# Hepatobiliary and Pancreatic Disorders

John T. Mullen, MD  
Eddie K. Abdalla, MD

For long-term cancer survivors, and especially for cancer patients receiving treatment, disorders of the liver, biliary tree, and pancreas are common. The goal of this chapter is to provide a framework for diagnosis and treatment of disorders of these organ systems in the context of the patient's treatment and cancer-related prognosis. Because of space constraints, this chapter will not discuss every hepatobiliary or pancreatic disorder that clinicians may confront.

For many of the disorders described herein, invasive or interventional tests are needed for the diagnostic work-up, requiring the expertise of radiologists, gastroenterologists, and surgeons. The referring oncologist provides a critical perspective on the underlying cancer and the patient's prognosis, and the work-up is modified on the basis of this background information. Every interventional test carries risks and must be applied judiciously—complications of the diagnostic work-up can have catastrophic consequences for patients and families if the individual patient circumstances are not taken into account. Thus, when interventions such as endoscopy or biopsy are suggested below, they are to be considered only when the clinical scenario is critically appraised in light of the underlying cancer diagnosis and prognosis by the consulting oncologist in concert with interventional radiologists, gastroenterologists, and surgeons. This chapter will address the most common hepatobiliary and pancreatic disorders seen in cancer patients: jaundice, hepatic toxic reactions due to anticancer therapies, cholecystitis, cholangitis, ascites, pancreatitis, and exocrine and endocrine pancreatic insufficiency.

## Hepatobiliary Disorders

### Jaundice

Jaundice, or icterus (yellow pigmentation of the skin and sclerae) is due to accumulation of bilirubin in the tissues. Causes of increased serum bilirubin levels include increased degradation of heme and impaired hepatic metabolism or excretion of bilirubin. The liver plays a central role in the metabolism of bilirubin. Hepatocytes take up unconjugated bilirubin, which is bound to

albumin, conjugate the bilirubin to glucuronic acid, and then excrete the conjugated bilirubin into bile. This last step, bilirubin excretion, is the rate-limiting step and the step most likely to be impaired when hepatocytes are injured. After excretion into bile, conjugated bilirubin is transported through the bile ducts and into the duodenum to emulsify fatty foodstuffs and facilitate absorption; unabsorbed conjugated bilirubin is either excreted unchanged in the stool or metabolized by ileal and colonic bacteria to urobilinogen, which is absorbed by the intestinal mucosa to be either re-excreted into bile or filtered by the kidneys and excreted in the urine.

### Causes of Jaundice

The first step in the evaluation of a patient with jaundice is to establish whether the jaundice is due to unconjugated or conjugated hyperbilirubinemia (Figure 1). Jaundice associated with unconjugated hyperbilirubinemia is most commonly seen in the setting of increased erythrocyte destruction, as occurs with intravascular hemolysis, massive transfusion, or resorption of a large hematoma. Less commonly, unconjugated hyperbilirubinemia is caused by decreased hepatic glucuronosyltransferase activity, such as occurs in end-stage hepatic failure or sepsis.

Jaundice associated predominantly with conjugated hyperbilirubinemia is generally caused by one of three groups of disorders: hepatocellular disease, intrahepatic biliary obstruction (cholestasis), or extrahepatic biliary obstruction. Hepatocellular diseases that can cause jaundice include viral hepatitis (see Chapter 17, "Viral Infections"), drug-induced (especially chemotherapy-induced) hepatocellular disease, and cirrhosis. Intrahepatic cholestasis can be caused by long-term administration of total parenteral nutrition, can occur after surgery, or can be caused by sepsis or drugs (eg, chemotherapy). Extrahepatic biliary obstruction can be classified as either benign or malignant. Benign causes include infections, gallstones, and strictures. Malignant causes include periampullary cancers, cholangiocarcinomas, lymphomas, and cancers metastatic to the portal lymph nodes.

In patients with jaundice due predominantly to conjugated hyperbilirubinemia, levels of the other liver enzymes, including the transaminases and alkaline phosphatase, may suggest either a hepatocellular disorder (transaminase elevation predominant) or biliary obstruction (alkaline phosphatase elevation predominant). If liver enzyme levels suggest a hepatocellular disorder, serologic tests for hepatitis infection should be performed, and then a liver biopsy should be performed as needed to obtain diagnostic information and for treatment planning. If biliary obstruction is suspected, abdominal ultrasonography should be performed. The remainder of this section will be devoted to the diagnosis and treatment of obstructive jaundice in the cancer patient.

### Diagnosis and Treatment of Patients with Obstructive Jaundice

In patients with suspected biliary obstruction, abdominal ultrasonography should be the initial radiologic imaging study (Figure 2).<sup>1</sup> Abdominal ultrasonography is noninvasive, inexpensive, and accurate, and the equipment required is portable. The study first and foremost provides information about the caliber of the biliary ducts, confirming the presence or absence of intra- and extrahepatic biliary ductal dilatation. With rare exceptions, ductal dilatation is present in all cases of obstructive jaundice. Abdominal ultrasonography has a sensitivity of greater than 95% in detecting gallstones, which may be the source of ductal obstruction.<sup>2</sup> However, abdominal ultrasonography may have a sensitivity lower than 50% in detecting common bile duct stones.<sup>1</sup>

In the event of normal findings on abdominal ultrasonography, abdominal computed tomography (CT) is often helpful to evaluate the entire hepatobiliary tract. Cholangiography should be delayed until after CT unless cholangitis necessitates immediate intervention, because the endoscopic manipulation of the biliary tree can significantly reduce the sensitivity of CT to detect biliary and pancreatic pathology. Endoscopy facilitates biopsy of lesions that can be identified; when no lesions are found, a liver biopsy should

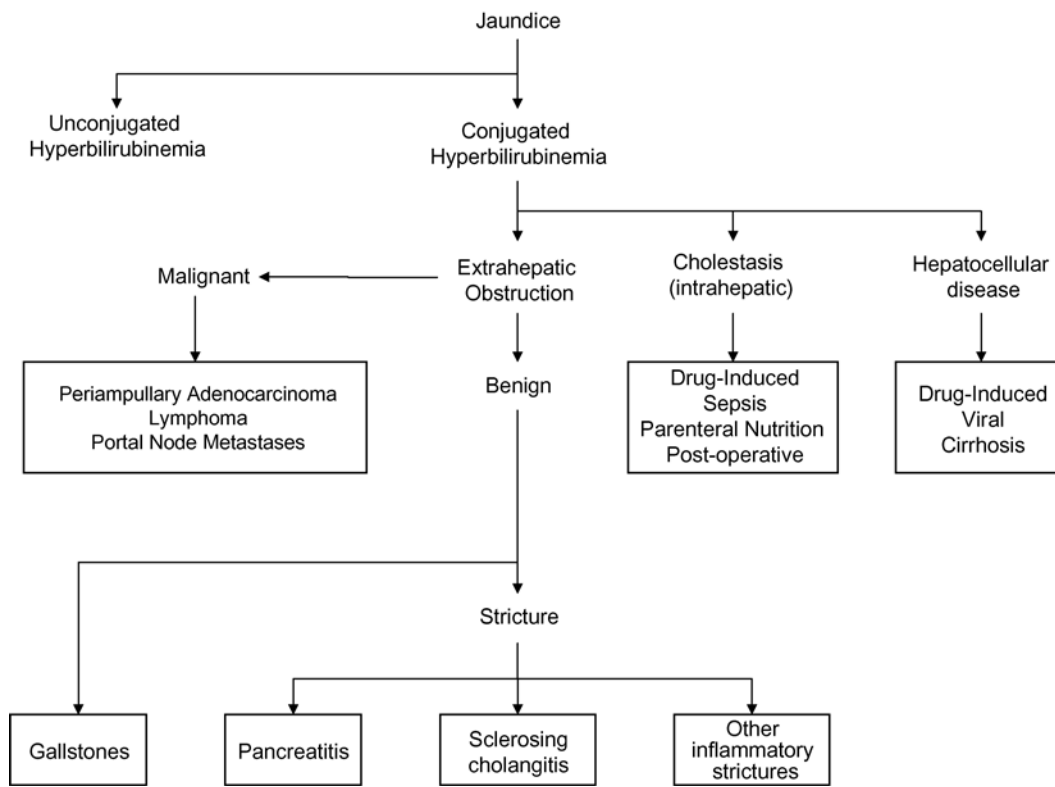

FIGURE 1 Flow diagram illustrating the causes of jaundice.

be considered to define the cause of the obstructive jaundice (see Figure 2) if the results of such a biopsy would guide treatment.

If ultrasonography documents intra- and/or extrahepatic biliary ductal dilatation and gallstones in a candidate for surgery, consultations with a gastroenterologist and surgeon can help to determine the options for percutaneous, endoscopic, and surgical intervention.

If the patient has the cardinal manifestations of cholangitis—fever, right upper quadrant pain, and jaundice—or severe pancreatitis, endoscopic retrograde cholangiopancreatography (ERCP) should be urgently performed after fluid resuscitation and administration of intravenous antibiotics to cover gram-negative organisms and anaerobes. If common bile duct stones are found, the calculi should be cleared, and a sphincterotomy should be performed. The patient can then undergo semi-elective cholecystectomy after resolution of the inflammatory process, usually during the same hospitalization. If a biliary stricture is found, brushings should be obtained for cytologic evaluation, if indicated, and a plastic stent should be placed. If a skilled endoscopist is available, endoscopic

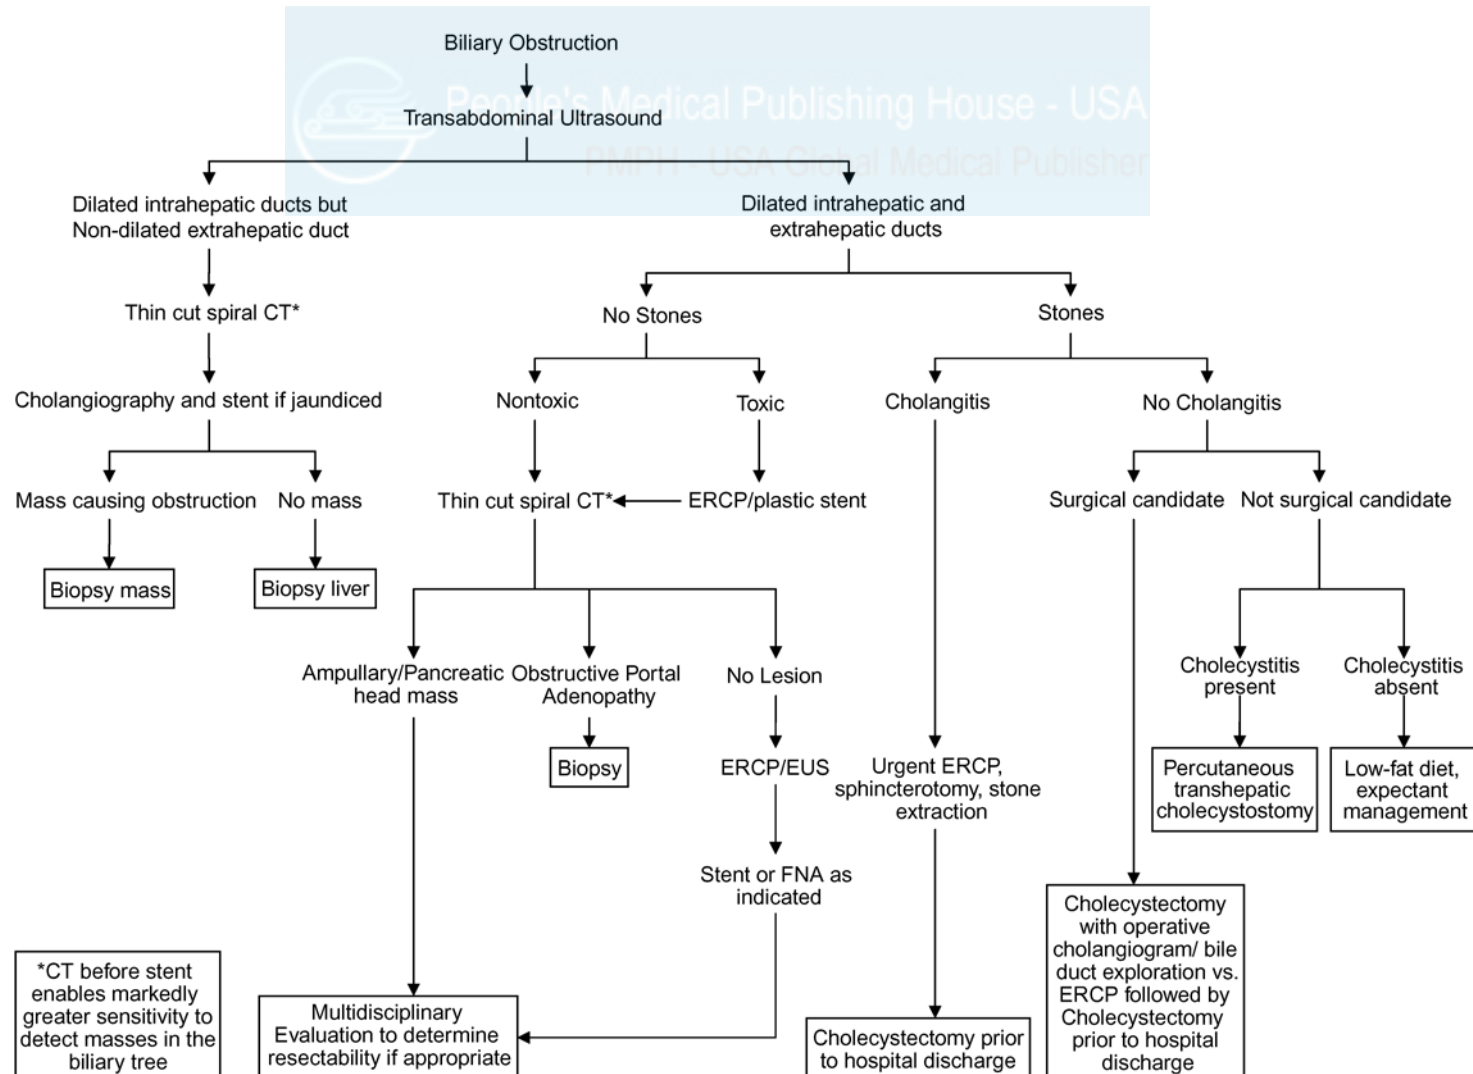

FIGURE 2 Algorithm for the diagnosis and management of biliary obstruction.

