Early-morning sputum, or gastric aspirates in patients who do not produce sputum may provide diagnosis in the majority of patients with pulmonary disease. Although AFB-negative sputum does not eliminate the possibility of *M. tuberculosis* infection, especially in immunosuppressed cancer patients, diagnostic bronchoalveolar lavage via fiberoptic bronchoscopy, with or without transbronchial biopsy, may be able to enhance diagnostic yield. Percutaneous fine-needle aspiration or video-assisted thoracotomy may be undertaken to obtain samples of lung, pleura, and lymph nodes in patients suspected of cryptic tuberculosis if other less invasive procedures fail to provide conclusive results.

### Treatment

Prior to the availability of effective anti-tuberculosis therapy, disease progressed in three out of four patients, despite various now-antiquated methods, including iatrogenic collapse of the affected lung. This changed dramatically with the availability of streptomycin and, more importantly, isoniazid and rifampin making sanatorium-based treatment obsolete. The post-antibiotic era, however, has become marred with the emergence and global spread of *M. tuberculosis* strains that are resistant to the bactericidal drugs isoniazid and rifampin (strains known as multi-drug resistant tuberculosis (MDR-TB)).

For infections due to drug-sensitive *M. tuberculosis*, the duration of therapy is suggested as 6 to 9 months, although shorter courses have been tried with variable success. The recommended four first-line drug regimen includes a combination of isoniazid, rifampin plus pyrazinamide for the first 8 weeks; ethambutol hydrochloride is included in most regimens, along with pyrazinamide, for the first 2 months of therapy. Patients receiving the ethambutol-based regimen should have visual examinations at frequent intervals to detect ocular toxicity before the patient become symptomatic.

Other anti-tuberculosis agents include streptomycin and levofloxacin, which are regarded as first-line agents, although they are not recommended in the initial choice of drug combinations for the patient who tolerates the suggested 3- or 4-drug combination. Agents known as second-line drugs are ethionamide, cycloserine, kanamycin, capreomycin, para-aminosalicylic acid, and clofazamine. These antimicrobials are reserved for patients who are either intolerant to the first-line drugs, or more importantly, in the treatment of infections due to MDR-TB.

Systemic corticosteroids may be used cautiously in patients who are on effective anti-tuberculosis therapy. Indications for a limited systemic steroid use include patients who are severely debilitated with serous anemia, hypoalbuminemia, protracted hectic fevers, and those with refractory life-threatening hypoxia.

### Extrapulmonary Tuberculosis

*M. tuberculosis* can infect almost any body site. Extrapulmonary tuberculosis is considered an infection involving a non-pulmonary end-organ site, and, at present, bloodstream invasion is the most common method of tuberculosis systemic spread. Bronchogenic spread of tuberculosis to the upper respiratory tract or larynx, or contiguous spread to the pleural space or to the chest wall are discussed elsewhere.

#### Tuberculous Lymphadenitis

Scrofula is the predominant form of extrapulmonary tuberculosis; the cervical lymph node chain along the anterior border of the sternocleidomastoid muscle is commonly involved. Infection is often unilateral with minimum constitutional symptoms. Excisional lymph node biopsy is diagnostic, although precautions are needed to prevent post-surgical fistula tract formation. In patients with bilateral, or multicentric tuberculous lymphadenitis, evaluation for an underlying HIV-associated immune suppression is warranted, as widespread tuberculous lymphadenitis represents more severe systemic disease; patients in this setting often have systemic symptoms and are ill-appearing.<sup>38</sup> In localized cervical infection, a short course (6 months) of therapy may be adequate in patients with drug-susceptible strains of *M. tuberculosis*. A paradoxical lymph node enlargement, pain, or fistula formation during or after completion of antituberculous therapy represent the hosts' inflammatory response, which may be treated with a short course of systemic corticosteroids, especially in patients with a clinically disabling paradoxical reaction. This, however, must not be confused with immune reconstitution syndrome noted in patients with highly active antiretroviral-therapy-induced immune reconstitution.

#### Miliary Tuberculosis

The current description of miliary tuberculosis is hematogenous dissemination of *M. tuberculosis* via the bloodstream to remote body sites. Miliary tuberculosis may either present as an acute or cryptic form of disease. In the post-antibiotic era, miliary tuberculosis is most frequently reported in patients with cancer, those receiving antineoplastic therapy, chronic alcoholism, cirrhosis of the liver, and patients with rheumatologic diseases.<sup>39-41</sup> Secondary foci of infection include the meninges, peritoneum, liver, adrenals, kidneys, and pleura. In the lungs, a miliary radiographic pattern may help in establishing the correct diagnosis, although lymphangitic spread of solid-organ cancer, widespread pulmonary lymphoma, and invasive fungal infections can present a miliary pattern, which is difficult to distinguish from tuberculosis. Rapid diagnosis is imperative, as is a biopsy of either enlarged lymph nodes or a scrotal mass; the finding of caseating granulomas on liver or bone marrow biopsy should alert the healthcare provider to the possibility of disseminated tuberculosis and to the prompt institution of combination therapy, including isoniazid, rifampin and pyrazinamide. In patients with severe hypoxemia refractory to supplemental oxygen therapy or patients with evidence of disseminated intravascular coagulation, adjuvant systemic corticosteroid therapy is suggested.

#### Skeletal Tuberculosis

In the developed countries, tuberculous spondylitis (or Pott's disease) involves elderly rather than young adults as it does in regions of endemic tuberculosis. This potentially devastating disease of the spine originates as either due to a remotely acquired infection via hematogenous route or, less likely, extension from pleural or peritoneal tuberculosis, and rarely via lymphatic spread. The primary site of infection is intervertebral disc space; adjoining vertebral bones become involved as the infection progresses. In nearly half the patients, at the time of diagnosis, infection may involve paraspinal space, and if unchecked, the paraspinal abscess may lead to fistula formation. Compromise of motor functions is a serious concern in patients with paraspinal abscess. Any sign of lower-extremity weakness, loss of sensation, or paresthesia must be investigated with a contrast-enhanced MRI scan to evaluate possible nerve root or spinal cord compromise, which, if untreated, will result in devastating paralysis. In some instances, paralysis may develop after anti-tuberculosis treatment has commenced; this paradoxical reaction may warrant emergent laminectomy to relieve pressure and prevent spinal cord damage.

Similarly, osteoarticular tuberculosis is a disease of the elderly; multiple joints may be involved with periarticular abscess formation. In one study,

the shoulder joint was the most frequently involved joint, in contrast with monoarthric disease of the past, which usually involved knee or hip joints.<sup>42,43</sup> Patients may also present with tuberculous tenosynovitis in the hand. A patient with chronic wrist joint tuberculous may seek medical attention due to carpal tunnel syndrome.

#### Genitourinary Tuberculosis

Most patients with renal tuberculosis have either a history of, or ongoing, active pulmonary tuberculosis. Rarely, patients with cryptic, slowly progressive miliary (hematogenous) tuberculosis may develop features of renal mycobacterial disease. Papillary necrosis, urethral strictures, scarring-related asymmetrical hydronephrosis, cavitory lesions in the renal cortex, and focal renal calcifications are all seen with, and considered, features of renal tuberculosis. Diagnostic workup consists of first-of-the-day voided urine sample, AFB stain, and mycobacterial cultures. An intravenous pyelogram may show the collection channel abnormalities mentioned above. In selected cases, renal biopsy may be undertaken to establish appropriate diagnosis. Renal function is often preserved, although compromised renal function and hypertension are the hallmarks of the rarely seen tuberculous interstitial nephritis.

Female genital tract tuberculosis starts as hematogenous seeding of the endosalpinx; infection then spreads to the endometrium, ovaries, and cervix; the vagina is rarely involved. Most patients are diagnosed during workup for infertility, although menstrual irregularities and dull lower abdominal discomfort are not uncommon. Cervical and endometrial tuberculosis may present as an ulcerative mass that is frequently mistaken for cancer; similarly, patients with ovarian tuberculosis may receive a misdiagnosis of malignancy. Those with tuberculous peritonitis have been incorrectly diagnosed with metastatic ovarian cancer with carcinomatosis.<sup>44,45</sup>

#### Gastrointestinal Tuberculosis

In the era prior to the availability of effective anti-tuberculosis therapy, a large proportion of patients with active pulmonary disease would have concomitant gastrointestinal (GI) tract tuberculosis. Any part of GI tract may be involved, although the ileocecal area is the most frequent site of GI tuberculosis, presenting as chronic weight loss, anorexia, diarrhea, intestinal obstruction, and bleeding. In chronic untreated cases, patients may present with a palpable, soft, nontender, lower abdominal mass. Other features of enteric tuberculosis include intestinal obstruction, perforation, and fistula formation between the bowel loops and/or small intestinal lumen and skin (enterocutaneous fistula).

Hepatic and biliary tract tuberculosis has prominent obstructive patterns; alkaline phosphatase levels are disproportionately high compared with often normal levels of transaminase and bilirubin. Pancreatic tuberculosis presents as a mass in the epigastric retroperitoneal region, and is difficult to distinguish from cancer.

#### Tuberculous Peritonitis

Of the two varieties of peritoneal tuberculosis, the “serous” variety is common, whereas the “plastic” form, which presents as a “doughy abdomen” on examination, is seldom seen. Patients present with chronic weight loss, and have dull abdominal pain, recurring fever, and occasionally, clinical presentation may mimic acute bacterial peritonitis, especially in patients with end-stage cirrhosis of the liver. Similar to pleural tuberculosis, peritoneal fluid is often non-diagnostic. Biopsy of the involved peritoneum and/or direct peritoneal fluid polymerase chain reaction may improve probability of correct diagnosis. Treatment is same as that for pulmonary infection, and we recommend against the use of adjuvant corticosteroids to prevent intestinal obstruction, which may occur either during or after completion of anti-tuberculosis therapy.

#### Aural Tuberculosis

Aural tuberculosis is a rare infection and often misdiagnosed as a refractory bacterial otitis media, or otitis externa; in most patients, the only symptom is painless otorrhea. Infection leads to gradual loss of hearing, and granulomatous inflammation is in abundance. If unchecked, infection can lead to extensive destruction of mastoid and temporal bones. In some cases, caseation necrosis may extend into intracranial cavity and present as new onset seizures and with other neurological abnormalities.<sup>46</sup> Clinical worsening after institution of anti-tuberculosis therapy similar to tuberculous cervical lymphadenitis, or tuberculous meningitis may represent paradoxical reaction resulting from uncontrolled inflammatory response. In these select patients, a short course of systemic corticosteroids may ameliorate symptoms, while effective combination anti-tuberculosis therapy is continued.

#### Cutaneous Tuberculosis

Skin involvement may result from either direct inoculation, or extension from an infected underlying structure such as bone, joint, or lymph node. In patients with severe immune dysfunction, hematogenous dissemination may lead to skin lesions that are often multiple, asymmetrical, and widespread. In general, cutaneous tuberculosis can mimic a variety of cutaneous disorders; nodular lesions with underlying induration or necrotic ulceration are prominent findings.

Diagnosis requires full-thickness skin biopsy. Treatment depends on the underlying primary site of infection. In patients with hematogenous disseminated disease, treatment is the same as that for miliary tuberculosis.

#### Tuberculosis Mimicking Tumor

Tuberculosis can imitate clinical and radiographic features of various diseases; as mentioned earlier, abdominopelvic tuberculosis may be misinterpreted as cancer—especially infections involving the peritoneum, ovaries, uterus, and pancreas.<sup>43,44,47</sup> In patients with chronic, slowly progressive, indolent pulmonary tuberculosis may be mistaken for lung cancer.<sup>48</sup> In one study, nearly 60% of patients with focal pulmonary tuberculosis were referred to a comprehensive cancer for treatment of presumed lung cancer.<sup>12</sup> It is also important to realize that certain malignancies may be mistaken for tuberculosis, especially bronchoalveolar carcinoma, and pulmonary non-Hodgkin’s lymphoma.<sup>49,50</sup>

In patients with an underlying malignancy, the risk of tuberculosis reactivation is higher than in the general population.<sup>51</sup> Therefore, a high suspicion that tuberculosis may coexist with an undiagnosed cancer, or (in patients with known malignancies) that tuberculosis may develop concurrently, may help in early identification and institution of appropriate therapy.<sup>52–54</sup> A diagnostic attempt may include fiberoptic bronchoscopic evaluation, transthoracic fine-needle aspiration, or evaluation of surgically obtained lung tissue, which may provide timely diagnosis in a select group of patients in whom the probability of concurrent cancer and tuberculosis may coexist.<sup>55–58</sup>

#### Nontuberculous Mycobacteriosis

The scope of mycobacterial infections due to species other than *M. tuberculosis* have expanded near-exponentially in the recent past. In part, this increase is attributed to the widespread availability of newer molecular identification methods.<sup>59</sup> Most nontuberculous mycobacteria (NTM) are ubiquitous in nature, and unlike *M. tuberculosis*, person-to-person spread is not a significant means of transmission of infection. Isolation of these low-virulence mycobacteria is not uncommon, and, in immunologically intact, non-susceptible individuals, they frequently represent either laboratory/environmental contaminant or non-disease associated colonization of respiratory, orointestinal or genitourinary tracts. In patients with severe adaptive cellular immune defects, these mycobacteria may pose a serious threat.

Another feature that distinguishes these organisms from *M. tuberculosis* is that they exhibit variable antimicrobial susceptibility profiles and

they are often not susceptible to the first-line anti-tuberculosis agents. The NTM are discussed under two broad headings based on the time needed for them to grow in the laboratory. Slow-growing mycobacteria (SGM) are somewhat similar to *M. tuberculosis* and take between 4 to 8 weeks to grow in enriched culture medium, whereas in the case of rapidly growing mycobacteria (RGM) growth becomes evident within 7 days.

## Slow-Growing Mycobacteria

### *Mycobacterium avium-intracellulare*

*M. avium* and *M. intracellulare* were originally differentiated on the bases of virulence to chickens and rabbits, respectively. Human infections were reported in 1943, and during the 1980s and 1990s, increased appreciation of diseases associated with MAC has been attributed in part due to the HIV epidemic, although a higher number of HIV-negative patients have also been described as having infection diseases due to these NTMs.

Pulmonary infections are most common, and isolation of MAC in respiratory tract samples, including tracheal aspirate, or bronchial samples, by itself is not diagnostic of pulmonary MAC infection. Diagnosis requires presence of a radiographic and clinical disease that is compatible with MAC infection. The radiographic feature suggestive of pulmonary NTM includes small, multicentric nodules, tree-in-bud appearances, and/or small thin-walled cavitory lesions. Cough is the most prominent symptom; sputum production is relatively minimal, except in patients with severe cystic bronchiectasis. Chronic lung disease is a well-recognized predisposing factor in non-immunosuppressed patients, including patients with silicosis, chronic bronchitis, emphysema, and cystic fibrosis. Patients with healed fibrocavitory tuberculosis remains at risk for secondary *M. avium-intracellulare* infection.

Since the 1980s, an increasing number of MAC-associated pulmonary NTM cases have been noted in middle-aged and elderly women with no obvious immune defects. The most common feature of this illness is chronic cough, fatigue, inability to gain weight, depression, and, in advanced cases, multicentric, cystic bronchiectatic pulmonary lesions; fever and night sweats are often not present. Some authors described an underlying defect in IFN- $\gamma$  production in patients who were initially mischaracterized as having Lady Windermere syndrome.<sup>30,31</sup> This defect in the critical cytokine pathway has led to otherwise healthy patients to develop indolent, locally destructive pulmonary lesions due to environmental mycobacteria with low disease-causing potential in otherwise healthy individuals.

MAC infections are difficult to treat owing to resistance to several antimicrobial agents; therapeutic regimens comprise three to four

drugs to which clinical isolates are susceptible; rifampin, ethambutol, macrolide derivatives such as azithromycin and clarithromycin, plus a quinolone (like ciprofloxacin) are often used. Clofazimine-based regimens are not suggested owing to unacceptable drug toxicity and high mortality seen in HIV-seropositive patients with disseminated MAC. The duration of therapy is longer than that for patients with pulmonary tuberculosis. Most patients are treated for 18 to 24 months; in those with extrapulmonary disease, duration may be extended to 36 months.

### *Mycobacterium kansasii*

*M. kansasii* is antigenically related to *M. tuberculosis* and may be associated with false positive PPD due to antigenic cross-reactivity. Most infections in the United States are seen in urban centers situated in the southeast and Midwestern parts of the country. As animal studies suggest, presence of dust by unexplained mechanisms enhances disease-causing potential of *M. kansasii*<sup>60</sup>; it is not surprising that patients with pneumoconiosis are more susceptible to *M. kansasii* lung infection compared to the general population; infections are fourfold higher in men compared to women. Similarly, infections tend to be common with certain occupations that involve chronic exposure to dust. These include miners, welders, sandblasters, and painters.

Pulmonary infections are slowly progressive, although, unlike MAC, *M. kansasii* leads to lung involvement difficult to distinguish from tuberculosis. Infections frequently involve the upper lung lobes, and thin-wall cavities are seen routinely in patients with *M. kansasii* pulmonary nontuberculous mycobacteriosis. Treatment is rifampin-based, although rifampin-resistant strains are on the rise, especially in patients with AIDS receiving rifampin prophylaxis.<sup>61,62</sup> *M. kansasii* is intrinsically resistant to pyrazinamide,<sup>63</sup> and a large study has shown that isoniazid can be excluded for antimicrobial regimen.<sup>64</sup> Clarithromycin is often added with rifampin plus ethambutol, while awaiting rifampin susceptibility results.<sup>65</sup> Duration of therapy is 12 to 18 months.

### Other Slow-Growing Mycobacteria

*M. ulcerans*, *M. marinum*, *M. genavense*, *M. haemophilum*, and *M. simiae* are occasionally associated with infection in human.

*M. haemophilum* was almost exclusively seen in patients with severe immune dysfunction, either due to AIDS<sup>66</sup> or in recipients of hematopoietic stem cell transplantation.<sup>67</sup> Disseminated infections were common, and predilection for tendon sheaths, bone, and joints was similar to infection seen with RGM.

*M. simiae* complex includes *M. simiae*, *M. lentiflavum*, and *M. triplex*; like *M. kansasii*, these

SGMs lead to pulmonary disease that is difficult to distinguish from tuberculosis. However, nearly three-quarters of clinical isolates may be associated with no discernable disease.<sup>68,69</sup> In certain regions of the United States, it has become the second most frequent NTM.<sup>69</sup> Infections tend to be more refractory to antimicrobial therapy, and high frequency of drug resistance further complicates options for effective drug regimen. Clarithromycin, quinolones, ethambutol, cycloserine, and ethionamide show favorable in vitro activity.<sup>70</sup>

## Rapidly Growing Mycobacteria

These organisms exhibit prominent growth on solid culture medium within 7 days after incubation. The most recent distribution of pathogenic species includes *M. fortuitum* complex, which besides *M. fortuitum*, *M. mucogenicum*, and *M. septicum*, now also incorporates formerly known species of *M. chelonae* complex (*M. chelonae* and *M. abscessus*). *M. smegmatis* forms the newly described second group, including *M. smegmatis*, *M. wolinskyi*, and *M. goodii*.<sup>71</sup>

### Pneumonia

In patients with pulmonary nontuberculous mycobacteriosis in the United States, RGM are the third most common cause of NTM after MAC and *M. kansasii*, respectively. *M. abscessus* is associated with most pulmonary infections in the RGM group, whereas infections due to *M. fortuitum*, sub. sp. *fortuitum*, *M. smegmatis* sub. sp. *smegmatis*, and *M. goodii* are less frequent.<sup>72</sup> *M. goodii* has been mostly isolated in patients with aspiration lipoid pneumonia. Similar to SGM, isolation of RGM from respiratory tract samples is not sufficient to make a diagnosis of RGM infection; as in most cases, these organisms may represent either colonization or environmental contamination.

To establish an RGM's link to pulmonary disease, microbiologic isolation should be accompanied with radiographic and clinically compatible disease.<sup>73</sup> Clinical symptoms of pulmonary NTM, which at best are non-specific of mycobacterial infection, include chronic, minimally productive cough, low-grade fever, weight loss, and, in severe cases, hemoptysis may occur.<sup>73</sup>

Clinical and microbiological response to antimicrobial therapy for RGM pulmonary mycobacteriosis is less encouraging compared to treatment response in patients with SGM infections.<sup>74</sup> Drug combination including clarithromycin, high-dose cefoxitin plus amikacin have been associated with good clinical response, albeit microbiologically refractory *M. abscessus* infections are not uncommon.

### Skin and Soft Tissue Infection

*M. fortuitum* is the most common RGM that is often associated with skin and soft tissue infection

in immunologically competent patients; most infections occur due to accidental inoculation, such as stepping on a nail. Whereas most infections due to *M. chelonae* is seen in patients with a underlying predisposing condition, such as chronic corticosteroid use, rheumatoid arthritis, lupus, and cancer.<sup>73,75</sup>

Health-related infections occur sporadically and have been seen in patients after deep intramuscular injection, sternal wound infection following cardiac surgery, and after a variety of reconstructive and plastic surgical procedures, including augmentation mammoplasty and chest wall reconstruction after tumor resection.<sup>76</sup>

### Catheter-Related Infections

These infections have become the most common health care-related infections due to RGM; most infections involve patients with long-term indwelling intravascular catheters, and often catheter-insertion sites are involved. In cancer patients, *M. chelonae* and *M. abscessus* are by far the most common in this setting.<sup>77</sup> Recently identified RGM species are increasingly reported in patients with cancer with catheter-related infection. They include *M. smegmatis*,<sup>78</sup> *M. neoaurum*,<sup>79</sup> *M. aurum*,<sup>80</sup> *M. lacticola*,<sup>81</sup> and *M. brumae*.<sup>82</sup>

It is important to emphasize the fact that RGM are frequently isolated in hospital and laboratory water supplies, and a number of pseudo-outbreaks involving contaminated blood culture materials and fiberoptic bronchoscope sterilizing machine contamination have been described.<sup>83,84</sup> Therefore, a strict criteria must be instituted before attributing catheter infection to these low-virulence ubiquitous nontuberculous mycobacteria.<sup>85</sup> Treatment includes prompt removal of infected devices, and systemic combination antimicrobial therapy for 6 to 12 weeks. Selection of antimicrobials depends on RGM species; as a general rule, RGM are resistant to most anti-tuberculosis agents with the exception of ethambutol. In patients with *M. chelonae*-*M. abscessus* infections, selection of appropriate drug therapy is even more limited due to high-level intrinsic drug resistance. Clarithromycin-based regimens are currently recommended, although so are newer fluoroquinolones, such as gatifloxacin and moxifloxacin; linezolid in vitro profile also appears promising, although further clinical experience is needed before such treatment is recommended. Other agents under investigation includes tigecycline, a new glycoacycline that shows promising activity against most clinical isolates of *M. abscessus*.<sup>86</sup>

### Summary

*M. tuberculosis* has become a rare infection in patients receiving antineoplastic therapy in the

United States and tends to be prominent in non-native, foreign-born patient population. In recent years, a change in the underlying malignancy has also been noted as patients with leukemia and non-Hodgkin's lymphoma have overshadowed head and neck and gastric cancers. Most cancer patients have a favorable response to therapy, and multi-drug resistant strains are seldom encountered in this patient population.

The spectrum of non-tuberculosis mycobacteria is changing rapidly, as the immunopathogenesis of SGM continues to improve. In recent years, difficult-to-treat infections due to RGM are on the rise; this may, in part, reflect newer molecular identification methods, but a rise in the susceptible immunosuppressed patient population and the frequent use of indwelling prosthetic devices are also important contributors in this trend. Despite resistance to a number of available antimicrobials, newer agents may provide the much-needed treatment options for high-risk cancer patients with mycobacterial infection-disease.

# Hypercalcemia of Malignancy

Gregory A. Clines, MD, PhD  
Theresa A. Guise, MD

Malignancy is the most common cause of hypercalcemia in the hospitalized patient, and malignancy-associated hypercalcemia is one of the more common paraneoplastic syndromes. Up to 30% of patients with cancer may develop hypercalcemia during the course of their disease.<sup>1</sup> Generally, the cancer is well advanced when hypercalcemia occurs, and the prognosis is poor.<sup>2</sup> Survival beyond six months is uncommon.<sup>3</sup> The relative frequencies of malignancies associated with hypercalcemia are listed in Table 1.<sup>4</sup>

## Symptoms of Hypercalcemia

Symptoms of hypercalcemia (Table 2) may vary in individual patients and are related both to the absolute concentration of serum calcium and to the rate of rise in serum calcium.<sup>5</sup> Nonspecific gastrointestinal symptoms of anorexia, constipation, nausea, and vomiting may predominate. Optimal neurological function is dependent on extracellular calcium level and symptoms can range from subtle neuropsychiatric manifestations, such as irritability and depression, to muscle weakness, delirium, and even coma. Cardiovascular manifestations of hypercalcemia include arrhythmias and hypertension. Hypercalcemia causes an impaired ability of the distal nephron to concentrate urine, resulting in polyuria and polydipsia. The hypercalcemic effects of anorexia, nausea, vomiting, and impaired renal concentrating ability lead to dehydration and, subsequently, altered mental status. This, in turn, may promote immobilization and lead to worsening hypercalcemia.

**Table 1** Malignancies Associated with Hypercalcemia

Malignancy	Frequency (%)
Lung	35
Breast	25
Hematologic	14
Head and neck	6
Renal	3
Prostate	3
Unknown primary	7
Others	7

Reproduced with adapted from Mundy GR and Martin TJ.<sup>4</sup>

**Table 2** Clinical Features of Hypercalcemia

Neurologic and psychiatric	Lethargy, drowsiness Confusion, disorientation Disturbed sleep, nightmares Irritability, depression Hypotonia, decreased deep tendon reflexes Stupor, coma
Gastrointestinal	Anorexia, vomiting Constipation Peptic ulceration Acute pancreatitis
Cardiovascular	Arrhythmias Synergism with digoxin Hypertension
Renal	Polyuria, polydipsia Hypercalciuria Nephrocalcinosis Impaired glomerular filtration

## Humoral Mediators of Hypercalcemia of Malignancy

Hypercalcemia occurring in the setting of malignancy may be due to (1) humoral factors secreted by tumors that act systemically on target organs of bone, kidney, and intestine to disrupt normal calcium homeostasis; (2) local factors secreted by tumors in bone, either metastatic or hematologic, which directly stimulate osteoclastic bone resorption; and (3) coexisting primary hyperparathyroidism (1°HPT). The first two of these situations should be viewed as opposite ends of a continual spectrum, rather than as completely unrelated pathologies. Clearly the pathophysiology of hypercalcemia in patients with solid tumors and no bone metastases at one end of the spectrum, and myeloma associated with extensive local bone destruction adjacent to the tumor cells at the other, is very different. However, in between these extremes are hypercalcemic patients with squamous cell carcinomas in which hypercalcemia may occur with some, but not extensive, osteolytic bone metastases, and hypercalcemic patients with advanced breast carcinoma in which hypercalcemia almost never occurs in the absence

of extensive osteolytic bone destruction. Separating hypercalcemia into subcategories based on the assumption that the underlying mechanisms are distinct is not entirely satisfactory. This is because the mediators may be identical, except that in one situation it is a local mediator, while in another it is a humoral mediator. Additionally, if the tumor burden in bone is great, local tumor-produced mediators of bone resorption may be produced in sufficient quantities to have systemic effects. Although this review will discuss the effects of cancer on bone organized into such categories, it is important to understand that a significant portion of cancer patients will fall into the middle of this spectrum, having both humoral and local effects of tumor on bone.

## Parathyroid Hormone-Related Protein

Hypercalcemia has been associated with malignancy since the development of serum calcium assays in the 1920s. Only in 1941, however, did Fuller Albright advance the hypothesis that parathyroid hormone (PTH) is ectopically produced by certain tumor types. Over the subsequent five decades, investigators determined that PTH was not, in fact, the cause of humoral hypercalcemia of malignancy (HHM), but that a “PTH-like factor” was responsible for most cases. In 1987, this PTH related-protein (PTHrP) was purified from human lung cancer,<sup>6</sup> breast cancer,<sup>7</sup> and renal cell carcinoma<sup>8</sup> simultaneously by several independent groups and cloned shortly thereafter.<sup>9</sup>

PTHrP shares 70% sequence homology with PTH over the first 13 amino acids at the N-terminus. Beyond the initial amino-terminal sequence, the protein is unique and shows no further sequence homology with PTH. The cloned PTHrP protein is larger than PTH and three distinct isoforms of 139, 141, and 173 amino acids have been demonstrated. Similarly, the human PTHrP gene is much larger and more complex than the parathyroid hormone gene, spanning 15 kilobase of genomic deoxyribonucleic acid (DNA) and having nine exons and three promoters. Despite these differences, both PTH and PTHrP bind to a common PTH/PTHrP receptor<sup>10</sup> and share similar biologic activities.<sup>11</sup>

PTHrP has been detected in a variety of tumor types as well as in normal tissue.<sup>12,13</sup> The widespread expression of PTHrP in normal tissue was the first evidence that the hormone had a role in normal physiology. In addition to the PTH-like effects, emerging work testifies to the fact that PTHrP plays a role in the (1) regulation of cartilage differentiation and bone formation<sup>14</sup>; (2) the growth and differentiation of skin,<sup>15</sup> mammary gland,<sup>16</sup> and teeth<sup>17</sup>; (3) cardiovascular function<sup>18</sup>; (4) transepithelial calcium transport in mammary epithelia and placenta<sup>19,20</sup>; (5) relaxation of smooth muscle in the uterus, bladder, arteries, and ileum<sup>21–24</sup>; and (6) host immune function.<sup>25,26</sup> Normal subjects do not have detectable circulating levels of PTHrP, suggesting that, in normal physiology, PTHrP acts as a local regulator or cytokine in the tissues where it is produced.

Approximately 80% of hypercalcemic patients with solid tumors have detectable or increased plasma concentrations of PTHrP.<sup>7</sup> In addition to the diverse normal physiologic functions of PTHrP, it has a multifunctional role in cancer as well. Such identified functions include (1) mediating hypercalcemia; (2) aiding in the development and progression of osteolytic bone metastasis, as will be discussed in subsequent sections; (3) regulating growth of cancer cells<sup>27–29</sup>; and (4) acting as a cell survival factor.<sup>30</sup> The first identified consequence of PTHrP in cancer was the humoral hypercalcemia of malignancy syndrome.

#### Humoral Hypercalcemia of Malignancy versus 1°HPT

Despite similarities between the syndromes of HHM and 1°HPT and the similar biologic activities of PTHrP and PTH, respectively, unexplained differences between these syndromes exist. First, patients with PTHrP-mediated HHM have low 1,25-dihydroxyvitamin D<sub>3</sub> (1,25-(OH)<sub>2</sub>D<sub>3</sub>) levels compared to patients with 1°HPT, even though both hormones stimulate 1 $\alpha$ -hydroxylase activity.<sup>31</sup> Moreover, infusion of PTH or PTHrP in healthy volunteers over a 48-hour period increased plasma 1,25-(OH)<sub>2</sub>D<sub>3</sub> levels; however, PTH was more effective than PTHrP.<sup>32</sup> Second, while both syndromes have marked increases in osteoclastic bone resorption, many patients with HHM do not have the normally coupled increase in osteoblastic activity experienced by those with 1°HPT. Studies using either serum markers of bone turnover<sup>33</sup> or quantitative bone histomorphometry<sup>34</sup> have demonstrated this uncoupling of bone resorption from bone formation. Finally, unlike the metabolic acidosis seen in patients with 1°HPT, patients with HHM often have a metabolic alkalosis with a low plasma chloride and high plasma bicarbonate concentration. Although many explanations have been postulated for the discrepancies between HHM and 1°HPT, such as the pulsatile secretion of PTH and the apparent

continuous secretion of PTHrP and biologically active PTHrP fragment,<sup>35</sup> and suppression of bone formation and 1 $\alpha$ -hydroxylase activity by other tumor-associated factors, the reasons for these differences have not been adequately elucidated.

#### PTHrP in Hypercalcemia Associated with Breast Cancer

The role of PTHrP in breast cancer-associated hypercalcemia deserves special consideration. Breast cancer predominantly affects bone through metastatic mechanisms, typically with lytic deposits in the skeleton. Approximately 10% of women with breast cancer will have hypercalcemia as a complication at some point in the disease. The association of hypercalcemia with extensive osteolytic lesions in breast cancer is so strong that the presentation of hypercalcemia without bone metastases should suggest the presence of coexistent primary hyperparathyroidism.<sup>36</sup> Based on this association, it was long held that breast cancer-associated hypercalcemia results from excessive reabsorption of bone around tumor deposits. However, clinical studies<sup>3</sup> failed to demonstrate any relationship between the extent of bone metastasis and serum calcium levels. Conversely, studies exploring the potential role for a humoral mediator of hypercalcemia in breast cancer clearly demonstrated altered renal handling of calcium and phosphate, as well as increased nephrogenous cyclic adenosine monophosphate (cAMP), suggesting that 10 to 60% of hypercalcemic patients with breast cancer had a circulating factor with PTH-like properties. The identification of PTHrP as this factor is hardly surprising when it is recalled that PTHrP appears to play an important role in normal breast physiology. In the case of breast cancer, PTHrP appears to have both paracrine and endocrine actions.

PTHrP was detected by immunohistochemical staining in 60% of 102 invasive breast tumors removed from normocalcemic women, but not in normal breast tissue.<sup>37</sup> At least four other studies have confirmed these percentages, and one of these demonstrated immunoreactive PTHrP within the cytoplasm of lobular and ductal epithelial cells in normal and fibrocystic breast tissues.<sup>38–41</sup> Furthermore, 65 to 92% of hypercalcemic breast cancer patients (with and without bone metastasis) had detectable plasma PTHrP concentration by radioimmunoassay similar to those documented in patients with humoral hypercalcemia of malignancy due to non-breast tumors.<sup>38,42</sup> PTHrP is an important mediator of hypercalcemia in breast cancer. It also plays a significant role in the pathophysiology of breast cancer metastasis to bone, as evidenced by clinical studies indicating that PTHrP expression by primary breast cancer is more commonly associated with the development of bone metastasis and hypercalcemia.<sup>39</sup>

#### PTHrP in Hypercalcemia Associated with Hematologic Malignancies

Hypercalcemia associated with hematologic malignancies results both from systemic effects of tumor-produced factors such as 1,25-(OH)<sub>2</sub>D<sub>3</sub> (discussed below), and from secretion of local bone-active cytokines, such as interleukin-6 (IL-6), IL-1, and lymphotoxin or TNF $\beta$ , from tumor in bone. PTHrP has been demonstrated to be an important pathogenic factor in the development of hypercalcemia in some patients with hematologic malignancies. In a clinical study of 76 patients with various hematologic malignancies, 50% of the 14 hypercalcemic patients had significant increases in plasma PTHrP concentrations.<sup>43</sup> Of these, five had non-Hodgkin's lymphoma, one had Hodgkin's disease, and one had multiple myeloma. The serum 1,25-(OH)<sub>2</sub>D<sub>3</sub> concentrations, when measured, were low in the hypercalcemic non-Hodgkin's lymphoma patients who had increased plasma PTHrP concentrations. Also of interest in this study is the fact that several normocalcemic patients with non-Hodgkin's lymphoma, Hodgkin's lymphoma, multiple myeloma, and Waldenström's macroglobulinemia had increased plasma PTHrP concentrations as measured by an amino-terminal PTHrP assay. Using a sensitive, two-site immunoradiometric assay, other investigators have noted increased plasma PTHrP concentrations in patients with adult T cell leukemia and B cell lymphoma.<sup>44</sup> Finally, in separate studies, circulating concentrations of PTHrP (comparable to those in HHM) were present in two of four hypercalcemic patients with non-Hodgkin's lymphoma, in three of nine with myeloma, and in a patient with myeloid blast crisis of chronic myeloid leukemia.<sup>45,46</sup> Thus, the humoral mediators in the hypercalcemia associated with hematologic malignancies include both 1,25-(OH)<sub>2</sub>D<sub>3</sub> and PTHrP.

#### 1,25-Dihydroxyvitamin D

Under normal physiologic conditions, serum calcium concentration and levels of 1,25-(OH)<sub>2</sub>D<sub>3</sub> are inversely related. In the setting of hypercalcemia, serum 1,25-(OH)<sub>2</sub>D<sub>3</sub> concentrations are suppressed unless there is persistent stimulation of 1 $\alpha$ -hydroxylase activity from an autonomous source of PTH, such as with primary hyperparathyroidism. Outside of this situation, lack of 1,25-(OH)<sub>2</sub>D<sub>3</sub> suppression indicates abnormal regulation of 1,25-(OH)<sub>2</sub>D<sub>3</sub> synthesis and further suggests extra-renal production such as that observed with granulomatous disease. In granulomatous disease, activated macrophages within the granuloma synthesize 1,25-(OH)<sub>2</sub>D<sub>3</sub>.<sup>47–49</sup> Similarly, a major mediator of hypercalcemia in Hodgkin's disease, non-Hodgkin's lymphoma, and other hematologic malignancies appears to

be an extra-renal production of  $1,25\text{-(OH)}_2\text{D}_3$ .<sup>50</sup> The mechanism is similar to that observed in granulomatous disease. In this scenario, hypercalcemic patients have increased plasma  $1,25\text{-(OH)}_2\text{D}_3$  concentrations with low or normal plasma PTH and urinary cAMP concentrations,<sup>51</sup> without the presence of bone involvement. Affected patients have also been shown to have increased fasting urinary calcium excretion<sup>51</sup> as well as increased intestinal calcium ( $^{47}\text{Ca}$ ) absorption.<sup>52</sup> Increased  $1,25\text{-(OH)}_2\text{D}_3$  concentrations were noted in 12 of 22 hypercalcemic patients with non-Hodgkin's lymphoma. In addition, 71% of 22 normocalcemic patients with non-Hodgkin's lymphoma were hypercalciuric, and 18% had increased serum  $1,25\text{-(OH)}_2\text{D}_3$  concentrations. These findings led the investigators to conclude that dysregulated  $1,25\text{-(OH)}_2\text{D}_3$  production was common in patients with diffuse large cell lymphoma.<sup>50</sup> The low serum PTH and urinary cAMP concentrations indicated that neither PTH nor PTHrP mediated the hypercalcemia in this setting. Prostaglandins, when measured, have been low, and selected patients had no calcium-lowering effect from indomethacin therapy.<sup>45</sup>

Thus, the mechanisms responsible for hypercalcemia in this setting appear to be multifactorial and include  $1,25\text{-(OH)}_2\text{D}_3$ -mediated increases in intestinal absorption of calcium and osteoclastic bone resorption. Additionally, many of the reported patients had altered renal function, a finding that suggests that impaired renal calcium clearance may also be contributing to the hypercalcemia in certain patients. It is likely that the lymphoma tissue itself hydroxylates 25-hydroxyvitamin D to the active  $1,25\text{-(OH)}_2\text{D}_3$  similar to the situation in hypercalcemia associated with granulomatous disease. One  $\alpha$ -hydroxylase activity has been demonstrated in human T cell lymphotropic virus type-I-transformed lymphocytes as well as in other extrarenal tissues.<sup>53,54</sup> None of the reported patients with  $1,25\text{-(OH)}_2\text{D}_3$ -mediated hypercalcemia had concomitant granulomatous disease; and hypercalcemia often improved with medical or surgical therapy that resulted in a decrease in serum  $1,25\text{-(OH)}_2\text{D}_3$  concentration. Recurrence of hypercalcemia and increased plasma  $1,25\text{-(OH)}_2\text{D}_3$  concentrations has been documented with recurrence of disease.<sup>55</sup>

### Parathyroid Hormone

For many years after Fuller Albright's observations in 1941, malignancy-associated hypercalcemia was attributed to ectopic-tumor-produced PTH. It is now clear that PTHrP is responsible in the great majority of cases of HHM. There have been rare cases, however, of authentic-tumor-produced PTH causing hypercalcemia. Specifically, ectopic PTH production has been

documented in a small cell carcinoma of the lung,<sup>56</sup> a squamous cell carcinoma of the lung,<sup>57</sup> an ovarian cancer,<sup>58</sup> a widely metastatic primitive neuroectodermal tumor,<sup>59</sup> a papillary adenocarcinoma of the thyroid<sup>60</sup> and a thymoma.<sup>61</sup> Molecular analysis of the ovarian carcinoma revealed both DNA amplification and rearrangement in the upstream regulatory region of the PTH gene. Interestingly, the primitive neuroectodermal tumor produced both PTH and PTHrP that resulted in severe hypercalcemia. These reported patients did not have coexisting primary hyperparathyroidism since the parathyroid glands were normal at the time of neck exploration or at autopsy in all cases. However, the fact remains that ectopic production of PTH is a rare event, and it is clearly documented that most patients with malignancy-associated hypercalcemia have suppressed plasma PTH concentrations.<sup>62</sup> It should be emphasized that the most likely cause of hypercalcemia in the setting of malignancy that is associated with a normal or increased serum PTH concentration is co-existing hyperparathyroidism.

### Other Tumor-Associated Factors

There is accumulating evidence that solid tumors may produce other humoral factors, either alone or in combination with PTHrP, that have the capacity to stimulate osteoclastic bone resorption and cause hypercalcemia. These factors include IL-1, IL-6, transforming growth factor  $\alpha$  (TGF $\alpha$ ), tumor necrosis factor (TNF) and granulocyte colony-stimulating factor (G-CSF). Administration of IL-1 injections to mice caused a mild hypercalcemia,<sup>63,64</sup> which has been effectively blocked by the IL-1 receptor antagonist.<sup>65</sup> Mice bearing Chinese hamster ovarian tumors transfected with the complementary DNA for IL-6 developed mild hypercalcemia,<sup>66</sup> as did mice bearing a renal carcinoma that cosecreted IL-6 and PTHrP.<sup>67</sup> High serum levels of IL-6 in patients with humoral hypercalcemia of malignancy have also been reported.<sup>68,69</sup>

Human TGF $\alpha$  and TNF $\alpha$  stimulated osteoclastic bone resorption in vitro and resulted in hypercalcemia in vivo.<sup>70-72</sup> TNF $\alpha$  also caused hypercalciuria, without an increase in nephrogenous cAMP, and increased osteoclastic bone resorption in vivo in a mouse model.<sup>73</sup> In addition, as noted in the previous section, some of these factors have been shown to modulate the end-organ effects of PTHrP on bone and kidney. In some instances, factors such as TGF $\alpha$ , IL-1, IL-6, and TNF enhanced the hypercalcemic effects of PTHrP. The ability of IL-6 to enhance PTHrP-mediated hypercalcemia appeared to be due to increased production of the early osteoclast precursors by IL-6 (as measured by granulocyte macrophage colony forming units), in combination with increased production of

the more committed osteoclast precursors by PTHrP.<sup>74</sup>

Prostaglandins of the E series are powerful stimulators of bone resorption,<sup>75</sup> although their role in bone destruction associated with malignancy remains unclear.<sup>76</sup> Some of the effects of cytokines on bone may be mediated in part through prostaglandins. Indomethacin, a prostaglandin synthesis inhibitor, and has been shown to block part of the osteoclast-stimulatory effects of IL-1 in vivo.<sup>63,64</sup> Although prostaglandins have been demonstrated to be produced by cultured tumor cells in vitro, indomethacin treatment of malignancy-associated hypercalcemia is only occasionally effective.<sup>77</sup> Thus, it is unlikely that prostaglandins have a major causal role in hypercalcemia associated with malignancy.

### Treatment of Hypercalcemia of Malignancy

The ultimate treatment of malignancy-associated hypercalcemia is eradication of the underlying cancer. However, cure is frequently not possible, and in patients with symptomatic or life-threatening hypercalcemia, therapy must be aimed specifically against the mediating mechanisms. Increased osteoclastic bone resorption is present in essentially every patient with hypercalcemia of malignancy and is, therefore, a key target for treatment and prevention of hypercalcemia. Two of these mechanisms in particular, increased osteoclastic bone absorption and increased renal tubular calcium reabsorption, are common to most patients with hypercalcemia of malignancy, even those cases not associated with PTHrP production.<sup>78</sup> Medical therapy is therefore aimed at inhibiting bone resorption and promoting renal calcium excretion.

Because many hypercalcemic patients are dehydrated at presentation, the latter can be effectively addressed with intravenous administration of isotonic saline. This first step of therapy serves to rehydrate the patient while enhancing calciuresis by increasing the glomerular filtration rate and reducing the fractional reabsorption of calcium and sodium. The use of loop diuretics, such as furosemide, to enhance calcium excretion is frequently overemphasized in clinical practice. These agents may exacerbate fluid loss; therefore their use should be limited to the volume-repleted patient and only then with close monitoring of volume status.<sup>79</sup> Hydration alone rarely results in full resolution of hypercalcemia,<sup>80</sup> however, and more aggressive therapies are usually needed.

Bisphosphonates are currently the mainstay for long-term treatment of hypercalcemia and osteolytic bone disease. They have an affinity for bone surfaces undergoing active resorption and are released in the bone microenvironment during remodeling. These compounds decrease

osteoclastic bone resorption by two described mechanisms. First, the nitrogen-substituted bisphosphonates, such as alendronate, risedronate and zoledronic acid, are potent inhibitors of the enzyme farnesyl diphosphate synthase, thereby blocking protein isoprenylation. It is believed that the prenylation of small GTP-binding proteins is important for structural integrity of the osteoclast; without it, the osteoclasts undergo apoptosis. Second, the non-nitrogen containing bisphosphonates, clodronate and etidronate, are less potent and also induce osteoclastic apoptosis but by a different mechanism. These bisphosphonates are metabolically incorporated into nonhydrolyzable ATP analogs that inhibit ATP-dependent intracellular enzymes. The bisphosphonates have been known to inhibit osteoclastic bone resorption for over 30 years.

There are also several lines of evidence that suggest bisphosphonates affect osteoclastic bone resorption indirectly through actions on osteoblasts. For example, bisphosphonates have previously been shown to have multiple actions on osteoblasts such as (1) modulation of proliferation and differentiation<sup>81</sup>; (2) prevention of apoptosis<sup>82</sup>; (3) modulation of extracellular matrix protein production<sup>83,84</sup>; (4) regulation of the expression and excretion of IL-6<sup>85,86</sup>; and (5) decrease of angiogenesis.<sup>87,88</sup> Recently, Viereck and colleagues presented *in vitro* evidence that bisphosphonates act directly on human osteoblasts to increase the production of both osteoprotegerin (OPG) messenger ribonucleic acid (mRNA) and protein.<sup>89</sup> Clearly, the implication is that by increasing OPG expression, the receptor activator of NF- $\kappa$ B ligand (RANKL)-mediated stimulation of osteoclasts can be neutralized.