ultrasonography (EUS) can be performed to examine the head of the pancreas and bile duct wall for possible lesions. If lesions are detected, a needle biopsy is performed. Most patients with intra- or extrahepatic biliary stricture should be promptly referred to a specialized center experienced in the care of these patients after stent placement. A pathologic diagnosis is unnecessary, and repeated attempts to obtain sufficient tissue for diagnosis only result in delay of definitive treatment.

If the patient does not have cholangitis or severe pancreatitis, ERCP should not be the first course of action. Supportive measures should be instituted, and the patient should be observed. If the serum bilirubin level is elevated or cholangitis develops, ERCP should be considered; otherwise, if the patient is deemed to be a candidate for surgery, a cholecystectomy is appropriate. Indeed, several randomized trials have demonstrated improved outcomes with a surgical approach (cholecystectomy with or without common bile duct exploration) as the first intervention in uncomplicated choledocholithiasis.<sup>3,4</sup> This selective approach to the use of ERCP is cost-effective and spares the majority of patients without impacted or persistent common bile duct stones the risks of ERCP, including pancreatitis and duodenal perforation.<sup>5</sup> For patients who are not candidates for surgery and who have no evidence of cholecystitis, a low-fat diet and expectant management should be considered. In gravely ill patients with cholecystitis, a percutaneous cholecystostomy tube should be placed under ultrasound guidance, and the patient should be given supportive care and intravenous antibiotics. After recovery from systemic disease, cholecystectomy is indicated.

If abdominal ultrasonography shows dilated intra- and/or extrahepatic ducts in the absence of gallstones, especially if the patient has a bilirubin level greater than 10 mg/dL or symptoms suggestive of malignancy (ie, painless jaundice and weight loss), an abdominal CT scan should be obtained. CT enables the identification of mass lesions or adenopathy in the liver, porta hepatis, or pancreas and is more sensitive and specific than ultrasonography in diagnosing the etiology of extrahepatic biliary obstruction.<sup>1</sup> For patients whose underlying cancer diagnosis is not associated with a poor long-term prognosis, work-up for treatment of a periampullary neoplasm can be considered. If the underlying cancer diagnosis portends a low likelihood of long-term survival, the extensive work-up required for a potentially resectable periampullary neoplasm is not necessarily sensible, and management with plastic or metallic stents can be considered.

A hypodense lesion in the head of the pancreas on CT is suggestive of typical pancreatic ductal adenocarcinoma. If no lesion is seen on CT, ampullary and distal common bile duct lesions must be considered. If the patient would

be a candidate for aggressive therapy, either the patient should be immediately referred to a center that specializes in the management of pancreatic cancer or the patient can be referred for ERCP with plastic stent placement by a gastroenterologist skilled in this procedure. Decision-making regarding appropriate stent placement requires consideration of several factors. If palliation of biliary stenosis is appropriate in light of the patient's overall clinical condition, stent selection must take into account future treatment plans and prognosis. Metallic stents have greater long-term patency than plastic stents but may interfere with future surgical interventions. In other words, even the decision regarding stent type requires careful consideration of the underlying disease process, prognosis, and potential future therapies.

Enlarged portal nodes related to lymphoma or metastatic disease can cause extrahepatic biliary obstruction. These nodes can be biopsied under CT guidance or at the time of ERCP or endoscopic ultrasonography. Treatment generally entails chemotherapy and/or radiation therapy, with or without biliary decompression. The preferred mode of biliary decompression is endoscopic, but when this route fails, transhepatic biliary drainage can be considered. Tube-free palliation can be achieved by internalizing external (transhepatic) stents at a second setting either by skilled interventional radiologists or by the endoscopist in concert with the radiologist. Such high level management of biliary obstruction requires close review of overall treatment plans, biliary anatomy and prognosis.

### Hepatic Toxic Reactions Due to Anticancer Therapies

Hepatic toxic reactions are relatively common in patients receiving anticancer therapy. Toxic reactions range from mild, transient abnormalities on liver function tests with standard-dose chemotherapy to full-blown hepatic failure due to graft versus host disease (GVHD) or sinusoidal obstruction syndrome (SOS) after hematopoietic stem cell transplantation. Moreover, fulminant hepatic failure may be the presenting clinical feature in patients with Hodgkin's<sup>6,7</sup> or non-Hodgkin's lymphoma<sup>7,8</sup> and may develop from an exacerbation of underlying chronic hepatitis B virus (HBV) infection in patients on immunosuppressive cytotoxic therapy.<sup>9,10</sup> This section describes hepatic toxic reactions related to chemotherapy, bone marrow transplantation (BMT), and radiation therapy.

#### Chemotherapy-Induced Hepatic Toxic Reactions

The diagnosis of chemotherapy-induced hepatic toxic reactions is difficult as there are no biochemical or histologic features unique to this

diagnosis. Diagnosis is further complicated by the fact that cancer patients often have other sources of liver disease related or unrelated to their cancer diagnosis (Table 1). A high index of suspicion is important. Clues to the proper diagnosis include the temporal relationship between the toxic reaction and drug administration and the response to drug cessation and rechallenge.

Chemotherapeutic agents commonly cause transient elevations in the values measured on liver function tests, particularly in aminotransferase values. Under most circumstances, the hepatotoxicity of standard-dose chemotherapy is not clinically significant. However, when hepatotoxicity is clinically evident, the responsible drug needs to be promptly identified and discontinued. If liver injury is a known dose-dependent adverse effect of a given drug, then that drug can be re-administered at a reduced dosage. Of course, the risk of adverse effects with re-administration of the drug needs to be weighed against the drug's effectiveness as an anticancer agent.

The list of chemotherapeutic agents reported to be hepatotoxic is extensive (Table 2). Some of the more common hepatotoxic agents are the alkylating agents cyclophosphamide (especially when given at a high dose and in conjunction with other agents),<sup>11,12</sup> busulfan,<sup>13</sup> and melphalan<sup>14</sup>; the antimetabolites methotrexate<sup>15</sup> and 6-mercaptopurine<sup>16,17</sup>; the hormones tamoxifen<sup>18,19</sup> and flutamide<sup>20,21</sup>; the cytokines interleukin-12 and interferon-alpha-2b<sup>22</sup>; and the monoclonal antibody gemtuzumab.<sup>23</sup>

Acute awareness of the potentially lethal complication of chemotherapy in hepatitis B carriers cannot be ignored. Viremia, acute fulminant hepatic failure, and death have been reported in patients receiving chemotherapy for solid tumors<sup>9</sup> as well as for hematologic malignancies,

@TF=SOS = sinusoidal obstruction syndrome.

and who are carriers of hepatitis B.<sup>10</sup> Viremia and subsequent lethal consequences can be completely obviated by prophylaxis with lamivudine, a highly effective nucleoside analogue against HBV, in all seropositive cancer patients receiving antineoplastic therapy.<sup>10,24</sup>

#### Hepatic Toxic Reactions Related to Hepatic Artery Infusional Chemotherapy

Infusion of chemotherapy directly into the hepatic artery was proposed in the 1960s<sup>25,26</sup> and has been promoted as a means to treat the liver with high-dose chemotherapy with minimal systemic toxicity.<sup>27-31</sup> Unfortunately, such regional therapy, particularly for colorectal liver metastases, has not improved survival but has generated a range of hepatic toxic reactions, from mild biochemical test abnormalities to lethal hepatic failure.<sup>32</sup>

The most common hepatic toxic reaction associated with hepatic artery infusional (HAI) chemotherapy is liver function test abnormalities, including a doubling of serum alkaline phosphatase levels in 29% of patients, a tripling of aminotransferase levels in 65%, and an increase in total

bilirubin levels to more than 3.0 mg/dL in nearly 20% of treated patients.<sup>31,32</sup> These liver function test abnormalities usually return to normal when the chemotherapy dose is lowered or when chemotherapy is discontinued. A less common but more significant, irreversible complication of HAI chemotherapy is biliary sclerosis, which may be mitigated by concurrent infusion of dexamethasone with chemotherapy.<sup>33</sup> Cholangiography should be performed in those patients who become jaundiced during the course of HAI chemotherapy. If there is a dominant biliary stricture, palliation can be achieved by placement of a biliary stent. Permanent biliary sclerosis with multiple strictures (9 to 17% of patients)<sup>34,35</sup> and death from fulminant hepatic failure (1%)<sup>32,36</sup> persist as dreaded complications of hepatic artery chemotherapy regardless of the infused chemotherapeutic agent. Other important hepatobiliary complications of HAI chemotherapy include hepatic artery thrombosis (6%),<sup>32</sup> which can be lethal or cause slow, progressive (untreatable) liver failure; catheter thrombosis (5%)<sup>32</sup>; catheter displacement (7%)<sup>32</sup>; and chemical cholecystitis, which occurs almost universally with HAI chemotherapy such that prophylactic cholecystectomy is now routinely performed at the time of infusion pump placement.<sup>37,38</sup>

#### Hepatic Toxic Reactions Related to Bone Marrow Transplantation

Hepatic toxic reactions occur in up to 70% of patients who undergo bone marrow transplantation (BMT); SOS and GVHD are the reactions associated with the highest morbidity and mortality.

SOS, formerly known as veno-occlusive disease, is a clinical syndrome characterized by jaundice, painful hepatomegaly, and fluid retention. The first signs of SOS are fluid retention and weight gain, which develop in the first 20 days after the pre-transplant chemotherapy regimen. Painful hepatomegaly and alterations in liver function tests occur later in the course of the disease. SOS is due to the synergistic toxicity of the high-dose chemotherapy and total-body irradiation that comprise the preparative regimen administered prior to BMT. The incidence of SOS is dependent on patient-related factors and the chemotherapy regimen, and ranges from less than 5% to as high as 70%.<sup>39</sup> The mortality rate from SOS varies from 20 to 50%.<sup>39</sup> Conditions that mimic SOS (including acute GVHD, sepsis with cholestasis, and heart failure) must be ruled out to establish the diagnosis. When the diagnosis is unclear, particularly in cases in which GVHD needs to be excluded, a liver biopsy should be performed. Percutaneous transjugular biopsy is preferred because procedure-related risks are extremely low, and this approach allows measurement of the hepatic venous pressure gradient,

which if greater than 10 mm Hg has a specificity of 90% in diagnosing SOS.<sup>40</sup> Histologic findings on liver biopsy in patients with SOS include sinusoidal congestion and fibrosis and hepatocyte necrosis.

The pathogenesis of SOS is not well understood but may be related to a disruption of the hepatic sinusoidal microcirculation. Treatment is largely supportive, including careful management of the patient's volume status. Mild to moderate SOS can typically be managed with diuretics, and complete recovery is the norm. Unfortunately, the majority of patients with severe SOS develop multisystem organ failure with hepatorenal syndrome, and the outcome is usually fatal.

The liver is the most common organ affected by GVHD after BMT; nearly 70% of patients with chronic GVHD exhibit hepatic involvement despite appropriate immunosuppression.<sup>41</sup> Hepatic GVHD typically develops 2 weeks after BMT and is characterized by a progressive rise in the values measured on liver function tests. Patients often have concomitant GVHD involving the intestine and skin, and the presence of these in conjunction with altered liver function tests should raise suspicion of hepatic GVHD. When the diagnosis is in doubt, a liver biopsy is diagnostic. The cornerstone of treatment is steroids; however, the majority of patients with acute GVHD of the liver go on to develop chronic GVHD.<sup>42</sup>

#### Radiation-Induced Liver Disease

Radiation-induced liver disease, or radiation hepatitis, is a dose-limiting complication of liver irradiation. The clinical syndrome consists of tender hepatomegaly without jaundice; ascites; and abnormal liver function tests, particularly an elevated serum alkaline phosphatase level. The syndrome is not unlike SOS seen in patients after BMT. In fact, the pathogenesis of radiation-induced liver disease is similar to that of SOS—radiation-induced liver disease is a veno-occlusive disease characterized histologically by marked venous congestion of the central portion of the hepatic lobule and sparing of the larger veins. The syndrome typically develops 2 weeks to 3 months after hepatic irradiation. The liver tolerates radiation poorly; radiation-induced liver disease is seen in 5 to 10% of patients treated with 30 to 35 gray of conventional radiation to the whole liver.<sup>43</sup> For this reason, radiation therapy has traditionally played a limited role in the treatment of hepatic malignancies.<sup>44</sup> Newer techniques of three-dimensional conformal radiation therapy enable the delivery of much higher doses of radiation to the affected liver while sparing an adequate volume of normal liver, thus substantially reducing the risk of radiation-induced liver disease. For patients who develop this disease, treatment is largely supportive and similar to that described

for SOS. In severe cases, liver failure and death can ensue.<sup>45</sup>

## Acute Cholecystitis

### Symptoms and Diagnosis

Acute cholecystitis is a clinical diagnosis made upon analysis of the patient history and physical examination. Patients with acute cholecystitis typically present with a history of constant, dull right upper quadrant pain and tenderness that is localized and reproducible with palpation below the right subcostal margin. Treatment based solely on radiographic findings is problematic because gallstones and slight gallbladder wall thickening are commonly seen on imaging studies, even in asymptomatic individuals. A careful patient history and physical examination are thus critically important for the proper management of any patient with suspected gallbladder pathology.

Even in cancer patients receiving therapy, the vast majority of cases of acute cholecystitis (90 to 95%) result from gallstones. Stones obstruct the cystic duct, causing gallbladder distention, edema, and inflammation, with eventual progression to venous obstruction and necrosis of the gallbladder wall. In the majority of cases, however, the stone will dislodge from the cystic duct, and the inflammation will resolve spontaneously (biliary colic).

Acute cholecystitis may also occur in the absence of stones, in which case it is called acalculous cholecystitis. The cause of this type of cholecystitis is most likely ischemia and biliary stasis, which results in exposure of the gallbladder mucosa to stagnant bile. It is possible that gallbladder sludge resulting from biliary stasis serves to obstruct the cystic duct much as the stone does in the calculous variant. Acalculous cholecystitis is most commonly seen in patients who are severely ill, such as those with sepsis, with multi-system organ failure, or receiving prolonged parenteral nutrition.

Finally, cholecystitis can be the presenting diagnosis in patients with metastatic<sup>46,47</sup> and relapsing cancers<sup>48</sup> that infiltrate the gallbladder wall, and it can be caused by cancer therapies such as HAI chemotherapy, radiofrequency ablation<sup>49</sup> and percutaneous ethanol injection of liver tumors,<sup>50</sup> and preparative chemotherapeutic regimens for BMT.<sup>51</sup>

Onset of pain after a meal is a virtually universal symptom in patients with acute cholecystitis. Nausea and vomiting can occur, and often the symptoms subside after vomiting. If symptoms do subside, the diagnosis is not cholecystitis but rather biliary colic, which is managed nonemergently. If pain progresses and persists, sometimes with radiation to the right scapula or shoulder, acute cholecystitis should be considered. Acute cholecystitis may be associated with fever and

anorexia, even in immunosuppressed patients. Jaundice is not a typical sign of acute cholecystitis unless complicated by common bile duct stones, although elevation in the bilirubin level to 2.0 to 2.5 mg/dL may occur in patients with uncomplicated acute cholecystitis. A bilirubin level higher than 3 mg/dL suggests common bile duct stones, while an elevated serum amylase level suggests pancreatitis. Pain radiating to the left side or to the back is more common with common bile duct stones than with cholecystitis alone. Mild leukocytosis (typically a leukocyte count of 12,000 to 15,000/mL) or a normal white blood cell count may be found, and mild liver function test abnormalities can occur. Some mild abdominal distention is common, and right subcostal tenderness to deep palpation is nearly universal. Occasionally, the gallbladder can be palpated.

Abdominal ultrasonography is the most sensitive (sensitivity  $\approx$  90%) and specific (specificity  $\approx$  80%) test to confirm cholecystitis when this diagnosis is suspected on the basis of clinical findings.<sup>52</sup> Typical findings on ultrasonography in patients with acute cholecystitis include gallstones, gallbladder wall thickening, pericholecystic fluid, and a ultrasonographic Murphy's sign. The gallbladder is dilated, not decompressed. Abdominal CT is much less sensitive and specific than ultrasonography and is usually not helpful in the clinical management of suspected acute cholecystitis. Functional nuclear studies such as a hepatobiliary technetium 99m-iminodiacetic acid scan can be helpful in rare circumstances, but if they are used without regard to clinical symptoms, they are generally not helpful in patient care.

### Treatment

The initial management of acute cholecystitis (Figure 3) of any cause includes bowel rest, intravenous hydration, and intravenous broad-spectrum antibiotics tailored to the flora of the gastrointestinal tract. Definitive treatment is cholecystectomy, preferably performed by the laparoscopic approach.

The timing of cholecystectomy is largely based on the overall medical condition of the patient. For patients who are medically fit, cholecystectomy should be performed at onset of pain or, in severe cases, after symptoms regress and the clinical situation permits surgery—usually during the same hospitalization. For patients receiving chemotherapy or other immunosuppressive medications and for medically unfit patients, the acute attack is managed with supportive care as outlined in the preceding paragraph and with interval cholecystectomy as appropriate. Surgery should be delayed until the white blood cell count rebounds after chemotherapy (until the absolute neutrophil count exceeds 1000/mL and is rising).

Typically, acute *calculous* cholecystitis resolves with the aforementioned regimen of bowel rest, intravenous hydration, and intravenous broad-spectrum antibiotics; cholecystectomy is performed once therapy is completed and the bone marrow and immune system have recovered. If the patient fails to improve or deteriorates on this regimen, a percutaneous cholecystostomy tube can be placed under ultrasound guidance, even at the bedside if the patient is too ill to be transported to the radiology suite.<sup>53</sup> The cholecystostomy tube effectively drains the gallbladder and leads to clinical improvement in the majority of patients. Failure to see clinical improvement suggests a gangrenous gallbladder; in such cases, laparotomy with cholecystectomy may be necessary to avoid gallbladder perforation.

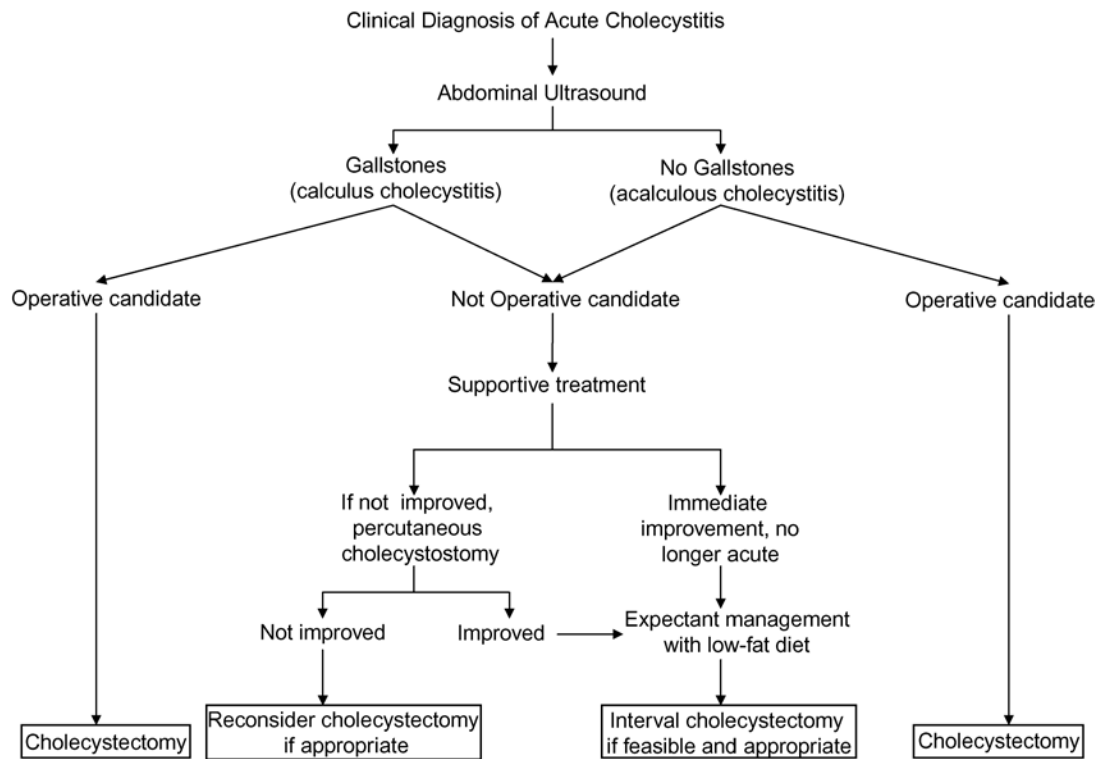

The treatment of acute *acalculous* cholecystitis is also tailored to the patient's medical condition (see Figure 3). Definitive treatment is cholecystectomy, but most patients with acalculous cholecystitis are too ill for an operation, so percutaneous cholecystostomy is the treatment of choice in most cases. The tube is left in place for at least 4 to 6 weeks to permit a mature fistula tract to form. A cholangiogram is obtained via the tube after this waiting period, and if it shows drainage into the biliary tree and duodenum, the tube is clamped and subsequently removed if the patient tolerates clamping. Elective cholecystectomy should be performed in medically fit patients with a reasonable prognosis (expected survival of more than 12 months) with respect to their cancer diagnosis.

## Cholangitis

Cholangitis is a septic process of the biliary tree due to biliary tract obstruction and consequent overgrowth of bacteria that colonize the bile from duodenal reflux or from the systemic circulation. In the general population, cholangitis is most commonly due to common bile duct stones and benign strictures; in cancer patients, malignant biliary strictures and obstructed indwelling biliary stents are the most frequent causes. Patients typically present with fever and jaundice; abdominal pain, the symptom completing Charcot's triad, occurs in only about 20% of patients. Abdominal ultrasonography is the study of choice to document biliary ductal dilatation and gallstones. In patients known to have a biliary stricture or an indwelling biliary stent, one can proceed directly to ERCP, as it is both diagnostic and therapeutic.

The initial management of cholangitis includes aggressive fluid resuscitation and broad-spectrum intravenous antibiotics tailored to the likely gram-negative and anaerobic biliary pathogens. Definitive management requires adequate biliary drainage, and endoscopic drainage has been shown to be superior to emergent surgical

**FIGURE 3** Algorithm for the diagnosis and management of acute cholecystitis.

drainage in terms of morbidity and mortality.<sup>54</sup> If common bile duct stones are present, they are cleared and a sphincterotomy is performed. Strictures are biopsied with brushings if a tissue diagnosis has not been established, and a stent is placed. Obstructed biliary stents are simply exchanged or removed. If endoscopic drainage is not available or technically feasible, the interventional radiologist can place a percutaneous transhepatic biliary drain. After the acute episode of cholangitis has resolved, efforts can be made to treat the underlying problem (eg, surgical resection of a biliary stricture).

### Ascites

Ascites in cancer patients is most commonly a finding of end-stage disease secondary to peritoneal carcinomatosis. In this condition, metastatic tumor cells lining the peritoneum exude proteinaceous fluid. This form of ascites, referred to as malignant ascites, is seen most commonly in patients with breast, colon, gastric, and pancreatic cancers. Patients with ovarian and appendiceal malignancies often present with ascites as the first symptom of their disease. Ascites can also be caused by replacement of the liver parenchyma or compression of the portal vein by massive liver metastases, resulting in portal hypertension. Extrahepatic portal, superior mesenteric, and splenic vein obstruction can occur with pancreatic tumors, leading to portal hypertension and ascites. Of course, benign forms of ascites are seen in cancer patients as well, the most common of

which is ascites due to portal hypertension in patients with cirrhosis or, rarely, after treatment for portal vein obstruction.