The various bisphosphonates available on the market vary in potency, but all are poorly absorbed from the gut and are most effective for treatment of hypercalcemia when used intravenously. Intravenous etidronate, the least potent of its class, normalized calcium concentration in 30 to 40% of patients when given in doses of 7.5 mg/kg on three consecutive days.<sup>90–92</sup> Oral etidronate, at dosages of 25 mg/kg/d for more than 6 months can cause bone mineralization defects.<sup>93</sup> Pamidronate, alternatively, combines high potency with low toxicity and has become the agent of choice for the treatment of hypercalcemia of malignancy. When used in the recommended doses of 30 to 90 mg intravenously over 4 to 24 hours, it is highly effective in normalizing serum calcium concentrations and is not associated with mineralization defects. The onset of clinically apparent action is somewhat delayed with the bisphosphonates. Clinical studies using a 90-mg infusion of pamidronate over 4 hours indicate that the mean time to achieve normocalcemia is approximately 4 days, while the mean duration of normocalcemia is 28 days.<sup>94</sup> An

effective method for achieving a rapid and sustained reduction in serum calcium concentration is to use pamidronate in combination with calcitonin. The combined use of a bisphosphonate with calcitonin lowers serum calcium levels more rapidly and effectively than either alone.<sup>95</sup>

Zoledronic acid, the most potent bisphosphonate available, is very effective for the treatment of hypercalcemia of malignancy. At doses of 4 mg and 8 mg, this bisphosphonate was compared to a single 90-mg infusion of pamidronate in patients with hypercalcemia of malignancy. Zoledronic acid was superior in respect to response rates, time to calcium normalization, and response duration.<sup>96</sup> The 4-mg dose is FDA-approved, as renal dysfunction occurred with the 8-mg dose.

Inhibiting osteoclastic bone resorption and renal tubular calcium reabsorption within minutes of administration, calcitonin also makes an excellent agent for the acute treatment of hypercalcemia. Unfortunately, tachyphylaxis frequently develops within 48 hours as a result of down-regulation of the calcitonin receptor. Concomitant use of glucocorticoids, however, can prolong the effective time of treatment.<sup>97</sup> This effect appears to result from a glucocorticoid mediated up-regulation of cell-surface calcitonin receptors and increased *de novo* production of calcitonin receptors in the osteoclast.<sup>98</sup> Calcitonin can be administered every 6 to 12 hours in doses of 4 to 8 U/kg. Human calcitonin is available, but salmon calcitonin is generally used. If salmon calcitonin is used, then a test dose of 1 unit should be administered first, since rare anaphylactic reactions have been reported.

Two antineoplastic agents have been used effectively for the treatment of malignancy-associated hypercalcemia, but are rarely used now. Plicamycin, formerly called mithramycin, is an inhibitor of DNA-dependent RNA synthesis and a potent inhibitor of bone resorption. The dosage used to treat hypercalcemia (25 mcg/kg) is one-tenth the usual chemotherapeutic dose and should be infused over 4 hours. It has considerable side effects of nephrotoxicity, hepatotoxicity, thrombocytopenia, nausea, and vomiting. Gallium nitrate is another antineoplastic agent with calcium-lowering effects. It also has serious nephrotoxicity and is somewhat inconvenient to use as it is administered over a continuous 5-day infusion. Use of these antineoplastic agents should be reserved for cases of hypercalcemia that are unresponsive to maximum doses of bisphosphonates.

Finally, about 30% of patients treated with glucocorticoids for malignancy-associated hypercalcemia respond with a fall in serum calcium concentration. Glucocorticoids are most likely to have clinical effect in the setting of hypercalcemia associated with multiple myeloma or hematologic malignancies associated with 1,25-(OH)<sub>2</sub>D<sub>3</sub>. In

these situations, glucocorticoids inhibit osteoclastic bone resorption by decreasing tumor production of locally active cytokines, in addition to having direct tumorolytic effects.<sup>99</sup> Glucocorticoids, in dosage equivalents of 40 to 60 mg of prednisone daily, should be given. If no appreciable response is observed within 10 days, then glucocorticoid therapy should be discontinued.

In conclusion, hypercalcemia of malignancy is due to a heterogeneous group of tumor-derived factors that disrupt normal calcium homeostasis. Regardless of the pathophysiology, in most instances, the central mediator of this process is the osteoclast. The standard of care for this complication of malignancy is now bisphosphonate treatment, which is effective in most cases. However, the possibility of bisphosphonate resistance has emerged. Thus, future therapeutic options should address this issue. Possible alternative therapies include inhibitors of the RANKL pathway or neutralizing antibodies to PTHrP. The latter would also reverse the increased renal tubular reabsorption of calcium caused by increased PTHrP concentrations. Clinical trials, in progress, should determine if these modalities will be as effective or complementary to bisphosphonate treatment.

# Endocrine Paraneoplastic Syndromes

Mimi I. Hu, MD

Sai-Ching Jim Yeung, MD, PhD

Robert F. Gagel, MD

Paraneoplastic syndromes are cancer-associated clinical syndromes caused by biologic or humoral factors, including hormones, cytokines, and immunoglobulins. In this chapter, we focus on the endocrine paraneoplastic syndromes, also known as ectopic hormone syndromes, other than hypercalcemia of malignancy, which is discussed in Chapter 23, “Endocrine Neoplastic Syndromes.”

Early awareness of a paraneoplastic syndrome is important clinically. An occult malignancy may initially manifest as a paraneoplastic syndrome, which can allow for early detection and treatment and potential cure. Treatment of the effects of the syndrome can be palliative even if a cure for the tumor is implausible. When a paraneoplastic syndrome mimics the effects of metastatic disease, however, a patient may be mistakenly considered an inappropriate candidate for potentially curative treatments. Development of the syndrome can also be used as a marker of tumor recurrence or to signify a poor prognosis. Autocrine growth hormones (GHs) causing the syndrome are potential therapeutic targets.

The mechanisms underlying ectopic hormone production may vary between different tumors. In some examples, the tumor cells may have produced the hormone during an earlier stage in their development. For example, parathyroid hormone-related protein, the cause of hypercalcemia of malignancy, is normally expressed in actively differentiating squamous cells but is expressed at low levels or not at all in completely differentiated squamous epithelium.<sup>1</sup> In addition, the production of hormone precursors and peptides that may be normally produced by nonendocrine tissues can increase with neoplastic transformation.<sup>2,3</sup> In other cases, the synthesizing machinery of a hormone-producing cell is coopted to produce a different hormone. Production of peptides by neuroendocrine tumors is the most common ectopic hormone mechanism of this type. Neuroendocrine cells are dispersed through nearly all organs: lung, gastrointestinal tract, pancreas, thyroid gland, adrenal medulla, breast, prostate, and skin. These neural

crest-derived cells may produce biogenic amines and a long list of polypeptide hormones, including adrenocorticotrophic hormone (ACTH), corticotropin-releasing hormone (CRH), growth hormone-releasing hormone (GH-RH), calcitonin, vasoactive intestinal peptide, and pancreatic polypeptide.

## Ectopic Adrenocorticotrophic Hormone Syndrome

Ectopic ACTH secretion causing Cushing’s syndrome was the second hormonal syndrome—after hypercalcemia of malignancy—to be associated with cancer in 1928.<sup>4</sup> Tumoral production of CRH is a rare cause of paraneoplastic Cushing’s syndrome.

### Tumors

Among all patients with Cushing’s syndrome, 40% have an obvious pituitary tumor causing Cushing’s syndrome, 28% have a nonvisible pituitary source, 17% have adrenal hypersecretion of cortisol, and 15% have ectopic ACTH secretion from an underlying tumor.<sup>5</sup> Extrapituitary tumors that produce ACTH are classically lung cancers, particularly of the small cell type, and comprise 50% of all tumors causing ectopic adrenocorticotrophic hormone syndrome (EAS) (Table 1). However, only 0.4 to 2% of all lung cancers and 2 to 5% of small cell lung carcinomas

are associated with ectopic ACTH production.<sup>4-6</sup> Recent reports have noted a greater association between benign tumors, such as carcinoids, and EAS. EAS tumors can be grouped into two histologic categories: carcinoid-oat cell and pheochromocytoma-neuroblastoma.<sup>5,7</sup>

Tumors can also produce CRH, the peptide normally produced by the hypothalamus that stimulates pituitary ACTH production and secretion, with or without ACTH.<sup>5</sup> Neoplasms that produce CRH include medullary thyroid carcinoma,<sup>8</sup> ganglioneuroblastoma,<sup>9</sup> and prostate cancer.<sup>10</sup>

Carcinomas of the liver, prostate, and breast have been documented to produce ACTH. Some malignancies can concomitantly produce ACTH and CRH.<sup>11,12</sup> Sarcomas have not been associated with EAS.<sup>6</sup>

### Pathophysiology

All tissues in the body make pro-opiomelanocortin-derived peptides, albeit in smaller amounts than that produced in the pituitary gland; tumors or carcinomas can produce excessive quantities of it.<sup>6</sup> Pro-ACTH, or “big” ACTH, a prohormone by-product of pro-opiomelanocortin, can be enzymatically cleaved into multiple biologically active peptides: ACTH (leading to adrenal gland stimulation and cortisol secretion), melanocyte-stimulating hormone (affecting skin hyperpigmentation), and  $\beta$ -endorphin and met-enkephalin (which have opiate-like activity).

### Clinical Manifestations

Ectopic ACTH secretion leads to bilateral adrenal hyperplasia (as does a pituitary source) and many of the classic findings of hypercortisolism (Table 2). A review of 90 patients by the National Institutes of Health found that the three most common signs and symptoms of EAS were proximal muscle weakness (92%), hypertension (78%), and menstrual irregularity (78%).<sup>3</sup> Because the adrenal glands are stimulated to produce excessive amounts of 11-deoxycorticosterone and cortisol, which have mineralocorticoid and glucocorticoid

**Table 1** Tumors Causing Ectopic Adrenocorticotrophic Hormone Syndrome

Lung cancer—50%
Carcinoid tumors—25%
Bronchus
Thymus
Small intestine
Neural crest tumors—15%
Pheochromocytoma
Neuroblastoma
Medullary carcinoma of the thyroid
Thymoma—10%
Carcinoma of breast, gastrointestinal tract, ovary, cervix, prostate—rare

**Table 2** Clinical Manifestations of Ectopic Adrenocorticotropic Hormone Syndrome

Proximal muscle weakness
Hypertension
Menstrual irregularity
Hirsutism
Osteopenia/osteoporosis
Fracture
Hypokalemia
Hyperglycemia
Edema
Weight loss
Psychiatric disorder (depression, psychosis)
Ecchymosis
Infection

effects, edema, metabolic alkalosis, and hypokalemia are more prominent features of EAS than they are of Cushing's syndrome from other causes.<sup>6</sup> Centripetal obesity, purplish axillary striae, moon facies, a dorsocervical fat pad, and hyperpigmentation of the buccal mucosa are not typical signs when there is an underlying malignant tumor, such as oat cell carcinoma of the lung; these are more frequently seen with indolent tumors.

Occasionally, especially with slow-growing disseminated neuroendocrine tumors, the onset of Cushing's syndrome may occur many years after the diagnosis of a tumor. Some tumors, such as thymic or bronchial carcinoids, may not cause any clinical manifestations of ACTH production because they do not produce a sufficient amount of the peptide. Highly aggressive malignancies, however, usually cause rapid development of Cushing's syndrome.

Occult tumors producing hypercortisolemia are defined as undetectable tumors of nonpituitary origin that produce excessive ACTH or CRH for more than 4 to 6 months before tumor identification.<sup>13</sup> A review conducted at the National Institutes of Health found that patients with unidentifiable primary tumors causing EAS survived longer than those with known tumors.<sup>3</sup> Of the identifiable tumors, primary pulmonary tumors, with the exception of small cell lung carcinomas, were associated with longer survival periods than other tumor types. The average survival time after diagnosis of an overt tumor was 24 months.<sup>3</sup>

## Diagnosis

The keys to diagnosing EAS are having clinical suspicion and conducting a rational, systematic series of biochemical tests prior to obtaining imaging studies. A typical clinical scenario that raises concern for the presence of EAS involves a patient with a known tumor who experiences weight loss, unexplained hypokalemic alkalosis, and abnormal glucose tolerance.

First, screening for hypercortisolism should be performed with a 24-hour urine collection for

free cortisol (UFC), a low-dose overnight dexamethasone (DXM) suppression test, or a midnight salivary cortisol test. The 24-hour UFC test has a 100% sensitivity and 98% specificity for Cushing's syndrome and can distinguish hypercortisolism from obesity.<sup>6,14</sup> An elevated 24-hour UFC level (>4 times the normal reference range) with a simultaneously elevated ACTH level (>10 pg/mL) is highly suggestive of EAS.<sup>15</sup> Three different urine collections on separate days may be needed because cortisol production is variable. A low-dose overnight DXM suppression test consists of 1 mg of DXM given orally at 11 pm followed by a blood sample drawn at 8 am to determine the serum cortisol level. A suppressed cortisol level of <1.8 µg/dL rules out hypercortisolemia, but a level of >14.3 µg/dL confirms the presence of Cushing's syndrome from any source (pituitary, adrenal, or ectopic).<sup>15,16</sup> A midnight salivary cortisol test is simple and noninvasive, but the results are highly variable, depending on the laboratory. A salivary cortisol level of >0.55 µg/dL is a good screen for Cushing's syndrome: this cutoff value identified 93% of patients with Cushing's syndrome and excluded 100% without it.<sup>17</sup>

After one confirms the presence of hypercortisolism, an ACTH level (with a two-site immunoradiometric assay) should be evaluated to determine whether the Cushing's syndrome is dependent on ACTH (ie, pituitary adenoma or EAS) or independent from ACTH (ie, primary adrenal disease). A plasma ACTH concentration >20 pg/mL suggests an ACTH-dependent process, whereas an ACTH level of <10 pg/mL is consistent with an adrenocortical process (adrenal adenoma or carcinoma).<sup>16</sup> Although a serum ACTH level of >200 pg/mL is suggestive of EAS, bronchial and thymic carcinoids and occult tumors may exhibit lower levels of ACTH, serum cortisol, and UFC than aggressive or overt tumors do.<sup>6</sup> If the ACTH level is within the range of 10 to 20 pg/mL, further dynamic testing with CRH stimulation (as described below) will be needed.

Identifying the source of ACTH (pituitary vs ectopic tumor producing ACTH vs ectopic tumor producing CRH) in ACTH-dependent Cushing's syndrome is one of the most difficult diagnostic evaluations in endocrinology (Figure 1). DXM suppression of cortisol and CRH stimulation of ACTH are tests that help distinguish the source of excessive ACTH. With EAS tumors, plasma cortisol is resistant to exogenous glucocorticoid suppression, and the ACTH level usually does not rise in response to CRH stimulation. One exception to this observation is that in the presence of a CRH-producing tumor, since the hypothalamic-pituitary axis is essentially intact, the clinical presentation is similar to that of a classic pituitary ACTH-producing tumor. In addition, in 30% of occult EAS tumors and 41% of thoracic

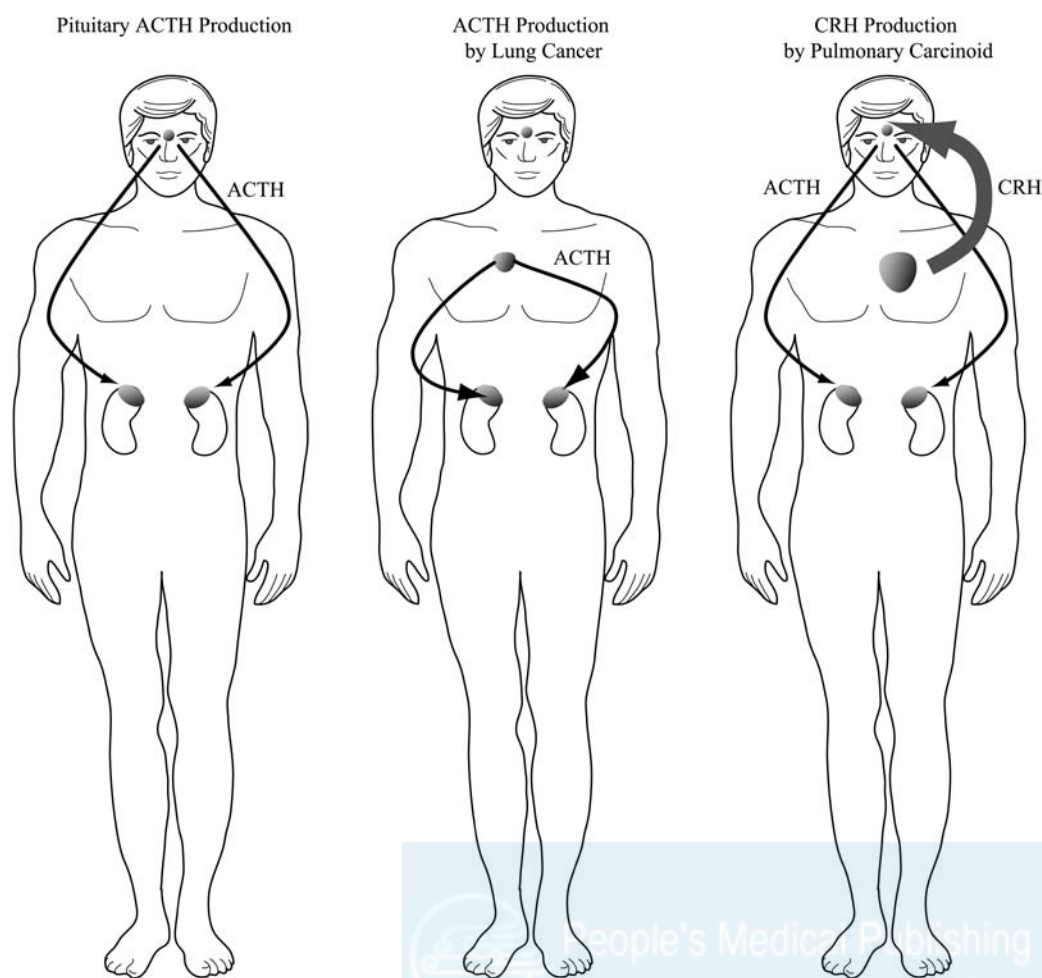

carcinoids, cortisol can be suppressed with DXM. Alternatively, in 9 to 25% of cases of pituitary-dependent Cushing's syndrome, DXM will fail to suppress cortisol production (Table 3).<sup>6</sup>

The response to dexamethasone is observed with the high-dose dexamethasone suppression test (HDDST), which can be performed in various ways. The 2-day HDDST consists of 2 mg of DXM given orally every 6 hours for 48 hours, with 24-hour urine specimens collected at baseline and after days 1 and 2 of DXM administration for determination of the UFC level. A decrease in the UFC level of >90% from the baseline level is suggestive of a pituitary source of ACTH. The overnight HDDST is performed by giving 8 mg of DXM orally once at 11 pm with an evaluation of the plasma cortisol level at 8 am the following day. A decline in plasma cortisol of >50% from the baseline level or a level of <5 µg/dL suggests a pituitary tumor. The overnight HDDST is more sensitive and accurate than the 2-day HDDST for pituitary ACTH production.<sup>6</sup>

A CRH stimulation test is performed by administering 1 µg/kg (maximum dose 100 µg) of synthetic ovine CRH intravenously and evaluating the plasma ACTH and cortisol levels at baseline and every 15 minutes after the injection for 60 minutes. EAS tumors will respond with stable or only minimally increased ACTH and cortisol levels. With pituitary tumors, ACTH and cortisol levels will rise >50% (sensitivity 86%, specificity 90%) and 20% (sensitivity 91%, specificity 95%), respectively, from baseline levels.<sup>18</sup> A combination of the 2-day HDDST and CRH stimulation tests, the DXM-CRH test, will increase the sensitivity and specificity of the evaluation for pituitary Cushing's syndrome.<sup>19</sup>

In the absence of an obvious pituitary tumor or other neoplasm, bilateral inferior petrosal sinus sampling (IPSS) should be done in patients with ACTH-dependent Cushing's syndrome to determine the source of the ACTH because the pituitary circulation drains directly into the inferior petrosal sinuses (IPSSs). Simultaneous blood samples for ACTH from the bilateral IPSSs and peripheral (P) circulation will reveal an IPS to P ratio of ≥3 after CRH stimulation in the presence of a pituitary tumor.<sup>20</sup> The sensitivity and specificity of IPSS for diagnosing pituitary Cushing's syndrome are about 94%.<sup>7</sup> IPSS is especially helpful in differentiating occult EAS from pituitary Cushing's syndrome because occult EAS tumors can respond to the previously described dynamic tests similarly to the way pituitary tumors do. The limitations of IPSS arise from technical inexperience, high cost, and rare neurologic and thromboembolic complications.

Other diagnostic modalities include radiologic studies or tumor markers. Chest radiography and computed tomography or magnetic resonance imaging of the neck, chest, and/or

**FIGURE 1** Sources of adrenocorticotropic hormone (ACTH)-dependent Cushing's syndrome. It is difficult to differentiate between a pituitary (*left panel*) and an ectopic (*middle panel*) source of ACTH, the most common causes of ACTH-dependent Cushing's syndrome. To differentiate with certainty, placement of catheters in veins draining the pituitary gland (inferior petrosal sinuses) combined with stimulation by exogenous corticotropin-releasing hormone (CRH) permits differentiation with certainty. Ectopic CRH production by a tumor results in increased ACTH production by the pituitary gland (*right panel*). It is difficult to differentiate between ectopic CRH production and pituitary gland-dependent Cushing's syndrome, necessitating the measurement of CRH in peripheral blood to make the diagnosis with certainty. Malignant tumors occasionally produce both CRH and ACTH, further complicating the diagnostic evaluation.

**Table 3** Differences between Ectopic Adrenocorticotropic Hormone Syndrome and Cushing's Disease

Laboratory Finding	Ectopic ACTH Syndrome	Cushing's Disease (Pituitary Source)
Hypokalemia	Common	Rare
Serum or urinary cortisol	Markedly elevated	Modestly high, high normal
Serum ACTH	High	Inappropriately "normal" or slightly high
High-dose dexamethasone suppression of urinary cortisol	Unusual	Usual
Rise in serum ACTH or cortisol with CRH administration	Unusual	Usual

ACTH = adrenocorticotropic hormone; CRH = corticotropin-releasing hormone.

abdomen are ordered to evaluate patients for pulmonary, thymic, or abdominal tumors. The use of OctreoScan with indium <sup>111</sup> pentetreotide (Mallinckrodt, Inc., St. Louis, MO) can identify neuroendocrine tumors that can express somatostatin receptors. Ninety percent of occult EAS tumors are neuroendocrine in nature; thus,

neuron-specific enolase or chromogranins can be useful tumor markers.

### Treatment

As with most paraneoplastic syndromes, the most definitive therapy for EAS is to treat the underlying tumor with surgery, chemotherapy,

or radiotherapy. However, a study at the Mayo Clinic on 106 patients with EAS showed only a 12% cure rate after surgical excision of the primary tumor,<sup>2</sup> and the National Institutes of Health showed a 29% curative rate with surgical removal.<sup>3</sup> Surgical excision of benign tumors (such as bronchial carcinoids or pheochromocytomas) causing EAS is associated with higher rates of cure.<sup>6</sup>

For incurable tumors producing EAS, pharmacologic agents can be used to inhibit adrenal production of cortisol; however, their use is often limited by their adverse side-effect profiles. In addition, hypoadrenalism and adrenal crises need to be avoided by using supplemental glucocorticoid and mineralocorticoid therapy. Mitotane, a derivative of the insecticide dichlorodiphenyltrichloroethane (DDT) that was found to cause necrosis and atrophy of the adrenal cortex, was the first adrenolytic used. Maximal benefit occurs after 4 to 6 months of continued use; however, the side effects of nausea, vomiting, diarrhea, and depression often become intolerable, causing most patients to discontinue therapy prematurely. Aminoglutethimide inhibits cholesterol processing, which disrupts the production of cortisol and aldosterone and androgens. Metyrapone, an 11- $\beta$ -hydroxylase inhibitor, prevents cortisol synthesis. Increasing ACTH in response to decreasing cortisol levels does not overcome the adrenolytic effects of metyrapone. The combination of metyrapone and aminoglutethimide can be used to lower the individual dosages needed. Ketoconazole is an antimycotic agent that inhibits P-450-dependent enzymes involved with adrenal and gonadal steroid production and prevents cortisol from binding to glucocorticoid receptors. Octreotide, a somatostatin analogue, and RU-486, a glucocorticoid antagonist used in investigational protocols, have been used with variable efficacy.

At times when the primary tumor or ACTH excess cannot be treated, bilateral adrenalectomy may be an option.<sup>21</sup> The risk of developing Nelson's syndrome, hyperpigmentation secondary to pituitary hyperplasia and increased ACTH production, is 47%.<sup>15</sup> There is limited clinical experience with selective adrenal arterial embolization in patients who are poor surgical candidates and fail medical therapy.

Patients with rapidly progressive small cell lung carcinoma and EAS form a unique subset of patients because of the need to initiate chemotherapy on a timely basis. Unfortunately, these patients are also highly susceptible to opportunistic infections, and initiation of therapy will often lead to death or serious morbidity related to infection.<sup>22</sup> Adrenolytic agents may be required in these patients to control the hypercortisolemia with the goal of normalizing the serum cortisol for a period of 1 to 2 weeks or longer. Although

this may correct the immune status, it can cause an unacceptable delay in the initiation of chemotherapy from an oncologic perspective. Prophylactic therapy for opportunistic infections caused by *Pneumocystis carinii* or other fungi is recommended during chemotherapy after normalization of the serum cortisol level.

### Non-Islet Cell Tumor Hypoglycemia

Tumor-induced hypoglycemia is an uncommon but challenging and serious complication for cancer patients. Hypoglycemia in association with an underlying tumor can occur in a variety of situations, three of which are endocrine related (Table 4). First, excessive insulin can be produced by an islet cell tumor or insulinoma. Second, involvement of the hepatic parenchyma by primary or metastatic lesions can lead to “liver failure” and insufficient gluconeogenesis from hepatic destruction or cytokine activity with tumor necrosis factor  $\alpha$  and interleukins 1 and 6. These cytokines have been shown to produce hypoglycemia in animal models.<sup>23</sup> Third, a tumor can secrete an aberrant form of insulin-like growth factor (IGF) type 2, which can mediate hypoglycemic effects by binding to insulin receptors. This process produces the endocrine paraneoplastic syndrome of non-islet cell tumor hypoglycemia (NICTH). NICTH is reported to be 25% as common as insulinomas, although this is most likely an underestimation.<sup>23</sup> Since the assays for IGF-1 and IGF-2 were established in 1990, more than 120 cases of NICTH were documented in just one region of the United Kingdom by 2004.<sup>24</sup>

### Tumors

NICTH is most commonly seen in patients with mesenchymal tumors such as fibromas and fibrosarcomas, which constitute about half of all tumors associated with NICTH. Tumors with epithelial and hematopoietic origins also have been seen with NICTH. About half of the epithelial tumors consist of hepatocellular carcinomas.<sup>25–27</sup> Overall, NICTH is associated with a wide range of tumors (Table 5).<sup>23,28</sup> Large fibrosarcomas usually arise in the thoracic or retroperitoneal spaces. NICTH-associated tumors are typically large and slow-growing.

### Pathophysiology

Aberrantly processed IGF-2 produced by tumor cells was first observed by Daughaday and colleagues in 1988 in a patient with leiomyosarcoma and recurrent hypoglycemia.<sup>29</sup> This abnormal IGF-2 was termed “big” IGF-2 because it has a higher molecular weight than normal mature IGF-2, indicating incomplete processing of pro-IGF-2 peptides. After tumor resection, big IGF-2 was nearly undetectable.<sup>29</sup> Lowe and colleagues found increased amounts of messenger ribonucleic acid in tumor tissue from patients with NICTH, thus establishing the role of big IGF-2 in this syndrome.<sup>30</sup>

In normal physiology, mature IGF-2 (molecular weight 7.5 kDa) is produced from a series of biochemical alterations of pre-pro-IGF-2, a 17 kDa molecule produced by the liver. IGF-1 and mature IGF-2 competitively bind to insulin-like growth factor binding protein type 3 (IGFBP-3) and other subtypes of IGFBPs. This IGF-IGFBP

complex then binds to a molecule called acid-labile subunit (ALS). More than 98% of mature IGF-2 is bound to IGFBPs, with the majority associated with the large ternary complex of mature IGF (1 or 2)/IGFBP-3/ALS (total molecular weight 150 kDa). Less than 2% of mature IGF-2 is free in the circulation and can readily cross the capillary barrier.<sup>27</sup> The ternary complex is too large to cross the capillary membrane into the interstitium.<sup>23,27,31,32</sup> The normal ratio of IGF-2 to IGF-1 in plasma is 3:1, with individual concentrations significantly greater than that of insulin. However, because of their formation of the large ternary complexes, which cannot access the insulin or IGF receptors in the interstitium, and the very small amount of free IGF-2 that can access the receptors, the IGFs are unable to exert any clinically relevant insulin-like effects.<sup>23</sup>

In the setting of NICTH, the tumor produces excessive amounts of IGF-2, which is primarily (60–77%) composed of the subgroup of big IGF-2 (10–15 kDa), which is unable to effectively form the ternary complex with ALS.<sup>29,32,33</sup> In addition, the high levels of big IGF-2 give negative feedback to the pituitary to cause a decrease in GH production, which, in turn, leads to decreased production of IGF-1, IGFBP-3, and ALS.<sup>25</sup> Alternatively, GH-independent IGFBP-2 will increase in response to hypoglycemia.<sup>34</sup> In the end, IGF-2 (normal and big) and the small amounts of IGF-1 present will be sequestered into binary complexes (molecular weight 50 kDa) with IGFBP-2 or IGFBP-3 rather than the larger ternary complexes. These smaller binary complexes, as well as free IGF-2, readily cross the capillary membrane, thus allowing IGF-2 to cross-react with insulin receptors in the interstitium (Figure 2).<sup>23</sup> The resultant

**FIGURE 2** Pathophysiologic mechanism of non-islet cell tumor hypoglycemia (NICTH). (1) Excessive levels of big insulin-like growth factor (IGF)-2 (black hexagon) produced by the tumor is released into the circulation and negatively feeds back on pituitary growth hormone (GH) secretion. (2 and 3) Decreased levels of GH lead to decreased hepatic production of acid-labile subunit (ALS) (green oval), IGF-1, insulin-like growth factor binding protein (IGFBP)-3 (blue semicircle), and mature IGF-2. IGFBP-2 (yellow inverted triangle) production increases in response to hypoglycemia. (4) Increased concentrations of binary complexes (big IGF-2 + IGFBP-2) cross the capillary membrane. (5) IGF-2 binds to insulin receptors, causing hypoglycemia. IR = insulin receptor.

hypoglycemia is mediated through increased glucose consumption in skeletal muscle, suppressed hepatic glucose production, and suppressed lipolysis in adipose tissue.

In response to the hypoglycemia, insulin levels decrease and insulin receptors are up-regulated.<sup>35</sup> Thus, patients with NICTH may have an increased sensitivity to insulin-like peptides.

### Clinical Manifestations

Neuroglycopenic and autonomic symptoms can occur anytime during the day but usually are associated with normal periods of fasting, that is, early morning and before meals. Recovery of neurologic function with administration of glucose or glucagon supports the diagnosis of symptomatic hypoglycemia. Occasionally, acromegaloid features may develop because of the actions of IGFs on GH receptors (Table 6).<sup>36</sup>

It is interesting that hypoglycemia can occur at any time during the course of the malignancy. In patients with NICTH treated with surgical excision or other antineoplastic therapy who have complete resolution of hypoglycemic episodes, production of big IGF-2 and hypoglycemia may not return with tumor recurrence for unclear reasons.<sup>37</sup>

### Diagnosis

The keys to differentiating NICTH from an insulinoma or hepatic destruction as a cause of hypoglycemia are to recognize the symptoms and to conduct the correct biochemical tests at the time of hypoglycemia. These tests include determining the levels of glucose, insulin, proinsulin, C-peptide, IGF-1, IGFBP-3, GH, IGF-2, and ketones (Table 7). In NICTH, total IGF-2 levels are usually inappropriately normal or elevated. The presence of a normal total IGF-2 level is explained

Laboratory Finding	NICTH	Insulinoma	Hepatic Tumor Burden
Insulin	Low	High	Low
C-peptide, proinsulin	Low	High	Low
GH	Low	Normal-high	Normal-high
IGF-1	Low	Normal	Normal
IGF-2	Normal-high	Normal	Normal
IGFBP-3	Low	Normal	Normal
β-Hydroxybutyrate	Low	Low	High

GH = growth hormone; IGF = insulin-like growth factor; IGFBP = insulin-like growth factor binding protein; NICTH = non-islet cell tumor hypoglycemia.

by two findings: the elevation of big IGF-2 levels is compensated for by a decrease in the normal IGF-2 level, and big IGF-2, which cross-reacts with the IGF-2 radioimmunoassay, is incompletely recognized by the assay.<sup>27,37</sup> Thus, an IGF-2 to IGF-1 ratio of > 10 is more sensitive than an IGF-2 level alone for diagnosing NICTH.<sup>23</sup>

A glucagon stimulation test (1 mg of glucagon administered intravenously over 2 minutes with blood drawn at 0, 15, 30, and 45 minutes after administration to test for glucose level) performed during a hypoglycemic episode can be useful in distinguishing whether the hypoglycemia is insulin mediated (insulinoma or NICTH). This test takes advantage of glucagon's gluconeogenic action on the liver to stimulate glycogen breakdown into glucose. An increase in glucose by > 30 mg/dL from baseline is consistent with either insulinoma or NICTH as the glycogen stores are maintained in these pathologic conditions because of the antiglycogenolytic effects of insulin.<sup>38</sup>

Localization of the primary tumor with radiologic imaging is not difficult because the tumors associated with NICTH are often large.

### Treatment

Surgical excision, chemotherapy, and radiotherapy to reduce tumor mass are the mainstays of treatment of the primary tumor and hypoglycemic effects. However, when a patient is unable to undergo surgical or chemoradiotherapy, palliative measures can be taken to control the hypoglycemic episodes. Glucose infusions (20% or 50% dextrose) can acutely manage hypoglycemia, and frequent small meals can prevent hypoglycemic episodes. Eventually, however, the progressive nature of the underlying malignancy will cause the hypoglycemia to become resistant to these conservative therapies.

Continuous infusion with glucagon has been described to maintain normoglycemia for a few months to allow for palliation or improvement of clinical performance status so that possible antineoplastic therapies can be provided in the future.<sup>38</sup> Unfortunately, the adverse side-effect profile and cost of the medication often limit its prolonged use.<sup>39</sup>

Glucocorticoids are also effective in the management of NICTH. A patient treated with prednisolone (30 mg/d) demonstrated increased IGF-1, IGFBP-3, and ALS levels but decreased IGF-2 levels, leading to an overall increase in the amount of ternary complexes and resolution of hypoglycemia.<sup>26</sup> Because IGF-2 may act as an autocrine growth factor for the primary tumor, control of IGF-2 levels with glucocorticoid therapy may stabilize tumor progression.<sup>40</sup> Glucocorticoids may decrease IGF-2 levels through a variety of mechanisms. They may induce enzymes to convert pro-IGF-2 into the mature form or increase clearance and/or suppress tumor production of big IGF-2.<sup>41</sup> Unfortunately, glucocorticoid therapy appears to be reversible and dose dependent, requiring prednisone equivalents of > 20 mg/d.

GH therapy has also been used, although with less efficacy. Relief of hypoglycemia is possible with high doses of GH daily (4 U/d); however, its prolonged use can lead to adverse side effects, such as arthritis from acral edema and other acromegaloid features. Its therapeutic effect does not appear to be sustained despite continuous treatment.<sup>23,26</sup> Additionally, the theoretical potential for GH to stimulate tumor growth raises concern about its use as a treatment of choice.<sup>28</sup>

### Syndrome of Inappropriate Antidiuretic Hormone

Hyponatremia was first associated with lung cancer in 1938, but its association with inappropriate secretion of an antidiuretic hormone (ADH)-like substance was made in 1957 by Schwartz and colleagues.<sup>5,42</sup> This report was followed by the finding of an ADH-like substance in lung carcinoma extract in 1963.<sup>43</sup>

### Tumors

Syndrome of inappropriate antidiuretic hormone (SIADH) is most commonly associated with small cell lung carcinoma and carcinoid tumors. Forty percent of patients with small cell lung carcinoma have high ADH levels, but only about 15% manifest SIADH.<sup>4,44,45</sup> Rarely, SIADH has been seen with other tumor types:

prostate carcinoma, breast carcinoma, adrenocortical carcinoma, esophageal carcinoma, pancreatic carcinoma, other gastrointestinal carcinomas, thymomas, Hodgkin's lymphoma, non-Hodgkin's lymphoma, and head and neck carcinomas.<sup>4</sup> One case of an immature teratoma was reported to cause SIADH (Table 8).<sup>46</sup>

### Pathophysiology

Under normal conditions, serum osmolality is maintained in a narrow range between 280 and 295 mOsm/kg by ADH (also known as arginine vasopressin), which is produced by the supraoptic and paraventricular nuclei in the hypothalamus. Although serum osmolality is the most important stimulus for ADH secretion, arterial underfilling, nausea, hypothyroidism, hypocortisolism, and various medications also stimulate its release.<sup>47,48</sup>

ADH binds to its receptor on the collecting duct of the renal system to allow for intracellular aquaporin 2 channels to be fused to the luminal membrane, thus permitting the flow of water from the lumen into the cell and then into the interstitium. Natriuresis is likely facilitated by the decreased action of the renin-angiotensin-aldosterone system caused by the increase in blood volume accompanying water retention.<sup>48</sup>

ADH, oxytocin, and their binding proteins, neurophysins, can be produced by tumors. ADH production by tumors is not suppressed by hypo-osmolality. Besides inappropriate ADH secretion, there is some speculation that atrial and brain natriuretic peptides play a role in cancer-associated hyponatremia. Elevated atrial natriuretic peptide levels may cause hyponatremia in patients who have normal ADH levels.<sup>44,49-51</sup>

### Clinical Manifestations

Most patients who develop SIADH are asymptomatic, with only mild hyponatremia, especially when the hyponatremia evolves slowly. The patients are euvolemic. When the serum sodium concentration falls below 120 mEq/L, however, 27 to 44% of patients may develop severe neurologic symptoms and signs (Table 9).<sup>44</sup> Focal neurologic disturbances can occur even in the absence of space-occupying lesions in the brain. In particular, premenopausal women who develop

**Table 9 Clinical Manifestations of Hyponatremia**

Gastrointestinal
Anorexia
Nausea or vomiting
Abdominal cramps
Pulmonary
Respiratory arrest
Noncardiogenic pulmonary edema

hyponatremia may develop profound cerebral edema and are at greater risk than men or postmenopausal women for severe neurologic symptoms and residual complications.<sup>52</sup>

### Diagnosis

The finding of hyponatremia should initiate a systematic investigation for the cause, which first entails an assessment of the tonicity. If the assessment reveals hypotonic hyponatremia, a distinction based on the patient's overall volume status can be made (Table 10).

Finding hyponatremia with serum hypo-osmolality and relative urinary hyperosmolality (usually serum osmolality < 280 mOsm/kg and urinary osmolality > 500 mOsm/kg) after excluding the presence of adrenal insufficiency or hypothyroidism supports the diagnosis of SIADH.

The urinary sodium level will be inappropriately elevated (urinary sodium > 20 mEq/L), in the absence of diuretics and renal dysfunction, for the level of hyponatremia (Table 11). SIADH owing to an underlying tumor or other causes (eg, pulmonary disease, central nervous system disorder) is difficult to distinguish by biochemical workup alone. Clinical correlation will assist with diagnosis.

ADH levels can be measured by radioimmunoassay, but their clinical significance is unclear because ADH values do not correlate with the clinical presentation of hyponatremia.

### Treatment

Aside from treating the underlying tumor with surgery or chemoradiotherapy, SIADH can usually be managed with free water restriction (ie, < 500 mL/24 h or replacement of the urine output by 50%); this can correct the hyponatremia slowly, over 7 to 10 days. In critically ill (eg,

**Table 11 Diagnostic Criteria for SIADH**

comatose) patients, more aggressive therapy with hypertonic saline and furosemide may be used with extreme caution to elicit a net fluid loss. The serum sodium level should be monitored closely for a rise of about 0.5 mEq/L/h to avoid central pontine myelinolysis or brain osmotic demyelination syndrome, which occurs with overly rapid correction of hyponatremia. Adroge studied 62 patients with hyponatremia (sodium <110 mEq/L) and found that a higher risk of neurologic complications occurred with correction rates of >0.55 mEq/L/h.<sup>53</sup>

Demeclocycline is an antibiotic in the tetracycline family that blocks ADH-induced cyclic adenosine monophosphate formation in the renal tubules. This medication, given as 600 to 1,200 mg/d divided into three or four doses, leads to a decline in intracellular aquaporin 2 channel phosphorylation, which prevents the channel from inserting into the luminal membrane. Demeclocycline takes from 4 to 21 days to work but is preferable to other therapies for long-term treatment of SIADH.<sup>44</sup> Lithium is also used sometimes, but it is less effective than demeclocycline and has an inferior adverse side-effect profile.<sup>54</sup>

Urea, given at a dosage of 40 g dissolved in 100 to 150 mg of normal saline every 8 hours along with a normal saline infusion (60–100 mg/h) for 1 to 2 days, can correct the salt-losing tendency in SIADH without the need for water restriction since it induces osmotic diuresis. Rapid water shifts do not usually occur with this treatment, as they do with mannitol, thus limiting the risk of cardiac failure.<sup>55</sup>

Vasopressin receptor type 2 antagonists are currently being studied in animal and clinical trials.<sup>56</sup> These agents are especially promising because they directly block the action of ADH on the receptors on the renal tubules without worsening renal function and with minimal adverse side effects.

Resolution of SIADH correlates well with tumor regression in response to chemoradiotherapy. With tumor recurrence, 60 to 70% of patients will also have a recurrence of SIADH. However, the presence or absence of SIADH does not affect the prognosis of patients with small cell lung carcinoma.<sup>44</sup>

## Tumor-Induced Osteomalacia

Oncogenic osteomalacia–rickets was first described by McCance in 1947,<sup>57</sup> but Prader and colleagues were the first to attribute it to the presence of tumor in 1959.<sup>58</sup> It has also been referred to as tumor-induced hypophosphatemic rickets, oncogenic osteomalacia, and tumor-induced osteomalacia (TIO).<sup>59</sup> TIO is a rare condition characterized by bone mineralization disease, hypophosphatemia, renal phosphate wasting, impaired calcitriol (1,25-dihydroxyvitamin D<sub>3</sub>,

the active form of vitamin D) synthesis, fractures, and resolution of all of these abnormalities after removal of an underlying tumor.

## Tumors

Only approximately 120 cases of TIO have been reported in the literature, although this may not reflect its true prevalence. Most tumors that cause TIO are mesenchymal in origin and are usually benign, although malignant types and other histologic types of tumors have been reported (Table 12).<sup>59,60</sup> The mesenchymal tumors can be further classified into the following four histologic subgroups<sup>61</sup>:

1. Phosphaturic mesenchymal tumor (PMT), mixed connective tissue type, is the most common of the subtypes, making up about 70% of the mesenchymal tumors associated with TIO.<sup>62</sup>
2. Osteoblastoma-like PMT
3. Ossifying fibroma–like PMT
4. Nonossifying fibroma–like PMT

TIO tumors are often small and slow-growing and present in obscure areas, which makes them extremely difficult to locate; thus, clinicians must conduct long-term follow-up and surveillance in patients with TIO. Often tumors are found within bone, especially in the craniofacial regions and extremities (eg, nasopharynx, mandible, sinus, femur, tibia). Occasionally, they are located in the brain or in the popliteal, inguinal, or suprapatellar areas. In a review of 100 cases, 87% of TIO tumors were benign, 50% were vascular in origin, and 50% were located in skeletal tissues.<sup>63</sup>

## Pathophysiology

Before discussing the pathophysiology involved with TIO, normal phosphate homeostasis should be reviewed briefly. A low serum phosphate level stimulates renal 25-hydroxyvitamin D<sub>1</sub>- $\alpha$ -hydroxylase (1- $\alpha$ -hydroxylase) activity, which converts 25-hydroxyvitamin D into 1,25-

dihydroxyvitamin D<sub>3</sub> (calcitriol). Calcitriol, in turn, increases calcium and phosphorus absorption by the intestine and enhances their mobilization from the bone. The resulting increase in calcitriol and calcium levels will decrease parathyroid hormone secretion, which increases renal calcium excretion and phosphorus reabsorption. In addition, hypophosphatemia itself will stimulate renal reabsorption of phosphate.

In TIO, tumors highly express one or more hormones (phosphatonins) that demonstrate phosphaturic activity and inhibit 1- $\alpha$ -hydroxylase activity in cultured kidney cells.<sup>64–67</sup> The fibroblast growth factor 23 gene (*FGF23*), although expressed in low levels in normal tissue, is highly expressed in tumors associated with TIO.<sup>68–70</sup> It is also expressed in X-linked hypophosphatemia and has a role in autosomal dominant hypophosphatemic rickets.<sup>71,72</sup> *FGF23* decreases expression of renal sodium–phosphorus cotransporters, which normally mediate phosphorus reabsorption, leading to hypophosphatemia. Excessive *FGF23* levels will also down-regulate 1- $\alpha$ -hydroxylase activity to cause decreased levels of calcitriol, contributing to the hypophosphatemia.<sup>66</sup>

Secreted frizzled-related protein type 4 and matrix extracellular phosphoglycoprotein are other phosphatonins cloned from TIO-associated tumors.<sup>73,74</sup> No assays for these are currently commercially available.<sup>75</sup>

The cause of hypophosphatemia in TIO is distinct from that seen in light-chain nephropathy associated with hematogenous malignancies, in which renal phosphate wasting is mediated by light-chain proteinuria.<sup>76</sup>

## Clinical Manifestations

Chronic hypophosphatemia causes inadequate mineralization of the osteoid, a condition called osteomalacia. Patients have long-term symptoms of bone and muscle pain. The poor quality of the bones will lead to recurrent fractures of the long bones, vertebral bodies, and ribs. In younger patients, growth retardation and bowing of the lower extremities can occur (Table 13).<sup>59</sup>

Patients typically have symptoms long before a diagnosis of TIO or identification of a tumor is

made. A review of the 120 published cases showed symptomatic periods ranging from 2.5 months to 19 years (average >2.5 years) before the diagnosis was made. In most patients, it was diagnosed in the sixth decade of life (range 1–74 years old), and only 15% were younger than 20 years old.<sup>60</sup>

## Diagnosis

The list of possible underlying causes of hypophosphatemia far surpasses that of osteomalacia (Tables 14 and 15). The workup for hypophosphatemia should include determinations of fasting serum phosphorus, serum calcium,

Renal phosphate wasting

alkaline phosphatase (bone specific), creatinine, intact parathyroid hormone, 25-hydroxyvitamin D, and calcitriol levels and a 24-hour urine collection for assessing phosphorus, creatinine, amino acids, and glucose levels. TIO is characterized by very low serum phosphorus (range 0.7–2.4 mg/dL) and normal serum calcium and 25-hydroxyvitamin D but low or normal calcitriol levels (Table 16). The presence of aminoaciduria and glucosuria reflect the proximal renal tubular defect caused by TIO, as in Fanconi's syndrome.

The results of biochemical testing for TIO are indistinguishable from those for X-linked hypophosphatemia and autosomal dominant hypophosphatemic rickets, but the clinical context of the abnormalities will help differentiate between these three disease states (Table 17). Most notably, patients with TIO will not have a family history of hypophosphatemia or bone disorders.<sup>66</sup> X-linked hypophosphatemia can be evaluated with genetic testing to detect a mutation of the *PHEX* gene (phosphate-regulating gene with homologies to endopeptidases on the X chromosome). Autosomal dominant hypophosphatemic rickets is associated with a mutation of the *FGF23*

Phosphorus	Very low	Very low	Very low	Mildly low
Calcitriol	Low–normal	Low–normal	Low–normal	High
Urine calcium	Normal	Normal	Normal	High
Genetic mutation	None	<i>PHEX</i>	<i>FGF23</i>	<i>SLC34A3</i>

ADHR = autosomal dominant hypophosphatemic rickets; HHRH = hereditary hypophosphatemic rickets with hypercalciuria; LE = lower extremity; TIO = tumor-induced osteomalacia; XLH = X-linked hypophosphatemic rickets.

gene. Resection of the tumor in TIO will reverse the biochemical abnormalities, which is the most definitive diagnostic criterion.

Radiographs of bones reveal osteopenia, pseudofractures, and coarsened trabeculae, and children will have wide epiphyseal plates. Bone scans yield findings typical of osteomalacia (eg, diffuse skeletal uptake, focal uptake at fracture sites) but are nonspecific for the cause.

Bone biopsies with tetracycline labeling can reveal a mineralization defect with increased mineralization lag time (reduced distance between tetracycline labels) and excessive unmineralized bone (osteoid).

Localization of the causative tumor may take years of surveillance and can exhaust biochemical and radiologic modalities. Besides computed tomographic, magnetic resonance, and positron emission tomographic scans, an indium 111 pentetreotide (octreotide) scan may be helpful because some mesenchymal tumors express somatostatin receptors.<sup>77</sup>

## Treatment

Therapy for TIO is first directed toward complete resection of the tumor; typically, that is curative. However, when complete resection of the causative tumor is unsuccessful or impossible, correction of the two major biochemical abnormalities (hypophosphatemia and calcitriol deficiency) will often lead to clinical improvement. The therapeutic goals are to improve the patient's symptoms, maintain a low or normal fasting phosphorus level, normalize the alkaline phosphatase level, and avoid hypercalcemia and hypercalciuria.

Oral or intravenous phosphate supplementation combined with calcitriol therapy is usually effective. In general, oral phosphate therapy is well tolerated, although 5 to 10% of treated patients develop dose-related adverse gastrointestinal side effects, with symptoms including nausea, vomiting, diarrhea, or abdominal pain.

Overreplacement of phosphate could lead to hypocalcemia from binding effects. Together, the hyperphosphatemia and hypocalcemia can lead to secondary hyperparathyroidism or parathyroid autonomy. Intravenous phosphate therapy has been given for extended periods when oral administration was not tolerated or there were concerns about metastatic calcification, hypocalcemia, cardiac arrhythmia, or unmanageable electrolyte disturbances.<sup>78</sup>

Calcitriol administration can improve the biochemical abnormalities and bone lesions, but care must be taken to avoid hypercalcemia, nephrolithiasis, or nephrocalcinosis.<sup>79</sup>

The data on treatment of TIO with octreotide, a somatostatin-receptor analogue, are limited and demonstrate mixed results.<sup>80</sup> Currently, its use is not recommended unless all other treatment modalities have failed.

### Ectopic GH-RH Syndrome

Acromegaly owing to elevated GH and IGF-1 production is rare (38–69 cases/million population), with an annual incidence of 2.8 to 4 cases per million. Most cases are due to excessive GH secretion from a functional pituitary adenoma. GH-RH is normally produced by the hypothalamus to regulate pituitary GH production. Ectopic GH-RH-secreting tumors account for 1% of cases of acromegaly, although only about 50 cases have been reported in the literature. The true prevalence and incidence are unknown.<sup>81</sup> The infrequency of this paraneoplastic syndrome may be partly attributable to the misdiagnosis of pituitary GH adenoma since chronically elevated GH-RH will produce somatotrophic hyperplasia.<sup>82</sup>

### Tumors

Among the cases of ectopic GHRH syndrome reported, carcinoid tumors, primarily of the bronchial and intestinal regions, are the most common (about 60%). Pancreatic islet cell tumors are the next most common,<sup>81</sup> but other neuroendocrine tumors and malignancies have also been associated with this syndrome (Table 18).

### Pathophysiology

In 1982, there were reports of three different forms of GH-RH produced by pancreatic islet cell

**Table 18 Tumors Causing Ectopic Growth Hormone–Releasing Hormone Syndrome**

Carcinoid (bronchial, intestinal)—60%
Pancreatic islet cell tumor
Pheochromocytoma
Retroperitoneal paraganglioma
Lung adenocarcinoma
Gastric adenocarcinoma

tumors: GH-RH(1-44)-NH<sub>2</sub>, GH-RH(1-40)-OH, and GH-RH(1-37)-NH<sub>2</sub>.<sup>83,84</sup> However, the full biologic activity is seen with a fragment as short as GH-RH(1-29).<sup>82</sup>

### Clinical Manifestations

The ectopic GH-RH syndrome occurs predominantly in female patients. Patients with lung tumors usually have a longer duration of symptoms of the syndrome before tumor diagnosis than do those with pancreatic endocrine tumors (10.6 vs 5.3 years). The signs and symptoms are similar to those of GH-producing pituitary adenomas, although hyperprolactinemia is seen more frequently with ectopic GH-RH syndrome. In addition, these patients have symptoms directly caused by the underlying tumor (Table 19).<sup>82</sup>

### Diagnosis

The initial evaluation for diagnosis of ectopic GHRH syndrome begins with checking the serum IGF-1 level. If IGF-1 is high, an oral glucose tolerance test (75 g) should be done to evaluate for physiologic suppression of GH levels. In normal subjects, the GH level (measured using sensitive immunoradiometric or immunochemiluminescence assays) will fall below 0.3 ng/mL within 2 hours of the glucose challenge.<sup>85</sup>

Next, the source of the excessive GH should be evaluated using magnetic resonance imaging of the pituitary gland since most cases are due to a functional pituitary adenoma. If the pituitary gland appears diffusely enlarged or does not show a clear adenoma, the clinician should evaluate for a source of ectopic GH-RH secretion. Imaging of other areas of the body may be needed to search for an underlying tumor.<sup>82</sup>

**Table 19 Clinical Manifestations of Ectopic Growth Hormone–Releasing Hormone Syndrome**

Macrognothia
Macroglossia
Acral swelling and overgrowth
Paresthesias of hands or feet
Coarsened facial features
Skin
Thickened skin
Skin tags
Hyperhidrosis
Increased hair growth or hirsutism
Impaired glucose tolerance or diabetes mellitus
Cardiovascular
Hypertension
Left ventricular hypertrophy
Diastolic cardiomyopathy
Tumor related
Cough
Hemoptysis
Recurrent pneumonia
Abdominal mass

Serum GH-RH is not a widely available test, but when measured by a reliable laboratory, the level of GH-RH has been 100 to 1,000 times the normal reference range in all reported cases.<sup>82</sup>

### Treatment

If the primary tumor causing ectopic GH-RH syndrome is not amenable to or fails surgical resection or chemoradiotherapy, the GH hypersecretion and its effects can be treated with a somatostatin analogue, such as octreotide. Octreotide can decrease the pituitary's secretion of GH, the size of the hyperplastic pituitary gland, and the growth of most neuroendocrine tumors.<sup>86,87</sup> Continuous infusion of octreotide may have greater efficacy than intermittent injections. If the pituitary enlargement causes compression on the optic chiasm or other serious effects, resection of the pituitary gland may be required; however, GH hypersecretion often persists because of residual pituitary tissue. Dopaminergic drugs are usually ineffective.

### Human Chorionic Gonadotropin Syndrome

Many common tumors produce human chorionic gonadotropin (hCG), which may or may not lead to clinical sequelae. Because the level of hCG is often associated with disease status, it can serve as a useful marker of the tumor's response to treatment.

### Tumors

Excessive production of hCG and gynecomastia are most commonly found in gestational trophoblastic tumors (eg, choriocarcinomas, hydatidiform moles), germ cell tumors of the testis or ovary (eg, seminomas, testicular embryonal carcinomas), and adenocarcinoma of the lung.<sup>88</sup> Fifteen percent of patients with lung cancer have detectable levels of  $\beta$ -hCG,<sup>89</sup> and 6 to 13% of patients with carcinomas of lung, stomach, colon, and pancreas have excessive  $\beta$ -hCG levels.<sup>90</sup> Rarely, hCG is produced by hepatoblastomas in children and by pancreatic adenocarcinomas in adults.

### Pathophysiology

Two different protein subunits encoded by separate genes form hCG. The  $\alpha$  subunit is homologous to that of all members of the pituitary glycoprotein hormone family (luteinizing hormone, follicle-stimulating hormone, and thyroid-stimulating hormone). The  $\beta$  subunit is unique to each of these hormones and confers biologic specificity. The homology of the  $\alpha$  subunit in hCG with these hormones allows for cross-reactivity on their respective receptors, thus mediating the clinical manifestations of the syndrome.

## Clinical Manifestations

The signs and symptoms of excessive gonadotropin activity by hCG differ depending on the age and sex of the patient. In preadolescent children, precocious puberty with premature development of sexual characteristics, accelerated skeletal growth, and prostatic hyperplasia will be the predominant features. Premenopausal women may experience oligomenorrhea or menometrorrhagia, abdominal discomfort from development of ovarian cysts, and false-positive pregnancy tests.<sup>91</sup> Men can develop gynecomastia, which may be painful.<sup>92</sup> Increased aromatase activity within a tumor (eg, hepatoma or sarcoma) may contribute to gynecomastia because the enzyme metabolizes androgen precursors (dehydroepiandrosterone or testosterone) into estradiol.<sup>4</sup> Testicular atrophy can also be seen in men with excessive hCG syndrome.<sup>93</sup>

Hyperthyroidism, either overt (high free thyroxine level with symptoms) or subclinical (normal free thyroxine level), with suppressed thyroid-stimulating hormone levels may develop from an interaction of hCG with the thyroid-stimulating hormone receptor, particularly when the level of  $\beta$  subunit is extremely high. A thyroid goiter can be noted on physical examination.

## Diagnosis

A male patient with unexplained gynecomastia should undergo evaluation of serum  $\beta$ -hCG level by radioimmunoassay, a physical examination of the testes, and radiographic studies of the chest and mediastinum.

## Treatment

Targeting therapy to the underlying tumor is the most effective therapy for clinical manifestations of excessive  $\beta$ -hCG production. Gynecomastia can regress with treatment of the causative tumor; its return can signify tumor recurrence.<sup>94</sup> Hyperthyroidism can be treated short term with thionamide therapy (ie, methimazole or propylthiouracil) if chemotherapy or other strategies to treat the underlying malignancy are likely to be effective; otherwise, thyroidectomy or radioactive iodine may be required.

## Miscellaneous Ectopic Paraneoplastic Syndromes

### Ectopic Renin Production

Renin production other than by the juxtaglomerular apparatus of the kidney is extremely rare. Production of renin by nonrenal tumors has been seen with lung cancer,<sup>95</sup> pancreatic carcinoma,<sup>96</sup> liver hamartoma,<sup>97</sup> leukemia,<sup>98</sup> Hodgkin's disease,<sup>99</sup> ovarian carcinomas,<sup>100</sup> and ileal carcinoma.<sup>101</sup> Ectopic renin produces a clinical syndrome characterized by hypertension,

hypokalemia, and metabolic alkalosis. These patients have evidence of hyperaldosteronism, but the renin activity levels are inappropriately elevated. The level of prorenin, the renin precursor, is also increased. Therapy with spironolactone, angiotensin-converting enzyme inhibitors, or angiotensin receptor antagonist inhibitors may lower the blood pressure and normalize electrolyte abnormalities in the patient whose tumor cannot be resected.

### Ectopic Prolactin Production

Ectopic prolactin production is rare but has been found in gonadoblastoma,<sup>102</sup> lymphoma,<sup>103</sup> leukemia,<sup>104</sup> renal cell carcinoma,<sup>105</sup> uterine cervical carcinoma,<sup>106</sup> and colorectal cancer.<sup>107</sup> The prolactin level may have prognostic value for colorectal cancer because it correlates with disease activity.<sup>107</sup> The clinical syndrome includes galactorrhea and amenorrhea in women and hypogonadism in men. Dopamine agonists such as bromocriptine and cabergoline, which are effective for treatment of pituitary prolactinomas, are generally ineffective for treatment of ectopic prolactin production. Treatment of the primary tumor offers the best chance for reversal of hyperprolactinemia and its effects.

### Ectopic Calcitonin Production

Excessive calcitonin production other than by thyroid C cells has been seen in some malignancies, such as lung carcinoma.<sup>108</sup> However, no known clinical syndrome is associated with ectopic calcitonin secretion.<sup>109</sup>

# Endocrine Neoplastic Syndromes

S. Jim Yeung, MD, PhD  
Robert F. Gagel, MD

Neoplastic diseases of endocrine tissues can lead to the dysregulated secretion of hormones that are normally produced by the endocrine tissue and thus to clinical syndromes caused by an excess of the hormones. Severe dysregulation of hormones may lead to abnormal bodily function or biochemistry, with significant morbidity or even mortality. In this chapter, we focus on the endocrine neoplastic syndromes owing to neoplastic diseases of endocrine tissues.

## Hyperparathyroidism

Parathyroid hormone (PTH) plays a major role in calcium homeostasis. Normally, secretion of PTH is regulated by negative feedback: when serum calcium levels rise, PTH production by the parathyroid cells decreases. In primary hyperparathyroidism, PTH secretion is dysregulated, leading to hypercalcemia.

Most cases of primary hyperparathyroidism are caused by benign parathyroid adenomas. Parathyroid carcinoma is a rare cause of hyperparathyroidism, accounting for less than 1% of the cases (Figure 1A). The pathogenesis of parathyroid carcinoma is largely unknown, but mutations of the hyperparathyroidism type 2 tumor suppressor gene, *HRPT2*, have been found in most parathyroid carcinomas.<sup>1</sup>

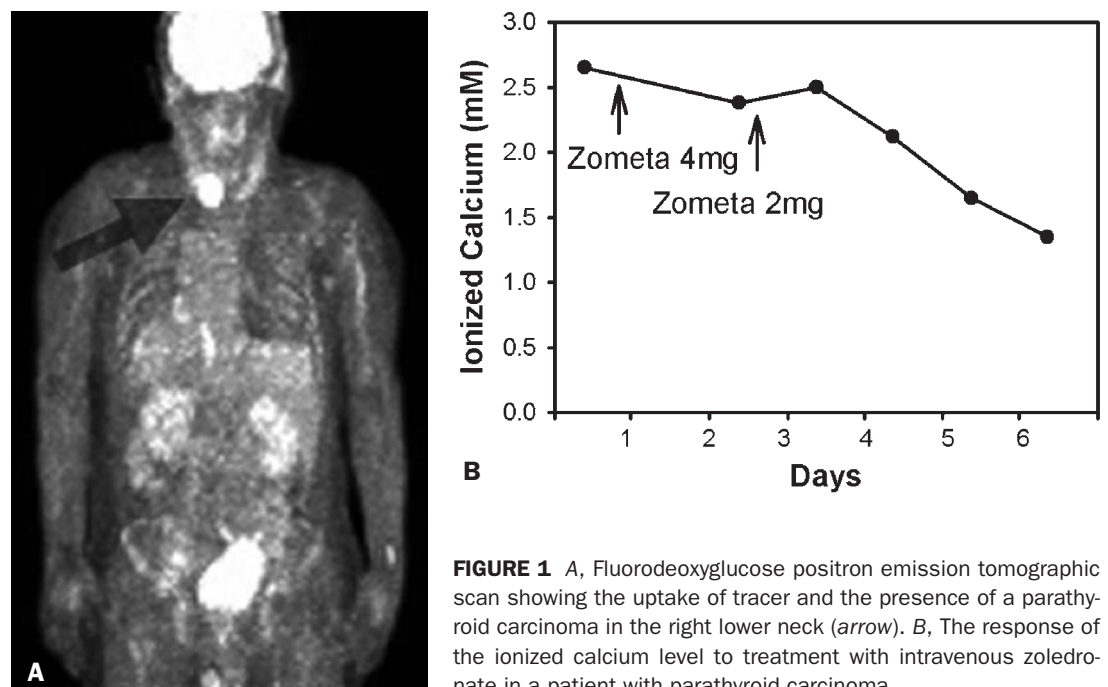

Parathyroidectomy with ipsilateral hemithyroidectomy and lymph node dissection may reduce the risk of local tumor recurrence,<sup>2</sup> but en bloc resection at the time of initial surgery may offer the best chance of cure. Distinguishing between adenomas and carcinomas can be difficult, and in some patients, the appearance of metastatic disease is the first sign that the previously resected parathyroid tumor was malignant.<sup>3</sup> The time between the initial diagnosis and the discovery of metastatic disease varies widely and may be as long as 20 years.<sup>4</sup> Resection of metastases should be attempted whenever possible because parathyroid carcinomas are usually slow-growing and resection can effectively control of hyperparathyroidism. Surgery followed by external beam radiation therapy may increase long-term survival compared with surgery alone. The

results of the limited experience with adjuvant chemotherapy suggest that its benefits are modest and short-lived.<sup>5</sup> Some patients may have extended survival despite the presence of metastatic disease.<sup>5</sup>

Patients with parathyroid carcinoma have severe hypercalcemia and extremely high PTH levels, but the basic strategy of clinical management for hypercalcemia remains unchanged. Initial management should focus on the reversal of dehydration, which is common in hypercalcemic patients, by infusion of a normal saline solution at rates between 100 and 300 mL/h. Hydration will commonly lower the serum calcium concentration by 10% over 6 to 12 hours. Patients with severe hypercalcemia (defined as a serum calcium concentration  $> 13$  mg/dL [3.25 mmol/L]), altered mental status, or evidence of renal dysfunction attributable to hypercalcemia should be treated with either intravenous pamidronate (60–90 mg over 4 hours), zoledronate (4 mg over 30 minutes) (Figure 1B),<sup>6</sup> glucocorticoids (40 to 60 mg/d prednisone equivalent), or gallium nitrate (200 mg/m<sup>2</sup>/d, infused daily for 7 days).<sup>7,8</sup>

Salmon calcitonin may lower the serum calcium concentration by 1 to 2 mg/dL early in the treatment course but rarely has long-term effectiveness. These drugs are often used in combination or sequentially in patients who do not respond well to only one treatment.

A new class of drugs known as calcimimetics has been used effectively in some patients to control the symptoms of severe hypercalcemia in a palliative setting.<sup>1</sup> Cinacalcet, a second-generation calcimimetic, is effective and well tolerated in the treatment of refractory hypercalcemia owing to parathyroid carcinoma.<sup>9</sup> Patients with parathyroid cancer should start cinacalcet therapy at a dosage of 30 mg twice daily. The US Food and Drug Administration–approved labeling recommends adjusting the cinacalcet dosage every 2 to 4 weeks to bring the serum calcium concentration into the normal range, 8.4 to 10.6 mg/dL. A maximum dosage of 90 mg four times daily is recommended in the package insert, although that dosage may be insufficient to normalize the serum calcium level in patients with parathyroid cancer.

**FIGURE 1** A, Fluorodeoxyglucose positron emission tomographic scan showing the uptake of tracer and the presence of a parathyroid carcinoma in the right lower neck (arrow). B, The response of the ionized calcium level to treatment with intravenous zoledronate in a patient with parathyroid carcinoma.

## Calcitonin Syndrome

Patients with advanced medullary thyroid carcinoma have high levels of calcitonin, which causes calcitonin syndrome, characterized by diarrhea, flushing, and fatigue. Medullary thyroid carcinoma originates from the C cells of the thyroid gland. Four-fifths of medullary thyroid carcinomas are sporadic, and the remaining familial forms are familial medullary thyroid cancer and multiple endocrine neoplasia (MEN) types IIA and IIB. The *RET* proto-oncogene is responsible for all known forms of heritable medullary thyroid carcinoma and may also be seen in some sporadic cases. This gene is located on the long arm of chromosome 10 and encodes a protein, tyrosine kinase.

Calcitonin is used to detect and confirm medullary carcinoma of the thyroid and is a tumor marker that increases as the disease progresses. Pentagastrin and calcium infusions are used as provocative challenge tests for diagnosis of C-cell hyperplasia or malignancy, and in medullary carcinoma of the thyroid gland, levels of calcitonin greater than 1,000 pg/mL are often seen. Although calcitonin inhibits osteoclastic activity and increases renal excretion of calcium, its overall effect is to compensate for hypercalcemia; elevated calcitonin does not cause hypocalcemia, and its absence does not cause hypercalcemia. No definitive imaging study has been established for medullary thyroid carcinoma, but <sup>131</sup>I-metaiodobenzylguanidine (MIBG) and <sup>99</sup>Tc-octreotide scanning may be useful.

The management of calcitonin syndrome includes reducing the tumor bulk when possible. Depending on the location of metastatic disease, surgical tumor bulk reduction, chemoembolization, or other palliative approaches may be considered. In addition to symptomatic antidiarrheal treatments, in one study, the combination of lanreotide with interferon- $\alpha$ 2b improved the symptoms in the majority of patients and decreased calcitonin by more than 50% in 40% of the patients.<sup>10</sup>

## Hormonal Syndromes Associated with Neuroendocrine Tumors

Each year, there are about 2,500 new cases in the United States of neuroendocrine or amine precursor uptake and decarboxylation tumors of the gastroenteropancreatic tract (also known as enterochromaffin tumors), of which roughly half (0.2 cases per 100,000 people) are associated with a clinical syndrome caused by ectopic hormone secretion. The most common kind of neuroendocrine tumors are carcinoid tumors, which secrete biogenic amines. Neuroendocrine tumors of the gastroenteropancreatic tract are classified according to the major secreted hormone as gastrinoma,

VIPoma, insulinoma, glucagonoma, somatostatinoma, and others.<sup>11</sup> Calcitonin-secreting neuroendocrine tumors are extremely rare, and they usually cosecrete vasoactive intestinal peptide (VIP), somatostatin, or pancreatic polypeptide. Neuroendocrine tumors vary in their clinical courses and in their clinical endocrine syndromes. For example, insulinomas cause hypoglycemia; gastrinomas cause Zollinger-Ellison syndrome; VIPomas cause watery diarrhea, hypokalemia, achlorhydria (WDHA) syndrome; and glucagonomas cause glucagonoma syndrome. Among these tumors, gastrinoma is the most common malignant tumor and insulinoma is the most common benign tumor.

## Carcinoid Syndrome

Carcinoid syndrome is caused by the release of a number of bioactive substances, but detailed knowledge of the pharmacologic mechanisms is still lacking. The most typical clinical manifestations of carcinoid syndrome are cutaneous flushing and diarrhea. Serotonin and biogenic amines cause the flushing, and motilin and substance P increase the motility of the small bowel and colon and cause the diarrhea. Other clinical manifestations of the syndrome include bronchoconstriction, telangiectasia, and cardiac valvular lesions (carcinoid heart disease).

Carcinoid tumors are the most common neuroendocrine tumors (estimated 7 to 13 cases per 1 million people per year). Carcinoid tumors can be part of MEN type I. Carcinoid tumors occur most commonly in the gastrointestinal tract and the lung. Most patients with carcinoid tumors are asymptomatic; only about 10% manifest carcinoid syndrome. Because the liver can metabolize and inactivate vasoactive amines efficiently, carcinoid syndrome rarely occurs in the absence of liver metastases or venous drainage from tumors entering directly into the systemic circulation (eg, pulmonary carcinoids or extensive bone metastases) instead of the portal circulation.

A biochemical tumor marker for carcinoid tumors is serum chromogranin A, and a specific marker for carcinoid syndrome is the increased urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA, a liver metabolite of serotonin excreted by the kidneys). The specificity of urinary 5-HIAA in the diagnosis of carcinoid syndrome approaches 100% after excluding the ingestion of certain foods and medications that are known to elevate 5-HIAA levels (eg, avocados, bananas, kiwi fruit, pecans, plantains, pineapples, plums, walnuts, guaiafenesin, and acetaminophen). On the other hand, false-negative tests can result from ingestion of aspirin or levodopa, either of which can lower 5-HIAA levels.

In some patients with carcinoid syndrome and normal urinary 5-HIAA, documenting elevated plasma or platelet serotonin concentrations

or plasma histamine and peptide hormone levels may establish the diagnosis. Imaging studies to localize carcinoid tumors include abdominal ultrasonography (US), computed tomography (CT), magnetic resonance imaging (MRI), abdominal angiography, indium <sup>111</sup>In pentetate scintigraphy, <sup>123</sup>I- or <sup>131</sup>I-MIBG scintigraphy, and carbon <sup>11</sup>C serotonin positron emission tomography. Endoscopy, with or without endoscopic US, or videocapsule endoscopy may help localize carcinoid tumors in the intestinal tract.

## Treatment

Surgical resection is the standard treatment modality for carcinoid tumors. If no metastatic disease is detectable and the primary carcinoid tumor is resectable, 5-year survival rates are 70 to 90%. Therapies for carcinoid syndrome are aimed at reduction of tumor bulk and inhibition of hormone secretion. To reduce tumor bulk, surgery, radiotherapy, hepatic artery embolization (chemo- or radiotherapy), alcohol sclerotherapy for liver metastases, radiofrequency ablation of liver metastases, cryosurgery for liver metastases, radioisotope-coupled somatostatin analogue (<sup>131</sup>I-MIBG) administration for targeted delivery of a treatment radiation dose to the tumor, and occasionally chemotherapy may be considered. Somatostatin analogues (eg, octreotide) are effective in inhibiting hormone secretion. Symptoms in patients with carcinoid syndrome can usually be palliated by subcutaneous injections of octreotide (50–200  $\mu$ g) two to three times a day. Pegylated-octreotide depot formulations for intramuscular injection can be administered once a month with equivalent efficacy. Some patients benefit from the use of interferon- $\alpha$ . Anecdotal reports of biologic activity indicate that some patients may respond to combined octreotide and interferon- $\alpha$  treatment.<sup>12</sup>

## Insulinoma-Induced Hypoglycemia

Found in only 1.5% of detailed autopsies, islet cell tumors are uncommon cancers (200–1,000 new cases per year in the United States). About 85% of patients with MEN type 1 have pancreatic islet cell tumors. Insulinoma is the most common islet cell tumor. Over 90% of insulinomas are benign and solitary, and about 10% are malignant, with metastasis to the lymph nodes or liver. Whereas benign insulinomas can be cured by surgical resection, metastatic malignant insulinoma is not curable, and the clinical course of malignant insulinoma is often indolent owing to the relatively slow growth rate of these cancers.<sup>13</sup>

## Diagnosis

The dysregulated release of insulin that occurs in insulinoma leads to fasting hypoglycemia, producing neuroglycopenic symptoms of confusion,

loss of consciousness, coma, or seizures. Hypoglycemia can also activate the sympathetic nervous system to release catecholamines, producing tachycardia, tremulousness, and diaphoresis.<sup>13</sup>

The following is the differential diagnosis of hypoglycemia in patients with cancer: liver failure, starvation, hypopituitarism, hypoadrenalism, sepsis, insulin overdose, sulfonyleurea overdose, insulinoma, and non- $\beta$ -islet cell tumor-induced hypoglycemia. Diagnosis of insulinoma requires the presence of Whipple's triad: symptoms of hypoglycemia, glucose level below 50 mg/dL, and relief of symptoms after administration of glucose. The glucagon stimulation test is a simple and fast evaluation that can clarify the etiology of hypoglycemia and guide effective long-term strategies for control of hypoglycemia.<sup>14</sup> The differential diagnosis of fasting hypoglycemia may include an insulinoma, a non- $\beta$ -islet cell tumor secreting insulin-like hormone, exogenous insulin, or stimulated release of insulin by secretagogues. Measurements of C-peptide and insulin levels, sulfonyleurea and meglitinide levels, and insulin-like growth factor 2 levels help determine the correct diagnosis. C-peptide and insulin levels will be higher than normal in cases of insulinoma or after administration of an insulin secretagogue, whereas in factitious hypoglycemia owing to exogenous insulin, insulin levels will be higher than normal, but C-peptide levels will be lower than normal because exogenous insulin contains no C-peptide. The different hormonal profiles in insulinoma-induced hypoglycemia and non- $\beta$ -islet cell tumor-induced hypoglycemia are shown in Table 1.

#### Treatment

Surgical resection is the treatment of choice for insulinomas. In the absence of preoperative localization and intraoperative detection of an insulinoma, blind pancreatic resection is not recommended.<sup>15</sup> Intraoperative US can be combined with other preoperative imaging modalities to improve tumor detection. Endoscopic US-guided

ablation may be a minimally invasive alternative.<sup>16</sup> Glucocorticoid therapy can increase insulin resistance, reduce glucose use, increase hepatic glucose production, and impair insulin secretion and is a valid option for the control of insulinoma-induced hypoglycemia.<sup>17</sup> Other options for control of hypoglycemia include oral intake of carbohydrate, glucagon, or diazoxide and glucose infusion. The use of continuous infusion of glucagons to treat tumor-induced hypoglycemia may lead to side effects that resemble the symptoms of glucagonoma.<sup>18</sup> Octreotide or lanreotide has been tried in patients with insulin-producing islet cell tumors, generally without success. The lack of success may relate to the fact that the somatostatin analogues currently available are more effective for inhibiting glucagon than insulin secretion.

#### Glucagonoma Syndrome

Glucagonoma syndrome consists of a venous thromboembolism, necrolytic migratory erythema (Figure 2), and angular cheilitis. Glucagon-induced hyperglycemia is transient because a glucagon-induced increase in glycogenolysis does not persist; during sustained hyperglucagonemia, gluconeogenesis increases progressively. The transient glycogenolytic response to sustained hyperglucagonemia is not the result of glycogen depletion but the result of induction of counterregulatory hormones, such as insulin.

Glucagonoma has been reported in association with MEN type 1. A fasting plasma glucagon level of more than 1,000 ng/L establishes the

diagnosis. More modest elevations of plasma glucagon levels may occur in diabetic ketoacidosis, renal failure, hepatic failure, sepsis, prolonged fasting, and gluten-sensitive enteropathy. Hypocholesterolemia and hypoaminoacidemia (ie, alanine, glycine, and serine levels <25% of normal) are common. Glucagonoma may be distinguished from other hyperglucagonemic states by the failure of glucose to suppress serum glucagon levels and the failure of arginine to enhance serum glucagon levels. To localize glucagonomas, angiography, CT, or MRI may be used. Glucagonomas are hypervascular and can be localized together with hepatic metastases by selective angiographic study of the celiac tripod. The CT and MRI studies of the pancreas may demonstrate the precise location of the tumor (in the tail of the pancreas in almost 90% of cases). Islet cell tumors have a marked increased signal intensity on T<sub>2</sub>-weighted MRIs, and gadolinium enhancement in the non-necrotic areas of the tumor will allow differentiation of islet cell tumors from pancreatic adenocarcinoma. Other imaging methods, such as MIBG scintigraphy, positron emission tomography, or scintigraphic study with <sup>111</sup>In octreotide or with <sup>11</sup>C levodopa, may be used in the early localization of the tumor.

#### Treatment

Octreotide causes symptom regression in some patients. Administering the long-acting somatostatin analogue may be the first step of a multimodal therapeutic strategy, which almost always includes surgical resection of the primary tumor.

**Table 1** Hormone Profiles of Tumor-Induced Hypoglycemia

Hormone	Change Compared with Normal	
	Non- $\beta$ -Islet Cell	Insulinoma
IGF-1	Equivocal	Equivocal
IGF-2	Increased	Equivocal
IGFBP-3	Decreased	Equivocal
Insulin	Decreased	Increased
Glucose	Decreased	Decreased
Growth hormone	Decreased	Increased
$\beta$ -Hydroxybutyrate	Decreased	Decreased

IGF = insulin-like growth factor; IGFBP = insulin-like growth factor binding protein.

**FIGURE 2** Necrolytic migratory erythema. A, Left inner upper thigh. B, Right leg.

Liver metastases may be treated by partial hepatectomy, hepatic arterial chemoembolization, and streptozocin-based systemic chemotherapy (doxorubicin plus streptozocin or 5-fluorouracil plus streptozocin).<sup>19</sup>

### WDHA Syndrome

VIPoma causes a clinical syndrome characterized by watery diarrhea, hypokalemia, and achlorhydria. The diagnosis is based on clinical features and hormonal profiles demonstrating high serum VIP levels and the dominance of VIP over other pancreatic hormones. VIP levels at the time of diagnosis are more than three times the upper normal limit in the majority of cases.

To localize the primary lesion, CT, MRI, endoscopic US, angiography, or octreotide scintigraphy may be used. In about two-thirds of the cases of WDHA syndrome, the primary lesion is located in the pancreas, whereas in the rest of the cases, it is in the duodenum or retroperitoneum. Surgical resection is feasible in about two-thirds of the cases. For metastatic disease or poorly differentiated tumors, treatment with octreotide and chemotherapy should be offered. Reduction of tumor burden by surgery or chemoembolization in combination with administration of octreotide or chemotherapy may prolong survival in patients with advanced disease.<sup>20</sup> Because VIPomas usually have a slow rate of growth, unlike more aggressive malignancies, it is recommended that patients with advanced and incurable VIPomas receive palliative treatment. These patients appear to survive longer when they are treated proactively with sequential multimodality treatments.<sup>21</sup>

### Zollinger-Ellison Syndrome

Neuroendocrine tumors associated with Zollinger-Ellison syndrome often cause gastric hydrochloric acid hypersecretion and upper gastrointestinal ulcer disease, which is often severe. Gastrin levels > 500 pg/mL in patients with basal acid hypersecretion are often indicative of gastrinoma, but gastrin levels > 500 pg/mL can also occur in patients with antral G-cell hyperplasia and hyperchlorhydria. Other conditions associated with moderately elevated gastrin levels include gastric ulcers, chronic renal failure, hyperparathyroidism, pyloric obstruction, carcinoma of the stomach, vagotomy without gastric resection, retained gastric antrum, and short bowel syndrome. If gastrinoma is likely but fasting gastrin levels are not diagnostic, the secretin test is the provocative test of choice. Intravenous secretin normally diminishes gastrin, but in gastrinomas, the gastrin level will be increased.

Gastrinoma-associated gastric acid hypersecretion is treated with antacids, proton pump inhibitors, and histamine receptor type 2 antagonists, and resectable gastrinoma is treated primarily with surgery. Gastrinoma can be staged by TNM criteria into four stages with different survival curves, with tumor size and distant metastases being statistically significant predictors of survival.<sup>22</sup> Patients with sporadic gastrinoma have a longer disease-free survival time than do patients with MEN type 1, although gross complete removal of the tumor improves survival in both types of patients.<sup>22</sup> Other disease complications that may require surgical intervention include a perforated viscus, acute gastrointestinal hemorrhage secondary to refractory peptic ulcer disease, and gastric outlet obstruction.

### Somatostatinoma Syndrome

Somatostatinoma is a rare tumor (1 case per 40 million people annually). Excess somatostatin causes a clinical syndrome of diabetes mellitus, steatorrhea, and cholelithiasis.<sup>23</sup> Other complications, such as diabetic ketoacidosis<sup>24</sup> and relapsing cholangitis,<sup>25</sup> have also been reported to be associated with somatostatinoma. Tumors of the pancreas and gastrointestinal tract that secrete excess somatostatin are classified as somatostatinomas, although 10% of such tumors also secrete other humoral factors, including glucagon, gastrin, VIP, insulin, calcitonin, and adrenocorticotrophic hormone.<sup>26–28</sup> Somatostatinomas are typically large, solitary, malignant tumors arising from the head of the pancreas and are often metastatic to the lymph nodes or liver at the time of diagnosis or surgery. They may be located in the pancreas (56%) or extrapancreatic sites (duodenum, ampulla, jejunum, or cystic duct). Duodenal somatostatinomas are often asymptomatic or only local symptoms rather than the clinical syndrome of excess somatostatin production.<sup>29</sup>

Like other tumors of the gastroenteropancreatic tract, somatostatinomas should be managed by surgery whenever possible. Palliative treatments and chemotherapy for progressive metastatic disease have been discussed for neuroendocrine tumors collectively,<sup>30</sup> but the literature on the management of specific types of advanced neuroendocrine tumors is lacking.

The prevalence of diabetes mellitus has more than doubled in the United States since 1980; currently, an estimated 20.8 million people living in the United States have diabetes, and for every two persons with diagnosed diabetes, there is one to two with undiagnosed diabetes.<sup>1</sup> Based on hospital records, it is estimated that approximately 20% of patients with various cancers are known to have diabetes.<sup>2</sup> It is well known that hospital records underreport the prevalence of diabetes mellitus.<sup>3,4</sup>

The prevalence of diabetes and cancer increases with age; there may be common risk factors for diabetes and some cancers; diabetes may predispose patients to certain cancers; and cancers and cancer therapies may worsen or precipitate diabetes. Cancer prognosis may be affected by glycemic status. Acute hyperglycemic complications of diabetes may interfere with timely cancer therapy, including surgery and chemotherapy. In a person with uncontrolled diabetes, the risks of infections may be higher and wound healing impaired. Cancer patients with diabetes may be at a higher risk of developing certain complications of cancer chemotherapy.

Timely diagnosis of diabetes is a prerequisite for its optimal management. Fasting plasma glucose is sufficient to screen for diabetes mellitus. A fasting plasma glucose  $\geq 126$  mg/dL following at least 8 hours (overnight) without caloric intake or a casual or nonfasting plasma glucose concentration  $\geq 200$  mg/dL with symptoms of diabetes clinches the diagnosis of diabetes, if confirmed on another day by at least one of the two tests. Some of the classic symptoms of diabetes, such as unexplained weight loss, may be confounded by the presence of the cancer.

Randomized controlled clinical trials in both type 1 and type 2 diabetes have conclusively demonstrated that tight blood glucose control reduces the risk of long-term complications of diabetes.<sup>5-7</sup> Tight blood glucose control with intensive insulin

therapy has also been shown to reduce morbidity and mortality among critically ill patients.<sup>8</sup> In contrast to the large evidence base that guides optimal diabetes management, there is very little research into effective management approaches and associated outcomes for patients with both cancer and diabetes mellitus. In this chapter, we review (1) the pathophysiology of both diseases, highlighting common pathways; (2) the available evidence indicating that hyperglycemia affects some cancer and cancer treatment outcomes; (3) what is known about the effect of cancer therapy on diabetes; and (4) management of diabetes in a cancer patient, including nutrition therapy and the care of diabetics with advanced cancer.

## Diabetes and Cancer Outcomes

There is increasing evidence that patients with diabetes or impaired glucose tolerance may be at an increased risk of cancer, cancer recurrence, cancer-related mortality, and all-cause mortality.<sup>9-11</sup> Specifically in large cohort studies, pancreatic, colon, breast, liver, and endometrial cancers have been shown to occur more frequently in patients with a history of diabetes mellitus. For certain malignancies, the presence of diabetes and/or impaired glucose tolerance may also adversely affect the response to cancer treatment. Patients with stage II–III colon cancer treated with adjuvant chemotherapy had a lower 5-year survival rate if they had diabetes.<sup>12</sup> Diabetes was found to be an independent risk factor for a shorter overall (19.8 vs 29.2 months) and disease-free survival (11.3 vs 17.2 months) in patients with resectable pancreatic cancer receiving adjuvant or neoadjuvant treatment, in addition to surgery.<sup>13</sup> Patients with acute lymphocytic leukemia treated with hyper-CVAD (fractionated cyclophosphamide, vincristine, Adriamycin, and dexamethasone) ( $N=278$ ) had a shorter median remission duration and (24 vs 52 months) overall survival (29 vs 88 months) when they had diabetes or hyperglycemia.<sup>14</sup>

Chemotherapy and radiotherapy may be more toxic in people with diabetes. It is believed that diabetes predisposes patients to neuropathy induced by chemotherapies.<sup>15</sup> Likewise, late-radiation toxicities are higher in people with diabetes.<sup>16</sup>

There is a lack of randomized trials investigating if optimal treatment of diabetes affects cancer outcomes. It is likely that the targets of therapy and optimal choice for diabetes treatment may well be cancer type, site, and stage dependent, with a great deal of individualization when life expectancy is very short.

Insulin, which is typically elevated in the early stages of type 2 diabetes, is a potential growth factor for malignancies. Insulin reduces sex hormone-binding globulin levels, thereby increasing concentration of free estradiol, which may play a role in inducing neoplasia of the breast, endometrium, and ovary. Insulin cross-reacts with the insulin-like growth factor 1 (IGF-1) receptor; the latter activates intracellular tyrosine kinase activity, which stimulates cell growth. In cell culture, growth of virtually all cell lines is stimulated by insulin and IGF-1. Tumor cells may also lose their ability to down-regulate insulin-binding sites and become more sensitive to the stimulatory effects of insulin.<sup>17</sup> In vitro insulin may also inhibit the apoptotic effects of certain antineoplastic therapies, such as anti-epidermal growth factor receptor monoclonal antibody.<sup>18</sup> However, the concentration of insulin used in in vitro models is several orders of magnitude higher than the prevailing insulin concentrations in patients with diabetes. In vivo insulin has been shown to ameliorate enhanced tumor growth in a streptozocin-induced diabetic hamster model.<sup>19</sup> Therefore, whether insulin promotes cancer growth in vivo is still an open question.

Hyperglycemia may also directly affect tumor cell biology. Tumor cells tend to exhibit increased glycolytic metabolism.<sup>20</sup> Glycolysis per se may promote carcinogenesis.<sup>21</sup> Hyperglycemia

may also reduce the sensitivity of certain tumor cell lines to certain types of chemotherapy.

## Wound Healing and Diabetes

Uncontrolled diabetes is associated with more frequent infections and a tendency toward more complicated infections.<sup>22</sup> Poor control of diabetes is associated with impaired white blood cell function,<sup>23</sup> and infection rates have been decreased with more aggressive control of blood glucose.<sup>24</sup> Significant hyperglycemia is associated with poor collagen content and wound healing.<sup>25</sup>

## Pathophysiology of Diabetes in Cancer

Certain neoplasms may produce hormones with counterinsulin (eg, glucagon, adrenocorticotropic hormone [ACTH], cortisol, catecholamine) or insulin-suppressant (somatostatin) actions. Diabetes may be one of the characteristics of these syndromes.<sup>26–29</sup> Acute diabetic complications have been reported with several of these tumors (glucagonoma,<sup>30</sup> ACTH-producing tumors,<sup>31</sup> and pheochromocytoma).<sup>32</sup> More commonly, on the other hand, malignancies not typically associated with secretion of the hormones mentioned above are associated with a new diagnosis of diabetes,<sup>33</sup> best exemplified for pancreatic cancer.

## Systemic Factors

Prevailing plasma glucose concentrations are a result of the balance of the amount of glucose entering the circulation and the amount leaving. Increased glucose entering, reduced leaving, or both can cause hyperglycemia. Cancers are associated with increased glucose production and gluconeogenesis<sup>34,35</sup> and decreased glucose uptake.<sup>36</sup> Cancers, cancer therapies, and concurrent infections are associated with elevated free fatty acids.<sup>37,38</sup> Elevated free fatty acid concentration has been shown to be associated with reduced glucose use and increased glucose production, with increased gluconeogenesis.<sup>39–41</sup> Many malignancies and several chemotherapies are associated with catabolic states and with elevated lactic acid concentrations.<sup>42,43</sup> Elevated lactic acid concentrations, in turn, promote hepatic gluconeogenesis and ketogenesis.<sup>44</sup>

Cytokines and other substances released from the cancers<sup>45</sup> can cause hyperglycemia by inducing insulin resistance. Certain infections may be associated with increased cancer and diabetes occurrence; for example, hepatitis C infection is associated with both (hepatocellular) cancer and diabetes mellitus.<sup>46</sup> Plasma cortisol and glucagon concentrations in patients with malignant tumors are significantly increased when compared with patients with benign surgical disorders,<sup>47,48</sup> causing anorexia, enhanced

tumor protein synthesis, stimulated tumor growth,<sup>49</sup> and an increased rate of appearance of glucose in the blood.

## Effects of Cancer Treatment on Diabetes Mellitus

As summarized in Table 1, several drugs used for cancer may have adverse effects on glycemic control. Glucocorticoids used as antitumor agents or for symptom relief and prevention of hypersensitivity reactions worsen glycemic control in people with established diabetes and may precipitate diabetes, especially in people predisposed to type 2 diabetes. In our experience, this is related to the dose and potency of the glucocorticoid. The mechanisms are multiple, including increased hepatic glucose output and decreased peripheral glucose use, in addition to reduced insulin secretion.<sup>50</sup> Interferon- $\alpha$ 2 is used to treat chronic myelogenous leukemia and melanoma; hyperglycemia is one of the main side effects of this drug. Some patients who develop interferon-alpha2 induced hyperglycemia require insulin for therapy. Therefore it is believed that Interferon-alpha 2 induced hyperglycemia may be immune mediated.<sup>51</sup> L-Asparaginase is used to treat acute leukemia and lymphoma; it is thought to cause hyperglycemia through inhibition of insulin activity or receptor synthesis.<sup>51</sup> Octreotide is a synthetic long-acting somatostatin analogue; it inhibits secretion of several hormones, including insulin,<sup>52</sup> and can cause hyperglycemia. Tacrolimus is an immunosuppressive drug used in both solid organ and stem cell transplantation. Hyperglycemia requiring insulin treatment has been observed in 5% of patients receiving it for graft-versus-host disease.<sup>53</sup>

Imatinib (Gleevec) binds to the BCR-ABL gene at the adenosine triphosphate binding

site. This results in an inhibition of the activity of BCR-ABL gene and elimination of these BCR-ABL gene (Philadelphia chromosome) positive cells.<sup>54</sup> Imatinib may decrease blood glucose in patients with known diabetes, sometimes in a dramatic fashion,<sup>55</sup> by an as yet unknown mechanism.

Specific surgical procedures (pancreatectomy for pancreatic and gastrointestinal cancers) and radiotherapy to the abdominal region may also be associated with new-onset diabetes mellitus.<sup>56</sup>

## Lifestyle Changes and Diabetes

Cancer-related fatigue, weakness, decreased muscle strength, anxiety, depression, and changes in body image are associated with decreased physical activity and can reduce insulin sensitivity.<sup>57</sup> Cancer patients have been advised to rest by the family and physicians, despite the benefits of regular physical activity.<sup>58</sup> Prolonged decreased physical activity can cause disuse muscle atrophy and a further decline in activity.

## Cachexia

Malignancies are associated with varying degrees of cachexia, with pancreatic and gastric cancer causing it most often. Unlike weight loss induced by regular exercise and dietary intervention, cachexia-associated muscle wasting leads to muscle weakness and fatigue, resulting in decreased physical activity and reduced glucose use. Infections are also common in cachectic persons because of poor immune function, complicating the insulin resistance of cachexia.

## Nutrition Supplements

Nutritional supplements, including tube feeding and intravenous parenteral nutrition, can increase plasma glucose concentrations, especially if the

**Table 1** Pharmacologic Agents in Oncology that May Affect Blood Glucose

Agent	Current Uses	Side Effect	Possible Mechanisms
Glucocorticoids	Chemotherapy for acute leukemia, lymphoma; symptomatic brain metastasis, nausea and vomiting, pain; premedication for taxanes and many other regimens	Hyperglycemia	Increased hepatic glucose production; decreased peripheral glucose use; decreased insulin effectiveness Decreased insulin secretion
Interferon- $\alpha$ 2 L-Asparaginase	Metastatic melanoma Acute leukemia	Hyperglycemia Hyperglycemia	Immune mediated Inhibition of insulin or insulin receptor synthesis
Octreotide (Sandostatin)	Carcinoid, pituitary tumors and VIP-secreting tumors	Hyperglycemia	Inhibition of insulin secretion
Tacrolimus (Prograf)	GVHD	Hyperglycemia and new-onset insulin-requiring DM	Inhibition of insulin secretion, peripheral insulin resistance
Imatinib (Gleevec)	CML; GIST	Improvement of hyperglycemia	Unknown; possibly reduced insulin resistance

CML = chronic myelogenous leukemia; DM = diabetes mellitus; GIST = gastrointestinal stromal tumor; GVHD = graft-versus-host disease; VIP = vasoactive intestinal peptide.

amount of glucose delivered is more than the body's ability to use it. Provision of extra insulin may not be able to compensate if overwhelming excess calories are provided to these patients with low muscle mass and diminished ability to use glucose.