The diagnosis of ascites is suggested by the characteristic symptoms of weight gain and increased abdominal girth and is confirmed by abdominal ultrasonography or CT. Paracentesis is used to obtain ascitic fluid for a cell count, albumin level measurement, gram stain and culture, and cytologic analysis as indicated. If the ascitic fluid appears milky, chyloform ascites is suggested, and triglyceride levels should be measured as well. Serum albumin should be measured at the same time to establish the serum-ascites albumin gradient (SAAG), which directly correlates with the portal pressure. The gradient is calculated by subtracting the albumin level of the ascites fluid from the albumin level of the serum. A SAAG  $\geq 1.1$  gm/dL (high SAAG) is diagnostic of portal hypertension; the most common causes include cirrhosis, Budd-Chiari syndrome, and cardiac ascites. A SAAG  $< 1.1$  gm/dL (low SAAG) indicates a high concentration of protein in the ascitic fluid, as in peritoneal carcinomatosis.

The treatment of high-SAAG ascites includes diuretics and salt restriction; symptomatic patients with ascites refractory to diuretics may benefit from large-volume paracentesis. The treatment of low-SAAG ascites centers on treatment of the underlying cause. Peritoneal carcinomatosis secondary to the most common malignancies (ie, those of the breast, colon, pancreas, and lung) portends a dismal prognosis,

and so treatment is essentially palliative. Patients with carcinomatosis due to ovarian and appendiceal cancers may be candidates for aggressive surgical debulking and intraperitoneal chemotherapy and enjoy long-term survival. Peritoneo-venous shunting is contraindicated in virtually all cases of malignant ascites because the shunt would lead to continuous circulation of cancer cells from the peritoneum throughout the vascular system.

## Pancreatic Disorders

### Acute Pancreatitis

Acute pancreatitis is a complex disorder of the exocrine pancreas characterized by acinar cell injury and local and systemic inflammatory responses. In the vast majority of patients, acute pancreatitis is mild and self-limited, characterized by gland edema and perhaps a small peripancreatic fluid collection or phlegmon. This is referred to as simple, uncomplicated acute pancreatitis. In approximately 10% of patients, however, the disease is far more virulent and life-threatening and leads to complications, including pseudocysts, abscesses, ascites, and pancreatic necrosis. These patients may suffer significant physiologic derangements secondary to the inflammatory response, leading to sepsis, multi-system organ failure, and death.

The diagnosis of acute pancreatitis must be considered in patients with abdominal pain, especially pain in the epigastrium radiating to the back and associated with nausea and vomiting. The diagnosis is usually confirmed by elevated serum amylase and lipase values; occasionally only hyperamylasuria is found. Abdominal ultrasonography is the only radiologic imaging study necessary in the initial evaluation of a patient with mild acute pancreatitis. This study confirms or excludes gallstones or a retained common bile duct stone after previous cholecystectomy as the cause of the pancreatitis; abdominal ultrasonography is not obtained to study the pancreas, which is typically obscured by overlying bowel gas. The role of abdominal CT in the diagnosis and management of acute uncomplicated pancreatitis is limited (details below).

Even in patients receiving cancer treatment, the most common causes of acute pancreatitis—namely gallstones and alcohol abuse—must be ruled out prior to considering the diagnosis of drug-related (chemotherapy-related) pancreatitis. Abdominal ultrasonography can establish gallstones as the cause, and the patient history can establish alcohol abuse as a potential etiology. Acute pancreatitis also has innumerable other causes which will not be listed here. Rather, we will focus on the causes pertinent to the cancer patient (Table 3).

Acute, uncomplicated pancreatitis has been reported to occur as a complication of a number

of different chemotherapeutic agents, including ifosfamide,<sup>55,56</sup> vinblastine,<sup>57</sup> L-asparaginase,<sup>58</sup> cisplatin,<sup>59</sup> capecitabine,<sup>60</sup> and paclitaxel (Table 4).<sup>61</sup> Attempts to administer the same chemotherapeutic agent(s) at a later time, even at a reduced dose, may result in a new episode of pancreatitis, necessitating a different antineoplastic regimen.<sup>55</sup> In addition, acute pancreatitis has been reported in 28% of BMT recipients at autopsy, although many of these cases were subclinical.<sup>62</sup> Although GVHD has been identified as a risk factor for the development of pancreatitis in BMT recipients, these patients also have a high incidence of other risk factors, including cytotoxic chemotherapy as part of the preparative regimen, prolonged treatment of GVHD with steroids and cyclosporine, and biliary sludge secondary to biliary stasis after BMT.<sup>62</sup>

In cancer patients, acute pancreatitis may result from ductal obstruction secondary to

metastatic disease that has spread to regional lymph nodes or to the pancreas itself. Such metastases have been described in patients with breast, renal, lung, and prostate cancer.<sup>63-65</sup> In addition, pancreatitis can be the presenting manifestation of lymphoma<sup>66,67</sup> or arise secondary to diffuse pancreatic invasion of adult T-cell leukemia cells.<sup>68</sup> Acute pancreatitis has also been reported as a complication in patients receiving HAI chemotherapy<sup>69</sup> and intraperitoneal chemotherapy at the time of cytoreductive surgery for peritoneal malignancies.<sup>70</sup>

The cornerstone of treatment is supportive care, including bowel rest and intravenous hydration. Although antibiotics have not been shown to prevent infectious complications in immunocompetent patients with mild pancreatitis,<sup>71</sup> immunocompromised patients undergoing chemotherapy (especially patients who are neutropenic) should be treated with broad-spectrum antibiotics.<sup>72</sup> Antibiotics are also indicated in patients with complicated pancreatitis. If there is no clinical improvement after several days of supportive care or if there is clinical deterioration at any point during treatment, a contrast-enhanced abdominal CT scan should be obtained to rule out complicated pancreatitis. CT is not required in cases of uncomplicated pancreatitis because it does not predict the course of the disease; rather, CT is used selectively to guide the treatment of patients whose episode of pancreatitis is severe or complicated (below) or whose symptoms persist after several days of conservative treatment.

Complications of acute pancreatitis include pseudocyst, abscess, pancreatic ascites and/or effusion, fistula, and necrosis. These conditions may carry a much worse prognosis than simple, uncomplicated pancreatitis, so treatment should be tailored to each patient on the basis of the stage of disease and the cancer-related prognosis. Appropriate management of these problems requires close interaction between referring oncologists, gastroenterologists, interventional radiologists, and, occasionally, surgeons.

For cancer patients with gallstone pancreatitis, treatment is based on the severity of the pancreatitis and the health status of the patient with respect to the cancer diagnosis. Mild gallstone pancreatitis is generally a self-limited disease, and patients should be treated with supportive care as outlined above. With clinical improvement, a low-fat diet is instituted, and elective laparoscopic cholecystectomy is planned for when cell counts recover after chemotherapy. ERCP is not indicated for the routine treatment of mild gallstone pancreatitis and, in fact, is associated with increased costs and length of hospital stay in this setting.<sup>73</sup>

Severe gallstone pancreatitis can be life-threatening and demands skilled surgical and critical care. For patients who fail to improve

with supportive measures over the first 24 hours or who have evidence of acute cholangitis, urgent ERCP is indicated to clear the biliary tree of all calculi and to perform a sphincterotomy. Aggressive supportive measures are instituted, including adequate fluid resuscitation to replace the at times massive third-space losses due to the retroperitoneal inflammation. Broad-spectrum antibiotics are instituted in most patients, particularly those immunocompromised because of chemotherapy. If clinical improvement is not seen fairly soon after successful ERCP and sphincterotomy, a contrast-enhanced CT scan of the abdomen should be obtained to rule out complications of pancreatitis, especially necrosis. Once the patient has completely recovered from severe pancreatitis, elective cholecystectomy should be performed. The timing of surgery depends on the status of the patient's cancer treatment and prognosis, but it is recommended that cholecystectomy be performed during the same hospitalization. Too long a delay may result in recurrent bouts of gallstone pancreatitis. For patients with a cancer-related predicted survival of only weeks or months, particularly patients with intra-abdominal carcinomatosis/sarcomatosis and ascites, cholecystectomy is not indicated.

### Pancreatic Exocrine Insufficiency

Exocrine insufficiency of the pancreas refers to impaired secretion of pancreatic enzymes via the pancreatic duct and consequent malabsorption of nutrients by the small intestine. This disorder manifests clinically as steatorrhea, increased stool frequency, crampy gas pains with meals, and weight loss. Pancreatic exocrine insufficiency is more common in diabetic patients, particularly those who are obese,<sup>74</sup> but the reason for the increased incidence in this population has yet to be elucidated. New-onset diabetes mellitus, especially in male smokers over the age of 70, should prompt consideration of pancreatic cancer. The mechanism by which pancreatic cancer can cause such findings is believed to be ductal obstruction by the pancreatic mass with distal gland atrophy. If data from the history and physical examination support a diagnosis of pancreatic cancer, a diagnostic work-up, including contrast-enhanced CT of the abdomen before endoscopy, should be considered.

There are no specific reports of pancreatic exocrine dysfunction secondary to chemotherapeutic agents. However, in patients who undergo hematopoietic stem cell transplantation, pancreatic exocrine insufficiency related to the preparative regimen can develop at any time after transplantation, though typically the condition develops within the first few years.<sup>75</sup> In addition, pancreatic exocrine insufficiency has been described in patients who develop either acute or chronic GVHD after allogeneic BMT.<sup>76</sup> Finally,

**Table 4** Chemotherapeutic Agents Known to Cause Pancreatitis

<i>As Single Agents</i>	<i>As Combination Therapy</i>
Azathioprine <sup>90,91</sup>	Methotrexate <sup>92</sup>
6-mercaptopurine <sup>93</sup>	Cyclophosphamide <sup>94</sup>
L-asparaginase <sup>58</sup>	Mitomycin-C <sup>95</sup>
Ifosfamide <sup>55,56</sup>	Vinblastine <sup>96,97</sup>
Prednisone <sup>98</sup>	5-fluorouracil <sup>92</sup>
Cytarabine <sup>99</sup>	Vincristine <sup>92</sup>
Capecitabine <sup>60</sup>	Cisplatin <sup>95,100</sup>
Paclitaxel <sup>61</sup>	Bleomycin <sup>101</sup>
	Thalidomide <sup>102</sup>

short-term exocrine insufficiency is common after a pancreaticoduodenectomy or other major pancreatectomy, and long-term insufficiency may be present in as many as 40% of these patients.<sup>77</sup> In our patients who have undergone pancreatectomy, we routinely provide enzyme supplementation and follow patients closely in the clinic for signs and symptoms of persistent malabsorption.

The diagnosis of pancreatic exocrine insufficiency is typically made on clinical grounds, with the classic symptoms described above, and treatment can be initiated on this basis. A response to therapy can be regarded as confirmation of the diagnosis, although biochemical tests, including serum pancreatic enzyme and pancreatic elastase II levels, and fecal fat measurements, can be performed when the diagnosis is in doubt.

Treatment consists of three equally important measures: (1) dietary manipulation to achieve a reduction in fat intake to 25 to 30% of normal; (2) pancreatic enzyme supplementation, with supplements taken throughout the meal and in sufficient quantity to eliminate steatorrhea; and (3) adequate acid suppression with a proton-pump inhibitor or H<sub>2</sub>-receptor antagonist to raise the intestinal pH to permit effective pancreatic enzyme activity and thus fat absorption.<sup>78</sup>

### Pancreatic Endocrine Insufficiency

As mentioned above, in patients who develop new-onset diabetes mellitus, especially in association with pancreatic exocrine insufficiency, one must consider a diagnosis of pancreatic cancer. In fact, diabetes mellitus has been implicated as a predisposing factor in the development of pancreatic cancer.<sup>79,80</sup> In addition, diabetes mellitus develops during the course of chemotherapy in a significant percentage of patients—particularly those receiving corticosteroids in combination therapy regimens for the prevention of transplant rejection, for GVHD, and for the prevention of nausea and vomiting. (Please see Chapter 24, “Management of Diabetes Mellitus,” for further detail about the management of diabetes mellitus in cancer patients.)

### Summary

Disorders of the liver, biliary tree, and pancreas are common in cancer patients at presentation, during anticancer therapy, and long after curative treatment. Although cancer patients can develop biliary and pancreatic disorders unique to their cancer diagnosis and treatment, the most common causes of these disorders in cancer patients are the causes in non-cancer patients. However, perspective on the prognosis of the underlying cancer diagnosis guides not only treatment but also clinical decision-making regarding the appropriate use of interventional diagnostic modalities. Just as for decision-making regarding cancer therapy,

diagnostic and therapeutic decision-making for non-oncologic issues in complex cancer patients is optimal when oncologists and other specialists work together in a multidisciplinary setting.

# Disorders of the Digestive Tract and Nutrition: Intestinal Issues

John R. Stroehlein, MD

Gastrointestinal difficulties occur in most cancer patients. These problems are responsible for impairing quality of life and interfering with therapy. This chapter addresses important gastrointestinal issues in the cancer patient and focuses on evaluation and management of these problems.