### Managing Diabetes in Patients with Cancer

Treating diabetes in a person with active cancer is often complicated by the very presence of cancer, cancer therapies, and treatment side effects, such as anorexia, nausea, and weight loss. Acute complications of diabetes and urgency of treating severe hyperglycemia often delay the treatment of cancer. The presence of diabetes increases the stress of cancer and cancer management.

The goals of diabetes management have become more stringent, with rapidly accumulating evidence of the benefits of tight glycemic control in preventing chronic complications from diabetes. However, in the presence of a severe illness, such as cancer, undergoing active therapy, the benefits of tight glycemic control are not clear. Extrapolating from the data, one could argue that glycemic control should be targeted to as close to normal as possible, without increasing hypoglycemic events or adding significant stress to the patient. Plasma glucose concentrations should be kept below 200 mg/dL (blood glucose below 180 mg/dL) since concentrations higher than that increase the risks of infection, poor healing, and possibly the risks of acute hyperglycemic complications.

### Diabetes Education

Diabetes mellitus should not be labeled as "hyperglycemia" unless the specific or another cause of hyperglycemia is not likely to recur. Even if hyperglycemia is apparently attributable to a specific medication or stress, patients and their physicians should realize that such situations can and possibly will arise again during the subsequent treatment cycles. It is safer if a patient believes that she or he has "diabetes" and continues to monitor periodically and more frequently when ill. In this way, severe hyperglycemia is prevented by early recognition and intervention. Family and caregivers should understand that adequate diabetes education and management facilitate timely evaluation and treatment of the cancer and reduce the risk of infection, poor wound healing, and unplanned hospitalizations and doctors' visits. Skills learned during this time would be helpful for a healthy life after cancer.

It is ideal that patients and their family members acquire the skills of diabetes self-management. These include blood glucose monitoring, techniques of insulin injection, knowledge and skills of correcting the insulin dose for blood

glucose, and self-adjustment of insulin doses based on a pattern emerging from a few days of monitoring. Hypoglycemia prevention and management plans (including glucagon injection technique if appropriate) and management plans for the days when sick, traveling, or fasting for tests should be in place for the patient. An identification card listing the current medicines and simple instructions for what to do when the patient is found with an altered mental status should be carried by patients taking agents that can cause hypoglycemia.

### Nutrition

Medical nutrition therapy plays a central role in the treatment of diabetes mellitus. Medical nutrition therapy involves a comprehensive nutrition assessment to evaluate current nutritional status. In addition to the diet history, the nutrition assessment should include the patient's medical history, social history, physical data including height and weight, and laboratory data.<sup>59</sup>

In a cancer patient, the nutrition assessment should also consider cancer treatment modalities (such as surgery, chemotherapy, and radiation) and management of their side effects. In general, the overall goal for a person with diabetes and cancer is to maintain optimal metabolic control and achieve a weight that is appropriate for the patient.<sup>59,60</sup> Some patients with cancer and diabetes are overweight and are advised to lose weight, so caloric restriction may be appropriate for them. Others may be losing too much weight or losing weight too quickly, and in such situations, weight maintenance or improvement may be a nutritional management goal. Therefore, these patients require oral nutritional supplements in addition to a healthy diet.

A registered dietitian plays an important role in making recommendations that are specific to the individual and should provide a strategy for achieving a healthy diet and lifestyle.<sup>60</sup> The dietitian should participate in monitoring patient progress in establishing a healthy diet, maintaining a healthy weight, and achieving adequate glycemic control. If established goals have been met, then there may be no need for further change.

In general, carbohydrate and monounsaturated fat should provide 60 to 70% of estimated energy requirements, protein should be approximately 15 to 20% of total caloric intake (1–1.5 g/kg body weight), and fat should be limited to less than 30% of total caloric intake, with less than 10% of total caloric intake from saturated fat. Diets such as those that are "low sugar" or "sugar free" or have "no concentrated sweets" are not synonymous with medical nutrition therapy for diabetes and are not indicated for glycemic control. Sucrose does not increase glycemia to a greater extent than isocaloric

amounts of starch. Therefore, sucrose and sucrose-containing foods do not need to be restricted by people with diabetes and should be eaten in the context of a healthy diet.<sup>60</sup>

If diabetes is being treated with sulfonylurea, other insulin secretagogues, or intermediate-acting or mixed insulin, the timing of meal and distribution of carbohydrate intake through the day are important, with the aim of preventing both significant hyper- and hypoglycemia. Spacing of meals, increasing fiber intake, and not skipping meals are critical. When actively treated cancer patients have anorexia, nausea, dysphagia, or other complications preventing timely food intake, they are encouraged to consume culturally appropriate foods that can be easily swallowed, retained, and digested. In such a setting, oral nutritional supplements may be most convenient. Alternatively, they may also need a change in their pharmacologic treatment of diabetes to avoid hypoglycemia.

If a person with diabetes needs intensive insulin therapy, prandial (meal related) insulin may need to be titrated to the total carbohydrate intake in the meal rather than the source or the type of carbohydrate. Initially, it may be convenient to teach the patient and the family to keep the carbohydrate content of each meal consistent, and this can be achieved by learning basic carbohydrate counting and meal exchanges. In this way, insulin doses can be titrated quickly. If required, later they can learn and work with the carbohydrate to insulin ratio.

Use of nutritional support may necessitate changes in the therapeutic regimen for diabetes. For example, patients being tube-fed overnight may need "prandial" insulin before their tube feeds in the form of Neutral Protamine Hagedorn (NPH). An enteral or parenteral nutritional supplement provides calories through an unphysiologic route and pattern, without a concomitant increase in incretin hormones; therefore, inadequate insulin concentrations in relation to the carbohydrates are provided. This, along with insulin resistance and relative insulin deficiency induced by sickness, cancer, and cancer therapies, necessitates careful calorie assessment and judicious provision of insulin. Broadly, wherever possible, regular food taken by mouth is better than enteral tube feeding, and the latter is better than parenteral nutrition. Parenteral nutrition should be restricted to situations with proven benefits or in a clinical trial setting. Parenteral feeding should be ramped down quickly whenever enteral or oral feeding can be resumed.

### In-Patient Diabetes Management

Insulin is the mainstay of therapy in the hospital. Unpredictable oral intake makes use of insulin secretagogues best avoided in the inpatient setting (Table 2). Nausea from other medications

Table 2 Types of Oral Glucose-Lowering Medications

Class name	Generic Name (Brand Names)	Primary Action	Contraindications	Adverse Effects	Benefits	Implications for Actively Treated Cancer Patients
Biguanides	Metformin (generic, Glucophage, Glucophage XR)	Decreases hepatic glucose production, reduces appetite, improves glucose uptake by muscles and fat	Renal dysfunction (high creatinine), cardiovascular shock, acute myocardial infarction, septicemia, congestive heart failure, acute or chronic metabolic acidosis	Nausea, diarrhea, weight loss	Modest weight loss	May cause confusion: GI side effects and weight loss can be confused as the effect of cancer or its therapy Shown in correlative and animal studies to be associated with possible cancer prevention Often stopped for ≈48 hours before contrast radiography
Thiazolidinediones	Pioglitazone (Actos) Rosiglitazone (Avandia)	Increases glucose uptake by muscle and fat and reduces glucose production by the liver.	Heart failure (especially NYHA grade III and IV)	Water retention, anemia, weight gain	Does not cause hypoglycemia	Weight gain—may be desirable in some Heart failure and fluid retention may be confused as the effects of cancer therapy Actively being investigated for anticancer properties for several cancers
α-glucosidase inhibitors	Acarbose (Precose/Glucobay) Miglitol (Glyset)	Inhibits enzyme that facilitates the breakdown of complex sugars to glucose in the small intestine; causes carbohydrate malabsorption	Chronic intestinal disorders, severe renal impairment (creatinine clearance <25 mL/min)	Flatulence, abdominal bloating, diarrhea	Hypoglycemia does not occur when used alone	GI side effects and weight loss confused with cancer or therapy Treat hypoglycemia with glucose, not sucrose or other carbohydrates
Sulfonylureas and other insulin secretagogues	Glyburide (generic, Glynase, DiaBeta, Micronase) Glipizide (generic, Glucotrol, Glucotrol XL), glimepiride (Amaryl) Nateglinide (Starlix) Repaglinide (Prandin)	Enhances insulin secretion	Most contraindicated in significant renal and hepatic diseases	Hypoglycemia: repaglinide, nateglinide, and glipizide least likely to cause hypoglycemia; chlorpropamide, glyburide most likely Hyponatremia: chlorpropamide, glyburide	Most accumulated experience	May be difficult to use during cancer therapy: nausea and anorexia may cause erratic intake, and predisposition to hypoglycemia In vitro studies imply anticancer action of some compounds and their derivatives

GI = gastrointestinal; NYHA = New York Heart Association.

Combination pills: metformin + glyburide (generic, Glucovance); metformin + rosiglitazone (Avandamet); metformin + glipizide (Metaglip).

and the risks of lactic acidosis in the inpatient setting with hypoxia, hypoperfusion, and renal insufficiency increase the risk of adverse events with metformin use (see Table 2). Oral

medications take a long time to have a full effect, are titrated upward slowly, and have a slow onset of action, especially with thiazolidinediones (TZDs). Therefore, oral drugs are not the best

option for most patients with hyperglycemia or diabetes during hospitalization.

There is increasing evidence that near-normal glycemia in the hospital has the potential

for improved mortality and morbidity and decreased health care costs. Insulin therapy itself may have direct beneficial effects independent of its effect on blood glucose.<sup>61</sup> In December 2003, the American Association of Clinical Endocrinology together with the American Diabetes Association held a consensus conference on the management of the hyperglycemic patient in the hospital.<sup>62</sup> Target blood glucose levels were determined from the available literature to be the following: on the inpatient wards, target plasma glucose levels are <110 mg/dL preprandially, with a maximum glucose of 180 mg/dL at any time. In the intensive care unit (ICU) setting, a goal of near-normoglycemia has been set to 80 to 110 mg/dL. Recently, the American Diabetes Association, American College of Endocrinology, American Association of Clinical Endocrinologists, and other organizations came together and produced a document highlighting the importance of implementation of optimal diabetes management for inpatients.<sup>63</sup>

In general, hospitalized diabetic patients require both basal and prandial (mealtime or bolus) insulin coverage, just as in the outpatient setting. Sliding scale insulins are to be avoided and actually increase the risk of hypoglycemia and hyperglycemia compared with basal and prandial insulin.<sup>64-66</sup>

Insulin needs to be adjusted once or twice daily to account for the rapid changes that occur in the hospital. Nausea, vomiting, changes in oral intake, intermittent enteral tube feeding, intravenous fluids, use of glucocorticoids, and parenteral nutrition all necessitate frequent reassessment of the doses. Illness-related insulin requirements are high at the onset of an illness and decrease as the illness improves (see Table 3 for the timing of insulin delivery).

In the mechanically ventilated surgical ICU patient, intensive glycemic control with a target glucose of 110 mg/dL with intravenous insulin has been shown to decrease mortality and morbidity.<sup>8</sup> Evidence strongly supports the use of intravenous insulin for patients in diabetic ketoacidosis and hyperosmolar coma. In addition, we use intravenous insulin therapy during cardiovascular surgery; after a stroke, myocardial infarction, or organ transplantation; and for many other patients who are difficult to control with other regimens. An appropriate transition protocol off the intravenous insulin drip to subcutaneous insulin should be in place in the hospital to avoid worsened hyperglycemia after the drip is turned off. Various insulin protocols have been published.<sup>67,68</sup> Often endocrinologists, intensivists, internists, and nutritionists need to work in close collaboration with the primary team for the management of the diabetic patient admitted to the hospital.

## Outpatient Diabetes Management

### Insulin

Insulin is indicated in all patients with uncontrolled diabetes for whom oral drugs are contraindicated (see Table 2). In addition, because of immediate onset of action, it is the most appropriate mode for quick control of severely uncontrolled diabetes, for example, glucose >350 mg/dL or >250 mg/dL with ketonuria. Treating outpatients with insulin using a “sliding scale” is also inappropriate.

Most patients needing insulin will at least require basal insulin; this can be in the form of two doses of NPH or one to two doses of glargine or detemir insulin. Many others will require splitting the dose, especially if the requirements are higher than 30 U/d. Premixed insulins are handy

for brief therapies, such as the postprandial hyperglycemia induced by glucocorticoids. Ideally, patients with poor beta cell reserve should be treated with a combination of basal long-acting insulin (detemir or glargine, to supply basal needs) with rapid-acting insulin boluses (aspart or lispro for prandial needs), a regimen called basal-bolus or MDI (multiple daily injection of insulin).

Adjustments of insulin doses are based on the expected physiologic action of the insulin and determination of the glucose pattern before changing the doses. By definition, the basal insulin dose is intended to keep glucose stable when no food, intravenous glucose, or other form of insulin is given. Too often long-acting insulin (detemir or glargine) is being used to control both basal and prandial glycemia. This can lead to serious hypoglycemia if scheduled nutrition is interrupted.

### Oral Antidiabetics

Sulfonylurea drugs are the least expensive but can precipitate hypoglycemia if food intake is erratic. Some, especially chlorpropamide and glyburide, can cause hyponatremia. These are used with caution in the elderly, those with liver and kidney diseases, and patients with erratic oral intake. Metformin is an underused drug but cannot be used in patients with liver, kidney, or heart failure. Metformin and drugs that prevent conversion of sucrose and starch to glucose (acarbose and miglitol) can cause gastrointestinal symptoms, which can be confused with complication of cancer or its therapies. Peroxisome Proliferator-Activated Receptors-gamma (PPAR- $\gamma$ ) receptor agonists (rosiglitazone and pioglitazone) can cause fluid retention and weight gain. All oral drugs are equally effective in bringing down

Table 3 Insulin

Duration of Action	Subcutaneous Insulin			
	Rapid	Short	Intermediate	Long
Common names	Aspart (Novolog), lispro (Humalog), glulisine (Apidra)	Regular (Novolin R, Humulin R)	NPH (Novolin N, Humulin N)	Glargine (Lantus), detemir (Levemir)
Onset of insulin action	15 min	30 min to 1 h	2–4 h	2–4 h
Peak time of insulin action	1–2 h	2–3 h	4–10 h	Peakless
Duration of insulin action	3–4 h	3–6 h	10–16 h	20–24 h
Recommended administration of insulin	Usually taken immediately before or after eating	Usually taken 30–60 min before eating	Taken once or twice daily	Usually taken twice or once daily
Visual appearance	Clear	Clear	Cloudy	Clear
Implications for cancer patients	Best insulin when intake is unreliable; can be given after meal, based on food (carbohydrate) intake. Safety in cancer patients not studied.	Only form approved for IV use	Most accumulated experience	Glargine binds avidly to IGF-1 receptor. Implications not clear. Detemir more reliably absorbed. Safety in cancer patients not studied

IGF-1 = insulin-like growth factor 1; IV = intravenous; NPH = Neutral Protamine Hagedorn.

Class	Generic Names (Brand Names)	Mechanism of Action	Contraindications	Indications	Major Adverse Effects	How Used	Implications for Cancer Patients
Glucagon-like peptide 1 analogues	Exenatide (Byetta)	Increases insulin and reduces glucagon response to glucose; reduces gastric emptying, reduces appetite and weight	Gastroparesis	Type 2 diabetes adjunctive with metformin, a sulfonylurea, or a combination of the two	Nausea, vomiting, diarrhea, feeling jittery, dizziness, headache, dyspepsia	Subcutaneous 5 µg twice a day with meals, increased to 10 µg twice a day after 4 wk, as tolerated	Weight loss may be confusing “Benign thyroid C-cell adenomas” in rats May promote islet differentiation May inhibit apoptosis of certain cell types Safety in cancer patients not studied
Amylin analogue	Pramlintide (Symlin)	Reduced gastric emptying; prevention of the postprandial rise in plasma glucagon; improved satiety and potential weight loss. Suppresses glucagon and stimulates insulin secretion.	Gastroparesis; hypoglycemia unawareness	Type 1 diabetes, adjunct for mealtime insulin therapy Type 2 diabetes, adjunct for mealtime insulin with or without a concurrent sulfonylurea agent and/or metformin	Nausea, headache, anorexia, vomiting, abdominal pain, fatigue, dizziness, coughing, pharyngitis	Subcutaneous Type 1 diabetes: 15 µg before each major meal, increased by 15 µg to 30 or 60 µg/dose, as tolerated Type 2 diabetes on insulin: 60 µg before each major meal, increased to 120 µg/dose, as tolerated	Weight loss may be confusing Safety in cancer patients not studied

hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) on an average by 1 percentage point (except acarbose, miglitol, nateglinide, and repaglinide being slightly less effective, bringing down HbA<sub>1c</sub> by 0.5 percentage point).

For the management of diabetes in a patient with cancer, usually metformin is the first-line oral drug for obese individuals and glipizide for nonobese individuals. Often TZDs are started as the primary agent. Metformin can be combined with glipizide or TZDs if either of them is not effective alone. Often the most difficult problem is to make sure that the adverse symptoms from cancer or its therapies are not compounded by the medications. Constant surveillance of the contraindications is also required while using these drugs in a cancer patient.

#### Newer Diabetes Treatments

Inhaled insulin, glucagon-like peptide 1 analogue, and amylin analogue were recently added to the options for diabetes management (Table 4). As with the newer subcutaneous insulin analogues, there are no good studies investigating the safety and utility of these drugs in cancer patients.

#### Management of Glucocorticoid-Induced Diabetes

There are no large studies investigating the options for management of glucocorticoid-induced diabetes. TZDs may be effective in preventing and treating diabetes in such patients. However, if hyperglycemia is significant, insulin is invariably required. It is generally believed that larger doses of prandial than basal insulin

are required for such patients, but not uncommonly, patients have very high fasting glucose concentrations that will necessitate increasing basal insulin doses. Management requires self-monitoring of blood glucose to identify the pattern of hyperglycemia and assess the treatment regimen.

#### Management of Diabetes during Tube Feeding

If the G-tube feedings are being given by gravity three to four times a day, subcutaneous regular insulin before each tube feeding may be sufficient, in addition to a basal insulin. However, if tube feeding is being provided using a pump over a length of time, we give NPH insulin before each tube feeding. In addition, long-acting insulin may also be given, for the basal insulin needs, based on changes in blood glucose during the time there is no tube feeding and no NPH insulin. Administration of subcutaneous insulin should be tapered off before feeding finishes to avoid hypoglycemia.

#### Management of Diabetes during Parenteral Nutrition

Insulin is often added to the parenteral nutrition solution, providing usually 1 unit per 10 g of glucose (range 0.5–2 U/g glucose) in the parenteral nutrition bag. This may not be sufficient to control glucose, and extra regular insulin is given intravenously or subcutaneously as needed. In patients with known diabetes and/or high insulin requirements, many people will provide a small dose of long-acting insulin subcutaneously. This

prevents onset of hyperglycemia if and when the parenteral nutrition is interrupted. Whenever diabetes is difficult to control and/or requires high doses of insulin, the amount of total calorie intake should be reassessed. Beyond a certain limit, excess calories cannot be compensated by extra insulin. This limit is often reached quickly in an insulin-resistant sick person, especially on unphysiologic nutritional support. Reassessment of nutritional support may require indirect calorimetric measurement of basal energy expenditure.

#### Management of Diabetes in a Person with a Very Short Life Expectancy

When life expectancy with terminal cancer is brief, diabetes management is not aimed at preventing chronic complications. It has been suggested that dietary restrictions should be relaxed and that blood glucose monitoring should be performed only if the patient is conscious and symptom control requires it.<sup>69,70</sup> Insulin and other diabetes medications should be reduced with reducing appetite and intake and with the sole aim of controlling symptoms to make the person comfortable. Specialist input should be sought for pain control, comfort care, and family counseling.

# Obesity and Cancer

Robert H. Lustig, MD  
H. Leon Bradlow, PhD

One of the unmistakable features of cancer is the cachexia and weight loss associated with both tumor presentation and treatment. However, the relation between cancer and energy balance is much more complex. Obesity appears to be a risk factor for the development of certain cancers; in particular, reproductive cancers. Conversely, the sequelae of therapy of certain cancers lead to long-term cachexia, while the sequelae of others lead to long-term obesity. This chapter will explore the biochemical relations between excessive energy storage and risk for cancer, and the mechanism and treatment of disorders of positive energy storage in the aftermath of cancer treatment.

## Obesity as a Risk Factor for Cancer

### Epidemiology

For a long time, obesity was considered to be a relatively harmless condition without serious side effects, and indeed a measure of prosperity in some cultures. Gradually over a period of years, it became generally recognized among scientists, and indeed the general public, that obesity was an important risk factor in cardiovascular disease, hypertension, lipid disorders, and Type 2 diabetes (collectively known as the Metabolic Syndrome),<sup>1,2</sup> although the endocrine role of fat had not yet been recognized.

Following the discovery of leptin as a specific cytokine released by adipocytes,<sup>3</sup> a spate of other adipose tissue-derived cytokines (resistin, adiponectin, TNF- $\alpha$ , and acylation stimulating protein) were characterized, and fat was recognized as a true endocrine organ.<sup>4,5</sup> In addition to being the source of adipocytokine synthesis and secretion, fat serves as a major source of circulating estrogen derived by the aromatization of androgens to estrogens,<sup>6</sup> particularly in postmenopausal women. All of these fat-derived hormones and cytokines are known to have powerful effects on the immune system and bone, and presumably other organs as well.<sup>7,8</sup>

Despite all the intimations about the potential biologic role of fat, the concept that obesity was a risk factor for cancer was slow to be accepted by the scientific community, and even slower by

the general public. More attention has been paid to specific macronutrients and to toxins ingested in the diet as potential carcinogens, rather than total body fat itself. However, the role of obesity as a primary risk factor for certain cancers is now clear. As an example, the role of obesity in promoting colon cancer in rats proved to be independent of the type of diet on which the animals were maintained, with obese rats developing more colon cancer than thin rats.<sup>6</sup> The site of the fat appears to be important, with visceral fat rather than subcutaneous fat being responsible for cancer risk.<sup>9-11</sup>

Although computerized tomography and magnetic resonance imaging (MRI) can distinguish between subcutaneous fat and visceral fat, both of these are too expensive and impractical for large-scale studies. Therefore, investigators have turned to the low-budget measurement of body mass index (BMI; weight (kg)  $\div$  height (m)<sup>2</sup>) to quantitate obesity in epidemiologic studies.<sup>12</sup> Although BMI is an accurate assessment of adiposity for most adults, it is not valid for well-trained athletes with a large muscle mass, nor is it valid for the elderly where there is a shift in body composition. Lastly, BMI does not distinguish between subcutaneous and visceral fat. Some studies have suggested that the waist-hip ratio or the waist circumference is a better measure for the determination of cancer risk.<sup>13,14</sup> This fits well with the putative primary role of visceral fat. Recent World Health Organization studies have also found that there are ethnic differences as to the BMI values that portend medical risk. For example, Chinese subjects are obese at lower levels of BMI than Caucasians,<sup>15</sup> while African-Americans at equal levels of BMI to Caucasians manifest a lower incidence of the Metabolic Syndrome.<sup>16</sup>

Examination of the literature reveals that there are two different comparisons that have been employed in estimating cancer risk, which in some cases lead to very different conclusions. One can compare degree of obesity against the risk of cancer incidence, or against the risk of cancer mortality. For example, in the case of prostate cancer, obesity shows no increased risk of cancer incidence and perhaps even a slight

protective effect<sup>17,18</sup>; while obesity is a very significant risk factor for advanced disease in prostate cancer.<sup>19</sup> How much of this is biologic, as opposed to other factors (eg, socioeconomic status) has yet to be elucidated.

Although, in general, no association has been found between prior obesity and cancer risk, several studies have reported that increased birth weight may be associated with increased risk for breast cancer and prostate cancer.<sup>20-23</sup>

Initially, a series of small studies showed that obesity conferred an increased risk for various cancers,<sup>24-28</sup> but because the sample sizes were relatively small, the results were not convincing. Large-scale studies (Table 1) began in earnest with the work of Garfinkel on a cohort of 750,000 persons followed for 12 years, which showed an increased risk of cancer in both men and women who were more than 40% overweight, although the relative risk was still lower than that of cardiovascular sequelae.<sup>29</sup> A series of prospective studies on large populations, which were analyzed for all cancers in the United States, Canada, parts of Europe, and Japan,<sup>30-34</sup> showed an overall increase in the incidence of most types of cancer in obese subjects (Table 2). Examination of studies focusing on specific cancers also showed an increased risk in obese subjects, with a particularly high incidence for those with BMI levels greater than 35 kg/m<sup>2</sup> (Table 3).<sup>35-44</sup> In general, the relative risk of obesity in cancer appears to be higher in women than in men. Again, it is not clear if biologic or sociologic determinants are responsible.

Support for this hypothesis of increased cancer risk with obesity is not universal. In a meta-analysis, McGee concluded that the increased cancer risk due to obesity was quite small and less than the risks for other obesity-associated conditions.<sup>45</sup> Although most studies report a positive relationship between obesity and colon cancer, there are occasional studies that fail to find an association.<sup>46</sup> Somewhat surprisingly, Lukanova and colleagues found that the incidence of ovarian cancer is inversely related to obesity,<sup>47</sup> disagreeing with earlier reports of a positive correlation. The interpretation of many studies relating cancer incidence to obesity are often confusing in that they often fail to adjust for

**Table 1 Overall Cancer Risk with Obesity**

Authors	Population Size	Overall Cancer Risk	
		Men	Women
Calle et al. <sup>34</sup>	900,000	RR = 1.52	RR = 1/62
Garfinkel <sup>29</sup>	750,000	RR = 1.33	RR = 1.55

 ALL = acute lymphoblastic leukemia; CrXRT = cranial irradiation; BMI = body mass index; SD = standard deviation; Gy = Gray; GH = growth hormone.

multiple risk factors or for indirect associations. For example, examination of the role of obesity regarding the risk of lung cancer in the general population suggests that there is no association. But if one instead restricts the analysis to non-smokers only, then there is a direct positive association.<sup>48</sup> Presumably smoking tends to decrease food consumption, which limits weight gain and protects against obesity, while ex-smokers tend to gain weight immediately after stopping smoking. Similarly, the overall association between obesity and cervical cancer is inconclusive; however, if one controls for human papilloma virus (HPV) infection, a twofold increase is then noted.

Unlike the positive association between obesity and endometrial and breast cancer, there are others like Giovanucci, who was concerned about the absence of mechanism and the failure to fulfill Koch's postulate by showing that weight loss reduces cancer risk.<sup>49</sup> This concern has recently been answered by an Iowa study showing that women who deliberately lost weight and kept it off for some years had a decreased incidence of cancer relative to those controls who did not lose weight.<sup>50</sup> Women who did not lose weight deliberately (but, rather, for other reasons) showed no such benefit. The paucity of studies correlating weight loss with decreased cancer incidence reflects in large part the failure of most previously obese subjects to maintain the weight loss. The typical pattern is an inexorably slow regain of the weight lost, plus extra.<sup>51</sup> For this reason, the cost of carrying out such a study in order to retain a sufficient number of reduced-weight subjects would be enormous.

**Putative Mechanisms by Which Obesity Promotes Cancer**

**Oxidative Stress and Adipocytokine Production**

In looking for a mechanism or mechanisms, one must keep in mind that fat is an important endocrine organ. As recently noted by a Japanese group,<sup>52</sup> fat tissue is a major source of reactive oxygen species (ROS) in the body due to oxidative stress in this tissue; indeed the obese exhibit significantly higher levels of 8-isoprostanes, a ROS-metabolite of arachidonic acid.<sup>53,54</sup> Aside from the possibility of direct DNA damage due to ROS, the oxidative stress results in dysregulation of the synthesis and release of adipocytokines, decreasing the formation of protective factors like adiponectin, and increasing the formation of NADP oxidase levels and risk-promoting cytokines like plasminogen activation inhibitor-1 (PAI-1), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), vascular endothelial growth factor, hepatocyte growth factor, heparin-binding epidermal growth factor-like growth factor, and interleukin-6.<sup>55</sup> Many of these promote angiogenesis, which may explain increased invasiveness and poor

prognosis of cancer in the obese. Lastly, the adipocytokine leptin appears to have an important relationship with cancer. As an example, in a case-control study, Stattin and colleagues found a threefold increase in cancer incidence with increasing concentrations of leptin,<sup>56</sup> and Skibola and colleagues found a positive association between BMI, leptin receptor polymorphisms, and lymphoma.<sup>57</sup> Leptin, similar to obesity in general, correlates with increased prostate cancer mortality.<sup>58</sup> Again, while these circulating factors have not yet been directly implicated in carcinogenesis, they clearly have effects on immunomodulatory system function, which may contribute indirectly to cancer initiation or tumor promotion, and mortality.

### Estrogen Synthesis and Metabolism

Breast, endometrial, and cervical cancer are examples of estrogen-dependent cancers, which increase their rate of growth in response to circulating estrogen levels.<sup>59,60</sup> Body fat, particularly postmenopausally, is a major source of estrogen derived by the aromatization of androstenedione to estrone (Figure 1).<sup>61</sup> Thus in obese women, increased amounts of estrogen substrate are manufactured, and the total estrogen burden is markedly increased over the lifetime of the individual. Indeed, Key and colleagues<sup>62</sup> suggested that the increased formation of estrone in adipose tissue is a significant factor in the increased rate of breast cancer observed in obese postmenopausal women. Once formed, estrogen can be metabolized either by hepatic 2-hydroxylation to the inactive 2-hydroxy- or catechol estrogens; or by 16 $\alpha$ -hydroxylation within the breast tissue itself to the reactive species 16 $\alpha$ -hydroxyestrone, which circulates and is finally cleared by the liver and 17 $\beta$ -oxidated to the final metabolite estriol, which is excreted in the urine. Obesity alters the metabolism of estrogen by decreasing the formation of 2-hydroxyestrone and increasing the amount of circulating active estrogen. This has been demonstrated by Schneider and colleagues both

in vitro<sup>63</sup> and in vivo.<sup>64</sup> Therefore, obese subjects have higher circulating levels of active estrogen in the forms of estradiol, estrone, and 16 $\alpha$ -hydroxyestrone, which theoretically promote tumor progression. In addition, in vitro studies by Bradlow and colleagues have shown that adipocytes secrete a protein that inhibits 2-hydroxylation of estrogen in MCF-7 cells in culture.<sup>65</sup> The level of active estrogens is further increased by a decrease in the synthesis in the liver of sex hormone binding globulin (SHBG), which normally avidly binds sex hormones; thus potentiating levels of circulating free hormone in the obese, in order to promote increased cell proliferation.

The human papilloma virus (HPV), associated with most cervical cancers, is unusual in that the virus is estrogen-sensitive, with 16 $\alpha$ -hydroxyestrone promoting viral proliferation, while the alternative metabolite 2-hydroxyestrone inhibits exons E6 and E7 resulting in inhibition of the virus<sup>66</sup> and causing remissions in children with laryngeal papillomatosis and cervical dysplasia.<sup>67,68</sup>

### Hyperinsulinemia, Insulin-like Growth Factor-1, and Insulin-like Growth Factor-Binding Protein-1

Obesity is also associated with hyperinsulinemia, although there is still some controversy as to whether the obesity causes the hyperinsulinemia or vice versa.<sup>69,70</sup> The hyperinsulinemia and insulin resistance of obesity clearly plays a role in the promotion of the Metabolic Syndrome.<sup>71-74</sup> In addition, the hyperinsulinemia of obesity may also indirectly play a role in tumor promotion. A putative role for hyperinsulinemia also comes from studies in Type 2 diabetes, which is associated with an increased incidence of colorectal cancer.<sup>75</sup>

The hormone insulin-like growth factor-1 (IGF-1) has been implicated in numerous cancers, including colon, breast, and prostate cancer.<sup>76</sup> IGF-1 is a primary signal for mitogenesis, by directly binding to the IGF-1 receptor on the cell

surface, and inducing cells to progress from the G1 to the S phase of the cell cycle. IGF-1 has been shown to be a proliferating agent and an inhibitor of apoptosis in tumor cells,<sup>77</sup> while IGF-1 deficiency has been shown to reduce and delay tumorigenesis in knockout mice.<sup>78</sup> States of increased IGF-1 synthesis, such as acromegaly, are known to predispose one to colorectal carcinoma.<sup>79</sup> Insulin increases the availability of IGF-1 to induce mitogenesis by reducing hepatic production of IGF-binding protein-1 (IGFBP-1), the primary carrier protein of IGF-1 in the circulation. Conversely, the tumor suppressor p53 increases the level of another protein, IGFBP-3, in the circulation, effectively clearing free IGF-1.<sup>80</sup> As a result, in the obese hyperinsulinemic state, there is increased free IGF-1 at the target cell to stimulate cellular proliferation. It should be noted that there is no clear relationship between total circulating levels of IGF-1 and the degree of adiposity, which makes epidemiologic associations between obesity, IGF-1, and cancer difficult to interpret.

The role of IGF-1 in breast cancer is mixed since there are papers by the same authors reporting a positive relationship<sup>43,81</sup> and the absence of a relationship.<sup>82</sup> Stattin and colleagues found that higher IGF-1 levels increased prostate cancer mortality. Similar to the situation with estrogens, there is some confusion caused by the failure to always measure free IGF-1 rather than total IGF-1.<sup>41</sup>

### Adipose Tissue as a Storehouse for Toxins

There are a variety of toxins [PCBs (polychlorinated biphenyls), Dioxins, PAHs (polycyclic aromatic hydrocarbon), etc] and estrogen modulators and synthetic estrogens [bisphenol A, nonylphenol, DDT (Dichlorodiphenyltrichloroethane), o,p-DDE (ortho, para-Dichlorodiphenyldichloroethylene), etc.] which are lipophilic and can accumulate in body fat for long periods of time. These compounds are released during weight loss<sup>83</sup> and during lactation.<sup>84,85</sup> These toxins and endocrine disruptors can be measured in mother's milk,<sup>86</sup> where these compounds could be potentially harmful to the nursing infant, although there is no evidence that their concentrations reach harmful levels.

Attempts to estimate static prior concentrations of these compounds from current levels in body fat have been unsuccessful. One problem is that many women engage in yo-yo dieting in which they lose body fat and subsequently regain it. In the course of this decrease in body fat, lipophilic compounds are flushed from the adipose tissue depot and cleared from the body. Following several such cycles the amounts of these compounds remaining in the body fat depot will be significantly reduced, blocking any attempts to use static measurements to estimate what was present back at the time when the

**FIGURE 1** Pathways of human estrogen metabolism in humans. Percentages refer to enzyme activity as measured by radiometric assay (efficacy of conversion of tritiated precursor to tritiated water).

tumors were initiated. In addition, because of current legal restrictions on the use of many of these compounds, current exposure has greatly diminished, so any attempts to calculate differences between cancer patients and controls would be extremely difficult.

Presumably, the concentration of these compounds in the lipid droplets of the adipocytes is in equilibrium with what is free in the rest of the cell and in the circulation. It is these latter two pools that would be the active sites for these compounds. There have been no good studies on this equilibrium, or what concentrations would have to be achieved to reach toxic levels.

### Summary

Obesity facilitates the production and availability of numerous mitogenic agents, (including estrogen and IGF-1), immune modulators (including leptin and IL-6), and angiogenic factors (including vascular endothelial growth factor and hepatocyte growth factor) to susceptible target cells throughout the body. These factors may be working at different levels of tumorigenesis in different tissues, thus a unifying hypothesis of obesity and cancer may not be forthcoming. Nonetheless, the epidemiologic and mechanistic data presented here implicate the process of obesity in an adjunct, if not a primary role, in carcinogenesis and mortality.

## Obesity after Cancer Therapy

### Epidemiology

Although cancer, its therapy, and its aftermath are routinely associated with cachexia, one unexpected outcome can be the development of obesity with all of its pathophysiologic sequelae.<sup>87-89</sup> This phenomenon has been noted primarily in the Acute Lymphoblastic Leukemia (ALL) and brain tumor survivor populations. A report from the Childhood Cancer Survivors Study documents an increased risk for BMI less than 18 (cachexia) in adult survivors of most childhood tumors, while the ALL survivor population demonstrates the opposite.<sup>90</sup> The incidence of obesity in adult survivors of ALL is 18.5% in females and 16.5% in males; while the odds ratio for developing obesity is 1.5 in females and 1.2 in males.

Several reviews document an increased prevalence of obesity in survivors of childhood ALL.<sup>91-100</sup> These evaluations have been retrospective, and suffer from several difficulties, including lack of control populations, variability of chemotherapeutic treatment, inclusion of patients who relapse, the use and dose of cranial irradiation, and the dose and type of long-term steroid use as a complicating variable. In addition, the literature questions the possible psychosocial etiologies of weight gain, particularly with respect to parental leniency and aggressivity regarding food availability and food choice in this vulnerable

population (ie, since the presenting cachexia signified illness, the manifestation of increased caloric intake may be misconstrued by parents as a sign of health). Nonetheless, the majority of these studies document an abnormal increase in BMI long after tumor therapy has been discontinued, suggesting dysregulation of energy balance.

Similarly, long-term survivors of brain tumors have also been shown to be at risk for the development of obesity. This phenomenon has been documented both in the pediatric<sup>90,101,102</sup> and adult brain tumor populations.<sup>103</sup> Again, these studies have been retrospective; and it is not entirely clear from these studies whether the obesity is due to the tumor, the surgery, and/or the cranial irradiation that such patients inevitably receive.

### Risk Factors for the Development of Obesity after Cancer Therapy

In the childhood ALL survivor population, the prevalence of adult obesity has been reported anywhere between 20 and 44%. Since these studies are retrospective, and it is difficult to compare specific treatment paradigms for risk, most of these analyses instead use multivariate linear regression analyses to extract specific risk factors for the development of obesity (see Table 3). In many of these studies, age at diagnosis, female gender, and the presence of cranial radiation have been found to be important risk factors for the development of obesity.

In the brain tumor population, the development of obesity appears to be restricted to involvement of the posterior fossa, and in particular, the hypothalamus. Since 50% of childhood tumors (while only 10 to 20% of adult brain tumors) involve the posterior fossa, the development of obesity after brain tumor therapy is most commonly manifest in the pediatric population. The phenomenon of obesity is most evident in children with craniopharyngioma (see Table 3). However, this is by no means exclusive to children; about 10% of craniopharyngiomas occur in late adulthood,<sup>104</sup> and a recent report demonstrates increased weight gain and BMI after brain tumor therapy in adults as well.<sup>105</sup>

A multivariate linear regression analysis of the BMI curves of children with brain tumors who survived longer than 5 years post-therapy determined risk factors for the development of obesity.<sup>101</sup> Five parameters were cited as being predictive. First, age at diagnosis and treatment was negatively correlated with risk for obesity; in other words, the younger at diagnosis, the more likely the subject would be obese as an adult. Second, those with tumors localized to the hypothalamus or thalamus, along with those originating in the temporal lobe (due to stereoscopic position of the hypothalamus during radiation for this area) gained weight much more rapidly than those with tumors in the rest of

the posterior fossa or other hemispheric areas. Third, those with tumor histologies routinely localized to the diencephalon (ie, craniopharyngioma, germinoma, optic glioma, prolactinoma, hypothalamic astrocytoma) also gained weight more rapidly.<sup>106-108</sup> Fourth, those with quantitative direct radiation exposure of the hypothalamus of greater than 51 gray gained weight twice as rapidly after the completion of tumor therapy, even after those with hypothalamic or thalamic lesions were removed from the analysis. Finally, those with some other form of permanent hypothalamic endocrinopathy (ie, GH deficiency, hypothyroidism, precocious or delayed puberty, ACTH deficiency, diabetes insipidus) exhibited a rapidly escalating BMI curve. Thus, those risk factors linked to hypothalamic damage or dysfunction were ominous in terms of obesity.

## Hypothalamic Obesity due to Central Nervous System Insult

### Clinical Presentation and Manifestations

Damage to the hypothalamus, either due to tumor, surgery, or radiation, appears to be the primary etiologic factor in weight gain in cancer survivors. This phenomenon is clearly established with the syndrome of “hypothalamic obesity”.<sup>109,110</sup> Originally described by Babinski and Frohlich, hypothalamic obesity is a testament to the primary role of the hypothalamus in the regulation of energy balance.<sup>111,112</sup>

The hypothalamus is the control center for several homeostatic hormonal systems, in which the pituitary is the primary effector. They include the GHRH (growth hormone releasing hormone)/SRIF (somatostatin)-Growth Hormone-IGF-1, TRH (thyrotropin-releasing hormone)-TSH (thyroid stimulating hormone)-thyroid hormone, GnRH (gonadotropin-releasing hormone)-gonadotropin-sex hormone, and CRF (corticotropin-releasing factor)-ACTH (adrenocorticotrophic hormone)-cortisol axes. In each case, the peripheral hormone product provides an afferent feedback signal, which binds to specific receptors within the ventromedial hypothalamus (VMH) to regulate efferent hypothalamic hormonal output. In addition, a fifth system, the AVP (arginine vasopressin)-water balance axis, is also controlled by the supraoptic and paraventricular nuclei of the hypothalamus, and in which the posterior pituitary is the storage site for AVP secretory vesicles. Here, the afferent inputs are osmoreceptors for sodium and baroreceptors for blood pressure, rather than a specific hormonal substrate.

The last 10 years has witnessed the documentation of yet another hypothalamic feedback system, in which the adipocyte hormone leptin, the  $\beta$ -cell hormone insulin, the gastric hormone ghrelin, and the intestinal hormone Peptide YY<sup>3-36,113-116</sup> bind to specific receptors within the

VMH to form the afferent arm of an axis that regulates energy balance (Figure 2).<sup>117</sup> Indeed, genetic abnormalities in leptin or its hypothalamic receptor,<sup>118,119</sup> or the hypothalamic melanocortin-4 receptor<sup>120</sup> which processes this information, have been shown to exhibit obese phenotypes, suggesting hypothalamic dysregulation of energy balance signal transduction. However, the efferent arm of this axis is extremely

complex, involving appetite/satiety, autonomic, hormonal, thermogenic, and motor effectors.<sup>117,121,122</sup> Presumably patients with hypothalamic obesity exhibit abnormal signaling within both arms.

In humans, hypothalamic obesity is the manifestation of hypothalamic damage from tumor, surgery, and/or radiation, resulting in an intractable weight gain, which is not amenable to

caloric restriction or exercise.<sup>123</sup> Craniopharyngioma accounts for half of the reported cases, with other posterior fossa tumors contributing smaller numbers. However, the syndrome has also been reported in cases of pseudotumor cerebri, trauma, and infiltrative or inflammatory diseases of the hypothalamus.<sup>124</sup>

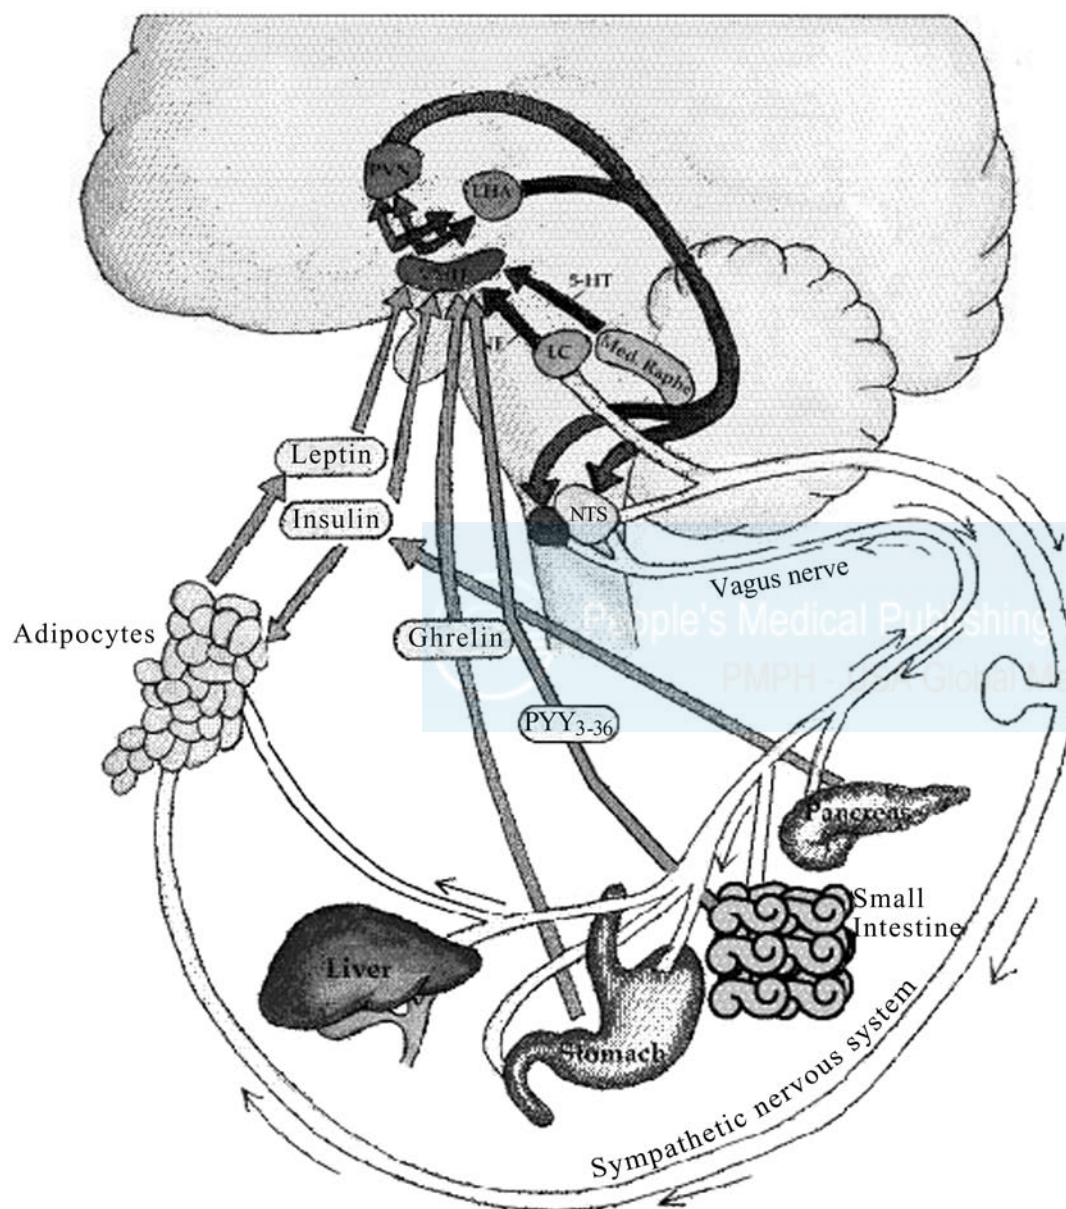

Aside from the symptoms of tumor-induced increased intracranial pressure, patients with hypothalamic obesity classically exhibit signs of limbic system involvement, such as hypogonadism, somnolence, rage and hyperphagia<sup>125</sup>; however, such classic presentations are actually rare.<sup>109</sup> The majority of patients actually exhibit normal or only slightly increased daily caloric intake. Indeed, caloric restriction of either VMH-lesioned animals or humans with hypothalamic obesity rarely attenuates the weight gain, suggesting that energy expenditure is also affected.<sup>126</sup>

Examination of the German craniopharyngioma database<sup>127</sup> demonstrates that children with craniopharyngioma already manifest an increased BMI for age by the time of diagnosis, suggesting that the tumor itself alters energy balance. However, after surgery and/or radiation, they can accelerate their weight gain even more rapidly. Most of these patients have other cranial endocrinopathies,<sup>101</sup> and require growth hormone, thyroxine, and hydrocortisone, sex hormone, and desmopressin replacement therapy due to GHRH/GH, TRH/TSH CRF/ACTH, GnRH/gonadotropin, and AVP (antidiuretic hormone) deficiencies, respectively. In some cases, lack of appreciation of the syndrome of hypothalamic obesity by physicians has led them to incorrectly deduce that the hydrocortisone dosage is contributing to the patient's weight gain, leading to well-meaning but potentially dangerous reductions of hydrocortisone dosage below 10 mg/m<sup>2</sup>/d. This accentuates the symptoms of malaise and lethargy exhibited by these patients.