## Short Bowel Syndrome

One of the most severe and potentially catastrophic forms of malabsorption results from shortening of the absorptive surface of the small bowel owing to resection or bypass, which may be necessary in the management of intra-abdominal malignancies. In this context, intravenous and enteral nutritional support, diet modification with supplementation, and pharmacotherapy are critical to lessen the multiple consequences of short bowel syndrome (SBS). The provision of medications can also be a challenge for the clinician. Whenever possible, oral administration should be provided, recognizing that absorption needs to be monitored and that problems with absorption have been described.<sup>1</sup> Knowing the site of absorption and intraluminal requirements for absorption of specific medications is clinically very useful in planning the use of orally administered medications in the SBS patient. Fortunately, many, if not most, medications are absorbed from the proximal jejunum, which is often preserved in the SBS.<sup>2</sup>

Although SBS occurs when less than 200 cm of the small bowel remains, the severity of symptoms and the type of complications related to SBS are dependent on the extent and anatomic segment of small bowel resected or bypassed. The most critical portions of the small bowel to preserve include the terminal ileum and ileocecal valve, duodenum, and proximal jejunum. As a result of specialized functions, loss of the duodenum and/or ileum impairs critical components of absorption much more than other portions of the small bowel. Preservation of the colon also helps limit the severity of diarrhea and allows the colon to serve as a digestive organ for short-chain

fatty acids (SCFAs) in patients with SBS.<sup>3</sup> If the colon is preserved, carbohydrate malabsorption is of limited significance because up to 80% of calories can be absorbed as SCFAs after bacterial conversion from carbohydrates in the colon.<sup>4</sup>

An acute phase, an adaptive phase, and a maintenance phase of management have been described for patients with SBS.<sup>5</sup> During the acute phase, intravenous fluids and total parenteral nutrition (TPN) are required; however, oral or enteral intake of gradually increasing quantity, administered in small feedings or by continuous infusion, can usually be started on the fourth or fifth postoperative day and advanced to small frequent feedings of a high-fat, carbohydrate-supplemented diet to which a small amount of medium-chain triglycerides can be added.<sup>5</sup>

It has been known for many years that adaptation of the remaining small bowel resulting from hyperplasia and lengthening of the villi can help compensate for an otherwise decreased absorptive surface.<sup>6-8</sup> Adaptive processes mainly involve increasing the number of cells and cell surface since enterocytes do not improve their individual absorptive function, except for facilitated absorption of sodium and calcium.<sup>9,10</sup> It has been proposed that the release of glucagon-like peptides, peptide YY, and/or neurotensin from the ileum in response to luminal nutrients represents some of the trophic effects on the remaining small intestine.<sup>11,12</sup> The global clinical relevance of these observations is uncertain, as is the role of glutamine, which is a major source of energy for the enterocyte. Randomized studies have failed to demonstrate a positive adaptive effect of glutamine and a negative clinical effect when administered with growth hormone.<sup>13,14</sup> Although the basis of the hyperplastic adaptive response is incompletely understood, a trophic adaptive response is clearly linked to luminal contact with nutrients.<sup>15,16</sup>

Given that most patients with SBS will malabsorb approximately 30% of ingested nutrients, to achieve target absorption of 30 to 40 kcal/kg/d (ideal body weight), about 45 to 60 kcal/kg/d will need to be ingested.<sup>5</sup> Even if inadequate for energy

needs, oral or enteral feedings should be started as soon as possible to take advantage of adaptive changes. The value of modified enteral formulations designed to promote immunomodulation and decrease the propensity for bacterial translocation (considered to be an important source on sepsis in the critically ill patient) remains controversial.<sup>17</sup> Recent studies have demonstrated, for the first time, that high-fat enteral nutritional infusion increases plasma triacylglycerol and apolipoprotein B levels and decreases endotoxemia and bacterial translocation after hemorrhagic shock in the rat.<sup>18</sup>

Besides the development of nutritional deficiencies, patients with SBS frequently experience severe watery diarrhea and electrolyte losses, which can be modulated in several ways. These include treatment with histamine<sub>2</sub> (H<sub>2</sub>) or proton pump inhibitors, considered to have an effect similar to that of intravenous cimetidine, which was initially shown to significantly reduce diarrhea.<sup>19</sup> Although individuals with less than 100 cm of jejunum secrete more sodium and water than consumed orally, the use of glucose-polymer-based oral rehydration solutions (ORSs), which are commercially available or can be easily modified with additional sodium to achieve optimal concentration of at least 70 mmol/L, can substantially increase absorption of fluid and electrolytes if the proximal jejunum has been preserved.<sup>2</sup> To take advantage of this process, patients with SBS should not rely on water for thirst but be provided with an ORS, which can provide considerable benefit, which has been too frequently overlooked.<sup>20</sup>

Other practical aspects of dietary and pharmacotherapy of diarrhea in SBS include the use of antidiarrheal medications to decrease the volume and frequency of evacuation and urgency.<sup>21,22</sup> Octreotide is known to decrease intestinal secretions, prolong transit time, and improve quality of life in some patients with SBS; however, treatment is expensive and results in pancreatic insufficiency and increased incidence of gallstones.<sup>23,24</sup> In animal models, octreotide has been reported to impair postresection intestinal adaptation.

Effective pharmacotherapy also includes (1) treatment of bacterial overgrowth to lessen the adverse effect of intraluminal bacteria on bile acid concentration in the small bowel and competitors for nutrients; (2) use of pancreatic enzyme supplements to compensate for impaired synchrony of digestion; (3) calcium supplementation to compensate for malabsorption and decrease hyperoxaluria and nephrolithiasis; (4) supplementation with fat-soluble vitamins and trace minerals; and (5) correcting magnesium deficiency, which usually needs to be accomplished parenterally; however, magnesium gluconate added to a rice-based commercial oral rehydration formula has been shown to enhance magnesium absorption equivalent to bolus dosages.<sup>25</sup> Iron supplementation is usually needed in the setting of duodenal and/or gastric resection. Tables 1 and 2 summarize macro- and micronutrient recommendations, and Table 3 summarizes the pharmacotherapy for SBS.

Optimal administration of enteral nutrients may require continuous infusion via a nasogastric tube, which can be placed by the patient for overnight infusion of nutrients, or via

**Table 2 Vitamin Therapy for Short Bowel Syndrome\***

<i>Intervention</i>	<i>Basis</i>	<i>Comments</i>
Vitamin B <sub>12</sub> (1,000 µg/mo)	Essential vitamin	Requires parenteral or intranasal route if ileal or gastric resection
Vitamin D (1,600 U/d)	Interruption of enterohepatic circulation contributes to deficiencies	Greater importance with ileal resection
Vitamin K (10 mg/wk)	Prevents deficiency if colon not preserved or antibiotic therapy needed	Uncommon in absence of jaundice and if colon is intact
Vitamin E (30 IU/d)	Deficiencies can cause hemolysis and neuromuscular disorders	Serum levels unreliable unless calculated as ratio to total serum lipid
Vitamin A (10,000–50,000 U/d)	Prevents ocular complications including visual loss and corneal ulceration	Use lower dose in presence of liver disease
Vitamin C (200–500 mg/d)	As precautionary measure	Deficiencies uncommon
Folic acid (1 mg/d)	Prevents anemia	More likely if proximal jejunum resected
Other water-soluble vitamins (minimum daily MDR)	As precaution to prevent deficiencies	Deficiencies uncommon Thiamine and biotin deficiency described

Adapted from Buchman AL et al.<sup>2</sup>

**Table 1 Diet and Supplement Therapy of Short Bowel Syndrome**

<i>Intervention</i>	<i>Basis</i>	<i>Comments</i>
Medium-chain triglycerides (if colon is present)	Micellar solubilization not required Can be absorbed from the colon Provide additional source of energy	May cause nausea vomiting or ketosis in high dosages
Carbohydrate (complex) (30–35 kcal/kg/d)	Usually well tolerated and may be converted to SCFAs and absorbed from the colon if present	Proximal jejunum where disaccharidases located usually preserved in SBS
High Fat diet (20–30% calories)	Increases available energy	Acceptable to have steatorrhea increased
Protein (intact) (1–1.5 g/kg/d)	Provides adequate nitrogen	Nitrogen absorption is least affected macronutrient by decreased absorptive surface
Soluble fiber (oats, psyllium, barley, some fruits and vegetables)	Conversion to SCFA energy source if colon is intact	Associated gaseousness and malodor of SCFA
Calcium (800–1,200 mg/d)	As calcium supplement Reduces oxalate absorption Compensates for intraluminal binding by fatty acids	As calcium carbonate Increased fat and ileal excreta described
Selenium (60–100 µg daily)	Compensates for increased loss in SBS	Serum levels are reliable
Zinc sulfate (220–400 mg/d for deficiencies)	Deficiencies reported to cause growth abnormalities, delayed wound healing, and immune dysfunction	Use parenteral if needed Blood levels helpful but may be unreliable
Low-oxalate diet (40–50 mg/d)	Helps prevent nephrolithiasis	Completely avoid draft beer, juice with berries, cocoa, tea, lemonade or limeade, and tomato juice

Adapted from Buchman AL et al.<sup>2</sup>

SBS = short bowel syndrome; SCFA = short-chain fatty acid.

gastrostomy or enterostomy. Although continuous infusion of nutrients may lessen the symptoms of diarrhea, it is considered routine if using gastrostomy to initiate feedings with 100 cc full-strength bolus feeding followed by 50 cc water flush and advanced by 50 cc every 4 hours if there is no significant gastric residual.<sup>26</sup> After maximum volume is reached, the interval can be reduced to every 2 hours over a 12-hour interval. Tube feedings can be further fortified by the addition of safflower oil or polycose or switching to a higher-caloric density product.

When initiating intravenous nutritional support (TPN), 25 to 30 kcal/kg ideal body weight using standard formulas is recommended for normally nourished patients. Although most patients initially require TPN, many are able to be weaned and eventually rely exclusively on oral intake following adaptation. If maintenance TPN is required, it is important, for clinical reasons and factors related to reimbursement, to consider if (1) the condition is expected to persist for at least 90 days, (2) objective evidence supports the presence of gut dysfunction, and (3) attempts were made to improve nutritional status by enteral feedings, diet modification, and/or drug therapy, which are described above. Most patients who have at least 80 cm of remaining small bowel, including the ileocecal valve, and who have not had colonic resection can, after 6 to 12 months of adaptation, be maintained on oral nutrition alone. When maintenance intravenous nutritional support is necessary, enteral nutrition

Table 3 Pharmacotherapy of Short Bowel Syndrome

Intervention	Basis	Comments
Loperamide (4–16 mg/d)	Slow intestinal transit	No systemic side effects
Codeine (30 mg bid)	Slow intestinal transit	May have systemic effect Response less predictable
Pancreatic enzymes (25,000–40,000 U/meal)	Ensure adequate intraluminal enzyme concentrations	Almost always useful because of asynchrony
H <sub>2</sub> or PPI (equivalent to ranitidine 300 mg bid or omeprazole 40 mg/d)	Reduces gastric hypersecretion	Initiate in acute phase using parenteral or sublingual formulation; continue at least 6 mo
Cholestyramine (4–16 g/d)	Decreases bile acid–induced diarrhea	May worsen steatorrhea Not advised if extended ileal resection May impair vitamin absorption
Antibiotics (oral for 7 d) (doxycycline 100 mg bid, metronidazole 250 mg tid, or cefalosporin 250 mg qid)	Treat bacterial overgrowth	Overgrowth predictable with ileocecal resection Retreatment usually needed every 6 wk
Octreotide (75 µg SC tid or 25 mg depo monthly)	Decreases secretions and prolongs intestinal transit	Expensive and concurrently decreases pancreatic secretions, may impair intestinal adaptation, and increases risk of cholelithiasis

bid = twice daily; H<sub>2</sub> = histamine; PPI = proton pump inhibitor; qid = four times daily; tid = three times daily;  
SC = subcutaneously.

by epithelial cells, as in the case of sprue; or (3) defective transport, which can occur with lymphatic obstruction. Many of these processes are interrelated as exemplified by decreased exocrine secretion resulting from decreased hormonal release in the presence of intestinal mucosal disease or the effect of bacterial overgrowth, which can decrease intraluminal bile acid concentration below a critical level needed for micellar solubilization of fats and also compete for nutrients, such as vitamin B<sub>12</sub>.

Although the symptoms or signs of malabsorption often include diarrhea, weight loss, or the presence of bulky, foul-smelling stools, these more classic features are not essential for the diagnosis of malabsorption, which, as indicated, may be limited to a specific nutrient(s). As a general rule, when nutrient deficiencies, such as deficiency related to folate, iron, vitamin K, carotene, or vitamin D, are present, the pathophysiology usually involves the small bowel, whereas malabsorption owing to pancreatic exocrine insufficiency is more often characterized by greater amounts of steatorrhea without coexisting nutritional deficiency(s). The approach to malabsorption is highly dependent on the clinical setting, which often determines the presence of specific deficiencies. It is likewise clinically relevant that vitamin and macronutrient deficiencies take time to develop and acute or transient malabsorption is of limited clinical significance. It is likewise impossible in this section to cover all aspects of malabsorption. Therefore, those aspects considered to be more common in cancer patients are addressed.

One of the most predictable forms of maldigestion or malabsorption in cancer patients is the presence of pancreatic exocrine insufficiency in patients with cancer of the pancreas or following pancreaticoduodenectomy. The impact of impeded flow of pancreatic juice owing to mechanical obstruction is greatest when the head of the pancreas is involved. Weight loss in these patients can be temporarily prevented with enzyme supplements.<sup>29</sup> During long-term follow-up after pancreaticoduodenectomy, a predictable set of micronutrient deficiencies, including vitamins A, D, and E, selenium, zinc, and iron, have been reported and observed to be compounded by insufficient dietary intake.<sup>30</sup> The implications are obvious and include aggressive enzyme replacement, diet modification, and vitamin supplementation, with enzyme replacement being the most important.

Lactase deficiency and lactose intolerance are clinically benign but very common forms of malabsorption. Although often genetically determined, lactase deficiency determined by breath hydrogen has been reported in approximately 30% of individuals undergoing chemotherapy.<sup>31–33</sup> The development of lactose

should be concurrently provided to take advantage of the remaining small bowel and adaptive processes and to avoid cholestatic liver disease, which may be associated with chronic TPN. Transition from continuous to cycled TPN must be gradual to accommodate pancreatic insulin secretion in response to concentrated glucose load. Infusion of total TPN volume should be compressed by increments of 2 to 4 hours daily along with a 30- to 60-minute taper at the beginning and end of the infusion cycle until the total infusion period is 10 hours, which will be tolerated by most individuals in the absence of cardiac or renal disease.<sup>2</sup>

A variety of surgical procedures designed to slow intestinal transit have been selectively performed, with very little success.<sup>2</sup> Small bowel transplantation, which is rarely applicable to cancer patients, is usually performed in conjunction with liver transplantation and should be highly selective since it is associated with a 45% 5-year survival rate when performed alone and only 37% when performed as combined liver and small bowel transplantation.<sup>2</sup> The use of tissue-engineered small intestine (TESI) is an intriguing new development that has now been tested in a rat animal model. The making of TESI by the transplantation of organoid units derived from neonatal tissue containing a mesenchymal core surrounded by polarized intestinal epithelium on a biodegradable polymer scaffold was first reported in 1997.<sup>27</sup> Following improvement of the protocol to yield more organoid units in

shorter time, these investigators have provided the first report of a tissue-engineered vital organ functioning as salvage therapy in a replacement model.<sup>28</sup> The results included the observation that the TESI contained intact epithelial, muscular, vascular, and neural components and that having an attached segment of TESI reduced the overall period of weight loss from 14.6 to 7.7 days, maintained and regained higher percentages of weight than did animals who have massive small bowel resection alone, prolonged transit time, improved vitamin B<sub>12</sub> absorption, and resulted in higher deoxyribonucleic acid (DNA) content of the native intestine.<sup>28</sup> The applicability of this to higher-order animals obviously remains uncertain but holds promise as a means to replace small intestine function without the morbidity and complications of other replacement techniques.

### Malabsorption

Malabsorption of nutrients, which may be limited to a single constituent, implies an interruption of normal digestion and/or absorption. This may be the result of (1) a defective intraluminal phase of digestion owing to pancreatic exocrine insufficiency, impaired solubilization of fat caused by inadequate intraluminal bile acid concentration, or inaccessibility of nutrients for uptake and absorption illustrated by pernicious anemia; (2) defective intestinal or mucosal processing resulting from brush border enzyme deficiencies, loss of mucosal surface, or impaired absorption

intolerance is not invariable, and lactose restriction is recommended only for symptomatic patients. A controversial aspect of lactose malabsorption involves the reported increased frequency of lactose malabsorption and possible galactose cytotoxicity in the pathogenesis of ovarian cancer.<sup>34</sup> The role of radiation in the development of lactose intolerance is debatable and likely related to the amount of bowel irradiated.<sup>35,36</sup> Iron deficiency occurs frequently after subtotal or extended gastric resection.<sup>37</sup> In this setting, atrophic gastritis and *Helicobacter pylori* involving the gastric stump seem to play an important role in the development of iron deficiency.<sup>37</sup> Iron deficiency is now also recognized as one of the most common manifestations of celiac disease (CD) in adults.<sup>38</sup>

Atrophic gastritis is also associated with vitamin B<sub>12</sub> malabsorption and is reported to be associated with a higher risk of noncardia gastric neoplasia in cohort studies; however, data are lacking regarding the value of surveillance endoscopy in this setting.<sup>39</sup> A study of 152 residents of Rochester, Minnesota, with well-documented pernicious anemia during a 30-year interval were followed for more than 1,550 person-years, and only one gastric carcinoma was observed compared with an identical expected incidence.<sup>40</sup> Recent observation resulting from an average 7.1-year follow-up of 21,265 patients hospitalized between 1965 and 1999 unexpectedly revealed that the incidence of squamous cell carcinoma of the esophagus is increased threefold in the setting of pernicious anemia.<sup>41</sup> Although parenteral or intranasal administration of vitamin B<sub>12</sub> is required for patients with pernicious anemia, those with food-cobalamin malabsorption may be effectively treated with crystalline cyanocobalamin 250 to 1,000 µg/d during clinical studies of 1-month duration.<sup>42</sup> In addition to more commonly recognized atrophic gastritis, ileal resection, and ileal disease, vitamin B<sub>12</sub> malabsorption may occur as a sequela to pelvic irradiation. During prospective study, it has been observed that vitamin B<sub>12</sub>, bile acids, and fat are malabsorbed as a consequence of radiation therapy.<sup>43</sup> Implications for therapy include administration of vitamin B<sub>12</sub> and treatment with cholestyramine to control bile acid catharsis provided that there are no signs of intestinal obstruction.

Vitamin K deficiency is rare since it is derived from plant sources and gut microflora. Deficiencies can occur in patients on TPN without supplementation, on long-term antibiotics, and when fat is malabsorbed. This may result in clotting disorders and disordered bone mineralization wherein vitamin K is a cofactor.<sup>44</sup> The prevalence of vitamin K deficiency with elevated prothrombin time and coagulation disorders in subclinical CD is reported to be less than 1% and does not independently require screening for CD.<sup>45</sup>

Vitamin D deficiency has historically been considered to be a condition of the elderly and related to a combination of decreased intake, diminished absorption, and reduced exposure to sunlight; however, a study of 290 hospitalized patients found that 57% were vitamin D deficient and that 37% ingested amounts exceeding the recommended dietary allowance.<sup>46</sup> One condition to always consider in this setting is CD since 28% of newly diagnosed celiac patients have osteoporosis and may present with osteoporosis in the absence of other symptoms.<sup>47</sup> CD was once considered rare, but following the development of reliable serologic tests, it is now recognized to affect 1 in 120 to 300 in North American.<sup>48</sup> CD has great relevance to cancer medicine since it is a common cause of malabsorption that may be unmasked by cancer surgery or other insults to the small bowel and carries an increased risk of gastrointestinal cancer and lymphoma. Given that most adults with CD do not present with diarrhea, nutritional deficiencies should be considered a manifestation of CD. Immunoglobulin (Ig)A anti-endomysial antibody (EMA) carries a very high sensitivity and specificity for CD, with a reported sensitivity of 85 to 98% and a specificity of 97 to 100%.<sup>38</sup> Originally recognized to react with the endomysial lining of microfibrils using monkey esophagus or cultured human umbilical vein cells, it is now recognized that tissue transglutaminase (tTG) is the antigen to which EMA reacts. Anti-tTG has become the serologic test of choice since it is less expensive, easier to perform, and more sensitive.<sup>49</sup> It is relevant that IgG tTG appears to be almost as sensitive and specific as IgA tTG and can be used in IgA deficiency, which is not uncommon in sprue. Tests for antigliadin antibodies are not preferred since they are less specific and only moderately sensitive.<sup>38</sup>

## Nausea and Vomiting

The management of nausea and vomiting in the cancer patient has been revolutionized by the development of antagonists to a 5-hydroxytryptamine (HT) neuronal mediator, 5-HT<sub>3</sub>, and an antagonist to a neurokinin (NK), NK-1 receptor. Following our understanding of the pivotal role of 5-HT in the gut and NK receptors in the central nervous system and their relationship to nausea and vomiting, the development of these antagonists has markedly reduced the incidence of chemotherapy-induced nausea and vomiting (CINV) and radiation-induced nausea and vomiting (RINV).

The gut is the only organ that can display reflexes and integrative neuronal activity when isolated from the central nervous system, and it is now known that peristaltic and secretory reflexes are initiated by afferent neurons stimulated by 5-HT. Blocking the 5-HT<sub>3</sub> receptors can attenuate

nausea and vomiting. 5-HT<sub>3</sub> not only mediates peristaltic and secretory reflexes, it also mediates signaling to the central nervous system, serotonergic transmission within the enteric nervous system, and activation of myenteric intrinsic pathways.<sup>50</sup> Meanwhile, blocking NK-1 receptors in the brain blocks the effect of this NK on substance P, the natural ligand in the central nervous system. This, in turn, helps control the development of CINV and augments the acute- and delayed-phase antiemetic effect of 5-HT<sub>3</sub> receptor antagonists.<sup>51</sup> Prior to the introduction of these newer agents, corticosteroids, adrenocorticotropic hormone, and metoclopramide were the primary mainstays to prevent or control CINV. As with all antiemetics, including the 5-HT<sub>3</sub> and NK-1 antagonists, they are more effective if given prophylactically, and it appears that a single dose given before chemotherapy is as effective as other dose schedules. Oral and intravenous formulations are equally effective, and one need give only the lowest dose needed to achieve a symptomatic effect. Five different 5-HT<sub>3</sub> receptor antagonists have now been developed and are often used in combination with steroids and NK-1 receptor antagonists in the control of CINV or the side effects of radiation therapy. CINV and RINV are covered in an earlier chapter and have been the subject of review articles and/or consensus reports.<sup>50-56</sup>

In addition to CINV, other causes of nausea and vomiting unique to cancer patients include the effects of graft-versus-host disease (GVHD) and abnormal motility that may result from a variety of retroperitoneal tumors that adversely affect gastric emptying without obstruction. Nausea and vomiting are a common occurrence when bone marrow transplantation is complicated by GVHD.<sup>57</sup> Involvement of the upper gastrointestinal tract with GVHD is being recognized more often since it was initially described in 1983.<sup>58</sup> It is characteristic for nausea and vomiting owing to GVHD (discussed in a separate chapter) to be associated with delayed gastric emptying and to respond to immunosuppressive therapy. When symptoms do not resolve, the probability of a coexisting infectious process such as cytomegalovirus or herpes simplex type 1 is more likely.<sup>57</sup>

The paraneoplastic syndrome of intestinal pseudo-obstruction has been associated with several types of malignancies, including small cell lung cancer, carcinoid, neuroblastoma, pancreatic adenocarcinoma, and retroperitoneal leiomyosarcoma.<sup>59-62</sup> Indeed, any process that causes myenteric ganglionitis may result in dysmotility and nausea and vomiting.<sup>63</sup> Although these conditions are rare, they are nonetheless important and should be considered when the cause of nausea and vomiting remains indeterminate. Gastroparesis with nausea and vomiting may also

be iatrogenic from celiac block.<sup>64</sup> Paraneoplastic syndromes and dysmotility following celiac block may respond to prokinetic medications, the effect of celiac block usually improves with time, and delayed emptying from nonobstructing retroperitoneal tumors can be palliated with prokinetic medications.<sup>65</sup>

In addition to the CINV and nausea and vomiting associated with GVHD or radiation therapy, or as a paraneoplastic syndrome, which are all unique to cancer patients, nausea and vomiting have many other causes in the cancer patient that may or may not be related to cancer. These include but are not limited to the side effects of nonchemotherapy medications, gastroduodenal or other forms of intestinal obstruction, gastrointestinal motility disorders, gastric ulceration, dumping syndrome, pancreatitis, hepatitis, renal failure, and neurologic disorders. It is unrealistic to cover all of these topics; however, some salient points help to clinically determine the cause of nausea and vomiting. For example, when nausea and vomiting are caused by obstruction, vomiting is usually delayed following a meal, worsens during the course of the day, may contain food retained from a much earlier meal, usually worsens over time, and is typically associated with early satiety. With current imaging and endoscopy, it is easy to identify the presence of an obstruction. Management is understandably determined by the cause and extent of obstruction plus the patient's general condition. Whereas benign obstructive process are usually managed surgically, the use of endoscopically placed stents, described in a separate chapter, offers effective palliative management of obstruction owing to malignancy.