Patients with hypothalamic obesity may also suffer from sequelae normally associated with exogenous obesity. These patients have been shown to have an increased incidence of the Metabolic Syndrome<sup>88</sup> and nonalcoholic fatty liver disease.<sup>89</sup> Furthermore they appear to have an increased risk for angina pectoris and other cardiovascular disease.<sup>87,102</sup> In addition to their obesity, the concomitant growth hormone deficiency that these patients manifest may also contribute to their adverse metabolic sequelae.<sup>128</sup>

### Pathophysiologic Mechanisms

It is well known that bilateral electrolytic lesions or deafferentation of the VMH in rats leads to intractable weight gain,<sup>109,129–132</sup> even upon food restriction.<sup>133</sup> Originally, the obesity was felt to be due to damage to a “satiety” center, which promoted hyperphagia and increased energy storage.<sup>134</sup> However, we now recognize that the

**FIGURE 2** The negative feedback pathway of energy balance. Afferent neural (eg, vagal) and hormonal (ghrelin, insulin, leptin, PYY<sub>3-36</sub>) signals are generated from the liver, gut, pancreas, and adipose. In addition, norepinephrine from the locus coeruleus and serotonin (5-HT) from the median raphe are elaborated. These signals of satiety versus hunger, and thinness versus fatness are interpreted by the nucleus tractus solitarius (NTS) and the hypothalamic gated neural network in the ventromedial hypothalamus (VMH). The peptides  $\alpha$ -melanocyte stimulating hormone ( $\alpha$ -MSH) and cocaine-amphetamine regulated-transcript are anorexigenic, while the peptides neuropeptide Y and agouti-related protein are orexigenic. These signals are integrated in the paraventricular nucleus (PVN) and lateral hypothalamus (LHA), through stimulation or inhibition of melanocortin receptors 3 and 4. Efferent signals from these areas in turn stimulate either the sympathetic nervous system to expend energy by activating  $\beta_3$ -adrenergic receptors and uncoupling proteins in the adipocyte, which releases energy the form of lipolysis, heat or physical activity; or stimulate the parasympathetic nervous system (efferent vagal) to increase insulin secretion, with resultant lipogenesis and energy storage. Reprinted with permission from Lustig RH, et al.<sup>199</sup>

HT = ; LC = ; DMV = ; Med. Raphe = ; PYY = ; NE = norepinephrine.

weight gain in this syndrome is actually secondary to: (1) inability to transduce peripheral hormonal energy balance signals; (2) overactivation of the parasympathetic nervous system, which promotes an obligate insulin hypersecretion and energy storage; and (3) defective activation of the sympathetic nervous system which retards lipolysis and energy expenditure.<sup>7</sup>

#### Defective Peripheral Hormonal Signal Transduction in the VMH

The negative feedback energy balance pathway (see Figure 2) is interesting in that the hormone insulin is a component of both the afferent and efferent limbs of the axis. In the afferent pathway, insulin conveys information about nutrients and energy balance to the hypothalamus, which limits food intake.<sup>135</sup> Insulin secreted by the pancreas in response to a meal provides blood-borne afferent information on nutrient intake and absorption to the VMH. A subpopulation of VMH neurons possesses insulin receptors,<sup>136</sup> and there is coordinated transport of insulin across the blood-brain barrier.<sup>137</sup> In experimental animals, acute and chronic ICV (intracerebroventricular) insulin infusions decrease feeding behavior and induce satiety.<sup>138–140</sup> The importance of central nervous system (CNS) insulin action was recently underscored by the construction of a brain/neuron-specific insulin receptor knockout (NIRKO) and an insulin receptor substrate 2 knockout mouse, which cannot transduce the CNS insulin signal.<sup>141,142</sup> They become hyperphagic, obese, and infertile, with high peripheral insulin levels. These mice suggest that peripheral insulin mediates a signal within the VMH to help control energy balance and other hypothalamic functions.<sup>114,143</sup>

Normally, in the fed state, both insulin and leptin levels are increased, which increase the synthesis and processing of hypothalamic pro-opiomelanocortin (POMC) to its component peptides, including  $\alpha$ -melanocyte stimulating hormone ( $\alpha$ -MSH), which along with its colocalized neuromodulator cocaine-amphetamine regulated transcript (CART), act at the lateral hypothalamic area (LHA) and paraventricular nucleus (PVN) to alter melanocortin-4 receptor (MC<sub>4</sub>R) occupancy, which decreases appetite and food intake.<sup>113,135,144,145</sup> Insulin and leptin also directly inhibit the release of neuropeptide Y (NPY) and agouti-related protein (AgRP), further limiting feeding and providing for unantagonized MC<sub>4</sub>R (melanocortin-4 receptor) occupancy.<sup>146</sup> Furthermore, PYY<sub>3–36</sub> (peptide YY<sub>3–36</sub>) levels are elevated, and this hormone binds to the Y<sub>2</sub> receptor in the VMH, activating  $\gamma$ -aminobutyric acid (GABA), which inhibits the orexigenic signal transduction of neuropeptide Y.<sup>147</sup> Conversely, in the fasting state, gastric secretion of ghrelin is increased,<sup>148,149</sup> while leptin,

insulin, and PYY<sub>3–36</sub> levels are low, which leads to stimulation of hypothalamic NPY/AgRP and antagonism of  $\alpha$ -MSH/CART. The resultant lack of anorexigenic pressure on the MC<sub>4</sub>R results in increased feeding behavior and energy efficiency (with reduced fat oxidation), in order to store energy substrate as fat. In the syndrome hypothalamic obesity, hypothalamic damage prevents integration of these peripheral energy and adiposity signals; thus, the VMH cannot transduce these signals into a state of energy sufficiency sense a subjective sense of satiety.<sup>132,150</sup>

#### Vagally-Mediated Insulin Hypersecretion and Increased Energy Storage

Normally, excess blood-borne energy substrates (glucose, fatty acids) which are not utilized immediately by other tissues are stored in adipose tissue via the lipogenic effects of insulin. In the efferent pathway, insulin is responsible for shunting blood-borne nutrients into adipose for storage. The amplitude and duration of pancreatic insulin secretion, and the activity of the insulin molecule at the adipose insulin receptor, play integral roles in the genesis of lipogenesis and weight

gain. Although there are numerous factors that promote lipolysis, the primary signal for lipogenesis is insulin.<sup>151</sup> Within the adipocyte, insulin increases: (1) Glut4 expression; (2) acetyl-CoA carboxylase; (3) fatty acid synthase; and (4) lipoprotein lipase.<sup>152</sup> Thus, the net effect of insulin on the adipocyte is the rapid clearance and storage of circulating glucose and lipid.

The LHA and PVN send efferent projections residing in the medial longitudinal fasciculus to the dorsal motor nucleus of the vagus (DMV).<sup>153</sup> The DMV, in turn, sends efferent projections throughout the alimentary system, including the  $\beta$ -cells of the pancreas.<sup>154</sup> This pathway is responsible for the “cephalic” or preabsorptive phase of insulin secretion, which is glucose-independent and can be blocked by atropine.<sup>155</sup> VMH lesions damage this pathway, leading to an increase in vagal firing rate.<sup>156</sup> For example, rats with VMH lesions exhibit both increased insulin levels and food intake; however, this can be prevented by pancreatic vagotomy.<sup>129,157,158</sup> Overactive vagal neurotransmission increases insulin secretion from  $\beta$ -cells through three distinct but overlapping mechanisms (Figure 3):<sup>159</sup>

**FIGURE 3** Vagal augmentation of insulin hypersecretion. (1) M<sub>3</sub> activation of a Na<sup>+</sup> channel augments  $\beta$ -cell depolarization, which augments calcium influx. (2) M<sub>3</sub> activation increases phospholipases A<sub>2</sub>, C, and D, which hydrolyze phosphatidylinositol (PIP<sub>2</sub>) to diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP<sub>3</sub>). DAG stimulates of protein kinase C (PKC) which phosphorylates myristoylated alanine-rich C kinase substrate (MARCKS), which binds actin-calcium-calmodulin, and induces vesicular exocytosis. IP<sub>3</sub> potentiates intracellular calcium release. (3) Release of glucagon-like peptide-1 (GLP-1) from intestinal L-cells. GLP-1 receptor activation induces adenylyl cyclase, increasing cAMP, activating protein kinase A (PKA) potentiates intracellular calcium release. Reprinted with permission from Lustig RH.<sup>200</sup>

AC = adenylyl cyclase; Ach = acetylcholine; ADP = adenosine diphosphate; ATP = adenosine triphosphate; Ca<sup>++</sup> = ionized calcium; cAMP = cyclic adenosine monophosphate; DMV = dorsal motor nucleus of the vagus; GLP-1 = glucagon-like peptide-1; GLP-1R = glucagon-like peptide-1 receptor; Glu = glucose; K = potassium; L-cells = L-cells; M = muscarinic; Na = sodium; PLC = phospholipase C; PO = I don't see a PO; SUR = sulfonylurea receptor; VCa = voltage-gated calcium channel.

Vagal firing increases acetylcholine availability and binding to the  $M_3$  muscarinic receptor, which is coupled to a sodium channel within the pancreatic  $\beta$ -cell membrane.<sup>160</sup> Under resting conditions, the ATP(adenosine triphosphate)-dependent potassium channel within the  $\beta$ -cell membrane remains open, and leads to a negative  $\beta$ -cell resting membrane potential of approximately  $-70$  millivolts (mV), with essentially no insulin release. In this state, activation of the sodium channel by acetylcholine only minimally increases  $\beta$ -cell resting membrane potential to  $-65$  mV, and has relatively minimal effects on insulin secretion and peripheral insulin levels. This phenomenon is responsible for the vagally mediated “cephalic” or preabsorptive phase of insulin secretion, which is glucose-independent and can be blocked by atropine.<sup>155</sup> As glucose enters the  $\beta$ -cell after ingestion of a meal, the enzyme glucokinase will phosphorylate glucose to form glucose-6-phosphate. This increases the generation of intracellular ATP, which induces closure of the  $\beta$ -cell’s ATP-dependent potassium channel. Upon channel closure, the  $\beta$ -cell experiences an ATP-concentration-dependent  $\beta$ -cell depolarization,<sup>161,162</sup> and the opening of a separate voltage-gated calcium channel within the membrane. Intracellular calcium influx increases acutely, which results in rapid insulin vesicular exocytosis. Concomitant opening of the sodium channel by acetylcholine binding to the  $M_3$  receptor augments the  $\beta$ -cell depolarization which, in turn, augments the intracellular calcium influx and results in insulin hypersecretion.<sup>129,130,163</sup> Conversely, knockout of the  $M_3$  receptor in mice reduces vagal-mediated insulin secretion, and results in a hypophagic and lean phenotype.<sup>164</sup>

Vagally mediated acetylcholine increases phospholipases  $A_2$ , C, and D within the  $\beta$ -cell, which hydrolyze intracellular phosphatidylinositol to diacylglycerol (DAG) and inositol 1,4,5-triphosphate ( $IP_3$ ).<sup>159</sup> DAG is a potent stimulator of protein kinase C (PKC)<sup>165</sup> which phosphorylates myristoylated alanine-rich protein kinase C substrate [MARCKS(myristoylated protein kinase C substrate)], which then binds actin and calcium-calmodulin, and induces insulin vesicular exocytosis.<sup>166</sup>  $IP_3$  potentiates release of calcium within  $\beta$ -cells from intracellular stores, which also promotes insulin secretion.<sup>167</sup>

The vagus also stimulates the release of the peptide glucagon-like peptide-1 (GLP-1) from intestinal L-cells, which circulates and binds to a GLP-1 receptor within the  $\beta$ -cell membrane. Activation of this receptor induces a calcium-calmodulin-sensitive adenylyl cyclase, with conversion of intracellular ATP to cAMP (cyclic adenosine monophosphate), which then activates protein kinase A (PKA). PKA causes both the release of intracellular calcium stores, and the phosphorylation of vesicular proteins, each contributing to an increase in insulin exocytosis.<sup>168,169</sup>

### Decreased Sympathetic Responsiveness, Physical Activity, and Energy Expenditure

The adipocyte also responds to sympathetic nervous system activation to promote lipolysis and thermogenesis.<sup>122</sup> The most prominent and concerning complaints in patients with hypothalamic obesity is persistent fatigue, lack of energy, and lack of physical activity. This generalized malaise is not due to hypopituitarism, as it persists even after full hormonal replacement. Harz and colleagues showed that the voluntary energy expenditure of patients with craniopharyngioma, as measured by accelerometry, was significantly decreased compared to BMI-matched obese, but otherwise healthy, controls.<sup>170</sup> This decrease in energy expenditure may be mediated through defects in the regulation of the sympathetic nervous system. Two reports demonstrate an impaired ability of such patients to mount an epinephrine response to insulin-induced hypoglycemia,<sup>171,172</sup> and document decreased 24-hour epinephrine excretion,<sup>172</sup> although norepinephrine excretion was similar to controls. It is thought that this malaise and decrease in sympathetic tone may account for decreased rates of lipolysis through the adipocyte  $\beta_3$ -adrenergic receptor,<sup>173</sup> which result in decreased resting and voluntary energy expenditure. Thus, the mechanisms of lipogenesis in this syndrome are due to autonomic endocrinopathy; a combination of parasympathetic hypertransmission and sympathetic hypotransmission secondary to VMH damage.

### Diagnosis

Patients with hypothalamic obesity gain weight despite attempts at diet and exercise. Indeed, Bray and colleagues showed that long-term caloric restriction was ineffective in modulating the weight gain in these patients,<sup>109,123</sup> attesting to the “obligate” nature of the weight gain in these patients. He and Gallagher also noted insulin hypersecretion in subjects with hypothalamic obesity.<sup>123</sup> Their results suggest that such patients exhibit a metabolic priority toward energy storage instead of expenditure.

Although some patients with hypothalamic obesity are already obese upon clinical presentation, most are normal weight-for-height. After surgery and/or radiation, their weight gain accelerates rapidly, usually at a rate of 1 kg/month or greater. Despite the high incidence of GH deficiency, most of these patients continue to exhibit normal linear growth,<sup>174</sup> probably due to insulin’s effects on the IGF-1 receptor.<sup>175</sup> Most of these patients have other cranial endocrinopathies and require hormonal replacement. In some cases, lack of appreciation of the syndrome of hypothalamic obesity by physicians has led to the incorrect deduction that the hydrocortisone dosage was contributing to the patient’s weight gain, resulting in well-meaning, but potentially

dangerous, reductions of hydrocortisone dosage below 10 mg/m<sup>2</sup>/d. This accentuates the symptoms of malaise and lethargy exhibited by these patients.

The insulin excursion to oral glucose tolerance testing (OGTT) defines the syndrome. Two prospective studies of children with hypothalamic obesity revealed only minimally elevated fasting insulin concentrations of  $22.7 \pm 1.3$   $\mu$ U/mL, as compared to  $36.3 \pm 5.7$   $\mu$ U/mL for an age- and BMI-matched group of subjects with obesity, insulin resistance, and acanthosis nigricans.<sup>176,177</sup> However, these patients demonstrated accentuated early insulin responses to OGTT, which were elevated in comparison to their degree of obesity. Peak insulin levels were reached by 60 minutes, and were  $281 \pm 47$   $\mu$ U/mL, as compared to normal adolescents, whose peak insulin concentrations are routinely 100 to 150  $\mu$ U/mL. The fall to baseline was reasonably rapid, suggesting that these patients did not exhibit defective insulin clearance, as is usually seen in insulin resistance. One report documents that the insulin hypersecretion in this disorder is primary, as controlling for the degree of insulin resistance did not reduce the statistical significance of the hypersecretion.<sup>178</sup>

### Treatment

Numerous therapies have been attempted in the treatment of hypothalamic obesity. The appreciation of the role of dysfunctional vagal tone and insulin hypersecretion in the pathogenesis of hypothalamic obesity originally led to anecdotal case reports of successful treatment with pancreatic vagotomy.<sup>179</sup> However, subsequent experience with the procedure was inconsistent, and it fell out of favor.<sup>180</sup> Several trials of anorectic medication have been attempted,<sup>181,182</sup> with temporizing, but not long-term, efficacy.

We have attempted to inhibit this insulin hypersecretion pharmacologically. Although diazoxide, an oral  $\beta$ -cell potassium channel opener, is routinely used to treat hypoglycemia due to hyperinsulinism,<sup>183</sup> this drug suppresses insulin secretion globally, such that the possibility of hyperglycemia or frank diabetes exists.<sup>184,185</sup> Furthermore, we wished to antagonize insulin secretion at a point downstream of the sodium channel activity (Figure 3). The voltage-gated calcium channel is coupled to a somatostatin ( $SSTR_5$ ) receptor.<sup>186,187</sup> Treatment with the somatostatin agonist octreotide limits the opening of this channel and the amount of insulin released acutely for any specific amount of glucose.<sup>188,189</sup> In an open-labeled pilot trial,<sup>176</sup> eight patients received subcutaneously administered octreotide for six months, at a dose of 5  $\mu$ g/kg/d (in total, divided, tid), escalating in monthly 5  $\mu$ g/kg/d increments to a maximum of 15  $\mu$ g/kg/d (in total, divided, tid) by the third month. Insulin responses

to glucose were normalized over 6 months. Of the eight patients, three lost substantial weight, two lost moderate amounts of weight, and three stabilized their weight. The degree of weight loss correlated both with changes in insulin response and with changes in leptin levels. The weight loss also appeared to correlate with decreases in appetite, and caloric intake in this cohort decreased by approximately 700 kilocalories per day. The lack of leptin negative feedback by the damaged VMH was not critical, as these patients responded with both weight loss, decreased caloric intake, and decreased leptin levels. In fact, an unexpected, but very welcome, side effect of the treatment was the resumption of normal physical activity by four patients, including vigorous exercise. A double-blind, placebo-controlled, six-month trial of octreotide in 18 subjects with hypothalamic obesity followed.<sup>177</sup> Prior to treatment, annualized weight gain in this population was  $15.9 \pm 2.9$  kg/yr. Although the weight loss in this trial was not as pronounced as in the pilot (probably due to a delay in achieving maximum dosage until the fifth month), octreotide was effective in stabilizing weight ( $+1.6 \pm 0.6$  kg) and BMI ( $-0.1 \pm 0.1$  kg/m<sup>2</sup>), as compared to placebo (change in weight  $+9.2 \pm 1.5$  kg, BMI  $+2.3 \pm 0.5$  kg/m<sup>2</sup>). Insulin secretion during the first 60 minutes was clearly suppressed by octreotide. Lastly, the Pediatric Cancer Quality of Life-32 (PCQL-32),<sup>190</sup> a validated instrument to measure improvements in quality of life in children, demonstrated marked improvements in physical activity as compared with those treated with placebo, and the improvement in quality of life correlated with the degree of insulin suppression. These findings suggested that insulin hypersecretion was responsible not only for weight gain in these patients, but for their lack of physical activity, which can be improved by normalizing their insulin response. Anecdotally, patients noted normal hunger at the time of meals, but noted the lack of drive to continue to eat past their first serving, or for snacking between meals. They also noted more interest in their schoolwork and in their social contacts. Treatment of those initially assigned to placebo in the second 6 months also resulted in stabilization of weight and improved quality of life. Studies of the long-acting somatostatin analog octreotide-LAR (octreotide long-acting release) are ongoing in this patient population.

Perhaps the best treatment for this syndrome is prevention. It is very clear that the hypothalamus represents the biologic seat of both food intake and energy balance in humans. Risk assessment of hypothalamic damage can be undertaken based on MRI, portal radiation dosimetry, and endocrinologic testing. In this way, oncologists can assess the risk for future development of obesity in populations with CNS insult so that clear explanation to patients and families, close follow-up, and early preventive measures can be instituted. Finally, the sensitivity of the

hypothalamus to both surgical trauma and/or external beam radiation cannot be underestimated. Neurosurgeons and neuro-oncologists must incorporate these risk factors when making a therapeutic plan to limit long-term morbidity and mortality in such patients.<sup>191,192</sup>

## Summary

The syndrome of hypothalamic obesity is the most obvious example of the organicity of obesity in a specific population. Prior to their cranial insult, these patients are completely normal, but afterward, they exhibit signs of hypothalamic dysfunction, including anterior pituitary endocrinopathy (hypopituitarism), posterior pituitary endocrinopathy (diabetes insipidus), and autonomic endocrinopathy (hypothalamic obesity). From combined data in rat and human, the primary etiologies appear to be defective insulin and leptin signal transduction at the level of the hypothalamus, increased vagal modulation, and decreased sympathetic modulation, leading to insulin hypersecretion with increased lipogenesis and decreased lipolysis. Diagnosis rests on documentation of accentuated early responses to OGTT, and at least one potentially beneficial therapeutic strategy involves suppression of the early insulin response.

# Thyroid Disorders in Cancer Patients

Steven I. Sherman, MD

As observed by Osler, “the thyroid gland supplies some essential secretion of first importance,”<sup>1</sup> and knowledge of the normal and diseased functions of the thyroid is essential in the care of the cancer patient. Disorders of the thyroid gland occur commonly in an oncology practice, with the potential for confounding diagnostic evaluation of the malignant disease, for complicating antineoplastic treatments, and for increasing mortality in cancer patients.<sup>2</sup> Similarly, abnormalities of the thyroid are common consequences of cancer or the treatment of cancer. These effects on the thyroid often develop years and decades after cure of the malignant disease, necessitating long-term follow-up and awareness of the risk for thyroid abnormalities by the treating oncologist and subsequent care providers.

## Physiology of the Hypothalamic-Pituitary-Thyroid Axis

The primary role of the thyroid gland is to produce thyroxine ( $T_4$ ) and triiodothyronine ( $T_3$ ), hormones that influence a broad variety of metabolic processes throughout the body. The synthesis of  $T_4$  and  $T_3$  begins with the active transport of iodide into the cell via an intrinsic plasma membrane sodium-iodide symporter.<sup>3</sup> Following oxidation by thyroid peroxidase, the iodide moiety is covalently attached to tyrosyl residues of thyroglobulin, and the resulting iodotyrosines are coupled and cleaved from thyroglobulin to form  $T_4$  and  $T_3$ , normally in a 10:1 ratio.<sup>4</sup> This process results in the total daily output of 80 to 100  $\mu\text{g}$  of  $T_4$ . In contrast, only 20% of circulating  $T_3$  is produced by the thyroid, the remaining 80% deriving from the enzymatic outer-ring or 5'-monodeiodination of  $T_4$  in extrathyroidal tissues such as the liver, kidney, brain, muscle, and skin.<sup>5</sup> Removal of the inner-ring 5-iodine of  $T_4$  forms the inactive metabolite reverse  $T_3$  ( $rT_3$ ). Similar to hepatic drug disposal mechanisms, other thyroid hormone inactivating pathways include glucuronidation, sulfation, deamination, and cleavage.<sup>6</sup>

In serum, at least 99.95% of  $T_4$  and 99.5% of  $T_3$  molecules are bound by the transport proteins thyroxine-binding globulin (TBG), transthyretin (thyroxine-binding prealbumin), and albumin.<sup>7</sup>

Although TBG is present in lower concentration than either transthyretin or albumin, its greater affinity for thyroid hormones makes it the predominant serum carrier of  $T_4$  and  $T_3$ . This large pool of protein-bound hormone provides a stable reservoir that maintains the supply of free, unbound hormone available for transport into the cells. Once within target cells,  $T_4$  is converted by the enzyme 5'-deiodinase to  $T_3$ , which in the nucleus binds to a heterodimerized thyroid hormone receptor, modulating transcription of thyroid hormone-responsive genes and producing the clinical effects recognized as the metabolic effects of thyroid hormones.

The primary regulatory influence on thyroid gland function is the circulating level of thyrotropin (thyroid stimulating hormone [TSH]). Produced by thyrotroph cells of the anterior pituitary, TSH is a two-subunit glycoprotein, the specificity of which is conferred by its  $\beta$ -subunit; the  $\alpha$ -subunit is structurally similar to that of follicle stimulating hormone, luteinizing hormone, and human chorionic gonadotropin. Negative feedback by  $T_4$  and  $T_3$  influences TSH synthesis and release, yielding a log-linear relationship between the serum concentrations of TSH and free  $T_4$ .<sup>8,9</sup> The hypothalamic tripeptide thyrotropin-releasing hormone (TRH) stimulates TSH secretion and modulates thyrotroph response to altered thyroid hormone levels. In conjunction with the suppressive effects of dopamine, corticosteroids, somatostatin, androgens, and endogenous opioids, TRH may be responsible for establishing the set-point for the negative feedback loop that controls thyroid hormone levels. Hypothalamic production of TRH itself is regulated by circulating thyroid hormones, as well as by multiple central nervous system factors.

TSH also functions as a trophic hormone for thyroid follicular cells. By binding to its cognate receptor on the plasma membrane, TSH triggers activation of multiple downstream signaling cascades through G-protein-linked adenylyl cyclases, phospholipases, phosphatidylinositol-3-kinases, and small GTPases. Downstream effectors of the actions of TSH include mitogen-activated protein kinases (MAPKs), c-jun N-terminal kinases (JNKs), and extracellular signal-regulated kinases (ERKs), which subsequently regulate thyrocyte proliferation, differentiation, and apoptosis.<sup>10</sup>

## Hypothyroidism

Hypothyroidism is the clinical state resulting from an insufficient amount of circulating thyroid hormone to support normal body functions. Gull first described the adult form of hypothyroidism, referring to it as “a cretinoid state supervening in adult life.”<sup>11</sup> That hypothyroidism occurs more commonly in women or is increasingly prevalent with advancing age did not escape Gull, or Vanderpump and Tunbridge. The prevalence of overt hypothyroidism, defined as the combination of clinical and biochemical findings of hypothyroidism, is approximately 1 to 2% in the general population and is about 10 times higher in women than in men.<sup>12</sup> Subclinical hypothyroidism, generally defined as a serum TSH between 5 and 20 mU/L in asymptomatic patients, occurs with a frequency of 2.5 to 10% but rises as high as 20% in women over age 70.<sup>13,14</sup>

## Clinical Manifestations

The clinical signs and symptoms of hypothyroidism occur as a result of deficient thyroid hormone actions. Because chronic primary hypothyroidism usually develops over a span of years, the clinical features may develop insidiously and not be readily noticed. In contrast, severe hypothyroidism occurring following thyroid resection, thyroiditis, or pituitary resection is usually associated with a more subacute onset of symptoms. Complicating the recognition of hypothyroidism is the non-specific nature of symptoms, likely to be even more confusing in cancer patients. Among patients in a general medical practice presenting with the most common symptoms of hypothyroidism (constipation, weight gain, menstrual irregularities, fatigue, depression, cold intolerance, and galactorrhea), only 4% will actually be hypothyroid, and fewer than 2% will have a TSH level at least 5 mU/L more than normal.<sup>15</sup> In studies of patients with either solid or hematologic malignancies, the high prevalence of fatigue correlates poorly with biochemical evidence of hypothyroidism.<sup>16,17</sup> Even among long-term survivors of Hodgkin's disease, of whom the majority develop hypothyroidism, there is little evidence of an association between fatigue and the diagnosis of untreated hypothyroidism.<sup>18,19</sup> In contrast, symptoms and signs (including slow movements,

coarse skin, decreased sweating, hoarseness, paresthesia, cold intolerance, periorbital edema, and delayed deep tendon reflex relaxation) may be more specific but have not been evaluated for their diagnostic value in cancer patients.

Nonetheless, an appreciation of the clinical manifestations of hypothyroidism is necessary to provide a degree of clinical suspicion for the diagnosis. Several manifestations of particular note in patients with cancer are discussed below.

#### The Neuromuscular System

Myopathies associated with malignancies, such as polymyositis and myasthenia gravis, may also be seen more commonly in hypothyroidism. The association of myasthenia gravis and hypothyroidism, may be of particular relevance in evaluating patients with thymoma.<sup>20,21</sup> Increased serum levels of creatine kinase (CK) are frequently found in hypothyroidism, regardless of the presence of overt myopathy. Fractionation studies revealed a preponderance of the MM isotype.<sup>22</sup> The elevated CK level is likely related to both a decrease in the enzyme clearance rate in hypothyroidism and sarcoplasmic damage. Aldolase, aspartate transaminase, and lactate dehydrogenase levels are also elevated, but are less sensitive or specific indicators of muscle dysfunction. Neuropathic symptoms such as paresthesia, painful dysesthesia, focal muscle weakness, and deafness can all result from compression of peripheral nerves. Central nervous system dysfunction in hypothyroidism can cause a wide variety of signs and symptoms that are also seen as a consequence of malignant disease and therapy. Typical encephalopathic findings in severe hypothyroidism include lethargy, depression, and impairment of memory without other evidence of intellectual deficits. Cerebellar ataxia can occur, characterized by gait disturbance, dysarthric speech, intention tremors, dysmetria and poor coordination.

#### The Cardiovascular System

Patients with thyroid hormone deficiency commonly present with inotropic and chronotropic cardiac abnormalities, including bradycardia and congestive failure. Reversible dilated cardiomyopathy can rarely be secondary to hypothyroidism.<sup>23</sup> Care must be exercised in the use of digitalis glycosides, as clearance is slowed and toxicity more likely. Pericardial effusion can contribute to enlargement of the cardiac silhouette in hypothyroid patients, although the development is sufficiently slow that tamponade is rarely observed. Increased systemic vascular resistance is commonly seen, along with diastolic hypertension. The cardiovascular effects of hypothyroidism can occur acutely, especially when thyroid cancer patients are withdrawn from their thyroxine therapy in anticipation of radioactive iodine treatment.<sup>24</sup>

#### The Respiratory System

Both hypoxic and hypercapnic ventilatory drives are impaired, leading to alveolar hypoventilation.<sup>25</sup> Pleural effusions are occasionally found in hypothyroidism, although usually in association with pericardial and peritoneal effusions.<sup>26,27</sup> As a result of increased capillary permeability, hypothyroid pleural effusates have moderate protein elevation. The volume of effusion is generally small, and the patients asymptomatic.

#### The Gastrointestinal System

Constipation, obstipation, or even megacolon due to decreased gut motility may be the cardinal presenting feature of hypothyroidism, with increased sensitivity to the effects of opiate analgesics.<sup>28–30</sup> Intestinal absorption is generally normal in hypothyroidism, although myxedematous infiltration of intestinal mucosa can rarely cause malabsorption. Patients with autoimmune thyroiditis are at increased risk for the development of pernicious anemia and achlorhydria due to atrophic gastritis. Aspartate transaminase levels may be increased due to impaired metabolic clearance of the muscle-derived enzyme.<sup>31</sup> The yellowish appearance that may be noted in the skin of hypothyroid patients, due to hypercarotenemia, should not be confused with jaundice; scleral and mucous membranes are generally anicteric.

#### The Integumentary System

The hypothyroid skin is generally pale with a tinge of yellowish discoloration, owing to the combined effects of elevated serum and tissue carotene levels (a consequence of the decrease in carotene metabolism), anemia, alopecia, and decreased cutaneous blood flow. It is also accompanied by non-pitting edema, secondary to increased accumulation of mucopolysaccharides and fluids in the dermis. Typically, this swelling is most marked around the eyes and hands. The skin also feels dry and cool, related to the decrease in eccrine and apocrine secretion. Peripheral vasoconstriction contributes to the cool sensation of the skin.<sup>32</sup>

#### The Hematopoietic System

Mild anemia is a common feature in hypothyroidism, occurring in about 25% of untreated patients.<sup>33,34</sup> Although decreased plasma volume may mitigate the reduction in total red cell mass, normochromic normocytic anemia is a consequence of decreased erythropoietin synthesis.<sup>34</sup> In general, red cell survival appears to be normal in hypothyroidism. Except for iron deficiency due to hypothyroidism-induced hypermenorrhea, thyroid hormone deficiency rarely affects serum ferritin, iron, or total iron binding capacity.<sup>33</sup> Macrocytic anemia can result from

malabsorption of either folate or vitamin B<sub>12</sub>. As many as 10% of patients with hypothyroidism due to autoimmune thyroiditis have pernicious anemia.<sup>34,35</sup> Hypothyroid dyslipidemia can lead to increased membrane lipid content, also causing macrocytosis.

White blood cell and platelet counts are usually normal in hypothyroidism, unless there is coexistent pernicious anemia or folate deficiency causing low cell counts. Despite reports of decreased platelet adhesiveness, few hypothyroid patients abnormal bleeding times.<sup>36</sup> Similarly, decreased levels of factors VIII, IX, XI, and XII may be seen as a result of the general decrease in protein synthesis.<sup>36,37</sup> Fibrinolytic activity is also decreased.<sup>37</sup> However, clinically significant bleeding is infrequent.

#### Endocrine and Metabolic Systems

Hyperprolactinemia is common in primary hypothyroidism, due to stimulation of the lactotroph by thyrotropin-releasing hormone, and occasionally leading to galactorrhea. In severe cases of primary hypothyroidism, thyrotroph hyperplasia may occur, misidentified in sellar imaging as a mass lesion.

Despite delayed cortisol clearance in hypothyroidism, cortisol production rates and circadian rhythmicity remain essentially normal.<sup>38</sup> Direct stimulation of adrenal glands with adrenocorticotrophic hormone (ACTH) frequently yields normal cortisol responses.<sup>39</sup> However, cortisol response to insulin-induced hypoglycemia may be subnormal, indicating slightly impaired hypothalamic-pituitary control over cortisol production.<sup>40</sup>

Hypothyroidism can be a cause of euvolemic hyponatremia, even in patients otherwise at risk for the syndrome of inappropriate antidiuretic hormone. Free water clearance is often decreased, which can be demonstrated by delayed water excretion following an acute water loading test.<sup>41</sup> Urine osmolality is inappropriately elevated for the degree of plasma hypo-osmolality. Although increased antidiuretic hormone secretion has been reported, vasopressin response to a saline-loading test is generally normal.<sup>42</sup> Postoperative hyponatremia occurs more commonly in unsuspected hypothyroid patients.<sup>43</sup>

Hypothyroidism leads to decreased oxygen consumption and carbon dioxide production, yielding a decreased basal metabolic rate. Substrate catabolism is reduced, and weight gain can be secondary to increased fat stores as well as fluid retention.

Altered pharmacokinetics of many medications occurs in hypothyroidism, including impaired metabolic clearance due to decreased hepatic levels of P450 and P450-reductase.<sup>44</sup> Studies of primary hepatocytes demonstrate

that thyroid hormone negatively regulates the transcription of CYP3A4 and may increase expression of CYP1A2, changes which, in theory, could affect metabolism of drugs such as paclitaxel, docetaxel, tamoxifen, flutamide, vincristine, vinblastine, doxorubicin, and etoposide.<sup>45,46</sup> Of particular importance is delayed clearance of drugs with a narrow therapeutic range, such as digoxin, theophylline, and phenytoin. Because catabolism of vitamin K–dependent clotting factors is decreased, warfarin requirements may be paradoxically increased in hypothyroidism, and doses may need to be reduced following thyroid hormone replacement therapy.<sup>47</sup> Although studies have not been published detailing the effect of hypothyroidism on the metabolism of specific chemotherapies in cancer patients, it is nonetheless reasonable to ensure that patients participating in pharmacokinetic studies of drugs metabolized by either CYP3A4 or CYP1A2 have hypothyroidism excluded or treated first.

### Etiology and Pathophysiology

Primary hypothyroidism, due to direct impairment of the gland's capacity to produce thyroid hormone, constitutes the great majority of the cases. In iodine-replete regions, autoimmune thyroid diseases and thyroablative therapy cause the majority of cases of primary hypothyroidism. Although most patients with chronic hypothyroidism are treated with thyroid hormone replacement therapy, regardless of the etiology, the cause of hypothyroidism should be determined in each patient. This is especially true in cases of secondary or tertiary hypothyroidism, in which concomitant hormonal insufficiencies may also require therapy. Reversible hypothyroidism may also occur due to transient thyroiditis, or drugs and food with antithyroid effects.

#### Autoimmune Thyroid Disease

Both humoral and cell-mediated immune mechanisms have been implicated in the pathogenesis of autoimmune thyroiditis, the primary cause of chronic primary hypothyroidism. Circulating antibodies to thyroid peroxidase (TPO) and thyroglobulin are present in up to 95% and 70%, respectively,<sup>48</sup> of patients with chronic autoimmune thyroiditis, but they are not likely to be pathogenetic despite the ability of anti-TPO antibodies to fix complement.<sup>49</sup> However, significant titers of these antibodies may identify euthyroid patients at risk of developing overt thyroid failure.<sup>50</sup> Uncommonly, antibodies that interfere with binding of TSH to its receptor on the follicular cell can block physiologic thyroid stimulation.<sup>51</sup>

In contrast, cell-mediated immunity due to failure of T cell tolerance is the predominant mechanism leading to chronic autoimmune

thyroiditis. Under stimulation from interferon- $\gamma$ -containing T cells, thyrocytes in autoimmune thyroiditis express antigen-presenting MHC class II molecules that can then bind to T cell receptors to induce activation of CD4 T cells.<sup>52</sup> The thyroid gland is infiltrated by lymphocytes characterized by Th1 differentiation. A variety of secreted cytokines directly affect thyroid follicular cells, including expression of Fas stimulated by interleukin-1 (IL-1); inhibition of the sodium-iodine symporter by interferon- $\gamma$ , IL-1, and tumor necrosis factor; and expression of intercellular adhesion molecule-1 which can then trigger binding to lymphocyte function-associated antigen-1 and increased T cell-mediated cytotoxicity.<sup>53,54</sup> The key role of the immune system in chronic thyroiditis is underscored by reports of passage of thyroid autoimmunity from donor to recipients of marrow and stem cell transplantation.<sup>55,56</sup> Once initiated, the rate of decline of thyroid function in patients with chronic autoimmune thyroiditis is typically slow, with only about 5% of affected women developing overt hypothyroidism yearly.<sup>50</sup> Acute exposure to large amounts of stable iodine, such as following infusion of iodinated radiographic contrast media containing 150 to 500 mg iodine per milliliter, can produce transient hypothyroidism, especially in patients with euthyroid autoimmune thyroiditis.<sup>57,58</sup>

Transient hypothyroidism may occur as part of the course of silent thyroiditis, typically of autoimmune etiology, and granulomatous subacute thyroiditis.<sup>59</sup> These disorders are characterized by subacute development of thyroid inflammation, typically without death of follicular cells. The initial inflammatory phase may produce thyrotoxicosis due to release of preformed thyroid hormone from disrupted follicles. Because the hyperthyroid phase is often clinically overlooked, patients frequently present during the hypothyroid phase that develops in 50 to 75% of patients, lasting up to several months. However, about 5% develop permanent hypothyroidism.

Both transient and chronic hypothyroidism occur frequently in patients treated with various cytokines for malignancy. An association between therapy with interferon- $\alpha$  (IFN- $\alpha$ ) and thyroiditis was first recognized in patients treated for carcinoid tumors and breast cancer.<sup>60,61</sup> Because of overlapping symptomatology between hypothyroidism and interferon toxicity, such as fatigue, hair loss, myalgia, and weight gain, the diagnosis of hypothyroidism is often overlooked. IFN-induced thyroiditis can be autoimmune, similar to Hashimoto's disease and silent thyroiditis, as well as non-autoimmune, subacute thyroiditis.<sup>62</sup> Although the frequency of IFN-induced thyroiditis is highest in patients treated for hepatitis C rather than cancer, risk factors for developing hypothyroidism include female gender, longer duration of IFN- $\alpha$  therapy, and older age. Preexisting

autoimmune thyroiditis, evidenced by the presence of anti-TPO antibodies before IFN therapy, increases the risk of thyroid dysfunction to 60% from 3 to 6%.<sup>63</sup>

Treatment with IL-2 is associated with a significant risk of hypothyroidism—up to 35% during therapy and 14% permanently.<sup>64,65</sup> Cumulative dose and duration of therapy with IL-2, along with female gender and preexisting autoimmune thyroid disease, increase the risk of subsequent thyroid dysfunction.<sup>66</sup> In patients treated with both IL-2 and IFN- $\alpha$ , the risk of thyroid abnormalities, primarily transient biphasic thyroiditis, can approach 90%. Thyroiditis leading to hypothyroidism has also been described in a significant proportion of patients treated with low-dose IL-2 combined with peptide vaccines for advanced melanoma, along with a wide variety of other autoimmune phenomena.<sup>67</sup> Use of monoclonal antibodies directed against the immunomodulatory protein CTLA-4 has also been associated with developing autoimmune thyroiditis.<sup>68,69</sup> Recently, transient fulminant thyroiditis leading to hypothyroidism was reported in patients with mycosis fungoides treated with denileukin diftitox, a novel fusion protein comprised of the cytotoxic diphtheria toxin and the ligand binding domain of IL-2.<sup>70</sup>

#### Postablative Hypothyroidism

Transient hypothyroidism can occur in patients who undergo surgical resection of a single thyroid lobe for nodular disease. Permanent hypothyroidism occurs in up to 25% of cases, especially if autoimmune thyroiditis is also present.<sup>71,72</sup> Following radioiodine therapy for Graves' disease, most patients eventually develop permanent postablative hypothyroidism.

External beam radiotherapy for lymphoma or head and neck carcinomas are usually given in doses of more than 20 gray (Gy) (2,000 rad). Thyroidal exposure is sufficient to produce hypothyroidism even in patients treated with total body irradiation before marrow transplantation, and the risk of eventual hypothyroidism increases with higher doses.<sup>73–75</sup> The frequency of hypothyroidism may be as high as 65% if laryngectomy or partial thyroidectomy is also performed.<sup>76</sup> As with other causes of postablative hypothyroidism, subclinical hypothyroidism may be present for many years before disease becomes symptomatic. In survivors of childhood Hodgkin's disease treated with radiotherapy, the relative risk of developing hypothyroidism within 20 years was 17, compared with sibling controls.<sup>77</sup> In addition to external radiotherapy, internal radiation emitters, such as (131)I-MIBG used in treatment of neuroblastoma or pheochromocytoma, can cause long-term hypothyroidism in a majority of patients, despite pretreatment prophylaxis with potassium iodide.<sup>78</sup>

### Central Hypothyroidism

Owing to the trophic and regulatory effects of TSH on the thyroid gland, disorders of TSH production or function can cause hypothyroidism. However, even in the absence of TSH, a basal level of thyroid hormone synthesis persists. Therefore, circulating  $T_4$  and  $T_3$  levels are typically not as low in central hypothyroidism as they are in primary thyroidal failure.<sup>79</sup>

More common causes of central hypothyroidism are acquired destructive processes affecting the pituitary gland. These generally produce multiple pituitary hormone deficiencies, although any combination is possible. Neoplastic diseases such as pituitary adenoma, craniopharyngioma and metastatic disease to the pituitary (eg, renal cell cancer, leukemia, and breast cancer) may cause acquired TSH deficiency. These mass lesions either destroy normal pituicytes or compress the pituitary stalk, thereby disrupting the portal supply of trophic factors from the hypothalamus. Patients with plurihormonal deficiency exhibit features of hypothyroidism as well as that of gonadotropin, ACTH and growth hormone deficiencies.

Disorders of hypothalamic function can affect the pituitary production of TSH by altered synthesis or release of trophic factors, particularly TRH. Neoplastic diseases such as germinomas, craniopharyngiomas or meningiomas often cause defective TRH secretion. Diabetes insipidus is a frequent feature due to impairment of vasopressin production and release. Cranial or head and neck irradiation in cancer patients can also lead to hypothalamic hypothyroidism.<sup>80</sup> Because dopamine transport to the pituitary is frequently affected, mild hyperprolactinemia is commonly seen in these patients.

Reversible central hypothyroidism occurs as a dose-dependent complication of therapy with bexarotene, a retinoid X receptor (RXR)-selective drug used in the treatment of mycosis fungoides and cutaneous T cell lymphoma.<sup>81</sup> Studies suggest that the mechanism of RXR-mediated hypothyroidism is suppression of transcription of the TSH  $\beta$  subunit gene, independent of the role of thyroid hormone receptors, and reduction of TSH concentrations can be seen within hours of a single oral dose of the drug.<sup>81-83</sup> Additional evidence suggests that the drug also accelerates thyroid hormone metabolic clearance, leading to markedly higher doses of thyroid hormone needed to treat the hypothyroid patient.<sup>84</sup>

### Miscellaneous Etiologies of Hypothyroidism

Damage to the thyroid can occur as a result of diffuse infiltration of the gland. Amyloidosis of various etiologies, including secondary to multiple myeloma, often produces asymptomatic infiltration and goiter, with hypothyroidism seen

in as many as 15% of patients.<sup>85</sup> Gammopathy-associated hypothyroidism can also be seen as a “minor” diagnostic criterion in the POEMS or Crow-Fukase syndrome, although cytokine-induced autoimmunity has been postulated.<sup>86</sup> Thalidomide has also been implicated to cause mild to severe hypothyroidism in up to 20% of treated myeloma and renal cell carcinoma patients, of uncertain etiology.<sup>87,88</sup> Aminoglutethimide has been associated with the development of hypothyroidism of uncertain etiology in prostate and breast cancer patients.<sup>89</sup> Exacerbation of preexisting hypothyroidism and increasing levothyroxine dose requirements have been described in cancer patients treated with numerous medications, including imatinib, bexarotene, estrogens, tamoxifen citrate, mitotane, fluorouracil, and methadone, likely due either to increased metabolic clearance of the hormone or altered serum transport proteins.<sup>84,90-92</sup> Increased metabolism of  $T_4$  and “consumptive hypothyroidism” has been reported in patients with tumors that express high levels of the type III deiodinase, including massive hemangiomas, hemangioma-epithelioma, and a malignant solitary fibrous tumor.<sup>93,94</sup>

### Diagnosis

Clinical manifestations, hypothyroxinemia, and an elevated serum TSH establish the diagnosis of overt primary hypothyroidism, and therefore first-line laboratory testing for suspected hypothyroidism should be measurement of the serum concentration of TSH, with abnormal results followed by measurement of free  $T_4$ .<sup>95</sup> Due to the greater sensitivity of TSH measurements, the presence of an elevated TSH with a free  $T_4$  level in the lower portion of the reference range would be consistent with subclinical primary hypothyroidism. In rare patients with central hypothyroidism, the serum TSH will generally not be elevated, but the diagnosis would be suggested by an inappropriately low free  $T_4$ . If pituitary or hypothalamic disease is suspected, other abnormalities of anterior pituitary function are often found (eg, inappropriately normal gonadotropin levels in a postmenopausal woman). Radiologic imaging of the sella is also often indicated. Additional tests can occasionally be helpful in establishing the diagnosis and cause of hypothyroidism. The diagnosis of autoimmune thyroiditis, either chronic or transient, is confirmed by the presence of serum anti-TPO antibodies.