Treatment of motility disorders is, on the other hand, nonsurgical. These occur in the form of poorly understood gastroparesis, which may occur as a result of diabetes, as post-vagotomy syndrome, and as other causes of enteric neuropathy, including paraneoplastic syndrome and the result of retroperitoneal tumors, described above. Whether idiopathic or caused by diabetes, gastroparesis is a challenge to manage and is further complicated by the fact that modifiers of symptomatology and the severity of symptoms may not correlate with apparent pathophysiology. Furthermore, some diabetics have episodes of nausea and vomiting, whereas others may have delayed emptying with minimal symptoms and some experience more severe persistent symptoms.

There is poor correlation between improvement in the rate of gastric emptying and symptom relief.<sup>66</sup> In this context, other causes of vomiting need to be considered before embracing a diagnosis of gastroparesis. Uncertainties notwithstanding, when nausea and vomiting occur in the diabetic patient and are without another cause, it

is quite reasonable to empirically initiate treatment with a prokinetic medication such as metoclopramide, erythromycin, or cisapride (the latter is available under special limited conditions from the manufacturer).<sup>67</sup> There is a dose-response relationship with the use of prokinetics; however, the incidence of side effects is likewise dose related and limits dosage escalation. The limited efficacy of these medications has prompted some investigators to take advantage of the role of pylorospasm, observed in association with diabetic gastroparesis, by using botulinum toxin injection of the pylorus, which has met with limited success in small open-label studies.<sup>68</sup> Attempts to address the putative pathophysiology are difficult, as is correlating symptoms with our very incomplete understanding of pathophysiology of gastric motility disorders. This is exemplified by the observation that sildenafil, known to induce pyloric relaxation, a major determinant of gastric emptying, did not improve gastric emptying in a study of 12 patients with end-stage renal disease.<sup>69</sup> Failure of medical therapy may lead to consideration of surgery, which is likewise poorly defined, reported as retrospective reviews or uncontrolled series, and should be approached with caution.<sup>70</sup>

Nausea and vomiting may be encountered as part of a dumping syndrome that results from osmotic fluid shifts, release of vasoactive neurotransmitters, and reactive hypoglycemia in the cancer and noncancer patient following gastric surgery. Up to 10% of patients have clinically significant symptoms, and up to 2% experience debility.<sup>71</sup> Measures to help achieve relief of symptoms should include minimizing ingestion of simple carbohydrates, excluding liquids with meals, and providing compounds such as pectin or guar to increase intraluminal viscosity and/or to give an  $\alpha$ -glucosidase inhibitor, acarbose, to blunt the rapid absorption of glucose.<sup>72</sup> Pharmacotherapy for dumping has otherwise focused on the use of octreotide in an attempt to delay transit and decrease release of vasoactive mediators. Seven randomized controlled trials involving 63 patients with severe dumping alleviated symptoms with statistical significance.<sup>73</sup> For patients with dumping that does not respond to standard measures without pharmacotherapy, octreotide in a dosage of 50 to 100  $\mu$ g subcutaneously or as a monthly depo intramuscular injection of 25 mg should be considered.

### Constipation

Constipation, generally defined as decreased frequency of evacuation, abnormally hard stools, or the need to strain to complete bowel evacuation, is a very common problem that occurs in one-quarter to half of patients age 65 years and older.<sup>74</sup> It is even more common in the cancer patient population and may result from prolonged

colonic transit, an abnormally firm consistency of stool, or an obstructive process. Although often multifactorial, determining the factors contributing to constipation is pivotal to selecting appropriate therapy. To prevent unnecessary suffering, a proactive approach is desirable in the management and prevention of constipation. The potential for proactive intervention has been demonstrated in hospitalized immobile vascular surgery patients in whom a protocol of dietary fiber, increased fluid, and hygiene measure over a 3-year period reduced the incidence of constipation from 59 to 9% and eliminated impaction.<sup>75</sup>

The clinical history is most important particularly as it pertains to (1) understanding the precise nature of the complaint, which may indicate an anorectal cause; (2) a history of constipation, which may indicate problems with gastrointestinal motility with colonic inertia or a history of laxative dependence; (3) the pattern of onset; (4) progression versus fluctuation of symptoms; (5) a history of neuromuscular and/or rheumatologic disorders; (6) relationship to medications, including over-the-counter and herbal medications; (7) the probability of an obstructive process; and (8) the presence of coexisting alarm symptoms, such as bleeding. Although the cause of constipation is often multifactorial, constipation most commonly occurs as a side effect of medications. This is not surprising when one considers the fact that 40% of patients reporting constipation defined by Rome II criteria were using medications known to cause constipation.<sup>76</sup> Of 392 patients in long-term care facilities, with a diagnosis of constipation and/or routine laxative use, over 72% had received at least one medication known to cause constipation.<sup>77</sup> The importance of constipation as an adverse drug reaction in a cancer patient population is underscored by the observation that constipation was the most common adverse drug reaction in a prospective study of 171 hospitalized oncology patients.<sup>78</sup> A list of medications commonly associated with constipation is summarized in Table 4. Although delayed transit secondary to medications is the most common

**Table 4 Medication-Induced Constipation**

Anticholinergics

Antidiarrheal agents
Antihistamines
Calcium supplements
Calcium channel blockers
Cholestyramine
Diuretics
Iron supplements
Nonsteroidal anti-inflammatory drugs
Opioid analgesics
Tricyclic antidepressants

cause of constipation, it is likewise important to be reasonably confident that metabolic or endocrinologic causes of delayed transit or an obstructive process are not responsible for constipation. Laboratory tests, including complete blood count, serum electrolytes, calcium and phosphorus, thyroid-stimulating hormone, glucose, and creatinine, help exclude the former, whereas imaging studies (which should include decubitus views when doing a plain abdominal series, thus using air in the colon as a contrast medium) and/or endoscopy help exclude the latter. Provided that obstruction and reversible metabolic causes are excluded, empiric therapy can be pursued (Table 5 and Figure 1).

Medical management of constipation consists of increased water intake, fiber supplementation, stool softeners, osmotic products, stimulant laxatives, prostaglandin analogues or colchicine, enemas, and 5-HT<sub>4</sub> receptor agonists given alone or in combination. Medical therapy for constipation needs to be individualized and should be initiated early or prophylactically to prevent, as well as control, constipation. This is particularly relevant in that constipation has been observed to produce what has been described as a “complete person-experience” that particularly affects the

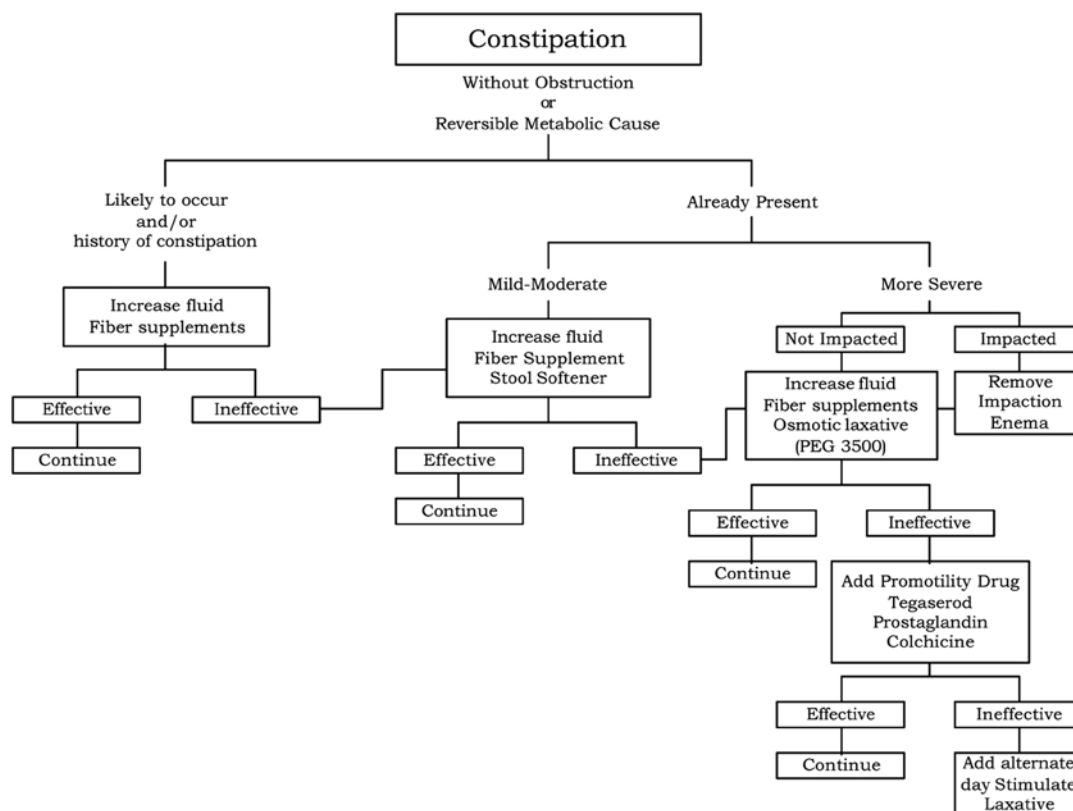

FIGURE 1 PEG = polyethylene glycol.

Table 5 Management of Constipation: Therapeutic Alternatives

Fiber and bulk laxative	
Dietary fiber	20 g daily
Methylcellulose	1 tsp or 2 caplets with 6 oz water bid
Polycarbophil	1 to 2 tablets bid
Stool softeners	
Docusate	100–200 mg daily to bid
Mineral oil	15–45 mL daily
Osmotic products	
Lactulose	15–30 mL daily to bid
Sorbitol	15–30 mL daily to bid
Polyethylene glycol	8–32 oz daily with water
Glycerin suppository	1 daily
Stimulant laxative	
Bisacodyl suppository	10–20 mg daily every 2–3 d
Senna or cascara	2–4 tablets daily to bid
Promotility agents	
Tegaserod	2–6 mg bid
Misoprostol	200 µg daily; increase to qid
Colchicine	0.6 mg tid
Magnesium products	
Magnesium citrate	200 mL daily
Magnesium hydroxide	2 g daily

bid = twice daily; qid = four times daily; tid = three times daily.

cancer patient receiving palliative therapy by causing discomfort, mental preoccupation, a reminder of death, and social isolation.<sup>79</sup> Constipation, without the complications related thereto, is of limited direct clinical importance; however, the recognition that constipation causes significant impairment of quality of life has led to the recognition that constipation is clinically a serious condition for the majority of people afflicted.<sup>80</sup>

Cancer patients are often limited in their ability to pursue lifestyle changes that are considered to lessen constipation and that include increased physical activity, improved fiber intake or eating a breakfast meal on a regular basis, and sitting on the commode for several minutes after breakfast to take advantage of the gastrocolic reflex. Although these limitations may prevail, it is important to recognize that the effective management of constipation simply includes recognizing the merits of adequate water consumption. This is intuitive; however, studies have demonstrated that water supplementation enhances the effect of a high-fiber diet and laxative consumption in individuals with functional constipation.<sup>81</sup> This applies to all causes of constipation. Concurrently, minimizing caffeinated beverages is recommended to minimize their diuretic effect.