Hypothyroxinemia and hypotriiodothyroninemia are common findings in patients with nonthyroidal illness.<sup>8,96</sup> In addition to deficiency of albumin and transthyretin, other proposed mechanisms include inhibition of hormone binding to TBG, perhaps due to free fatty acids released from damaged tissues or cytokines such as tumor necrosis factor.<sup>97</sup> Numerous medications

interfere with thyroid hormone binding to serum proteins, including diphenylhydantoin, furosemide, heparin, sertraline, and certain anti-inflammatory agents.<sup>98</sup> L-asparaginase causes frank reduction in TBG concentrations. Inhibition of 5'-monodeiodinase activity in extrathyroidal tissues, probably related to increased levels of interleukin-6 and TNF- $\alpha$ , reduces production of  $T_3$ , reduces clearance of  $rT_3$ , and accelerates clearance of  $T_4$  through non-deiodinative mechanisms, thus contributing to reduced levels of  $T_4$  and  $T_3$  but increased  $rT_3$ .<sup>6</sup> Medications such as glucocorticoids, amiodarone, oral radiocontrast agents, gold, and high dose propranolol and propylthiouracil (PTU) also inhibit  $T_4$  deiodination to  $T_3$ ; however, clinical signs of hypothyroidism are unlikely to develop. Pituitary TSH production is suppressed by endogenous and/or exogenous glucocorticoids, dopamine, somatostatin, and endorphins, and may also be mediated by reduced hypothalamic TRH secretion.<sup>99</sup> Alteration of TSH sialylation and bioactivity may occur in critical illness as well.<sup>100</sup> Mild illness is typically accompanied by reductions in  $T_4$  to  $T_3$  conversion, resulting in a low  $T_3$  state; similar changes have been reported after intravenous chemotherapy administration.<sup>101</sup> With increasing severity of nonthyroidal illness, all of the proposed mechanisms presumably result in a low  $T_4$ , low  $T_3$  state. These laboratory abnormalities reverse with recovery from the nonthyroidal illness or discontinuation of the interfering medication.

The sequence of thyroid hormone changes in nonthyroidal illness has been studied in considerable detail in patients undergoing bone marrow transplantation. During the first several weeks following transplant,  $T_4$ ,  $T_3$ , and TSH levels all markedly decline, inversely proportional to rises in serum levels of IL-6 and TNF- $\alpha$ .<sup>102-104</sup> In one study, one-year mortality due to transplant complications was sixfold higher in patients whose serum total  $T_4$  levels fell below 4 mcg/dL, consistent with the proposition that the severity of hypothyroxinemia correlates with the severity of the underlying nonthyroidal illness as suggested in studies of critically ill patients.<sup>102</sup>

Although most of the effects of nonthyroidal illness may represent energy-conserving adaptive mechanisms, the traditional view of these patients as being “euthyroid” is not universally held.<sup>105,106</sup> However, no survival benefit from thyroid hormone supplementation has ever been demonstrated in clinical trials in severely or critically ill patients, and increased catabolism and protein wasting have been reported. In this context, it is important to emphasize that diagnosis of nonthyroidal illness is a clinical diagnosis that does not require laboratory testing, such as measurement of  $rT_3$  levels, for identification; the challenge, instead, is to determine whether there is any reason to suspect a preexisting thyroid disease

underlying the changes that are superimposed by nonthyroidal illness. Therefore, judicious therapy is suggested only in patients with evidence of elevated TSH levels despite acute illness.<sup>106</sup>

## Treatment

The goal of therapy for overt hypothyroidism is to make the patient clinically and biochemically euthyroid, which is usually associated with normalization of the serum TSH level. The treatment of choice to accomplish this is oral synthetic levothyroxine sodium, which is available in 12 individual dose strengths. For individuals under age 60 with overt and symptomatic disease, full hormone replacement requires an average of 1.7 mcg/kg daily, although there is considerable variation around this mean. Owing to the long half-life of the hormone and the gradual rise in serum concentration over several weeks after initiating daily oral treatment, most of these patients can be started directly on this full replacement dose without toxicity. However, in older patients and those with known or suspected cardiovascular disease, even this gradual rise is too rapid, inducing anginal symptoms or palpitations in a small proportion. Thyroid hormone does improve the efficiency of myocardial contractility and is a potent vasodilator, and thus an equivalent proportion of patients may instead experience an improvement in their angina.

Whether patients with subclinical or mild hypothyroidism absolutely require supplemental doses of levothyroxine to normalize their laboratory tests remains controversial. However, patients with active autoimmune disease or who have radiation-induced hypothyroidism are very likely to progress to overt disease, thereby justifying earlier intervention to prevent development of symptomatic hypothyroidism. Low doses of hormone, 50 to 100 mcg daily, are usually sufficient to normalize the TSH.

When levothyroxine sodium is administered daily by mouth, decreasing serum TSH concentrations plateau within 4 to 6 weeks, and measurement of the TSH level should await this new equilibrium. Patients with persistently elevated serum TSH levels generally require an increased dose of levothyroxine, whereas those patients with a low serum TSH concentration usually require a decrease in dose. Serum  $T_4$  and  $T_3$  levels are usually normal during therapy, although mild hyperthyroxinemia can occur in as many as 20% of patients who are otherwise euthyroid. Once a hypothyroid patient becomes euthyroid, follow-up evaluation should be performed after several months, given the gradual increase of  $T_4$  clearance that occurs in these patients. Subsequent evaluations generally are required only annually. To monitor therapy in patients with secondary or tertiary hypothyroidism, the patient's clinical status and serum free  $T_4$  levels should be assessed.

The goal of therapy should be attainment of a clinically euthyroid state, with normal or high-normal free  $T_4$  levels since the serum TSH concentration is not a reliable indicator of thyroid hormone status in this setting.<sup>107</sup>

In cancer patients, the routine approach to oral hormone replacement therapy is occasionally inadequate. As described previously, several medications appear to increase metabolic clearance of levothyroxine, therefore leading to increased dose requirements. Patients who require enteral administration through a feeding jejunostomy may also require considerable increase in their hormone dose, a problem that is apparently avoided by administration of the drug into the stomach first.<sup>108</sup> High thyroid hormone dose requirements can sometimes be a clue to the presence of a broader malabsorption condition, such as short bowel syndrome or Whipple's disease.<sup>109</sup>

Patients receiving therapy with  $T_3$ -containing preparations, which are shorter acting than levothyroxine alone, may be more difficult to monitor. Individuals who take desiccated thyroid or other formulations containing triiodothyronine are likely to have variable  $T_3$  levels during the day. Most recent placebo-controlled studies have demonstrated that there is no significant measurable benefit accrued to patients when treated with combination formulations of varying ratios of  $T_4$  and  $T_3$ , compared with  $T_4$  alone.<sup>110</sup>

## Thyrotoxicosis

Thyrotoxicosis refers to the clinical state of increased metabolism due to increased serum concentrations of  $T_4$  and/or  $T_3$ . Whereas hyperthyroidism defines the forms of thyrotoxicosis secondary to increased synthesis of thyroid hormones, other etiologies can include thyroiditis and excessive ingestion of thyroid hormone. The prevalence of thyrotoxicosis, including both mild and overt disease, is only about 1% in the United States, but is generally more common in women than men.<sup>14</sup> Thyrotoxicosis as a consequence of cancer or its treatment is also considerably less frequent than similarly caused hypothyroidism.

## Clinical Manifestations

Thyrotoxicosis is generally more likely to be more symptomatic, even in its mild forms, than hypothyroidism. A common constitutional symptom is fatigue, often misconstrued to indicate hypothyroidism. Weight loss is generally secondary to increased metabolic rate, despite increased appetite and food intake, but occasionally weight gain can be seen as well. Organ system-specific manifestations are addressed below.

### The Neuromuscular System

Multiple neuromuscular abnormalities result from thyrotoxicosis. A majority of patients

experience proximal muscle weakness and tremor, often a presenting symptom of the patient's thyroid disease. Less common manifestations include bulbar weakness and fasciculations that can be mistaken for amyotrophic lateral sclerosis. Increased protein catabolism is a key contributory factor, along with depletion of glycogen and ATP.<sup>111</sup> A common autoimmune pathophysiology links thyrotoxic Graves' disease and myasthenia gravis, and 5 to 10% of patients with myasthenia have coexistent Graves' disease; thymic hyperplasia, however, is a common finding in thyrotoxic patients even in the absence of myasthenia.<sup>112,113</sup> Recurrent episodes of severe muscle weakness associated with marked hypokalemia characterizes thyrotoxic periodic paralysis, but unlike familial periodic paralysis, the relation between potassium channel function and thyrotoxicosis is unknown.<sup>114,115</sup> Neuropsychiatric consequences of thyrotoxicosis are common, including anxiety, irritability, emotional lability and difficulty concentrating.

### The Cardiovascular System

A complex web of direct and indirect effects converge on the cardiovascular system, leading to a broad variety of symptoms and abnormalities, including palpitations, tachycardia, and increased "cardiac awareness."<sup>116</sup> Increased metabolism leading to increased oxygen demand contributes to tachycardia, along with direct stimulation of the sinus node pacemaker.<sup>117</sup> Perhaps secondary to increased nitric oxide production by vascular endothelial cells, systemic vascular resistance can decrease by as much as 70% in thyrotoxicosis, causing decreased diastolic blood pressure, activation of the renin/angiotensin/aldosterone system, sodium retention, and eventual increased preload. Combined with enhanced calcium release and reuptake by myocardial sarcoplasmic reticulum, these peripheral hemodynamic effects lead to increased myocardial contractility and output; however, heart failure has been reported in patients who experience a disproportionate rise in systemic vascular resistance associated with exercise.<sup>118</sup> Beyond sinus tachycardia, atrial fibrillation occurs three times as frequently in older patients with suppressed TSH levels compared with euthyroid controls, with less frequent spontaneous cardioversion and possibly a higher rate of thromboembolic complications.<sup>119,120</sup>

### The Respiratory System

Patients with thyrotoxicosis demonstrate various respiratory abnormalities, many arising due to increased metabolic demand for oxygen. Oxygen consumption and carbon dioxide production are invariably increased, leading to tachypnea and increased minute ventilation. Although airway resistance is typically normal, chronic thyrotoxicosis can lead to respiratory myopathy

and possibly alterations in lung compliance.<sup>121</sup> In contrast with hypothyroidism, ventilatory responses to hypercapnia and hypoxia may be enhanced.<sup>122</sup> Patients with concurrent lung disease are therefore more likely not to be able to meet their demand for increased gas exchange and become symptomatic.

Substernal goiter can lead to upper airway compression, which in the thyrotoxic patient can exacerbate the respiratory consequences. About 15% of patients with substernal goiter have symptoms to suggest upper airway obstruction, including exertional dyspnea. On pulmonary function testing, flow volume loops tend to be flattened. If the obstruction is extrathoracic, the changes occur primarily on inspiratory airflow, whereas intrathoracic obstruction causes expiratory flattening.

#### The Gastrointestinal System

The common manifestations of thyrotoxicosis in the gastrointestinal tract include increased gut motility, rapid transit, and hyper-defecation. Despite increased esophageal peristalsis, dysphagia can occasionally result from pharyngeal and esophageal myopathy.<sup>123</sup> Due to overlapping autoimmune conditions, antiparietal cell antibodies, vitamin B<sub>12</sub> malabsorption, and pernicious anemia are considerably more common. Cases of extreme fat malabsorption have also been described, but whether due simply to increased motility or due to thyroid hormone effects on small bowel lining function is controversial.<sup>124</sup> Hepatic function is frequently altered in thyrotoxicosis, with increased hepatic oxygen consumption. However, arterial blood flow to the liver is generally not increased, and therefore centrilobular necrosis has been reported in severe cases. Splenomegaly, previously a common finding in thyrotoxic patients, is now rarely seen.<sup>125</sup>

#### The Integumentary System

Direct skin effects of thyroid hormones are experienced by both the epidermis and dermis as well as cutaneous appendages. The skin is generally thin but without atrophy, perhaps secondary to inhibition of dermal fibroblasts.<sup>126</sup> Thyroid hormone also affects the transcription of numerous genes involved in keratin synthesis. Although it has been reported that surgical wound healing might be delayed in hypothyroidism, thyrotoxicosis does not appear to accelerate healing.<sup>127,128</sup> Hair and nail changes include increased hair growth rate, leading to fine and soft hair, and soft nails with distal onycholysis. Increased transcutaneous heat loss and erythema of face and palms accompanies peripheral vasodilatation. Due to exaggerated adrenergic responsiveness, hyperhidrosis is commonly experienced.

A characteristic autoimmune dermatopathy can be seen in thyrotoxicosis due to Graves'

disease. Skin thickening because of glycosaminoglycan deposition can vary from a localized "peau d'orange" appearance to a rare generalized infiltration.<sup>129</sup> Typically, the affected skin is raised, waxy, slightly hyperpigmented, and rarely pruritic. Thyroid acropachy is characterized by clubbing, soft tissue swelling of hands and feet, and periosteal new bone formation. Both dermatopathy and acropachy are also seen more commonly in patients with severe orbital complications of Graves' disease. Other autoimmune cutaneous phenomena are more common as well, including alopecia, bullous disorders, and urticaria.

#### The Hematopoietic System

Erythropoiesis is stimulated in thyrotoxic patients, with increased levels of erythropoietin likely due to alterations in tissue oxygen demand.<sup>130</sup> In bone marrow, erythroid hyperplasia can be seen, provided no nutritional deficiencies coexist.<sup>131</sup> However, increased plasma volume can result in normochromic, normocytic anemia in up to 25% of thyrotoxic patients.<sup>132</sup> Ferritin levels are generally increased, due to direct stimulation of ferritin synthesis by thyroid hormones.<sup>133</sup> Mild granulocytopenia and lymphocytosis can occur, of uncertain etiology. Both granulocytopenia and thrombocytopenia can be related to autoimmune destruction, but increased reticuloendothelial consumption has also been reported. The clearance of various clotting factors is increased, but clinical measures of coagulation tend to be normal. However, thyrotoxic patients are more sensitive to the anticoagulant effects of warfarin owing to increased clotting factor clearance and possible decreased plasma protein binding.<sup>134</sup>

#### Endocrine and Metabolic Systems

Thyrotoxicosis leads to increased transcription and secretion of growth hormone and prolactin, but clinical consequences are uncommon.<sup>135,136</sup> Metabolic clearance of cortisol is augmented, causing increased production of ACTH and consequently cortisol itself.

As thyrotoxicosis stimulates osteoblast and osteoclast activity, bone turnover is accelerated, leading to increased calcium efflux from the bone, hypercalciuria, and often hypercalcemia with parathyroid hormone suppression.<sup>137</sup> Hypomagnesemia occurs secondary to increased renal magnesium wasting, which also contributes to parathyroid suppression, and can exacerbate hypomagnesemia from platinum chemotherapy.<sup>138</sup> Other less frequent abnormalities of relevance in cancer patients include hyperuricemia, hypophosphatemia, and hypokalemia.<sup>139</sup>

Little is known about the impact of thyrotoxicosis on the pharmacokinetics of drugs used in the treatment of cancer. However, hepatic microsomal enzyme activity is likely to be enhanced in thyrotoxic patients, as suggested

by the reduction in the serum half-life and area under the concentration-time curve of antipyrine.<sup>140</sup>

#### Etiology and Pathophysiology

The causes of thyrotoxicosis include increased thyroid hormone production (hyperthyroidism), accelerated release of previously synthesized hormone, and excessive exogenous hormone administration. Hyperthyroidism can result from excessive stimulation of follicular cells through their TSH receptors to produce hormone, or TSH-independent autonomously hyperfunctioning neoplasms.

#### Graves' Disease and TSH Receptor-Mediated Hyperthyroidism

The most common etiology of hyperthyroidism is Graves' disease, an autoimmune condition in which immunoglobulins interact with and stimulate the TSH receptor. As postulated for autoimmune thyroiditis leading to hypothyroidism, class II-expressing thyroid follicular cells in Graves' disease likely acquire the capacity to present autoantigens to intrathyroidal CD4-expressing lymphocytes. In animal models, immunization with human TSH receptor, in the presence of class II antigens, can induce the production of immunoglobulins directed against the TSH receptor, often capable of stimulating receptor function and downstream signaling.<sup>141,142</sup> Modest associations exist between HLA alleles -DR3, -DR4, and -DR5 and Graves' disease, but a stronger association has been recently identified with polymorphisms of CTLA-4 in a variety of populations.<sup>143,144</sup>

Similar to autoimmune thyroiditis, patients exposed to a variety of treatments for cancer have increased risk for developing Graves' disease, especially IFN- $\alpha$  and IL-2.<sup>62,65,66</sup> However, Graves' disease has been reported as a potential adverse event of treatment with IL-4, GM-CSF, and possibly denileukin diftitox.<sup>70,145,146</sup> Hyperthyroidism clinically consistent with Graves' disease was reported to be eightfold more common in survivors of childhood Hodgkin's disease treated with irradiation than in their siblings.<sup>77</sup> However, other malignancies treated with irradiation are not associated with such a degree of risk for Graves' disease, suggesting to some that an underlying immune dysregulation may be responsible.<sup>147</sup>

A distinguishing feature of Graves' disease is that the ophthalmopathy coexists in about one-third of patients. Likely due to an autoantigen or epitope that is shared between thyroid follicular cells and orbital tissues, Graves' ophthalmopathy is characterized by a broad variety of clinical abnormalities, ranging from minimal exophthalmos, lid retraction, and retrobulbar discomfort to restrictive strabismus, corneal damage, and sight loss. An increased frequency of

ophthalmopathy has been reported in Hodgkin's disease survivors who develop Graves' disease.<sup>148</sup> Rarely, lymphoma, myeloma, and other malignancies have been reported to present with similar findings of ophthalmopathy, and therefore, the clinician should carefully evaluate the patient with orbital complaints for a variety of etiologies.

Although not autoimmune, other etiologies can be responsible for hyperthyroidism mediated through the TSH receptor but would not produce ophthalmopathy. About 1 to 2% of pituitary adenomas secrete bioactive TSH, often producing severe hyperthyroidism. Most will present with a large pituitary mass, and often, findings include visual field deficits and headache.

Although capable of interacting with the TSH receptor, the thyroid stimulating activity of one unit of hCG is equivalent to only  $1 \times 10^{-9}$  units of TSH. Nonetheless, hydatidiform moles, choriocarcinomas, and other germ cell tumors can often secrete sufficiently large amounts of hCG to produce hyperthyroidism that generally improves with aggressive treatment of the underlying neoplasm.<sup>149,150</sup>

#### Toxic Nodular Disease

Solitary and multiple adenomas of the thyroid can develop with autonomous, TSH-independent thyroid hormone production. Most such neoplasms can be found to harbor constitutively activating mutations of the TSH receptor or the  $\alpha$  subunit of the receptor-coupled stimulatory guanine nucleotide-binding protein that signals through cyclic adenosine monophosphate, but other downstream mutations are likely to be identified as well.<sup>151</sup> Neoplastic autonomy is more common in areas of relative iodine deficiency, with evidence suggesting a progression from hyperplasia to frank neoplastic hyperthyroidism following acquisition of constitutive, growth-stimulating mutations.<sup>152</sup> Rarely, malignant follicular tumors can also produce sufficient amounts of hormone to yield hyperthyroidism, but these typically are associated with a large metastatic burden.<sup>153</sup>

#### Transient Thyroiditis

Destructive inflammation of the thyroid can cause either thyrotoxicosis or hypothyroidism (as described previously), and commonly both can occur sequentially. During the thyrotoxic phase, rapid tissue injury leads to disruption of follicular structure and proteolysis of thyroglobulin, resulting in elevated levels of free  $T_4$  and  $T_3$ . Mild symptoms typical of thyrotoxicosis can be seen, including fatigue, nervousness, and tachycardia. Thyrotoxicosis can last up to three months but is typically shorter.

Evidence for an autoimmune basis for silent thyroiditis includes (1) increased frequency of

personal or family history of autoimmunity; (2) increased frequency of HLA-DR3 and -DR5 haplotypes; and (3) presence of intrathyroidal T cells similar in phenotype to chronic autoimmune thyroiditis. Initiating factors include treatment with amiodarone (type I thyrotoxicosis), lithium, IL-2, IFN- $\alpha$ , granulocyte colony-stimulating factor, and leuprolide acetate, and the disease has been associated with thymomas.<sup>154-157</sup>

Subacute thyroiditis, in contrast, is not a primary autoimmune disease, although thyroid autoimmunity may appear due to sensitization to thyroid antigens during inflammation. Instead, subacute thyroiditis typically occurs following an upper respiratory infection with adenovirus, coxsackievirus, Epstein-Barr virus, and influenza virus.<sup>156</sup> It has also been reported in patients treated with interferon and ribavirin therapy for hepatitis C. Genetic susceptibility is associated with HLA-Bw35 antigen. Acute suppurative thyroiditis is a rare cause of thyrotoxicosis and has usually been reported from bacterial or opportunistic infections, particularly in immunosuppressed hosts. Radiation injury to the thyroid can trigger release of thyroglobulin and transient thyroiditis, lasting for up to 3 months after thyroid exposure to at least 40 Gy.<sup>158</sup> A non-autoimmune destructive thyroiditis is also associated with amiodarone therapy (type II thyrotoxicosis).

#### Diagnosis

Clinical manifestations, elevated serum thyroid hormone concentrations, and a subnormal serum TSH level typically establish the diagnosis of thyrotoxicosis. In hyperthyroidism, the ratio of serum  $T_3:T_4$  levels tends to be increased, reflecting relatively greater production of  $T_3$  in these states; conversely, in transient thyroiditis, release of previously formed hormone is typically associated with lower  $T_3:T_4$  ratios. Patients with  $T_3$  toxicosis due to mild or recurrent Graves' disease or hyperfunctioning adenomas can present with normal or occasionally low serum free  $T_4$ , and the diagnosis of hyperthyroidism may be missed by not measuring  $T_3$  levels in patients with suspected thyrotoxicosis as well.

Measurement of free  $T_4$  levels is critical to distinguish the patient with true thyrotoxic hyperthyroxinemia from euthyroid hyperthyroxinemia owing to increased hormone binding to serum proteins. Most commercially available, free  $T_4$  assays can account for the common hormone-binding abnormalities, such as those due to excess levels of TBG in patients with hyperestrogenemia or being treated with tamoxifen, raloxifene, or methadone. But, paraneoplastic production of transthyretin in pancreatic and hepatic neoplasms leading to increased serum hormone binding may not be readily identified, and documentation of a normal TSH is often necessary to distinguish from thyrotoxicosis.<sup>159,160</sup>

Unfortunately, most commercially available free  $T_3$  assays are unreliable, and total  $T_3$  levels must suffice instead.

Additional tests are occasionally useful in establishing the diagnosis and etiology of thyrotoxicosis. In a patient with a tender goiter and hyperthyroidism of short duration, an elevated erythrocyte sedimentation rate is characteristic of subacute thyroiditis. An elevated radioiodine uptake is typically found in Graves' disease and hyperfunctioning nodular disease, but is not seen in subacute or silent thyroiditis. Similarly, the serum thyroglobulin and radioiodine uptake are typically low in factitious and iatrogenic thyrotoxicosis. Testing for TPO antibodies or thyroid stimulating immunoglobulins may assist in the discrimination between Graves' disease and toxic multinodular goiter. Radiologic imaging of the sella and a serum  $\alpha$ -subunit level would be indicated in the evaluation of the patient with TSH-mediated hyperthyroidism.

#### Treatment

Treatment of hyperthyroidism relies upon use of therapies directed toward (1) reduction in production of thyroid hormones, and (2) amelioration of the symptoms of thyroid hormone excess. Whereas the latter approach is also of value in the symptomatic patient with destructive thyroiditis, treatment to reduce hormone production is only of value in hyperthyroidism.

Antithyroid drugs have been a mainstay of treatment of hyperthyroidism for six decades. Thionamides, including propylthiouracil (PTU) and methimazole available in the United States and carbimazole elsewhere, work by a variety of intrathyroidal mechanisms, including inhibition of iodine oxidation, organification, iodotyrosine coupling, and possibly thyroglobulin synthesis and function. Outside the follicular cell, PTU at high doses inhibits the type 1 deiodinase, thus blocking  $T_4$  to  $T_3$  conversion. Immunosuppressive actions have been attributed to thionamides as well that could be of benefit in treatment of Graves' disease, but it remains unclear whether clinically achieved concentrations produce these effects. Because methimazole is more potent, has a longer half-life, and has better patient compliance with once-daily dosing, methimazole therapy is more effective at reducing serum  $T_4$  and  $T_3$  levels.<sup>161</sup> Daily starting doses of methimazole range from 10 to 40 mg, higher doses being required for patients with more severe hyperthyroxinemia; the typical initial dose of PTU is 100 mg three times daily.<sup>162</sup> With gradual normalization of thyroid hormone levels, doses can typically be reduced by about half. Toxicities commonly include urticarial rash, arthralgias, mild granulocytopenia, and fever. More serious and less common side effects include an autoimmune agranulocytosis (in 0.2 to 0.5%

of treated patients), aplastic anemia, fulminant hepatitis, and vasculitis. Because the typical presentation of thionamide-induced agranulocytosis is a gram-positive pharyngitis, patients are instructed to discontinue their medication and contact their physician when developing fever and a sore throat. Antibiotics and, when necessary, G-CSF therapy allow for rapid recovery from this consequence.

Definitive therapy of hyperthyroidism usually requires either radioiodine ablation or surgical resection of the overactive gland. Treatment with  $^{131}\text{I}$  delivering 50 to 150 Gy to the thyroid gland induces acute and chronic radiation necrosis, eventually leading to hypothyroidism in most patients with Graves' disease. Long-term safety of this treatment is excellent, with only case reports linking radioiodine treatment of Graves' disease with increased risk of secondary malignancies. Thus, except in children for whom long-term follow-up data are more sparse, radioiodine therapy is the most commonly applied definitive treatment for hyperthyroid Graves' disease. In contrast, recent data suggest an increased risk for developing thyroid carcinoma in patients with toxic nodular disease treated with  $^{131}\text{I}$ , likely due to sublethal and mutagenic radiation doses absorbed by the paranodular thyroid cells.<sup>163</sup> Thyroidectomy remains an excellent treatment option for hyperthyroidism, particularly for those patients with severe Graves' ophthalmopathy (which can acutely worsen following radioiodine administration), for younger patients with toxic nodular goiters, and for patients with large obstructing goiters.

Symptoms of thyrotoxicosis are generally ameliorated with therapy with  $\beta$ -adrenergic receptor blockers. In the patient who cannot tolerate this treatment, calcium channel antagonists can also be of benefit. In anticipation of surgery for the hyperthyroid patient, combined administration of  $\beta$ -adrenergic receptor blockers and thionamides are generally necessary to lower hormone levels toward normal and reduce the risk for decompensated thyrotoxicosis or thyroid storm; addition of large doses of inorganic, stable iodine for no more than 10 to 14 days can also accelerate presurgical preparation.

Because normalization of the serum TSH concentration may lag behind thyroid hormone levels by several months, initial therapy should be directed to reducing thyroid hormone levels. Once the TSH level is detectable, it is again a sensitive indicator of thyroid hormone status. Given the increased  $\text{T}_3/\text{T}_4$  ratio typical of increased glandular synthesis of hormone, the  $\text{T}_4$  level may become normal or even low while the  $\text{T}_3$  level remains elevated, producing persistent  $\text{T}_3$ -toxicosis. In addition, an elevated  $\text{T}_3$  level may be the earliest sign of recurrent hyperthyroidism. Thus, both the  $\text{T}_3$  and free  $\text{T}_4$  levels should be

monitored during treatment of hyperthyroidism. In patients with TSH-mediated hyperthyroidism, clinical assessment and thyroid hormone levels are the only measures of use, as the serum TSH level does not reflect thyroid hormone status.

## Thyroid Neoplasia

### Clinical Manifestations

Thyroid nodules are approximately four times more common in women than in men. These nodules increase in frequency throughout life, reaching a prevalence of about 5% in the US population aged 50 years and older. Nodules are even more prevalent when the thyroid gland is examined at autopsy or surgery, or when using ultrasonography; as many as 67% of thyroids so studied have nodules, which are almost always benign.<sup>164</sup> New nodules develop at a rate of about 0.1% per year, beginning in early life, but they develop at a much higher rate (about 2% per year) after exposure to head and neck irradiation.

About 5% of all incident nodules prove to be malignant, mostly being primary carcinomas of the thyroid gland (papillary, follicular, medullary, and anaplastic). Like thyroid nodules, thyroid neoplasia occurs two to three times more often in women than in men. With the incidence increasing by 4% per year, thyroid cancer is currently the seventh most common malignancy diagnosed in women.<sup>165</sup> Among persons aged 15 to 24 years, thyroid cancer accounts for 7.5% to 10% of all diagnosed malignancies. The disease is also diagnosed more often in white Americans than in African Americans. Although thyroid carcinoma can occur at any age, the peak incidence was around age 50 to 54 in women and 65 to 69 in men for the period 1996 to 2000.

Nonthyroidal malignancies can occasionally metastasize to the thyroid gland, and are often detected many years after the initial disease diagnosis. The most common primary sites for metastatic disease to the thyroid include kidney, breast, colon, lung, esophagus, and uterus.<sup>166,167</sup> Metastatic melanoma may be disproportionately more commonly found at autopsy and less commonly seen clinically. Conversely, metastatic thyroid carcinoma is occasionally identified in patients undergoing treatment for other head and neck malignancies; in these patients, the thyroid cancer is rarely clinically significant or a cause of subsequent morbidity or mortality.<sup>168</sup>

With increasingly sensitive radiologic and scintigraphic technologies used to follow patients with cancer, new clinical syndromes are identified due to incidental discovery of unanticipated abnormalities. Thus, ultrasound reports of the neck commonly comment on incidental thyroid nodules being detected. Recently, the incidental "PEToma" has been described as focal uptake of

$^{18}\text{F}$ -deoxyglucose in the thyroid in patients undergoing positron emission tomography (PET). Between 1 and 4% of patients undergoing FDG-PET or FDG-PET-computed tomography (CT) studies for evaluation of malignancy have been reported to have such incidental thyroid findings.<sup>169-171</sup> Of those patients subsequently evaluated cytologically, 30 to 40% were found to have malignant disease, perhaps best predicted by low attenuation characteristics on the accompanying CT images and minimal degrees of FDG uptake.<sup>169</sup>

### Etiology

The only well-established risk factor for papillary thyroid cancer is radiation exposure, especially during infancy.<sup>172</sup> External radiation, delivered therapeutically decades ago for benign conditions, such as thymic and tonsillar enlargement, and currently for malignant diseases, such as Hodgkin's lymphoma and before bone marrow transplantation, is associated with an excess relative risk for thyroid malignancy of 3 to 9 per Gy. The risk of radiation-induced thyroid carcinoma is greater in females, certain Jewish populations, and patients with a family history of thyroid carcinoma. Exposure to internal sources of radiation after the Chernobyl nuclear accident led to a three- to 75-fold increase in the incidence of papillary carcinoma, the highest risks seen in younger children.<sup>173</sup> Although nuclear weapon testing and other sources of radiation fallout have affected large areas of the United States, follow-up studies have yet to identify definite evidence of increased rates of thyroid cancer.<sup>174,175</sup>

Differentiated (papillary or follicular) carcinoma is a component of several inherited syndromes, including familial adenomatous polyposis, Gardner's syndrome, Cowden disease, Turcot's syndrome, and Carney's complex. Familial non-medullary carcinoma, described in families with at least two first-degree relatives with the disease, has been reported in 5% of all papillary carcinoma patients, and may portend a more-aggressive disease course. Medullary carcinoma can occur in a variety of familial syndromes, including multiple endocrine neoplasia (MEN) types IIa and IIb and isolated familial medullary thyroid carcinoma. Patients with MEN syndromes may often be identified on the basis of the non-thyroidal tumors, parathyroid adenomas and pheochromocytomas, but increasingly, these patients are identified by prospective familial screening programs.

### Diagnosis

The primary method for evaluating a thyroid nodule is fine needle aspiration, often guided by ultrasonography.<sup>176</sup> Ultrasonographic criteria that increase the likelihood of malignancy include

the presence of microcalcifications, hypoechogenicity, and increased intranodular vascularity.<sup>177</sup> In the setting of an unsuppressed serum TSH concentration, thyroid ultrasonography followed by cytologic examination of a fine-needle aspirate (FNA) of solitary nodules at least 1 cm in size is the most appropriate diagnostic procedure; in the setting of multiple nodules, those with suspicious ultrasonographic appearances should be preferentially aspirated.<sup>178</sup> Papillary, medullary, and anaplastic carcinomas can be readily diagnosed on the basis of cytologic criteria. However, the distinction between follicular carcinoma and benign follicular adenoma requires histologic demonstration of either invasion through the tumor capsule or vascular invasion. Hence, follicular adenomas and carcinomas are grouped together cytologically as indeterminate or suspicious follicular neoplasms. Up to 25% of aspirations are inadequate or nondiagnostic, largely because of aspiration of cystic, hemorrhagic, or hypocellular colloid nodules.<sup>179</sup> The false-positive and false-negative rates for nodules characterized as “malignant” and “benign,” respectively, are less than 5%.<sup>180</sup> For suspicious follicular lesions, the overall rate of carcinoma is approximately 20%, with higher rates associated with larger nodule size, older age, and male gender.<sup>181–183</sup> Intraoperative frozen section evaluation adds little to the evaluation of follicular neoplasms, but may occasionally be helpful to confirm the diagnosis of cytologically suspected papillary carcinoma.<sup>184,185</sup> For nodules in which fine-needle aspiration yields inadequate diagnostic material, repeat aspiration, particularly with ultrasonography guidance, can augment the accuracy of the procedure.<sup>186</sup>

By radionuclide scanning, malignant thyroid lesions are usually hypofunctioning or “cold,” but this finding is both nonspecific and nondiagnostic. In contrast, a “hot” hyperfunctioning nodule causing thyrotoxicosis is highly likely to be a benign follicular adenoma. Thus, only patients with a suppressed TSH should undergo radioiodine scanning to determine the function of significant nodules, and FNA only performed for nonfunctioning lesions. Other imaging procedures, such as CT, magnetic resonance imaging (MRI), and PET have no role in the routine diagnostic evaluation of thyroid nodules.

## Treatment

Patients with benign thyroid nodules rarely require therapy for an asymptomatic neoplasm. In iodine-sufficient populations, there is little evidence of significant clinical benefit from use of thyroid hormone suppression therapy for euthyroid benign nodular disease.<sup>176,187</sup> As discussed for the management of thyrotoxicosis, surgical resection is often the preferred approach to treatment of the toxic follicular adenoma. The management

of patients with thyroid carcinoma is the subject for other treatises.<sup>176,188,189</sup>

As for patients with isolated metastatic disease to the thyroid gland, long-term benefit can result from thyroidectomy.<sup>190</sup> However, in the setting of disseminated metastases, appropriate diagnosis of an intrathyroidal metastasis can permit avoidance of unnecessary thyroidectomy and instead lead to consideration of systemic interventions.<sup>166,167</sup>

# Pituitary and Adrenal Complications in Cancer Patients

S. Jim Yeung, MD, PhD  
Robert F. Gagel, MD

Cancer and its treatment can lead to endocrine dysfunction and to clinical and laboratory abnormalities that obscure or mimic endocrine diseases. The pituitary is the “master” gland in the body; among the various endocrine axes regulated by the hypothalamic-pituitary system, the hypothalamic-pituitary-adrenal axis is one of the vital hormonal systems, severe dysfunction of which can lead to death. In this chapter, we focus on the impact of cancer and cancer treatments on the hypothalamus, pituitary gland, and adrenal glands.

## Hypothalamic-Pituitary Dysfunction

Radiotherapy is a common cause of hypothalamic and pituitary dysfunction in cancer patients. In contrast, there is no strong direct evidence to implicate chemotherapy as a cause of permanent hypothalamic or pituitary dysfunction. (Glucocorticoid-induced hypoadrenalism and targretin-induced central hypothyroidism are reversible after cessation of the drugs.) Metastasis to the hypothalamic region or the pituitary gland is uncommon,<sup>1</sup> and clinical manifestations of endocrine dysfunction owing to metastatic disease in this region are even rarer. However, benign tumors, such as pituitary tumors and craniopharyngiomas, frequently affect this anatomic region and cause endocrine dysfunction.

Radiation-induced anterior pituitary hormone deficiencies are irreversible and progressive. Although the hypothalamus is the regional structure most affected by radiation damage, hypothalamic damage can lead to pituitary atrophy over time owing to the lack of hypothalamic trophic factors. The pituitary gland may also be directly damaged by radiation. The severity, frequency, and timing of onset of hypothalamic and pituitary hormone deficiencies correlate with the total dose and fraction size of radiation in the hypothalamic-pituitary area and previous pituitary compromise by tumor and/or surgery and correlate inversely with the age of the patient at the time of radiotherapy.

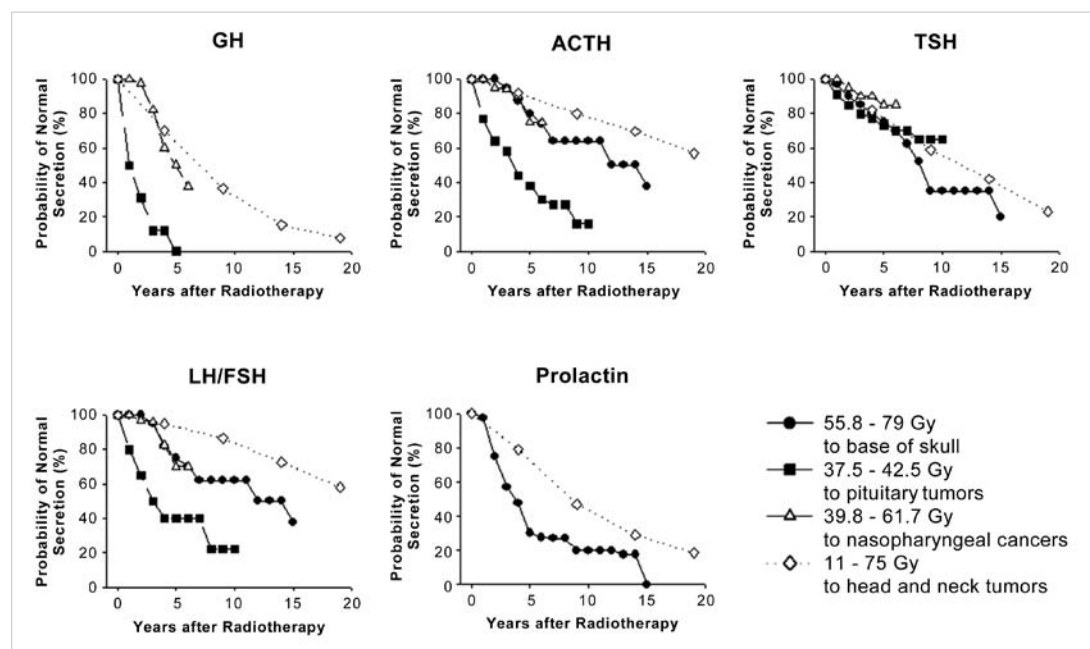

The development of radiation-induced hypothalamic dysfunction is usually insidious; hormone deficiencies can manifest clinically years after radiation exposure. There is considerable variation in the sequence and frequency of hormonal dysfunctions among the several axes of hypothalamic-pituitary function. The somatotrophic axis appears to be the most sensitive to radiation. Growth hormone (GH) deficiency typically occurs in isolation following exposure of the hypothalamic-pituitary area to less than 30 Gy of radiation; with higher levels of radiation exposure (30–50 Gy), the frequency of GH deficiency substantially increases to as high as 50 to 100%. The thyrotropic axis appears to be the least sensitive to radiation (Figure 1).<sup>2–5</sup> Abnormalities in gonadotropin secretion are dose dependent: precocious puberty owing to dysregulation of gonadotropin secretion can occur after radiation doses less than 30 Gy in girls and after doses of 30 to 50 Gy in boys and girls. Gonadotropin deficiency occurs infrequently and is usually a long-term complication following a radiation dose of 30 Gy or more. Much higher incidences of gonadotropin, adrenocorticotropic hormone (ACTH or corticotropin), and thyroid-stimulating hormone (TSH or thyrotropin) deficiencies (30–60% after 10 years) occur after the more intensive irradiation typically used for nasopharyngeal carcinomas and tumors of the skull base (>70 Gy) and for pituitary tumors (30–50 Gy). In a recent study, 41% of adult patients treated with cranial irradiation for primary nonpituitary brain tumors had hypopituitarism, which was time and dose dependent.<sup>6</sup>

The diagnosis of hypothalamic-pituitary dysfunction requires vigilance by the physician because most of the presenting symptoms are nonspecific and can easily be attributed to other causes. For example, fatigue and weakness, symptoms of pituitary dysfunction, are common among cancer patients. Regular screening examinations and testing are required to ensure timely diagnosis and early hormone replacement

therapy to prevent short stature and ill health in children cured of cancer and to prevent ill health, sexual dysfunction, and osteoporosis and improve the quality of life in adults. An initial diagnostic evaluation for hypothalamic and pituitary dysfunction may include serum GH and insulin-like growth factor 1 (IGF-1) measurements and evaluation for gonadal failure. Signs of overt hypopituitarism include hypoglycemia, hypotension, and hypothermia.

In children and teenagers, evaluation of sexual development is a useful diagnostic tool. The investigation should include staging of sexual development according to the Tanner staging criteria, examination of pubic and axillary hair, and review of menstrual history in girls and penile or testicular size in boys. In children who have had cranial irradiation, height and growth velocity should be measured at 6-month intervals. In children treated with spinal or craniospinal irradiation, local rather than general growth abnormalities may be present and, if so, require further specific evaluation. Foot size is a reliable indicator of growth that can be measured on a routine clinic visit.<sup>7</sup> A child whose growth rate is not within the limits of a normal growth curve should be evaluated for GH deficiency, hypothyroidism, and adrenal insufficiency. If the initial evaluation of GH, IGF-1, TSH, and free thyroxine levels and radiographic bone age reveals abnormalities, then detailed dynamic testing to evaluate secretion of GH, ACTH, and gonadotropin-releasing hormone should be performed (Table 1).

In adults who have received cranial or head and neck irradiation, detection of hypothalamic-pituitary abnormalities is more challenging. One strategy to detect hypothalamic-pituitary abnormalities in adults consists of routine screening for abnormal GH and IGF-1 levels and gonadal failure, the most sensitive indicators of radiation-induced hypothalamic-pituitary damage. It is recommended that measurements of IGF-1 and testosterone levels in men and documentation of menstrual history in women be performed

**FIGURE 1** Probability of normal pituitary hormone secretion over time after exposure of the hypothalamic-pituitary area to radiation. Data from four studies are plotted. In the study by Pai and colleagues (closed circles), patients received 55.8 to 79 Gy to the base of the skull.<sup>3</sup> In the study by Shalet and colleagues (solid squares), patients with pituitary tumors received 37.5 to 42.5 Gy.<sup>32</sup> In the study by Lam and colleagues (open triangles), patients with nasopharyngeal carcinoma received 39.8 to 61.7 Gy.<sup>2</sup> In the study by Samaan and colleagues (open diamonds), patients with head and neck tumors received 11 to 75 Gy.<sup>4</sup> ACTH = adrenocorticotropic hormone; GH = growth hormone; LH/FSH = luteinizing hormone/follicle-stimulating hormone; TSH = thyroid-stimulating hormone.

annually for the first 5 years and then at 5-year intervals for the next 10 years. Any abnormalities noted should be pursued with further dynamic testing to evaluate all of the axes of hypothalamic-pituitary function (see Table 1).

Once specific hormonal deficiencies are diagnosed, hormone replacement therapy is quite straightforward, except for GH. GH therapy in cancer patients is an extremely controversial issue because of the association between GH and cancer. Experimental data have shown that GH and IGF-1 promote cancer cell survival and proliferation, and epidemiologic studies of patients with acromegaly indicate an increased risk of colorectal cancer. Although IGF-1 replacement to levels within the normal range is expected to have the same risk as the general population, GH therapy may result in a small increase in cancer risk compared with untreated patients with GH deficiency. The risk of tumor progression needs to be weighed against the known morbidity of GH deficiency and potential benefits in terms of improvement in quality of life.<sup>8</sup>

Pituitary apoplexy is a potentially life-threatening medical emergency with acute symptoms of headache, nausea, vomiting, visual field changes, ptosis, and diplopia owing to acute pituitary hemorrhage. In addition to the mass effect and resulting neurologic symptoms and sequelae,

pituitary apoplexy can lead to adrenocortical insufficiency. A wide variety of conditions related to cancer and its treatment can trigger pituitary apoplexy, such as pituitary irradiation, general anesthesia, pituitary stimulatory tests, and medications such as bromocriptine and cabergoline, used in the treatment of prolactinoma. In men with locally advanced prostate cancer who are prescribed leuprolide, the initial stimulatory effects of this gonadotropin-releasing hormone analogue may induce pituitary apoplexy if an unrecognized or asymptomatic gonadotroph adenoma is present.<sup>9</sup> Tumors in the sphenoid sinus with extension into the sella turcica can cause symptoms similar to those of pituitary apoplexy.<sup>10</sup> Patients with pituitary apoplexy with acute neuro-ophthalmologic signs may need neurosurgical intervention, and those patients who do not have neuro-ophthalmologic signs or progressive clinical signs can be managed conservatively in the acute stage with monitoring for subsequent development of hypopituitarism.<sup>11</sup>

## Adrenal Diseases

### Adrenal Metastasis

Hematogenous metastasis to the adrenal glands is common, with the adrenal glands being the fourth most frequent site of hematogenous metastasis

after the lungs, liver, and bones.<sup>12</sup> Autopsy studies have documented that 9 to 27% of patients who died of malignant diseases had adrenal metastasis, with bilateral involvement in half to two-thirds of affected patients. Ninety percent of adrenal metastases are carcinomas, and 60% of these are adenocarcinomas.<sup>12</sup> The primary tumors that most commonly metastasize to the adrenal glands are, in order of decreasing frequency, cancers of the lungs, stomach, esophagus, and liver or bile duct.<sup>13</sup> Many adrenal metastases are discovered shortly (about 7 months) after the diagnosis of the primary cancer.

The presence of adrenal metastasis may have important implications for diagnostic and therapeutic planning. When patients with cancer have an adrenal mass but no evidence of metastasis elsewhere, it is vital to determine whether the mass is a metastatic deposit or a separate, unrelated adrenal lesion. Recent advances in imaging techniques have allowed the identification of adrenal lesions as part of the tumor staging evaluation. The location of the adrenal glands in the perinephric fat allows the detection of almost all normal glands and contour-deforming masses as small as 5 mm. Computed tomography (CT) is sensitive and specific in the detection of adrenal masses. CT characteristics that suggest adrenal metastasis rather than primary adrenal disease include heterogeneity, contrast enhancement, bilaterality, and size greater than 3 cm.

Without other evidence of metastatic disease, whether an adrenal mass is actually a metastatic tumor is critical information in determining the appropriate cancer therapy. Evaluation of a patient who is suspected of having an adrenal metastasis should include a history and physical examination to elicit evidence of adrenal insufficiency, Cushing's syndrome, mineralocorticoid excess, or pheochromocytoma. Biochemical assessment should include a short ACTH stimulation test to rule out adrenal insufficiency. A 24-hour urine collection should be obtained to measure urinary free cortisol, aldosterone, catecholamines, and metanephrines. Pheochromocytoma must be excluded, especially if the patient has hypertension or an operative procedure of any type is contemplated. It has been reported that half of patients who had a clinically unsuspected pheochromocytoma and underwent a non-adrenal gland-related surgical procedure had clinical deterioration or even died immediately following surgery.<sup>14</sup>

If the biochemical assessment for pheochromocytoma is negative, CT-guided fine-needle aspiration should be considered. This procedure has a sensitivity of 85% in detecting malignant diseases in the adrenal glands.<sup>15</sup> Magnetic resonance imaging (MRI) also may be helpful in the diagnosis of adrenal lesions. Functional scintigraphy using 6-[<sup>131</sup>I]iodomethyl-19-nor-cholesterol (NP-59) may be used in conjunction with CT and

Table 1 Dynamic Testing of Hypothalamic-Pituitary Function

Test	Method	Interpretation
Insulin tolerance test	Position patient recumbent for 30 min prior to rapid IV injection of regular insulin, 0.10 U/kg. Collect samples at baseline, 30, 60, and 90 min for glucose, GH, ACTH, and cortisol. Monitor blood glucose levels at bedside. Adequate pituitary stimulation is evident when the patient becomes symptomatic (sweating or tremor) and/or when the glucose level drops below 45 mg/dL within 30 min. May give additional insulin at 30 min if these criteria are not met. In this case, collect an additional (120 min) sample.	Peak cortisol >20 µg/dL suggests that the hypothalamic-pituitary-adrenal axis is intact. GH and ACTH levels 3–5 times higher than baseline reflect normal pituitary secretion of GH and ACTH, respectively.
GH-RH + arginine test <sup>33</sup>	Give GH-RH, 1.0 µg/kg IV bolus, and arginine hydrochloride, 0.5 g/kg IV, over 30 min. Collect samples for GH at baseline and 30, 60, 90, and 120 min.	The lower the peak GH responses to this test, the more severe is the degree of hypopituitarism <sup>33</sup>
GH-RH stimulation	Give GH-RH, 1.0 µg/kg IV bolus. Collect samples for GH at baseline and 30, 60, 90, and 120 min.	GH levels 5–10 times higher than baseline indicate normal pituitary GH secretion
Arginine stimulation	Give arginine hydrochloride, 0.5 g/kg IV over 30 min. Exercise (10–15 min) may be added to potentiate the response. Collect samples for GH at baseline and 30, 60, 90, and 120 min.	Peak GH >7 ng/mL or increase of more than 5 ng/mL above baseline indicates normal GH secretion
Metyrapone stimulation test, overnight	At 11 pm, patient takes metyrapone (30 mg/kg, maximum 3 g) orally with a snack to prevent gastric irritation. At 8 am next day, collect blood sample for cortisol and 11-deoxycortisol.	11-Deoxycortisol >7 µg/dL indicates normal function of the hypothalamic-pituitary-adrenal axis
GH suppression test	Should be performed after an overnight fast with the patient maintained at bedrest. The patient should drink a solution of 100 g of glucose. Collect samples for GH at baseline and 90 and 120 min.	Suppression of GH to <5 ng/mL indicates the absence of acromegaly
Gn-RH stimulation test	Give Gn-RH, 100 µg IV. Collect samples for serum LH at baseline and 40 min.	LH level 2–5 times higher than baseline indicates normal responses of the gonadotropic axis
High-dose dexamethasone test, 48 h	Collect samples for serum cortisol at 9 am. Give dexamethasone (2.0 mg; 50 µg/kg in children) immediately afterward and again every 6 h for 8 doses. Collect second sample for serum cortisol at 9 am, 6 h after the last dexamethasone dose.	Patients with functional adrenal adenomas show no suppression of cortisol levels in the 48 h sample relative to the initial (baseline) sample. Seventy-eight percent of patients with a pituitary source of excess ACTH show >50% suppression of plasma cortisol, whereas only 11% of patients with an ectopic source of excess ACTH have >50% suppression.
Low-dose dexamethasone test, overnight	Based on the principle that the sensitivity of the pituitary is greatest at night. Give dexamethasone orally (1.0 mg; 20 µg/kg in children) between 11 pm and midnight. Collect sample for serum cortisol at 8–9 am the next morning.	Cortisol level <1.8 µg/dL essentially excludes Cushing's syndrome
ACTH stimulation test, 48 h	Beginning at 9 am, obtain 24 h urine for 17-OHCS and creatinine for baseline. The next day beginning at 9 am, give 250 µg cosyntropin in 250 mL normal saline IV every 8 h for 48 h. Alternatively, 40 IU of depot formulation of purified bovine ACTH in gelatin can be injected IM every 12 h for 48 h. Repeat 24 h urine collections.	>18 µg/dL or 2–5 times over basal values higher than baseline indicates adequate response of the adrenal glands to ACTH
ACTH stimulation test, 1 h	Draw blood for baseline cortisol with or without aldosterone. Inject 250 µg cosyntropin IM or IV (if IV, dilute cosyntropin in 2–5 mL of sterile saline and inject over 2 min). Draw blood for cortisol (with or without aldosterone) at 30 and 60 min.	Cortisol >18 µg/dL indicates adequate adrenal gland function, and central adrenal insufficiency is unlikely

ACTH = adrenocorticotropic hormone; GH = growth hormone; GH-RH = growth hormone-releasing hormone; Gn-RH = gonadotropin-releasing hormone; IM = intramuscularly; IV = intravenously; LH = luteinizing hormone; 17-OHCS = 17-hydroxycorticosteroids.

MRI to aid in the diagnosis of a unilateral adrenal mass greater than 2 cm.<sup>16</sup> [<sup>18</sup>F]Fluorodeoxyglucose positron emission tomography can accurately characterize adrenal lesions and is informative in about half of cancer patients with inconclusive adrenal lesions on CT. Image-guided fine-needle aspiration biopsy in conjunction with MRI (as the sole imaging modality) is cost-effective in the management of patients with an adrenal lesion

and may be the strategy of choice to distinguish between benign and malignant nonfunctioning adrenal masses larger than 2 cm in diameter.<sup>17</sup>

Adrenal metastasis in the absence of extra-adrenal metastases is rare, and the use of surgery, especially laparoscopic adrenalectomy, is controversial in the management of adrenal metastasis. Although laparoscopic adrenalectomy for adrenal metastasis is feasible, similar to the case of

primary adrenal malignancy, the procedure should be performed with special care to avoid the dissemination of tumor cells in the surgical cavity. When laparoscopic surgery is performed for adrenal tumors larger than 6 cm or for tumors that are considered potentially malignant after preoperative imaging or endocrine studies, the operation should be performed only by a highly skilled laparoscopic surgeon, who should

immediately switch to open surgery if the laparoscopic surgery becomes difficult.<sup>18</sup> In a retrospective study, laparoscopic adrenalectomy achieved an acceptable 5-year overall survival rate, comparable to that with open surgery.<sup>19</sup>

### Adrenal Hemorrhage

Spontaneous massive retroperitoneal hemorrhage from an adrenal gland is rare,<sup>20</sup> although the risk factors of coagulopathy and thrombocytopenia are frequently present in cancer patients. Hemodynamically unstable patients who experience an adrenal hemorrhage may require transfusions and hemodynamic support in the intensive care unit, embolization if deemed feasible, or urgent surgical exploration. In patients with active bleeding, angiography with arterial embolization is a valuable therapeutic option to achieve hemostasis and allow for further evaluation of the adrenal tumor to plan the subsequent surgical resection. Emergency surgical removal of a malignant adrenal tumor within a large retroperitoneal hematoma should be avoided because optimal oncologic resection may not be possible under emergency situations.

### Adrenal Insufficiency

Despite the relatively high prevalence of adrenal infiltration by many common cancers, clinically evident adrenal hypofunction occurs infrequently in cancer patients, except when both adrenal glands are affected by metastatic disease.<sup>21</sup> It is estimated that more than 80% of adrenal tissue must be destroyed before corticosteroid production, under both basal and stress conditions, is impaired.<sup>22</sup> Only about 1% of patients with adrenal metastases have adrenal insufficiency.<sup>13</sup>

The clinical manifestations of adrenal insufficiency are nonspecific and overlap with other common findings in cancer patients. For example, the cachexia and weakness that often occur gradually in patients with adrenal insufficiency can mimic the general wasting seen in patients with extensive metastatic disease; and electrolyte abnormalities can easily be explained by poor intake, malnutrition, the side effects of chemotherapeutic agents, or paraneoplastic syndromes. Therefore, a high index of suspicion is required to detect adrenal insufficiency.

Adrenal insufficiency will develop in 20 to 30% of patients with bilateral adrenal metastasis.<sup>21</sup> Measurements of plasma ACTH and serum cortisol in simultaneous samples can be useful in the differential diagnosis of a variety of adrenal disorders (Table 2). Patients with suspected adrenal insufficiency should all be evaluated by an ACTH stimulation test and should receive glucocorticoid and mineralocorticoid replacement therapy when adrenal insufficiency is suspected and until normal adrenal function is documented.

**Table 2** Typical Adrenocorticotrophic Hormone and Cortisol Levels in Various Clinical States

<i>Disease</i>	<i>ACTH Level</i>	<i>Plasma Cortisol Level</i>
Cushing's syndrome	Elevated to high-normal	Elevated
Ectopic ACTH syndrome	Markedly elevated	Elevated
Adrenal carcinoma or adenoma	Low to undetectable	Elevated
Addison's disease	Consistently elevated	Decreased
Nelson's disease	Consistently elevated	Decreased
Adrenogenital syndrome	Elevated	Decreased

ACTH = adrenocorticotrophic hormone.

Patients who are stable should receive 20 mg of hydrocortisone in the morning and 10 mg in the early afternoon. In the event of circulatory instability, sepsis, emergency surgery, or other major complications, stress dosages of a parenteral glucocorticoid should be given (eg, 100 mg of hydrocortisone succinate intravenously every 8 hours).

Other causes of primary adrenal insufficiency in cancer patients include autoimmune adrenalitis, adrenal hemorrhage, and granulomatous diseases. In immunocompromised cancer patients, particularly patients with leukemia or lymphoma and patients who have undergone bone marrow transplantation, infection of the adrenal glands by cytomegalovirus, mycobacteria, or fungi may lead to adrenal insufficiency.

Adrenal insufficiency also may be drug-induced. Etomidate,<sup>21</sup> a common intravenous anesthetic, and ketoconazole, an antifungal drug, both inhibit the production of cytochrome P-450-dependent enzymes in the glucocorticoid synthesis pathway, leading to low levels of glucocorticoids. Aminoglutethimide and metyrapone are drugs that inhibit enzymes in steroidogenesis, and both may cause adrenal insufficiency when used in the treatment of prostate, breast, and adrenocortical cancers. Mitotane, structurally related to the insecticide dichlorodiphenyltrichloroethane (DDT), has selective toxicity for normal and neoplastic adrenocortical cells. Adrenal insufficiency is common after mitotane is administered in the doses necessary to treat adrenocortical cancer; glucocorticoid replacement therapy is mandatory in such patients.<sup>23</sup> Increased protein binding may lead to an increased daily requirement of glucocorticoid dosages during replacement therapy. Suramin, recently proposed as an anticancer agent based on its activity against the tumor growth factors, also may cause adrenal insufficiency.

Secondary adrenal insufficiency owing to metastasis to the pituitary or hypothalamus may also occur. The most common cause of secondary adrenal hypofunction, however, is exogenous glucocorticoid therapy that suppresses the hypothalamic-pituitary-adrenal axis. A prolonged course of therapy may lead to hypothalamic-pituitary suppression lasting for many months.

Short periods of steroid therapy (ie, 1–4 weeks) in patients with leukemia and lymphoma suppress adrenal function for 2 to 4 days beyond the end of therapy in most patients but for longer in some patients. In patients who have received glucocorticoids for more than 2 weeks, a tapering period of 10 to 14 days should be considered. This is especially true for patients who receive chemotherapy regimens that include high-dose glucocorticoids, such as regimens for acute leukemia and lymphoma. Using low-dose (1 µg) cosyntropin stimulation tests, high-dose glucocorticoid therapy can cause adrenal suppression lasting more than 1 week in children with acute lymphoblastic leukemia, even after tapering the dose.<sup>24</sup> Researchers have reported that adrenocortical insufficiency occurs and may persist for several months in children with acute lymphoblastic leukemia after treatment with high doses of prednisolone or dexamethasone.<sup>25</sup> Furthermore, glucocorticoid replacement during stress episodes is indicated within 1 to 2 months after discontinuation of a short course of high-dose glucocorticoid therapy and thereafter based on selective testing of adrenal function in accordance with symptoms. In addition, patients who have been treated within the past year with prolonged glucocorticoid therapy should receive stress dosages of glucocorticoid if acute medical or surgical complications occur (eg, neutropenic fever with hypotension, acute typhlitis).

Megestrol acetate, a progesterone analogue used as a palliative therapy for breast and endometrial cancers and as an appetite stimulant for cancer-related cachexia, has weak glucocorticoid activity that can also lead to secondary adrenal suppression.<sup>26–29</sup> Megestrol (800 mg for 12 weeks) can decrease TSH, luteinizing hormone, ACTH, and cortisol and increase prolactin and estradiol.<sup>30</sup>

Another cause of secondary adrenal insufficiency is irradiation of the hypothalamic-pituitary region. ACTH deficiency and secondary adrenal insufficiency occur in 19 to 42% of patients who receive this therapy<sup>2,3,4,32</sup> (see Figure 1). In a retrospective review of 310 childhood cancer survivors referred for evaluation of slow growth, fatigue, or abnormal pubertal timing, ACTH deficiency was diagnosed by low response

to metyrapone and/or low-dose ACTH testing in 18%.<sup>31</sup>

Several diagnostic approaches have been used to evaluate secondary adrenal insufficiency, including basal 8 am serum cortisol measurements and dynamic tests with 1 µg of cosyntropin (synthetic ACTH<sub>(1-24)</sub>), insulin-induced hypoglycemia, or metyrapone (see Table 1). Pituitary and adrenal complications of cancer and its treatment usually have non-specific signs and symptoms, making it challenging for the clinicians to diagnose. Once diagnosed, the management of these complications are relatively straight forward.

# Hypogonadism and Hormone Replacement in Men with Cancers

Christine Lee, MD  
Shehzad Basaria, MD  
Adrian S. Dobs, MD, MHS

Hypogonadism, regardless of its etiology, results in decreased sex hormone production from the gonad. There is a well-known association between increasing age and incidence of hypogonadism in men. In a longitudinal study of 890 men from ages 22 to 91, followed over a 40-year period, the incidence of hypogonadism diagnosed by free testosterone index was 9%, 34%, 68%, and 91% at for men in their 50s, 60s, 70s, and 80s, respectively.<sup>1</sup> With subgroup analysis of chronic illnesses within this population, only cancer was associated with a greater decrease in testosterone levels than the decline occurring with aging alone. In a retrospective analysis, hypogonadism was found to be present in 50 to 59% of 122 men with malignant lung cancer compared to 10% of 106 normal men.<sup>2</sup> Patients with cancer have a variety of etiologies that may lead to the development of hypogonadism, including cancer cachexia. In this chapter, we will discuss various etiologies, clinical manifestations, and diagnosis and treatment of men with cancer who develop hypogonadism. Since cancer cachexia itself is a known cause of hypogonadism, and hypogonadism itself may be responsible for wasting, this entity is discussed in even greater detail.

## Normal Physiology of the Hypothalamic-Pituitary-Gonadal Axis

Gonadotropin-releasing hormone (GnRH) is secreted from the arcuate nucleus of the hypothalamus in a pulsatile fashion and targets the gonadotrophs in the anterior pituitary via the portal venous system. When stimulated by GnRH, the gonadotrophs synthesize and secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In males, LH acts on the Leydig cells in the testes to produce testosterone. FSH targets the Sertoli cells (which results in the production of inhibin) and seminiferous tubules to stimulate spermatogenesis.<sup>3</sup> Both testosterone

and inhibin cause negative inhibition of LH and FSH, respectively.

Total testosterone levels in postpubertal males range between 300 to 1,000 ng/dL. Although there is some debate on the definition of the normal range, total testosterone levels below 300 ng/dL in conjunction with symptoms of low androgen levels constitutes male hypogonadism. Signs and symptoms of hypogonadism in adult males include reductions in libido, erectile function, body hair, testicular size, muscle mass, bone density, prostate size, energy level and a sense of well-being. Women will commonly present with irregular menses, amenorrhea, infertility, vasomotor instability, decreased libido and reduced bone density.

## Differential Diagnosis of Hypogonadism in Cancer Patients

The classical approach to hypogonadism is to classify it into primary, secondary, and tertiary disease based on the site of defect along the hypothalamic-pituitary-gonadal axis attributing for decreased sex hormone levels (Table 28-1).

### Primary Hypogonadism

In primary hypogonadism, the defect is located in the testis or ovaries, resulting in the classically laboratory finding of low serum testosterone and elevated gonadotropins. Examples of primary hypogonadism include Klinefelter's syndrome, anorchism, gonadal dysgenesis, aplastic Leydig cells, testicular trauma, and orchitis. Primary hypogonadism also occurs in patients with testicular, ovarian or hematologic malignancies treated by cytotoxic chemotherapy and radiation. The most gonadotoxic chemotherapeutic drugs are alkylating agents, such as cyclophosphamide, chlorambucil, mustine, melphalan, busulfan, carmustine and lomustine. Other agents (eg, cytarabine, vinblastine, cisplatin, and procarbazine)

Table 1 Causes of Hypogonadism

#### Primary Hypogonadism

Klinefelter's syndrome  
Noonan's syndrome  
Anorchism  
Gonadal dysgenesis  
Aplastic Leydig cells  
Testicular trauma  
Orchiectomy  
Cytotoxic chemotherapy (Cyclophosphamide, chlorambucil, melphalan)  
Testicular/Pelvic irradiation  
Chronic Illnesses (Renal failure, Cirrhosis, COPD, AIDS)  
Infiltrative diseases (sarcoidosis, hemochromatosis)

#### Secondary Hypogonadism

Prolactinoma  
Pituitary macroadenomas  
Pituitary apoplexy  
Post-surgical pituitary damage  
Infiltrative diseases (sarcoidosis, hemochromatosis)  
Cerebral trauma  
Cranial irradiation  
Medications (glucocorticoids, GnRH agonists)

#### Tertiary Hypogonadism

Kallmann's syndrome  
Prader-Labhart-Willi syndrome  
Laurence-Moon-Bardet-Biedl syndrome  
Infiltrative diseases (sarcoidosis, hemochromatosis)  
Trauma  
Anorexia/weight loss  
Critical Illness  
Vascular Insufficiency  
Cranial irradiation  
Post-surgical hypothalamic damage  
Medications (Opioids, GnRH analogs)

AIDS = acquired immunodeficiency syndrome;  
COPD = chronic obstructive pulmonary disease;  
GnRH = gonadotropin-releasing hormone.

are also known to cause gonadal dysfunction. These drugs predominantly affect germinal epithelium and spermatogenesis more than Leydig cells. Patients with lymphoma treated with chemotherapy tend to develop azoospermia, high FSH and LH, and normal or low-normal testosterone levels. Use of cyclophosphamide along with procarbazine results in permanent azoospermia as well as Leydig cell damage. Radiation to the testis or surrounding tissues also results in damage to sensitive germinal epithelium. Transient azoospermia and oligospermia may result from doses as low as 0.1 gray (Gy).<sup>4</sup> Leydig cell damage is more commonly seen at high-dose treatments of 20 to 30 Gy.

In addition to chemotherapy and radiotherapy, malignancy itself, by a poorly understood mechanism, may result in primary hypogonadism. Patients with bronchial carcinoma were found to have lower testosterone—but elevated LH—levels compared to healthy controls.<sup>5</sup> Furthermore, testosterone levels were significantly lower in patients with metastases. Elevated levels of circulating cytokines may be responsible for the impaired production/secretion of testosterone.

### Secondary Hypogonadism

In secondary hypogonadism, there is inadequate or lack of secretion of LH/FSH from the anterior pituitary. Causes of secondary hypogonadism include medications (glucocorticoids), tumor infiltration of the pituitary, trauma, radiation, pituitary macroadenomas, pituitary apoplexy, infiltrating diseases (sarcoidosis, hemochromatosis) or hyperprolactinemia (of any etiology).<sup>3</sup> The induction of secondary hypogonadism, with leuprolide, goserelin, or abarelix, is used therapeutically in patients with prostate cancer. The first two are GnRH analogs that cause an initial surge in gonadotropins and testosterone after binding to the GnRH receptors on the anterior pituitary. However, over time, they result in a decrease in secretion of gonadotropins via invagination of the GnRH receptors. Abarelix is a GnRH antagonist that immediately suppresses gonadotropin and testosterone levels.

### Tertiary Hypogonadism

Low-level, or absence of, GnRH secretion from the hypothalamus results in tertiary hypogonadism. In cancer patients, this can result from cranial irradiation, trauma, tumor, infiltration, anorexia, drugs, infection, vascular insufficiency, and extreme stress (see Table 28-1). As noted above, patients with intracranial neoplasms may develop tertiary hypogonadism if they undergo cranial irradiation or resection that may result in damage to the hypothalamus. Medications can also result in tertiary hypogonadism. Cancer patients on chronic high-dose opioids may be at

increased risk for central hypogonadism. Both intrathecal and oral opioids have led to central hypogonadism with low LH and testosterone levels, likely by inhibiting GnRH secretion via opioid receptors located in the hypothalamus. Another possibility is opioid-induced hyperprolactinemia that, in turn, causes suppression of GnRH synthesis. However, this hyperprolactinemia is transient.<sup>6</sup> Cancer patients in general may also develop tertiary hypogonadism in the setting of critical illness. A transient hypogonadal state has been noted in critically ill patients (patients with sepsis or burns) and patients undergoing surgery. More importantly, weight loss can result in a hypothalamically mediated GnRH suppression, likely due to increased production of cytokines or CRH, both of which can suppress GnRH.<sup>7</sup> The amount of weight required to result in hypothalamic deficiencies is unclear, but is likely due to reductions in body fat. Cancer cachexia is mentioned here as a cause of hypogonadism but, in turn, can be a result of the low testosterone as well.

## Consequences and Clinical Manifestations of Hypogonadism

If hypogonadism is left untreated, the sequelae of androgen and estrogen insufficiency can cause significant morbidity and mortality. The most significant effects of untreated hypogonadism include cachexia, anemia, osteoporosis, and depression. It is crucial to make the diagnosis, since the clinical effects of low testosterone or estrogen may not be appreciated and simply attributed to the malignancy itself.

### Cachexia

Although cachexia is not a common occurrence in conventional hypogonadism, it can contribute to cancer cachexia, similar to the well-described acquired immunodeficiency syndrome (AIDS) wasting syndrome. Weight loss in cancer patients is associated with increased morbidity and mortality. The weight loss in this population is multifactorial due to decreased caloric intake from anorexia, mechanical obstruction of the alimentary tract, and nausea as a result of chemotherapy. Moreover, there are a variety of disturbances in glucose, lipid, and muscle metabolism that occur in and contribute to cachexia in cancer patients. Significant muscle wasting, weight loss, and nutritional deficiencies are associated with poor outcomes. In the Eastern Cooperative Oncology Group study, patients with more wasting and weight loss had a poor prognostic response to chemotherapy, decreased performance status, and decreased survival.<sup>8</sup> With loss of muscle mass and strength, patients become more debilitated and ultimately lose

independence and become bed-bound. This increases the risk of complications such as bedsores, deep venous thrombosis formation and even pulmonary embolism. Decreased mobility itself also perpetuates the cycle of muscle wasting.

### Mechanism of Cachexia

*Changes in Fuel Metabolism* In cancer cachexia, there are specific alterations in the metabolism of glucose, lipids and protein. Cancer patients have a state of glucose intolerance which results in increased serum glucose levels. The consequence of this hyperglycemic state is decreased glucose storage and oxidation. The increased hepatic gluconeogenesis utilizes peripheral lean tissue mass, contributing to muscle wasting.<sup>9</sup> Peripheral muscle wasting is not only due to increased peripheral muscle catabolism, but also decreased muscle protein synthesis. Increased serum levels of glycerol and free fatty acids are seen in cancer patients and suggest increased lipolysis. These provide substrate for gluconeogenesis and possibly for tumor growth.<sup>10</sup>

*Role of Cytokines* Researchers have investigated the role of various cytokines in contributing to cancer cachexia and anorexia. Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-1 (IL-1) have been found to act directly on the brain to cause anorexia. However, there is no convincing evidence that either one is responsible for the cachectic. IL-6 has been shown to directly cause muscle protein catabolism in vitro and has also been found at increased levels in both animal and humans with cancer cachexia.<sup>11</sup>

*Role of Catabolic Factors* Increased catabolic factors may contribute to weight loss. Skeletal muscle catabolism in cancer cachexia may be mediated through proteolysis-inducing factor (PIF). Elevated levels of this factor have been isolated in both animals and humans with cancer and wasting. In vivo studies show that PIF may cause protein degradation by stimulating ubiquitin-proteasome pathway in skeletal muscle. Lipolysis may be induced from a lipid-mobilizing factor (LMF) that has been identified in animal and human models of cancer cachexia. This factor targets adipocytes and stimulates lipolysis via cyclic adenosine monophosphate. LMF has been isolated in cachexia-inducing murine tumor (MAC16) and has also been found in the urine of cachectic patients with pancreatic carcinoma.<sup>11</sup>

*Hormonal Factors* Hormonal changes also contribute to cachexia. Muscle breakdown in

cancer cachexia results from decreased anabolism and increased catabolism. Factors that play a role in decreased anabolism include decreased insulin-like growth factor (IGF) or resistance to IGF-1, decreased androgenic steroids, and decreased growth hormone. Increased catabolism in cancer cachexia may also be mediated by an increase in serum glucagon and cortisol levels. In a study from the Netherlands, 10 newly-diagnosed, untreated lung cancer patients with >10% decrease in body weight were compared to those patients losing <10% of body weight.<sup>12</sup> There was a statistically significant decrease in testosterone, IGF-1 and albumin levels in patients with >10% weight loss. This does not, however, explain causality, since weight loss can cause depression in hormones, or the hormonal deficiency can decrease anabolism.

#### Treatment of Cachexia

Prior efforts in treating cancer cachexia due to anorexia have focused on agents that increase weight and appetite. Corticosteroids, progestational agents and cannabinoids have all been used in the past to meet these goals. However, corticosteroids are catabolic and use of corticosteroids or progestational agents result in weight gain primarily by increasing fat mass. Based on the understanding of mechanisms driving cancer cachexia, studies have used anti-inflammatory agents such as omega-3 fatty acids, cyclooxygenase-2 inhibitors, nonsteroidal anti-inflammatory drugs, anticytokine antibodies and thalidomide to treat cachexia.<sup>13</sup> Supplementing anabolic hormones in cachectic patients has also been studied. Unfortunately, in cancer patients, growth hormone and IGF-1 are contraindicated since they promote tumor growth.<sup>14</sup> In contrast, anabolic-androgenic steroids have been used to help build lean body mass (LBM) in cachectic patients with human immunodeficiency virus (HIV), renal disease, and, more recently, cancer patients.<sup>15</sup>

Testosterone and anabolic steroids improve muscle mass in cachectic patients by countering abnormalities in the endocrine system, in fuel metabolism, and in cytokine concentration. Testosterone is a lipophilic molecule that traverses cell membranes via diffusion and binds to a steroid hormone receptor within the cell. This complex acts as a transcription factor to up-regulate or inhibit transcription of DNA within the cell.<sup>16</sup> Studies have shown that testosterone increases skeletal muscle protein synthesis by up-regulating androgen receptors in muscle cells.<sup>17,18</sup> Further anabolic effects of testosterone may be due to its effects on growth hormone and IGF-1. Both growth hormone (GH) and IGF-1 increase skeletal muscle protein synthesis. Androgen administration increases pituitary release of GH, skeletal muscle IGF-1 production, and

hepatic synthesis of IGF-1.<sup>19,20</sup> With the exception of possibly stimulating the growth of prostate cancer, there are no data to implicate testosterone in the induction or spread of cancer. Testosterone also counters catabolic effects of glucocorticoids on a molecular level through competitive inhibition of the intracellular glucocorticoid receptor and by impeding various hormone response elements in the glucocorticoid signaling pathway.<sup>21</sup> Finally, as noted above, TNF- $\alpha$  and IL-1 have been implicated in cancer anorexia, and IL-6 has been shown to correlate with protein catabolism and cachexia. Testosterone has been found to decrease production of these cytokines in vitro and in vivo.<sup>22,23</sup> Therefore, based on these studies, it may be reasonable to treat cancer cachexia and anorexia with testosterone.

The use of anabolic-androgenic agents was first adopted by the athletic community for building muscle mass. This prompted studies on the action of testosterone on muscle. Testosterone supplementation in hypogonadal men was shown to improve muscle mass.<sup>24</sup> Further studies have found that testosterone replacement in men with HIV and hypogonadal elderly men also results in increased muscle mass and strength.<sup>25–27</sup> Given the correlation between hypogonadism and more profound cachexia in cancer patients, it seems intuitive to supplement these patients with testosterone.<sup>12</sup> Unfortunately, the use of androgen replacement in cancer cachexia has not been extensively studied. A study in mice with poorly differentiated sarcoma was performed to study both tumor growth and cachexia with and without administration of intraperitoneal nandrolone.<sup>28</sup> This study showed increased weight in the mice treated with nandrolone; however, the weight gain was felt to be due primarily to water because there was no significant increase in protein mass. Furthermore, muscle enzyme activity measured in muscle biopsies appeared equal in both groups. There was no change in tumor weight, size, or overall mortality between the two groups. A 4-week, randomized, placebo-controlled trial of weekly nandrolone 200 mg intramuscularly (IM) versus placebo in 37 patients with unresectable non-small cell lung cancer on chemotherapy showed decreased weight loss and improved survival in the nandrolone group.<sup>29</sup> However, the difference in weight loss between the two groups was not statistically significant. Oxandrolone has also been studied in cancer cachexia. Boughton reported on 131 patients with various cancers treated with oxandrolone 20 mg daily over a 4-month period.<sup>30</sup> By the end of the study, 80% of the patients gained weight or maintained the same body weight. There was an average 4-pound increase in LBM. Furthermore, there was an improvement in physical function.

Further large-scale studies of cancer cachexia need to be performed with use of testosterone and

other anabolic agents measuring functional status, mortality, muscle mass, strength, testosterone, GH, IGF-1, cortisol, and cytokine levels to aid in the understanding and treatment of cancer cachexia.

#### Anemia

Anemia is commonly encountered in cancer patients. A retrospective study found that patients with lymphoma had the highest incidence of anemia on presentation (82%), followed by those with colon cancer (71%), lung cancer (70%), ovarian cancer (68%), and breast cancer (44%).<sup>31</sup> While anemia in cancer patients can be a result of nutritional deficiencies, blood loss, immune-mediated hemolysis or myelofibrosis, many cancer patients develop an anemia that resembles an anemia of chronic disease. Furthermore, anemia in cancer patients may be due to a relative deficiency of erythropoietin as well as suppression of CFU-E formation by inflammatory cytokines.<sup>32</sup> Hypogonadism in cancer patients may also contribute to anemia. Studies in eunuchoid men have demonstrated erythrocytopenia and anemia, which improve with administration of androgens. Similarly, men with prostate cancer who have undergone castration are anemic compared to eugonadal men.<sup>33</sup> Furthermore, treatment of 68 women with advanced breast cancer with androgens has shown an improvement in hemoglobin and hematocrit.<sup>34</sup>

Prior to the discovery of recombinant human erythropoietin, anemia of chronic disease, especially in patients with chronic renal disease, were treated primarily with blood transfusions, nutritional supplements and androgen therapy. There are few trials showing improvement in hemoglobin with the use of testosterone enanthate in patients with chronic renal insufficiency.<sup>35,36</sup>

Many studies have also been performed using alkylated androgens to treat anemia in this population. Seventeen patients in one double-blind crossover study were noted to have a mean rise in hematocrit from 23 to 27% while on the anabolic steroid nandrolone, with no improvements seen on placebo.<sup>37</sup> Another double-blinded, placebo-controlled study yielded similar results.<sup>38</sup> With the introduction of recombinant human erythropoietin, androgen use in anemia of chronic disease lost popularity. However, recently, a randomized prospective study was conducted comparing recombinant human erythropoietin with nandrolone in patients on peritoneal dialysis. Both resulted in a statistically significant rise in hematocrit of approximately 8%. The added benefits of nandrolone were increases in weight, body mass index, triceps skinfold, mid-arm circumference, mid-arm muscle circumference, total protein, albumin, prealbumin, and transferrin.<sup>39</sup> The mechanism by which nandrolone raises

red cell mass is not completely known. Hypotheses include increasing the responsiveness of erythroid progenitors to erythropoietin, aiding in red blood cell survival, or possibly affecting erythropoietic precursors directly in their maturation process.<sup>40</sup>

At this time, only recombinant human erythropoietin and epoetin alfa can be recommended to treat cancer-related anemia. However, if a man is found to be hypogonadal, testosterone replacement therapy can provide an added benefit of producing an erythropoietic effect, while being more economical.<sup>41</sup>

### Reduced Bone Density

Osteoporosis predisposes to increased risk of fracture; hypogonadism is a known risk factor for osteopenia and osteoporosis. Androgen receptors are found on epiphyseal chondrocytes, stromal cells, osteoblasts, and osteoclasts. Thus, decreased bone mineral density could result directly from the absence of testosterone or indirectly via a deficiency in testosterone's aromatization to estradiol. In addition, androgens also work indirectly again by stimulating the growth hormone/IGF-I axis.<sup>42</sup>

Most of the cancer literature has focused on men rendered hypogonadal by medical or surgical castration for the treatment for prostate cancer. Androgen deprivation therapy (ADT) is usually employed in men with metastatic or recurrent prostate cancer. In one study, men lost an average of 2.4% and 10% of bone mineral density after one and two years following surgical castration, respectively. Those who had medical castration lost an average 3.4% and 6.5% of bone mineral density after one and two years, respectively, following initiation of therapy.<sup>43</sup> Similarly, men treated with orchiectomy have a twofold risk of fractures compared with controls.<sup>44</sup> Not only do men on ADT suffer from decreased bone mineral density, but they are also at greater risk for increased morbidity from fractures. Several other studies on ADT in men with prostate cancer have reported similar findings.<sup>45,46</sup>

Further evidence supporting the relation between hypogonadism and osteoporosis exists in studies of hypogonadal men who have improvements in bone mineral density with testosterone repletion. Spinal bone mineral density was measured in 36 hypogonadal men and 44 eugonadal men at baseline. The hypogonadal men then received testosterone supplementation at 100 mg/wk and had bone mineral density measurements taken up to 18 weeks out. Hypogonadal men had a significantly lower bone mineral density than eugonadal men. Furthermore, there was a statistically significant increase in spinal bone mineral density among the hypogonadal patients receiving testosterone supplementation. In this situation, markers of bone formation increase, and markers of bone

resorption decrease.<sup>47</sup> Similar findings were reported with transdermal testosterone preparations.<sup>48,49</sup>

There have been no studies evaluating the benefits of testosterone replacement in male cancer patients. One could assume that the effects would be similar to those in men without cancers. Thus, men who are at increased risk of developing osteoporosis (eg, from glucocorticoid treatment, immobility, nutritional deficiency, and hypogonadism) should undergo a DEXA scan. Supplementation with calcium and vitamin D should be recommended for most patients, assuming no contraindications (eg, hyperparathyroidism). Testosterone replacement should be offered to men with osteopenia and hypogonadism. Bisphosphonates should be considered for subjects diagnosed with osteoporosis.

### Depression

Depression in cancer patients is often unrecognized and untreated. This may be in part due to difficulty in diagnosing major depression with coexisting somatic symptoms. However, in epidemiologic studies, major depression has been found in approximately 25% of cancer patients. If depression in this population is left untreated, it can predispose the patient to decreased quality of life, increased pain, non-compliance with treatment, a depressed immune system, lower life expectancy and even suicide.<sup>50,51</sup> In cases where hypogonadism exists in the cancer patient, a low testosterone level may contribute to depression.

Hypogonadal men have a significantly increased rate of depression (21.7%) versus eugonadal men (7.1%).<sup>52</sup> Men with prostate cancer who are rendered hypogonadal with ADT show higher depressive and anxiety scores.<sup>53</sup> Similar associations between low testosterone levels and depression have been seen in non-cancer patients. For example, hypogonadal men with HIV show improvement in depression scores on testosterone replacement.<sup>54</sup>

There have been limited studies to investigate the effects of hypogonadism and androgen replacement at the cellular level in the brain. When male rats are castrated, 5HT<sub>2A</sub>R sites in the frontal, cingulate, piriform cortex, olfactory tubercle and nucleus accumbens were significantly decreased compared to normal male rats. The brains of castrated rats supplemented with testosterone propionate were also studied and found to have increased 5HT<sub>2A</sub>R sites in the regions mentioned above that were comparable to or greater than those in normal male rats.<sup>55</sup> In humans, increased blood perfusion has been documented on single photon emission computed tomography images in the midbrain, superior frontal gyrus, and cingulate gyrus in hypogonadal older men receiving testosterone replacement. While this study did not use formal mood or psychiatric assessment to correlate the

findings with testosterone replacement, the authors did note an increased sense of well-being and social interactions based on questionnaire data.<sup>56</sup> Testosterone may be affecting mood by modulating serotonin activity in these areas of the brain.

Although there have been no studies evaluating hormone replacement in cancer patients, there may be some improvement in mood. This symptom should be distinguished from clinical depression, in which antidepressants would be needed. Depression and the resulting effect on decreased quality of life need to be treated appropriately.

### Cognitive Dysfunction

Hormones have been known to influence memory. Castrated male rats show decreased performance in visuospatial tasks.<sup>57</sup> Since there is also growing concern that hypogonadal elderly males may be more prone to developing cognitive difficulties and dementia, more clinical studies have been targeted at this group. However, it would be important to also be aware of potential cognitive impairments that may also develop in cancer patients as a result of coexisting hypogonadism. Of particular concern in this patient population is the potential to have impaired decision-making skills and decreased activating brain function, which may impact on quality of life and medical decision-making.

Studies on cognition in hypogonadal males have focused on elderly men and men undergoing androgen suppression therapy for prostate cancer. Because most studies examining cognition were designed from previous studies noting a cognitive difference in men and women (with men having better visuospatial ability and women scoring better on tests of verbal fluency), there was an underlying hypothesis in these studies that hypogonadal men would experience reduced visuospatial ability compared to eugonadal men or men receiving testosterone supplementation. The studies primarily used a block design test to evaluate visuospatial organization. To test verbal measures, the vocabulary subsets of the Wechsler Adult Intelligence Scale were often used. Several studies incorporated the Mini-mental Status Exam (MMSE) or Cambridge Examination for Mental Disorders of the Elderly (CAMCOG) to test changes in general cognitive function.

Two large cohort studies were performed in elderly men to examine whether varying levels of testosterone would correlate with cognitive functioning. In one cohort of 547 men aged 59 to 89 years, there was a positive correlation of long-term memory, mental control, and verbal memory with age- and education-adjusted testosterone levels.<sup>58</sup> Another longitudinal cohort of 407 men aged 50 to 91 years showed that high levels of free testosterone were associated with a

decreased rate of visual memory. The data in this cohort was also analyzed to compare hypogonadal men with eugonadal men. When controlled for age, the hypogonadal men had lower cognitive scores on tests of visual memory, verbal memory, and visuospatial skills.<sup>59</sup> Both of these studies imply that higher levels of testosterone in elderly men are associated with less cognitive decline, and the latter study suggests that lower testosterone levels correlate with some degree of decreased cognitive skills.

Two studies evaluating cognitive function in men prior to, during, and after treatment with flutamide and leuprolide had varied results. One found no significant change in any tests of cognitive function, but did note improvement in CAMCOG and one of the verbal tests with cessation of anti-androgen treatment.<sup>53</sup> The other study also did not find a significant change in the tests during the treatment phase, but noted improvement of verbal memory and decline in spatial rotation once the treatment was stopped.<sup>60</sup>

There are also studies testing cognitive function in hypogonadal men before and during treatment with testosterone replacement and comparing them with eugonadal men with and without testosterone supplementation. One study found that all groups of men had improvements in cognitive tests on verbal ability, visuospatial ability, and perceptual speed. Hypogonadal men were found to have significantly lower cognitive skills in verbal ability, compared to the eugonadal men at baseline, which improved with testosterone replacement.<sup>61</sup> Another similar study found no significant change in performance on tests of auditory verbal learning, perceptual motor speed, manual dexterity, and verbal intellectual functioning in all groups. There was a small improvement in word fluency and decrease in visuospatial skills among eugonadal men treated with testosterone. Hypogonadal men were also noted to have lower verbal intellectual functioning and perceptual motor speed at baseline compared to eugonadal men.<sup>62</sup>

Overall, the studies on cognition in various groups of hypogonadal men, with and without testosterone supplementation, are inconsistent. Some studies, which appear to show improved cognitive functioning on testosterone replacement, may actually be reflecting improved scores from retesting with the same test. Nevertheless, the studies seem to suggest that hypogonadal men score lower on various aspects of cognitive testing in comparison with eugonadal men. This needs to be investigated in a cancer population. At this point, there is not enough evidence to define the type of cognitive dysfunction in hypogonadal cancer patients or support the use of testosterone supplementation in improving any cognitive dysfunction.

## Sexual Dysfunction

Hypogonadism results in erectile dysfunction and a decrease in libido and can be treated well with replacement therapy. In a study of 32 hypogonadal men, sexual dysfunction was evaluated at baseline and during testosterone replacement. Men experienced significant improvement in their libido and potency on testosterone replacement compared to baseline.<sup>63</sup> Another study used more objective measures to evaluate erectile dysfunction due to low testosterone levels. In this study, 15 hypogonadal men had erectile function evaluated with penile color duplex ultrasound, nocturnal penile tumescence, and visually stimulated erection evaluation before and after testosterone supplementation. Hypogonadal men had a significantly decreased number of nocturnal erections, lower cavernous arterial inflow and resistive index by duplex Doppler, and impaired visually stimulated and pharmacologically stimulated erections compared with healthy controls. After 6 months of a testosterone 5 mg patch daily, there were significant improvements in all of these measures.<sup>64</sup>

The data in young, hypogonadal men may not be applicable to older men or men with chronic diseases, such as cancer. In the latter situation, vascular insufficiency, depression, or non-specific fatigue may explain a large proportion of the sexual dysfunction. Therefore, testosterone therapy may not completely alleviate the problem, but rather it may be used in combination with PDE-5 inhibitors.

## Laboratory Diagnosis of Male Hypogonadism

Currently, there are no guidelines for screening and diagnosing hypogonadism in cancer patients. A morning serum testosterone level (to take into account the circadian rhythm of the androgen) should be obtained in all men with cancer who have any of the signs and symptoms mentioned above (ie, weight loss, anemia, osteoporosis, depression, fatigue or sexual dysfunction). If total testosterone is between 200 and 400 ng/dL, a measure of free testosterone should be done (bioavailable or free testosterone level by free dialysis method), since many of these patients are malnourished and may have reduced sex hormone binding globulin (SHBG) synthesis.<sup>65</sup> The free testosterone value can be measured by free dialysis method or calculated from serum total testosterone and SHBG levels.

Once hypogonadism is confirmed, LH, FSH, and prolactin levels should be checked to distinguish between primary and secondary mechanisms. Pituitary magnetic resonance imaging (MRI) should be performed in those subjects without a known etiology for central hypogonadism such as irradiation, (especially with serum total testosterone levels < 150 ng/dL) to rule out

a mass lesion. However, it is important to be cognizant of the fact that, even if the patient has primary hypogonadism, the gonadotropins levels may not be appropriately elevated in these patients since increased corticotrophin-releasing hormone may suppress GnRH secretion during illness.<sup>7</sup> Patients with history of cranial irradiation, surgical resection of pituitary tumors, treatment with high-dose glucocorticoids, or GnRH analogues will likely have secondary hypogonadism and low gonadotropin levels. In such patients with known etiology of secondary hypogonadism, there is no need for MRI.

## Treatment Options for Hypogonadal Men with Cancer

Testosterone replacement therapy is absolutely contraindicated in patients with prostate or breast cancer since there is a risk of growth/recurrence of the cancer. Various modalities of testosterone replacement therapy are currently available (Table 28-2).

Esterified forms of testosterone have been used the longest and are associated with a longer half-life. Testosterone enanthate, testosterone cypionate and testosterone propionate are all derived from esterification of the 17 $\beta$  hydroxyl group of testosterone. Testosterone enanthate is the most commonly used of the three preparations, given as 200 mg IM every 2 weeks. The maximum concentration is reached in approximately 10 hours, and the half-life is 4 to 5 days.<sup>66</sup> There are multiple studies showing the use of testosterone enanthate in treating anemia in patients with chronic renal insufficiency<sup>35,36</sup> and for treating osteoporosis, depression, and erectile dysfunction in hypogonadal men.<sup>47,66,67</sup> Testosterone enanthate has also been shown to increase muscle mass in elderly men, hypogonadal AIDS patients, and chronic obstructive pulmonary disease patients.<sup>25,26,68</sup>

There are very few studies specifically evaluating cancer patients. In hypogonadal elderly males and in men rendered hypogonadal after high-dose chemotherapy for hematologic malignancies, testosterone cypionate has been shown to improve libido and erectile performance.<sup>69,70</sup> Men with HIV and hypogonadal symptoms were found to have improved libido, energy, mood, and muscle mass on testosterone cypionate.<sup>71</sup>

Testosterone scrotal patches were developed and had to be worn over 24 hours delivering approximately 4 to 6 mg/d with peak levels obtained after 2 to 4 hours.<sup>72</sup> Scrotal patches are no longer available in the United States. Androderm is another transdermal testosterone preparation that is applied to non-scrotal skin. Typically, 5-mg patches are applied on non-scrotal skin over 24 hours with peak concentrations at 8 hours.<sup>73</sup> It has been shown to maintain mood and sexual function in hypogonadal men

Table 2 Modalities of Testosterone Replacement

Testosterone		
Drug	Route of delivery	Dosage
<i>Testosterone Esters</i>		
Testosterone propionate	IM	10–25 mg 2 to 3 times/wk
Testosterone enanthate	IM	200 mg every 2–4 wks
Testosterone cypionate	IM	200 mg every 2–4 wks
Testosterone undecanoate	IM	1000 mg every 12 wks
<i>Testosterone patch</i>		
Androderm	Topical	5 mg/d
<i>Testosterone gel</i>		
Androgel, Testim	Topical	5 g/d l
<i>Buccal Testosterone</i>		
Striant	Buccal	30 mg twice a day

IM = intramuscularly

while delivering testosterone levels that are within the physiologic range. However, there is a fairly high incidence of skin irritation (33%).<sup>74</sup> Transdermal testosterone gel (Androgel and Testim) have recently become available. It is applied in 5 to 10 mg doses daily. In hypogonadal males, this form of testosterone replacement has been shown to improve sexual function, mood, bone mineral density, and hematocrit. It has also been shown to increase lean body mass, but did not result in statistically significant increase in muscle strength.<sup>75</sup>

The newest form of testosterone delivery has been developed in a buccal mucoadhesive testosterone preparation. A 30-mg twice daily buccal administration dose of testosterone was studied and shown to elevate testosterone levels into the normal range. It did not cause significant polycythemia or prostate enlargement. The primary side effect of this preparation is buccal mucosa irritation.<sup>76</sup>

Oral free testosterone should not be used owing to insufficient serum levels from hepatic inactivation and side effects of hepatotoxicity.

Alkylated androgens have also been studied for treatment of many clinical symptoms of hypogonadism. These androgens were formulated by the addition of an alkyl group to the 17 $\alpha$  position of testosterone. Examples of the alkylated androgens include methyltestosterone, fluoxymesterone, oxymetholone, oxandrolone, ethylestrenolone, stanozolol, methandrostenolone, norethandrolone, and danazol. Nandrolone has been found to increase muscle mass and muscle strength in HIV patients and patients on chronic glucocorticoid therapy.<sup>77,78</sup> It has also been shown to be comparable to recombinant human erythropoietin in peritoneal dialysis and hemodialysis patients.<sup>40,79</sup> The data on its use for osteoporosis is conflicting. When studied in men on chronic steroids, there seems to be no change in bone mineral density<sup>78</sup>; however, multiple studies in post-menopausal

women suggest that nandrolone increases bone mineral density.<sup>80–82</sup> While there is evidence in the use of nandrolone for increasing muscle mass, hematocrit, and bone mineral density, there are no direct studies on its use for improving mood, sexual dysfunction, or cognition. Oxandrolone has been studied for improving muscle mass in cancer patients, pediatric burn patients, HIV patients, and elderly men.<sup>30,83–85</sup> While there is convincing evidence for the use of oxandrolone to increase muscle mass and treat cachexia, it is associated with liver function abnormalities. At this point, there would be no indication to use alkylated products for treatment of male hypogonadism.

### Summary/Recommendations

Hypogonadism may be under-recognized and under-diagnosed in cancer patients. Cancer patients who are most predisposed to hypogonadism include those who have testicular cancers or hematologic malignancies treated with gonadotoxic chemotherapeutic agents and those undergoing cranial irradiation. Patients who are critically ill and treated with opioids also develop hypogonadism. However, since malignancies in general may predispose patients to lower testosterone levels via Leydig cell dysfunction and reduced gonadotropins secretion, any cancer patient who present with symptoms of hypogonadism, including cachexia, anemia, decreased bone mineral density, depression, sexual dysfunction and cognitive dysfunction, should be screened for hypogonadism.

There are different types of androgens and delivery modalities to use for replacement therapy. Currently, there is good evidence for the use of testosterone supplementation to improve sexual function, mood, bone mineral density, hematocrit, and lean body mass in hypogonadism. Testosterone preparations with shorter

half-lives (gel and patches) may mimic physiologic levels more accurately than esterified testosterone preparations with longer half-lives. Alkylated androgens such as oxandrolone and nandrolone have been shown to be good agents in treating anemia and cancer cachexia; due to potential hepatotoxicity, negative effect on plasma lipids, and a lack of benefit in terms of sexual function, however, we recommend testosterone replacement in this patient population as the first-line therapy. While data from these studies can likely be extrapolated and applied to hypogonadal patients with cancer, there is great need for larger scale studies on the effects of androgen and testosterone preparations on muscle mass, mortality, anemia, bone mineral density, quality of life, mood, cognitive function, and sexual function to be performed directly in cancer patients with hypogonadism.

# Gastroesophageal Issues

Alexander A. Dekovich, MD

Primary and metastatic tumors of the aerodigestive tract themselves and the modalities of surgery or radiation used to treat these cancers can result in mechanical obstructions that require treatment or palliation to restore function. Because eating is a social event, the loss of the ability to ingest a meal in the usual manner leads to a great decrease in the quality of life, even if alternative means for maintenance of hydration and nutrition such as hyperalimentation or enteral tube feeding can be provided. The goal of intervention is to restore this function to as close to the original physiology as possible for as long as possible and, therefore, to allow for a better quality of life. Palliation of obstruction of the gastrointestinal and biliary tract has improved considerably over the past 25 years by the introduction of percutaneous endoscopic gastrostomy (PEG) for enteral feeding, thermal and chemical tumor ablative procedures, and the evolution of stents for the biliary tract, esophagus, duodenum and colon.

## Esophageal Obstruction

Esophageal obstruction results most often from primary cancer of the esophagus, although cancer in the mediastinum can often lead to esophageal obstruction due to extrinsic compression. Obstruction due to strictures resulting from primary treatment (surgery or radiation) and tumor recurrence is also frequently encountered.

Squamous cell carcinoma and adenocarcinoma together comprise 90% of esophageal cancers. Rarely, other cancers (including metastatic malignant melanoma, metastatic breast cancer, leiomyosarcoma, lymphoma, and other more rare tumors) may develop in the esophagus.<sup>1</sup> Worldwide, squamous cell carcinoma of the esophagus is still the predominant cancer. In the United States, adenocarcinoma of the esophagus and gastric cardia has rapidly increased in incidence during the latter part of the twentieth century, primarily in the white male population. This is thought to be, in part, due to a number of factors, among them the aging of the population coupled with a change in diet (leading to an increase in obesity and gastroesophageal reflux) and the general decrease in cigarette smoking that contributes both to the decline of squamous cell

cancer of the esophagus and to the increase in adenocarcinoma.<sup>2,3</sup> Adenocarcinoma now comprises at least 50% of all esophageal cancers<sup>4</sup> diagnosed in the United States and is usually found in the mid to distal esophagus and rarely involves the more proximal esophagus. Although the overall 5-year survival rate for esophageal cancer is low, 15.8% for the period 1995 to 2000,<sup>5</sup> it has improved from the 4% overall survival rate reported for the period 1950 to 1954. More favorable 5-year survival is dependent on discovery and treatment of the esophageal cancer at an earlier stage. Patients with metastatic disease at diagnosis and treated with palliative chemotherapy or irradiation have a median survival of less than one year.<sup>6</sup>

Dysphagia to a normal solid food diet is generally not present until the esophageal lumen has been reduced to less than or equal to 13 mm in diameter. Some dietary adjustment is necessary when the lumen is reduced to approximately 18 mm—a reduction to 70% of the normal lumen diameter.<sup>7</sup> This accommodation by the esophagus to the growing tumor coupled with delay in seeking medical evaluation that is prompted by improvement of symptoms with modification of diet and denial leads to progression and spread of the disease, so that, unfortunately, more than 50% of patients with esophageal cancer, at presentation are unresectable.<sup>6</sup> Palliation becomes the primary goal in these patients as amelioration or relief of anorexia, dysphagia, nausea, vomiting, and pain adds greatly to the quality of remaining life.<sup>4</sup> Although the anorexia and pain are more difficult to treat successfully, there are multiple modalities and combinations of modalities available for the palliation of dysphagia.

## Chemo-Radiation

Although both adenocarcinomas and squamous cell carcinomas are responsive to chemotherapy and external beam radiation therapy, palliation occurs in only about 40 to 60% of cases, is short-lived, and may take 2 to 8 weeks for dysphagia to improve. It appears that chemotherapy is as effective as radiation for palliation of dysphagia.<sup>6</sup> The combination of chemotherapy and radiotherapy is associated with significant morbidity. In a study of 121 patients reported by Herskovic and

colleagues,<sup>8</sup> the combination of chemotherapy and radiation therapy alleviated dysphagia in 58% of their patients and was more effective than radiation alone, but life-threatening complications occurred in 20% of the patients, and serious complications occurred in 44%. In a retrospective study of 57 patients with T<sub>3</sub> or T<sub>4</sub> squamous cell cancer of the esophagus, Kaneko and colleagues reported that 90% of their patients had grade 3 or 4 dysphagia prior to chemoradiotherapy but following definitive chemoradiotherapy, 70% of these patients downgraded their dysphagia scores to 0 or 1.<sup>9</sup>

## Dilatation

Dilatation of a benign stricture of the esophagus encountered in the post-esophagectomy patient can be accomplished with balloons or bougies, usually with good overall results and low complication rates.<sup>10-12</sup> Although dilatation of radiation-induced strictures of the esophagus can generally be accomplished with adequate palliation in the majority of patients, it is more difficult to perform and may be associated with more complications.<sup>13</sup> The esophageal lumen needs to be dilated to a diameter greater than 13 mm for solid food dysphagia to be partially relieved, and preferably to a 16 to 17 mm diameter for solid food dysphagia to be adequately palliated. The frequency of dilatation depends on the recurrence of dysphagia. Early dilatation, shortly after recurrence of symptoms, is preferable to late dilatation after near obstruction of the esophageal lumen has recurred.

Dilatation of the esophageal lumen obstructed with tumor can also be accomplished with balloons or bougies and has been shown to be safe for procedure related needs.<sup>14,15</sup> However, patients treated with dilatation primarily for malignant obstruction have a higher incidence of perforation (5% to 10%), and the perforations tend to be more severe. The resulting palliation from dilatation is usually very short-lived.<sup>16-18</sup> In a small series of 20 patients with obstruction due to esophagogastric junction cancer, Ko and colleagues showed that balloon dilatation of the stricture followed immediately by chemotherapy and/or radiation therapy was effective in improving dysphagia in 15 of the 20 patients (75%) reported, and 7 of the 15 responders (35% of the

total group) did not require any further intervention.<sup>19</sup> Although esophageal luminal dilatation can be accomplished in patients with obstruction due to a malignant tumor, on average, the palliation is short-lived (sometimes for only a few days), and with continued attempts at dilatation, the procedure becomes more difficult and more likely to result in serious complication. Fortunately, other modes for the palliation of dysphagia exist.

### Thermal and Other Ablative Techniques

Other palliative modalities for the restoration of a tumor obstructed esophageal lumen are thermal tumor ablation techniques utilizing the laser or argon plasma coagulator, injection of absolute alcohol into the tumor substance, and photodynamic therapy. Experience in the application and availability of these modalities is variable. When properly applied, all these modalities can palliate dysphagia but have not been consistently associated with prolonged survival. These modalities can be used in various combinations depending on the nature of the particular clinical problem at hand. Ultimately deployment of a self-expanding metal stent can be considered.

### Laser

Tumor ablation using the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser is not widely available, probably due to the cost of the apparatus, maintenance requirements of the equipment and fibers, need for a dedicated operating room, laser precautions, and time needed for therapy. The introduction of self-expandable metal stents (SEMS) has led to the supplanting of laser as well as other ablative modalities for the treatment of malignant luminal obstruction.<sup>20</sup> Three to five treatment sessions using the laser are needed initially to achieve palliation, and the interval between interventions is usually short—on the order of 3 to 4 weeks.<sup>21</sup> The application of the high power laser is usually done retrograde using the non-contact method after pre-dilatation of the lumen, when necessary, in order to lessen the possibility of perforation. But sometimes the pre-dilatation itself can cause perforation.<sup>21</sup> Wu and colleagues reported similar good results with the use of the low-power contact laser passed in the antegrade manner.<sup>22</sup> Complication rates increase and laser ablation becomes more difficult<sup>23</sup> with increasing frequency of application, serious complications ranging from 4 to 9%.<sup>24–26</sup>

Use of the Nd:YAG laser can be limited by the location and growth characteristics of the tumor and the need for accurate aiming of the laser beam, which can be obscured by the smoke generated during application. Laser therapy is best applied to exophytic mid-esophageal tumors where the lumens are not too long or tortuous.<sup>27</sup>

It cannot be used for the treatment of flat tumors invading the wall of the esophagus or for the relief of obstruction due to extrinsic compression.

Alexander and colleagues reported a series of 29 patients with locally advanced esophageal cancer who underwent laser debulking of their tumors with good results in the relief of dysphagia and, when coupled with aggressive multimodality therapy, an improved survival when compared to historical controls.<sup>28</sup> Although placement of an esophageal stent is associated with fewer interventions and a more immediate relief of dysphagia, the overall costs of the two procedures are not markedly different, and laser therapy may have a survival advantage and may be associated with fewer significant complications.<sup>29,30</sup>

### Argon Plasma Coagulation

Argon Plasma Coagulation (APC) is a non-contact diathermy-based technique that uses an electrosurgery frequency current to ionize a cloud of argon gas in order to propagate a spark to the nearest tissue contact, inducing electrocoagulation necrosis. The tissue injury occurring as a consequence of APC is seldom deep enough to cause perforation, penetrating the tissues less than 2.5 mm.<sup>31,32</sup> APC is useful to control tumor bleeding, to recanalize tumor obstructed stents, and to control small or non-circumferential cancers of the esophagus. Although some have reported very good palliation with effectiveness and complications comparable to Nd:YAG laser,<sup>33</sup> APC is unlikely to restore adequate luminal patency to the esophagus obstructed by large tumors.<sup>34</sup>

### Absolute Ethanol Injection

The injection of absolute ethanol into an exophytic tumor of the esophagus in order to induce chemical tumor necrosis is less widely practiced than other ablative procedures. It has been shown to be effective in palliating dysphagia<sup>35,36</sup> and has been found to be equivalent to Nd:YAG laser therapy.<sup>37</sup> Ethanol injection is inexpensive and the expertise for delivery is more readily available. However, diffusion of the ethanol into the tissues of the esophageal wall is difficult to control, leading to worries about perforation. Significantly more post-procedure pain requiring narcotic analgesia occurs in patients treated with ethanol injection as compared to laser therapy.<sup>37</sup>

### Photodynamic Therapy

Photodynamic therapy for tumor ablation utilizes a photosensitizing agent—porfimer sodium (Photofrin II), injected intravenously 40 to 50 hours before the endoscopically guided placement of a diffusing tip fiber to deliver non-thermal 630 nm (red) light from a tunable dye laser. The Photofrin accumulates in the substance of the tumor in greater proportion than in normal

tissue—at least in a 2:1 ratio. When cancer cells containing the Photofrin II are exposed to the 630 nm (red) light, a cytotoxic superoxide is formed causing oxidation of cellular components such as tumor cell nuclei and mitochondria leading to cell death.<sup>38,39</sup> Because the patient is likely to remain photosensitive for at least 4 to 6 weeks, the patient must be warned to avoid bright direct and indirect light, whether indoors or out, and to wear protective clothing when venturing out of doors. Conventional sunscreens that block ultraviolet rays do not protect patients who have been injected with porfimer sodium because activation of the drug is by visible light. Severe erythema and edema of the skin can occur upon light exposure outdoors, even on cloudy days. Once the patient has been injected with a photosensitizer, there is no antidote.

Very good palliation of dysphagia was reported by Litle and colleagues in a series of 215 patients.<sup>40</sup> She found that the ideal patient for photodynamic therapy was one with an obstructing esophageal cancer. She noted effective palliation in 85% of treatment courses with a 2% incidence of perforation, 2% incidence of stricture and 1.8% procedure-related mortality with a mean dysphagia-free interval of 66 days. As with all palliative modalities, the longer the patient survives, the greater the chances that the palliation becomes less effective due to significant complications. Careful evaluation and recommendation for the application of specific palliative measures is very important in the satisfactory management of these unfortunate patients. Frequent trips to the hospital to undergo potentially dangerous procedures are a true burden to patients with a limited time to live.

### Self-expandable Metal Stents

Ultimately, a stent can be placed to palliate esophageal luminal obstruction when other modalities have failed or the circumstances, such as stage of the disease and life expectancy, dictate that stent placement is the most likely modality to effectively and quickly palliate dysphagia. Palliation of dysphagia with patients able to tolerate at least liquids or a soft diet occurs almost immediately or within 24 to 48 hours after successful deployment of an esophageal stent.<sup>41</sup> Stent placement can be accomplished in an outpatient setting.

Over the years, stents have evolved from the rigid plastic type that necessitated dilation of the lumen to a diameter greater than 16 mm to the modern self-expandable metal stents which most often do not require dilation of the lumen at all, or only minimally. They are much easier to place and are associated with fewer immediate complications—particularly perforation. Other advantages of metal stents over plastic stents are the greater internal diameter, once deployed, and the ability to span more complicated stenoses due

to their more flexible nature and thinner delivery systems.<sup>42</sup> For all these reasons, plastic stents have been supplanted by the self-expandable metal stents. Although the initial cost of self-expandable metal stents is higher than the cost of the plastic stents, the lower serious and life-threatening complication rate, fewer endoscopic re-interventions, and less need for hospitalization makes them a safe and cost-effective alternative to plastic esophageal stents.<sup>42</sup> Some manipulation of the self-expandable stent can be accomplished immediately after deployment (some stents are better than others in this regard). For all intents and purposes, however, once the stent is deployed, it cannot be removed. Therefore, careful evaluation and pre-procedure planning are necessary to ensure the intended palliation post-procedure with the least possibility of complication.

The most common indications for stenting the esophagus are dysphagia for liquids and saliva, treatment of tracheoesophageal fistula and, occasionally, control of tumor bleeding.<sup>41</sup> Probably, the successful treatment of a tracheoesophageal fistula, either with primary esophageal stenting or in conjunction with endotracheal or endobronchial stenting, may be the only instance in which esophageal stents can be said to not only improve the quality of life but to actually prolong it.<sup>43,44</sup>

The average survival of patients after esophageal stent placement, whether using the old plastic stents or the newer self-expandable metal stents, ranges from three to six months.<sup>7,45,46</sup> As with other palliative treatments, tumors in the mid-esophagus are more amenable to stenting with fewer resultant problems.<sup>44</sup> Stenting tumors of the distal esophagus can result in severe gastroesophageal reflux, which for the most part, can be treated by anti-reflux measures and proton pump inhibitors. A stent with a sleeve at the distal end has been designed in an effort to lessen gastroesophageal reflux. This type of stent may present additional deployment problems and does not seem greatly effective in eliminating reflux.<sup>47</sup> Stenting tumors of the proximal esophagus, if too close to the cricopharynx, can result in intractable pain, tracheal compression, proximal migration and foreign body sensation although some have reported satisfactory results even when the stent bridges the cricopharynx. But more usually, stents can be deployed through lesions close to the cricopharynx safely with low rates of difficulty if close attention to detail is paid in the selection of the stent and preventing the stent from migrating proximal to the cricopharynx.<sup>48</sup>

Stent deployment in the esophagus commonly results in chest pain most likely due to the expansion of the stent. This pain usually responds to narcotic analgesics and usually improves after several days.<sup>49</sup> If a bulky tumor is located in the proximal esophagus, one must always anticipate

that expansion of the stent may lead to compression of the tracheal lumen leading to respiratory embarrassment. Patients with an esophageal tumor proximal to the level of the left main stem bronchus should have bronchoscopy to determine tracheal compromise prior to esophageal stent deployment<sup>7</sup> and, choosing a stent of a lesser diameter for placement, when available, would be prudent in this situation. A barium esophagogram prior to any interventional palliative procedure for dysphagia is recommended, not only for planning purposes prior to the procedure but for follow-up as well.<sup>7</sup>

Most stents deployed in the esophagus today are of the covered variety, with short segments of the proximal and distal ends left uncovered to help control the tendency for these covered stents to migrate. The coated portion of the stent is designed to impede ingrowth of the tumor into the mesh of the stent and thereby delay occlusion of the stent lumen. Stenosis of the lumen due to proximal and distal tumor ingrowth and overgrowth into the uncovered portion of the stent occurs over time, as well as luminal stenosis or occlusion consequent to exuberant growth of granulation tissue in response to the irritation caused by the uncovered portions of the stent. These problems are such that treatment with laser, argon plasma coagulation, débridement with a snare, endoscopic adjustment of position, or telescoping placement of another stent may be necessary to relieve renewed dysphagia.<sup>50</sup>

Palliation of dysphagia due to compression of the esophagus by an extrinsic tumor or metastatic deposit can be accomplished by SEMS and cannot easily be accomplished by any other means. The palliation of dysphagia is not as good in this situation as it is in those patients with an intrinsic esophageal lesion.<sup>51</sup>

The ideal stent has not been created, but a new generation of plastic stent has become available lately in the United States. It is a self-expandable plastic stent (the Polyflex stent) which is made of a polyester mesh covered with a silicone membrane. The inside of the stent is smooth and the outside is slightly textured. The proximal portion of the stent is slightly flared, whereas the middle and distal portions are not.<sup>52</sup> The major advantage of this stent is that it can be removed even several months after deployment, but the major disadvantage is that the esophageal lumen must be dilated to at least 1 mm larger than the application device, which is 12 or 14 mm in diameter, depending on the size of the stent itself, in order for the delivery system to pass through the tumor lumen and allow stent deployment.<sup>53</sup> Because the delivery system is thicker than the delivery systems of the self-expandable metal stents, it is, therefore, stiffer and more difficult to pass and position. Because of this stiffer delivery system and need to dilate the esophageal stricture

prior to deployment, there is a higher failure rate on initial deployment of the Polyflex stent.<sup>52</sup> Unlike the metal stents, the Polyflex stent must be loaded into the delivery system just prior to insertion, which sometimes may result in the flared end being improperly oriented in the delivery system and which would not be apparent until deployment.

The Polyflex stent has been used in the esophagus in all situations that metal stents have been used<sup>54</sup>; but, because it induces only minimal tissue reaction and granulation tissue formation, it does not become incorporated into the substance of the esophagus, and therefore, has a role in the management of benign but recalcitrant strictures of the esophagus.<sup>55</sup> The stent can be used as a scaffold for the remodeling of the stricture, and subsequently, it can be removed, resulting (it is to be hoped) in dysphagia-free swallowing. The Polyflex stent is cheaper than its metal counterparts in Europe but comparable in price to metal stents in the United States.

## Gastric Outlet Obstruction

Severe nausea, regurgitation, vomiting, bloating, abdominal pain, and distention associated with a succussion splash leading to severe esophagitis, malnutrition and dehydration, and electrolyte imbalance are the common signs and symptoms of gastric outlet obstruction. These all lead to debilitation and a markedly decreased quality of life. Prior to the advent of H<sub>2</sub> blockers, complicated peptic ulcer disease was the most common cause for gastric outlet obstruction. Today, however, malignancy is the primary cause of gastric outlet obstruction and is encountered in more than 50% of cases.<sup>56,57</sup> Cancers of the pancreas, duodenum, ampulla, stomach, and biliary tree, as well as metastatic disease from other organ sites, can all lead to gastric outlet obstruction. Locally advanced pancreatic cancer, however, is the most common cause of malignant gastric outlet obstruction. In approximately 90% of patients with malignant gastric outlet obstruction the pylorus and the first and second part of the duodenum are the most common sites of obstruction. The distal portion of the duodenum is infrequently involved.<sup>58,59</sup> Ten to 20% of patients with pancreatic carcinoma develop gastric outlet obstruction late in the course of their disease.<sup>60</sup>

Although nausea, vomiting and weight loss are common presenting features of patients with pancreatic cancer, mechanical gastric outlet obstruction due to tumor ingrowth is present in only 5% of these patients.<sup>61</sup> True gastric outlet obstruction is due to invasion by tumor into the pylorus or duodenum, leading to stenotic mechanical obstruction. One must demonstrate this obstruction to be indeed mechanical by various diagnostic modalities such as endoscopy, upper gastrointestinal barium contrast study, or

abdominal CT because up to 60% of patients with pancreatic cancer have slowed gastric emptying without evidence of gastroduodenal tumor invasion.<sup>62</sup> Pancreatic carcinoma has been shown to induce changes in the gastric myoelectric activity, usually bradygastria, leading to symptomatic decrease in the emptying of solids and liquids without actual mechanical obstruction.<sup>63</sup>

Consequent to gastric outlet obstruction, malnutrition, weight loss, dehydration, and electrolyte abnormalities develop, leading to poor performance status and a decreased quality of life. Malignant gastric outlet obstruction is often considered a pre-terminal event.<sup>64</sup>

By the time that mechanical gastric outlet obstruction occurs, treatment options for control of the primary cancer have usually been exhausted. The primary goal of palliative treatment should be to relieve symptoms by means that have minimal morbidity so as to improve or maintain the quality of the short remaining life.<sup>65</sup> In patients with good performance status, surgical bypass of biliary and duodenal obstruction and splanchinectomy for the control of pain has been advocated.<sup>66</sup> However, in patients with advanced disease, associated malnutrition, limited life span, and poor tolerance for surgery, the choices remaining for palliation of these patients are limited.

### Laparotomy/Laparoscopic Surgery

Laparotomy to relieve mechanical gastric outlet obstruction has been the most common treatment modality employed in the past.<sup>66</sup> However, it has been reported that the greater the need for gastrojejunostomy palliation of pancreatic cancer, the less likely is a favorable outcome.<sup>67,68</sup> For those patients who are taken to surgery with curative resection in mind but who are found to be unresectable because of locally advanced disease (major blood vessel involvement), palliation by gastrojejunostomy is advocated if there is not widespread metastatic disease. Prognosis is more favorable in those patients with locally advanced disease than in those with more widely metastatic disease, and thus, the likelihood for late gastric outlet obstruction is greater.<sup>69</sup>

Today, in the era of minimally invasive procedures, palliation of the obstructed duodenum can be accomplished not only by laparotomy but also by laparoscopic surgery, and more recently, by a novel application of self-expandable metal stents. Espat and colleagues reported that, if staging laparoscopy revealed advanced or metastatic pancreatic cancer, then routine prophylactic biliary and duodenal bypass procedures were not necessary in 152 of 155 patients studied,<sup>70</sup> that surgical biliary bypass should only be advocated in those patients in whom endoscopic biliary stenting has failed, and that gastroenterostomy should be reserved to those patients with

confirmed gastric outlet obstruction. However, Lillemoe and colleagues reported that, in their prospective randomized trial, prophylactic gastrojejunostomy significantly decreased the incidence of late gastric outlet obstruction—0% in the prophylactic group versus 19% in those not so treated.<sup>71</sup> Shyr and colleagues concurred in advocating prophylactic gastrojejunostomy in addition to biliary bypass in patients with unresectable periampullary carcinoma because of the high incidence of late gastric outlet obstruction in those patients not initially treated by gastrojejunostomy.<sup>72</sup> Palliation of biliary and gastric outlet obstruction can be accomplished by laparoscopic construction of a cholecystojejunostomy (if the cystic duct enters the common bile duct at a point distant from the tumor) and gastroenterostomy. In a small series reported by Nagy and colleagues of 10 patients with gastric outlet obstruction (9 due to malignancy), there were no operative deaths, and the most significant postoperative complication was delayed gastric emptying with mean time to regain gut function of 10 days.<sup>73</sup> Twenty percent of Nagy's laparoscopic surgeries had to be converted to the open procedure. In another small study, Alam and colleagues reported that there were no perioperative complications in 8 patients with malignancy-induced gastric outlet obstruction treated with laparoscopic gastrojejunostomy.<sup>74</sup> The median time to solid food intake was 4 days, and the median postoperative stay was 7 days. Choi also reported better tolerance for laparoscopic gastrojejunostomy versus open gastrojejunostomy with fewer postoperative complications and better postoperative hormonal and immune function, which may be responsible for the more rapid recovery and decreased pain in the laparoscopic group.<sup>75</sup>

### Self-expandable Metal Stents

In the quest for a less invasive means to palliate malignant gastric outlet obstruction, the use of SEMS is evolving into the preferred method for palliation in all but perhaps the most medically fit patients for whom surgical palliation may still hold some advantage.<sup>76,77</sup> Before deciding to place a SEMS to relieve gastroduodenal obstruction, adequate assessment of the site and length of stricture and assessment of the bowel distal to the obstruction must be made in order to increase confidence that placement of the stent will result in the desired palliation.<sup>78</sup> Simultaneous palliation of malignant biliary and duodenal obstruction with SEMS can be accomplished in the outpatient setting with a very high success rate, low morbidity, and no procedure-associated mortality, although endoscopic access to the papilla after stent deployment can be very difficult.<sup>79</sup> SEMS have been placed by radiologists<sup>80</sup> utilizing only fluoroscopic techniques and by gastroenterologists utilizing both endoscopic and

fluoroscopic methods.<sup>59,79</sup> It is intuitive that utilizing both endoscopic and fluoroscopic methods leads to a better success rate in more difficult circumstances, especially in the patient with a dilated stomach due to prolonged obstruction. Palliation is almost immediate, and the patient is able to at least take liquids shortly after the deployment of the stent<sup>77</sup> or, at most, within 4 days after stent placement.<sup>81</sup> This immediate relief of gastric outlet obstruction and resumption of oral intake, ranging from liquids to soft and pureed food to a regular diet, results in an improved sense of well being and an improved quality of remaining life. In a review of 32 studies relating to the use of SEMS in malignant gastric outlet obstruction, which was conducted by Dormann and colleagues, pooled results were calculated involving 606 patients.<sup>81</sup> Ninety-four percent of these patients were unable to take nourishment orally. Stent deployment and placement was successful in 97%. Of the group in which technical success was achieved, 89% achieved clinical success—defined as resolution of symptoms of gastric outlet obstruction and ability to take in an oral diet—representing 87% of the total group in which stent placement was attempted. There were no procedure-related deaths. Severe complications (bleeding and perforation) were seen in only 1.2%, and stent migration in an additional 5%. Stent obstruction occurred in 18% mainly due to tumor ingrowth. The mean survival period was 12.1 weeks. Fiori and colleagues reported a randomized prospective trial of surgical gastroenterostomy versus endoscopic stenting and found no statistical difference between the two procedures at 3 months but noted that endoscopic stenting was significantly more effective with respect to operative time, restoration of oral intake and length of hospital stay.<sup>82</sup> Based on these findings, it appears that duodenal stenting for relief of obstruction is a safe, effective, and maybe the preferred, treatment.

Although no specific study has been done to determine cost-effectiveness per se, several studies suggest that the deployment of SEMS is cost-effective when compared to surgical intervention. SEMS are expensive, but the deployment can be made on an outpatient basis without the additional expenses of the operating room and postoperative hospitalization.<sup>66</sup> Yim and colleagues reported that the median survival time for patients with pancreatic cancer who underwent stenting of gastric outlet obstruction, compared with those who underwent surgical gastrojejunostomy, was 94 and 92 days, respectively; charges were \$9,921 and \$28,173, and the duration of hospitalization was 4 and 14 days, respectively.<sup>83</sup> The use of SEMS in the setting of malignant gastroduodenal obstruction is proving to be a cost- and clinically effective palliative treatment for these unfortunate patients.

The two most significant problems, stent migration and tumor and/or granulation tissue ingrowth with re-obstruction of the gastric outlet, have been addressed, but a perfect solution has not emerged. As in the case of esophageal tumors, the placement of covered duodenal stents has been proposed. Good technical and clinical success rates with a low incidence of stent migration and stent-related biliary outflow obstruction at the papilla have been reported.<sup>84–86</sup> Jung and colleagues reported favorable results in decreasing the migration rate of covered duodenal stents and improving resistance to tumor ingrowth of uncovered stents by coaxial placement of a covered stent inside a previously deployed uncovered stent.<sup>87</sup>

### Venting Gastrostomy

In patients with gastric outlet obstruction due to malignancy in whom all other modalities of palliative treatment have failed, a percutaneous palliative venting gastrostomy should be offered because nausea and vomiting may be effectively palliated in a high percentage of patients and may even restore some level of oral intake.<sup>88</sup> If feasible, the addition of a feeding jejunostomy may also be considered.

### Gastroesophageal Reflux after Esophagectomy

Transhiatal esophagectomy (the Ivor-Lewis operation) is often employed as a curative procedure in the treatment of cancer of the distal esophagus. It is a major operation that is associated with significant morbidity, among which are dysphagia, early satiety, stricture and inflammation at the anastomosis, regurgitation, heartburn and emotional problems that impact quality of life. Although more than one-half of the patients studied by de Boer and colleagues still experienced some of these symptoms,<sup>89</sup> the overall conclusion was that the quality of life of long-term survivors (minimum follow-up of 2 years) was comparable with reference values for the same age group, and in some parameters (ie, emotional well-being) was even better than the reference group. It is interesting to note that in a study of quality of life in patients with various gastrointestinal conditions, patients with functional disorders displayed more emotional distress than did patients with organic disease.<sup>90</sup>

A high incidence of gastroesophageal reflux has been reported in patients treated for head and neck cancers<sup>91,92</sup> and in patients after esophagectomy for cancers of the esophagus.<sup>93</sup> Reflux after esophagectomy occurs because the normal anti-reflux mechanisms of the intact esophagus and lower esophageal sphincter, and the normal hiatal anatomy that contributes to normal lower esophageal sphincter function, have been disrupted by the resection. After resection and anastomosis,

a large portion of the stomach is in the thorax, where negative pressure predominates, and this (combined with the positive pressure of the abdominal cavity) leads to free reflux of gastric and duodenal contents across the anastomosis into the esophageal remnant. This, coupled with impaired gastric motility and the return of acid secretion by the gastric conduit, leads to heartburn, regurgitation, night-time aspiration, dysphagia, esophagitis, sleep disturbance and general decrease in the quality of life.<sup>93</sup>

For most patients, gastric emptying is delayed in the supine position and improved in the upright position for 3–12 months after esophagogastrectomy, but some 4 to 6% of patients have long-lasting chronic gastroparesis after esophagectomy.<sup>94</sup> The denervated stomach, whether used in whole or fashioned into a tube as an esophageal substitute, progressively recovers more and more motor activity, even displaying a real phase 3 motor pattern in patients followed for more than 3 years post-operation.<sup>95</sup> Motor recovery is much better when the stomach is maintained as a whole, rather than when a conduit is fashioned from the greater curvature.<sup>96</sup>

The colon, small bowel, and stomach have all been used as substitutes for the resected esophagus.<sup>97</sup> The creation of a gastric tube is favored because of the simplicity of the operation and the lower postoperative morbidity and mortality.<sup>98</sup> Because vagotomy is an inevitable consequence of esophagectomy there is loss or disruption of the normal physiology of the stomach, such as accommodation to meals, tonic motility, and neuro-humoral enterogastric feedback leading to delayed gastric emptying of solids but more rapid emptying of semisolids and liquids.<sup>99</sup> The delay in gastric emptying contributes to reflux, among other symptoms.<sup>100</sup> This dysfunction of gastric emptying coupled with reflux of duodenal contents into the stomach can lead to pathologic exposure of the gastric and remnant esophageal mucosa to bile acids in the early post-vagotomy period,<sup>101</sup> perhaps leading to more severe esophagitis and its consequences, such as stricture and Barrett's epithelium.<sup>102</sup> Acid reflux is more likely to be symptomatic than bile reflux, but erosive esophagitis can occur in isolated bile reflux.<sup>103</sup> The study by Logeman and colleagues concludes that, by constructing a narrow gastric tube as an esophageal substitute, a small distal gastric remnant is created with low compliance leading to an increased pressure gradient between the stomach and the duodenum, therefore favoring gastric emptying in the face of pyloroplasty or pyloromyotomy.<sup>100</sup> In a study, reported by Finley and colleagues, of 249 cases of esophagectomy performed for the treatment of malignancy, the rate of gastric emptying was not dependent on whether or not a gastric drainage procedure was employed,<sup>104</sup> but it seemed that the construction

of a narrow gastric tube fixed in the posterior mediastinum as a substitute for the esophagus was associated with less delay in gastric emptying. As regards food intake and functional dysphagia following esophagectomy and reconstruction, fixing the esophageal substitute in the posterior mediastinum appears to be more physiologic and associated with fewer symptoms than fixing the gastric tube in the retrosternal space.<sup>105</sup> The gastric tube is not inert but produces phasic contractions on distention in response to feeding, and in time, after the operation, there is at least partial recovery of gastric tone.<sup>100</sup> A study reported by Walsh and colleagues in which the whole stomach was used as the conduit after esophagectomy, demonstrated that the stomach functions as a dynamic conduit, and that erythromycin, which appears to primarily directly effect motilin receptors but which may also effect cholinergic transmission, induces peristaltic activity in the vagally denervated stomach to a greater extent than in normal controls.<sup>99</sup>

### Treatment

Treatment of gastroesophageal reflux following Ivor-Lewis esophagogastrectomy must take into consideration the alteration of normal esophagogastrointestinal physiology and the abolition of natural anti-reflux mechanisms. As has already been discussed, delayed gastric emptying plays an important role in the perpetuation of symptomatic reflux. Therefore alteration of the diet is important, particularly eating smaller, more frequent meals that are low in fat, maintaining a standing posture after meals, and avoiding large meals approaching bedtime. Elevation of the head of the bed on 4-inch to 6-inch blocks is advised. The use of proton pump inhibitors is always helpful as acid secretion by the intrathoracic stomach after truncal vagotomy and esophagectomy may be unchanged,<sup>106</sup> and erythromycin as a pro-motility agent, particularly in the early postoperative period, should be considered.<sup>107</sup> Several anti-reflux surgical procedures<sup>93</sup> have been described, such as the intercostal pedicle esophagogastropepy<sup>108</sup>; all have proved complex to create and have not met wide acceptance.

### Tube Gastrostomy

Frequently, a patient with cancer (particularly cancer of the upper aero-digestive tract) will need enteral nutrition because of dysphagia due to tumor involvement of the pharynx or esophagus. Sometimes access to the gastrointestinal tract will be obtained in anticipation of complications due to chemotherapy and/or radiotherapy leading to severe oro-pharyngeal-esophageal mucositis precluding the ability to swallow. It has been shown that early nutritional intervention through PEG tube insertion and maintenance of nutrition and

hydration in patients with head and neck and esophageal cancer leads to better tolerance of treatment, completion of treatment at recommended doses, and avoidance of hospitalization. PEG placement in these circumstances has been associated with a low morbidity and mortality. Rarely, metastasis of the primary tumor to the PEG site has been reported. PEG placement does not preclude the stomach from being used to construct a conduit as an esophageal replacement during resection of distal esophageal cancers, as some thoracic surgeons have feared.<sup>109–111</sup> In this last regard, however, it is best to ascertain the surgeon's preferences.

In cancer patients, nutritional deficiencies can be restored and the quality of life can be maintained or improved by appropriate placement of a PEG tube.<sup>112</sup> Although nasogastric tubes and other methods have been used to provide enteral nutrition and hydration in times past and at present,<sup>113</sup> PEG tubes are preferred because they are socially and cosmetically better tolerated, better anchored and more comfortable for the patient, and easier for caregivers to manage. A PEG tube can be safely placed in the outpatient setting and full strength iso-osmolar formula feedings can be safely started as little as 3 hours after tube placement.<sup>114,115</sup> Because PEG tubes are more easily managed by caregivers, more feeding formula can be infused in a shorter period of time resulting in better nutrition and hydration for most patients and better productivity for nursing home personnel. Therefore, most nursing homes demand that patients needing feeding assistance have PEG tubes in place before admission to their facilities.

In contradistinction to nasogastric tubes, a PEG tube in non-acutely ill patients is better tolerated over a longer period of time and is associated with improved survival, less aspiration, and is less likely to be pulled out. Achievement of overall nutritional status was similar in patients with a PEG tube as in patients with a nasogastric tube.<sup>116,117</sup> PEG tubes need to be exchanged only occasionally and, usually, this exchange can be accomplished easily at the bedside. A variety of modifications of the replacement PEG tube have been developed. A modified replacement tube can be used for the exchange and will provide a more comfortable gastrostomy with less patient and caregiver anxiety about accidental dislodgement.<sup>118</sup>

Whether in the cancer or non-cancer patient, one should consider the placement of a nasogastric-enteric feeding tube if the anticipated need for tube feedings will be 30 days or less. For long-term tube feeding (greater than 30 days), it has been shown that a PEG tube is better tolerated and results in a better quality of life for patients and caregivers alike.<sup>116</sup>

Whenever a decision regarding artificial enteral nutrition is made, ethical considerations

enter into the picture. The anticipated benefits must outweigh the potential harm due to possible complications. Decision regarding the placement of a PEG tube is often made difficult by emotions and misconceptions surrounding the benefits and risks of the procedure and the uncertainty, in some cases, that the intervention will bring material long-term benefit. The decisions about offering or withdrawing artificial nutritional support should be considered in the same ethical light as any other medical treatment.<sup>119</sup> Even now, more than 25 years since the introduction of the PEG into clinical practice, physicians are struggling with understanding the proper role of PEG and long-term enteral nutrition in the management of patients at the end of life. Because a procedure is readily available and relatively easily performed by experienced operators, it does not mean that it should be employed in all circumstances without regard to ethical standards.

### Percutaneous Endoscopic Gastrostomy

The first PEG was performed on a 4 ½-month old infant in June 1979. Gauderer and Ponsky first reported this technique, including an additional 11 pediatric patients, in 1980.<sup>120</sup> The germinal ideas, however, and the experimental demonstration for feasibility of percutaneous gastrostomy placement were reported in 1967 by both Jasclevich and Edlich and colleagues.<sup>121,122</sup> Since the introduction of PEG into clinical practice, it has become the procedure of choice to obtain enteral access in patients who for a variety of reasons have impaired swallowing but otherwise have a functioning upper gastrointestinal tract. It has virtually replaced open surgical gastrostomy because of lower morbidity and mortality rates, ease and speed of placement, avoidance of general anesthesia and lower cost.<sup>113</sup> Open gastrostomy is useful, however, when placed as an adjunct to an abdominal operation being done for some other reason.

In the setting of cancer management, PEG is most commonly placed in patients with oropharyngeal and esophageal malignancy before, during or after treatment with chemo-radiation or surgery.<sup>123</sup> Several techniques have been developed ranging from the original Ponsky-Gauderer 'pull' method,<sup>120</sup> the over the guide wire 'push' Sachs-Vine method,<sup>124</sup> the 'introducer-push' or Russell method,<sup>125</sup> and the fluoroscopic-assisted Seldinger technique.<sup>126</sup> Gastrostomy tubes can be placed by the interventional radiologist,<sup>126</sup> by the surgeon using either the open or laparoscopic technique,<sup>127</sup> or by the gastroenterologist.<sup>128</sup>

Patients needing a PEG should be carefully screened and a primary determination made as to whether the patient's condition is such that a life expectancy of at least 30 days is likely. When compared to a similar nursing home population, factors that adversely affect the 30- and 60-day

mortality rates after PEG placement in hospitalized patients are a serum albumin < 3, chronic obstructive pulmonary disease, and diabetes mellitus.<sup>129</sup> The reported procedure-associated mortality and major complication rates are low, with minor complication rates around 13%. Early mortality (< 30 days) has ranged from 8 to 22%,<sup>130–132</sup> 30-day mortality is improved considerably if the PEG tube is not placed during hospitalization for an acute illness. Patients who had PEG tube insertion 30 days after discharge achieved a 40% lower 30-day mortality rate than patients who had PEG tubes placed while hospitalized.<sup>133</sup>

Complications can be modified or averted by paying meticulous attention to details before and after PEG placement, such as using pre-procedure antibiotics,<sup>134</sup> being aware of the contraindications to PEG tube placement, carefully selecting patients who are more likely to benefit from PEG placement,<sup>135</sup> and ascertaining that, post-procedure, the external bumper does not exert undue pressure on the gastric or abdominal wall.<sup>136</sup> If improvement in the patient's condition and nutritional state cannot be reasonably expected, then placement of a PEG tube should be avoided.<sup>119</sup>

The decision to place a PEG tube prior to therapy for head and neck cancer can be difficult. The consistency of the diet consumed by the patient prior to institution of treatment may be a guide. The less like a normal diet that a patient consumes, the more likely a PEG will be needed.<sup>137</sup> PEG tube placement can be safely accomplished with greater than a 90% success rate in head and neck cancer patients with a low complication rate, several days or weeks before the anticipated treatment, at the time of other associated operative interventions, or in the postoperative period.<sup>123,138–140</sup>

The "pull" percutaneous gastrostomy technique as described by Ponsky and Gauderer is most commonly employed because of its simplicity and relative ease of placement.<sup>120,141</sup> An unsedated transnasal approach to PEG tube placement using an ultrathin endoscope has recently been reported and may be useful in patients with nearly obstructing lesions of the pharynx and in patients with trismus.<sup>142</sup>

There may be advantages to placing a PEG tube using the Russell "push" technique,<sup>125</sup> relative to the incidence of rare PEG-site metastasis,<sup>124</sup> stomal infections, and other minor complications associated with the procedure.<sup>143,144</sup> The Russell procedure has not been widely practiced by gastroenterologists. The introduction and placement of the gastrostomy tube is more complicated and time-consuming, and the feeding tube is of a lesser diameter than can be placed by the pull technique. It is also associated with a greater incidence of major complications.<sup>145</sup> In patients with advanced head and neck cancer who are elderly

and have comorbid medical conditions, it is prudent to plan placement of the PEG at the time of anticipated resection.<sup>146</sup>

Although the placement of PEG tubes for enteral feeding has been proven safe, with a low incidence of minor and major complications, there has been concern about the occurrence of metastatic tumor implantation in the PEG stoma site. There have been approximately 30 patients reported with metastatic tumor implantation at the PEG tube site since 1989.<sup>147</sup> The incidence of this complication is unknown but it has been variably estimated at less than 1% to as high as 3%. The exact mechanism for this complication is unknown, and various theories have been advanced. The mechanisms that have been proposed include the direct contamination with malignant cells of the PEG tube as it traverses the tumor in the “pull technique” and the hematogenous and lymphatic spread of circulating tumor cells to predisposed tissues, such as the fresh PEG tube stoma. The majority of patients reported had squamous cell cancer of the head and neck although esophageal tumors have also been reported to metastasize to the PEG stoma as well. The discovery of the metastatic deposit has occurred on average 7 to 9 months after PEG placement. The most common signs and symptoms in patients with this complication include stomal leakage, stomal induration, exuberant and friable soft tissue growth and abdominal wall pain. The continued presence of the PEG tube was not necessary for this complication to occur. Some of the PEG tubes had been removed several months prior to the discovery of PEG site metastases. The PEG tubes continued to function in the face of metastatic disease to the stoma. The majority of reports have been in patients with aggressive, advanced cancers (stage III and IV) who also had evidence of other distant metastasis. It appears that, since 1989, all the cases reported have been in patients who have had the PEG placed by the “pull technique.”<sup>148-150</sup> This may be due to the fact that the “pull technique” is by far the most popular technique employed and not due to some inherent but undefined problem with the technique. Some authors have proposed that alternative methods be employed in the placement of PEG in these patients.<sup>147</sup>

### Other Uses

Sometimes percutaneous endoscopic gastrostomy is employed not for establishment of nutrition but for palliation of intractable nausea and vomiting due to intestinal obstruction caused by inoperable intraluminal tumor or abdominal carcinomatosis. Intractable nausea and vomiting can be palliated in the majority of these patients, obviating admission to the hospital. Some may return to a clear liquid diet which can boost the quality of life. If feasible, the combination of

venting gastrostomy and feeding jejunostomy may be considered.<sup>88,151,152</sup>