Because the patient population under discussion is often elderly and for other reasons may also not be able to consume adequate fiber as dietary fiber, supplements in the form of methylcellulose, psyllium, or polycarbophil are

often needed. Although fiber supplements may intensify symptoms of bloating and discomfort if constipation is more severe, they are useful as proactive intervention for less severe cases or prevention of constipation. Their slow onset of action and limited effect in more severe cases limit their use as single agents. Nonetheless, their efficacy in less severe cases of constipation or the prevention of constipation is well documented.<sup>82–85</sup>

The most commonly prescribed products to offset constipation are stool softeners.<sup>86</sup> Although frequently prescribed, their empiric use has been questioned.<sup>87</sup> Their efficacy, or lack thereof, may be, in part, related to the product used in that dioctyl calcium sulfosuccinate has been reported to increase the number of spontaneous bowel movements by 62%, whereas an increase of only 30% was observed with dioctyl sodium sulfosuccinate given once or twice daily in a homogeneous group of institutionalized patients.<sup>88</sup> Acute treatment with stimulant laxatives can be useful; however, long-term use is associated with a diminished colonic motor response to such agents.<sup>89</sup> These agents are therefore not preferable for long-term treatment; however, their use two to three times a week is not considered harmful.<sup>89</sup>

Since the introduction of polyethylene glycol (PEG) 3500, it has become a preferred osmotic laxative. Studies have demonstrated its effectiveness compared with placebo and with no clinically significant changes in blood chemistry, complete blood count, or urinalysis observed in a

dosage of 17 g daily.<sup>90,91</sup> Like other osmotic products, PEG has no adverse effect on nerve and muscle cells in the colon and is better tolerated than poorly absorbed carbohydrates, such as lactulose or sorbitol, which cause more flatulence and abdominal distention.<sup>92</sup> If the desired effect is not achieved with 17 g PEG suspended in 6 oz water daily, the dosage can be safely increased to twice daily. Lactulose is preferable when using an osmotic product in the setting of hepatic encephalopathy. Sorbitol is a cost-effective alternative to lactulose in the treatment of chronic constipation.<sup>93</sup>

A novel approach in the treatment of constipation involves the use of misoprostol, a prostaglandin E<sub>1</sub> analogue, which is known to stimulate intestinal transit in healthy individuals and patients with chronic constipation. Although misoprostol is subject to causing cramping as a side effect and is not acceptable in young women who wish to become pregnant, it has a very high margin of safety and no significant drug-drug interactions. An initial short-term double-blind crossover study of nine patients with severe constipation and a subsequent long-term open-label trial of misoprostol in the treatment of chronic refractory constipation have demonstrated efficacy in the management of chronic refractory constipation.<sup>94,95</sup> To obviate cramping, starting at a dose of 200 µg every other day and gradually increasing, as tolerated, to three or four times daily has been advocated.<sup>89</sup> Colchicine is another drug known to stimulate motility in animal model studies and cause diarrhea as a side effect that has been used in a dosage of 0.6 mg orally three times daily for the treatment of chronic constipation.<sup>96,97</sup> There are no long-term studies of colchicine for chronic constipation, and its use is limited by side effects, including increased abdominal pain, during therapy.<sup>97</sup>

Although primarily investigated in the setting of constipation associated with an irritable bowel syndrome, tegaserod has been studied in two double-blind randomized placebo-controlled trials involving over 2,000 patients.<sup>98,99</sup> Response, defined by complete spontaneous evacuation, was significantly greater in patients treated with either tegaserod 2 (41%) or 6 (43%) mg twice daily compared with placebo (25%) in one study and significant improvement in subject global symptom assessment in the other randomized trial.<sup>98,99</sup> The effect of tegaserod is observed within the first week of treatment and is maintained over 12 weeks without significant side effects and the return of symptoms without rebound effect after withdrawal.

Enemas (tap water, oil retention, saline, soap suds, milk, and molasses) are often used for the acute management of constipation; however, they are not recommended in the treatment of chronic constipation. They must furthermore be used

with caution since mucosal injury, bowel penetration, proctocolitis, and life-threatening metabolic complications can occur, particularly in patients with renal insufficiency and in the pediatric population.<sup>100,101</sup> Although adverse outcomes have been described much more often with preparations other than milk and molasses, even this preparation has been reported to result in severe complications.<sup>102</sup>

Acute colonic pseudo-obstruction often prompts emergency consultation and globally falls into the category of constipation. Unlike constipation, which is clinically defined as described above, pseudo-obstruction or Ogilvie's syndrome is determined by acute onset of colonic dilatation without obstruction, as documented on radiographs. Characteristically the result of a wide variety of associated medical or surgical conditions in hospitalized patients, the diagnosis is of concern because of the risk of perforation, which has been reported in 3% of cases when the cecal diameter reaches 12 cm.<sup>103</sup> Although most cases respond to conservative management, the risk of ischemia with increasing distention has prompted the use of colonoscopy for decompression in selected cases or more often medical intervention with 2 mg neostigmine given intravenously over 3 to 5 minutes with continuous cardiac monitoring and immediate availability of atropine to treat drug-induced bradycardia. This pharmacologic approach is predicated on the premise of ineffectual colonic motility caused by excessive sympathetic stimulation.

When neoplastic obstruction is the cause of constipation, an alternative to surgery, discussed in more detail in a following chapter, includes endoluminal stenting, which offers effective palliation for malignant obstruction. Stenting may also allow time to improve a patient's condition and permit definitive surgery or minimize the need for staged procedures. Although reported studies are retrospective, they are consistent in the observations that stenting offers a shorter hospital stay and effective palliation but does not otherwise prolong survival.<sup>104,105</sup> Although the overall technical success rate is reported to be 93%, with relief of obstruction in 80 to 92% cases, not all cases are suitable for stenting. Limitations include a tortuous delivery pathway and require advancing a guidewire across the obstruction.<sup>106</sup> The presence of a 3 cm segment of uncovered wire at the ends of the stent to enhance stabilization and minimize migration limits the use of stents for distal rectal obstruction. Restenosis owing to tumor ingrowth has been reduced by the use of covered stents; however, this remains a significant problem. To minimize intraluminal obstruction from fecal residue, a low-residue diet and use of stool softeners or osmotic laxative are routinely required. Endoscopic laser therapy can be useful in acutely relieving an obstruction

and/or controlling bleeding from colorectal cancer.<sup>107</sup> Argon plasma coagulation and photodynamic therapy provide other endoscopic alternatives.<sup>108</sup> Unfortunately, ablation therapy is limited to the exophytic component of disease, whereas the process of obstruction, in the course of disease progression, usually becomes intramural or the result of extraluminal compression and limits the long-term efficacy of therapy using ablation techniques.

## Diarrhea

Diarrhea is the result of excess water in stool and is defined as increased frequency or stools of loose consistency. The conditions that lead to diarrhea are so broad that recommending restricted investigative pathways and management is unrealistic; however, this does not preclude the fact that the probable pathophysiology is dependent on the pattern of diarrhea and the clinical setting in which it occurs. Considerations include but are not limited to an acute versus a chronic history of diarrhea, coexisting gastrointestinal disease, concurrent or recent drug therapy, immunodeficiency, the persistence of diarrhea when fasting, recent surgery or altered anatomy, a history of bone marrow transplantation, previous radiation therapy, malignancies known to cause secretory diarrhea, a history of diabetes, and the presence of systemic symptoms. A complete differential diagnosis of diarrhea is beyond the scope of this section; however, salient points relevant to the cancer patient will be considered and are summarized in Tables 5 and 6.

In the care of the cancer patient, it is readily recognized that many chemotherapeutic agents and abdominal or pelvic radiation frequently cause diarrhea, which is more likely when chemotherapy and radiation are combined.<sup>109</sup> If diarrhea, in this setting, is mild to moderate, as defined by the absence of systemic symptoms, severe cramping, neutropenia, or nausea / vomiting, management consists of intravenous or oral rehydration (including repletion of electrolytes) and loperamide 4 mg orally followed by 2 mg every 4 hours after every loose bowel movement (not to exceed 16 mg daily).<sup>109</sup> Revised guidelines for more severe diarrhea induced by chemotherapy or radiation recommend the use of octreotide 100 to 150 µg subcutaneously three times daily or 25 to 50 µg intravenously/hour, which has proven more effective than conventional antidiarrheal treatment in prospective studies.<sup>109-112</sup> The presence of severe diarrhea as defined above warrants withholding chemotherapy until the diarrhea has subsided for 24 hours. Octreotide, deodorized tincture of opium, paregoric, codeine, diphenoxylate with atropine, and loperamide also represent second-tier alternatives for persistent mild to moderate diarrhea. Sucralfate, a widely

investigated agent used in an effort to prevent diarrhea, has not been shown to be effective in preventing diarrhea caused by chemotherapy or radiation.<sup>109</sup> Olsalazine, an anti-inflammatory medication used in the treatment of inflammatory bowel disease, is contraindicated during radiation therapy since it has been shown to increase diarrhea.<sup>110</sup> Chemotherapy- or radiation-induced diarrhea is usually self-limited; however, prolonged duration of radiation may cause persistent diarrhea and require the use of maintenance loperamide in a dosage up to 2 mg every 2 to 4 hours or the other second-tier medications described above. If diarrhea becomes chronic in the setting of pelvic radiation, bile acid malabsorption is a recognized pathophysiologic mechanism that has been reported in the majority of patients who experience chronic diarrhea after radiotherapy for gynecologic cancer, with bacterial overgrowth also reported in 45%.<sup>113</sup> Treatment with oral antibiotics and/or bile acid binding resins is reported to decrease the frequency of chronic diarrhea caused by radiation therapy.

In the management of all causes of diarrhea, it is important to remember that any agent that enhances fluid absorption in the intestine, regardless of the applicable mechanism, is potentially useful in counteracting diarrhea. The addition of glucose to ORSs can not only contribute significantly to the management of infectious diarrhea and SBS, as described in an earlier section of this chapter, it can also facilitate supportive care and rehydration in other cancer treatment-related diarrhea. Although the addition of glucose or free amino acids to ORSs does not necessarily inhibit a pathologic secretory process, they can facilitate the absorption of ingested electrolytes and water that otherwise would not be absorbed.<sup>114</sup> In the absence of secondary abnormalities that require diet modification, there is no need for specific dietary restrictions in the management of diarrhea.

If diarrhea is not directly the result of chemotherapy or radiation and particularly if it occurs in a hospital setting, *Clostridium difficile* diarrhea (CDAD) should be considered since this has become the most common cause of infectious diarrhea in hospitalized patients.<sup>115</sup> Although commonly associated with the use of broad-spectrum antibiotic therapy, the risk factors for CDAD or colitis also include bowel surgery, an immunocompromised state, and any process that suppresses the normal flora, including antifungal and chemotherapeutic agents. It has been documented that chemotherapy is a risk factor for the development of CDAD and augments the probability that antibiotic therapy will cause CDAD.<sup>116</sup> The diagnosis of CDAD consequently should be suspected when a patient without a primary gastrointestinal disease process develops diarrhea following treatment that can affect the normal

microflora. The confirmation of diagnosis is dependent on detection of *C. difficile* toxin in the stool or the presence of pseudomembranous colitis on endoscopy. It is important for clinicians to recognize the sensitivity and specificity of available tests and to know the limits of the tests that are used by a specific laboratory. Organism identification by culture or antigen is nonspecific since toxigenic and nontoxigenic strains are identified by these methods. Toxin A, an enterotoxin, and toxin B, a cytotoxin, may, however, be detected by tests using either latex agglutination, which actually detects glutamate dehydrogenase enzyme produced by *C. difficile*, enzyme immunoassays (EIAs) for toxins A and/or B, or tissue culture tests for toxin B. Latex agglutination and EIA are rapid and relatively inexpensive; however, the former is nonspecific and some of the EIA methods have limited sensitivity. Six commercially available rapid tests for direct detection of *C. difficile* and its toxins in fecal samples have been compared with fibroblast cytotoxicity assay.<sup>117</sup>

Mild cases of CDAD may resolve by discontinuing antibiotics, thus allowing reestablishment of colonic microflora, which is known to inhibit the growth of *C. difficile*. Metronidazole (250 mg four times daily to 500 mg three times daily for 10 to 14 days), given orally or intravenously, appears to be as effective as vancomycin (125 mg orally four times daily for 10 to 14 days) for mild to moderate cases.<sup>118,119</sup> Although debatable as first-line therapy, vancomycin given orally or by enema is the preferred treatment for more severe cases. The standard dose of vancomycin is 125 mg orally four times daily and appears to be comparable in efficacy to 500 mg orally four times daily.<sup>119</sup> Bacitracin given orally is a therapeutic alternative, and cholestyramine is a useful adjunct that may be used alone for mild cases.<sup>115,119,121</sup> The majority of patients with diarrhea or colitis caused by *C. difficile* respond to initial therapy; however, up to 20% experience relapse when treatment is discontinued and require repeat or prolonged therapy.<sup>122,123</sup> Since environmental contamination by *C. difficile* is common and may be carried by health care personnel, this illustrates yet another importance on hand washing to reduce the spread of nosocomial infection and is pivotal for optimal care of all cancer patients. Noninfectious nosocomial causes of diarrhea more commonly include the direct effect of medications or the ingestion of dietary products or medications that contain sorbitol or mannitol.

Other infectious causes of diarrhea cannot be discounted in the cancer patient but are more likely to occur in the setting of neutropenia, immunodeficiency related to human immunodeficiency virus (HIV), or bone marrow transplantation.<sup>124,125</sup> Although non-*C. difficile* infection is more common in association with

immunodeficiency, CDAD has been reported in 7% of all cycles of myelosuppressive chemotherapy on a retrospective review of almost 900 courses of treatment.<sup>126</sup> Diarrhea in the setting of neutropenia warrants broad-spectrum antibiotic therapy that includes metronidazole. Neither fecal leukocytes nor occult blood is predictive of the presence of CDAD.<sup>127</sup>

In the setting of acquired immune deficiency syndrome (AIDS), a potential infectious cause has been reported in at least one-third of cases of chronic, unexplained diarrhea.<sup>128</sup> The likelihood of an infectious process and the enhanced diagnostic yield of colonoscopy over sigmoidoscopy are greater when the CD4 count is below 100 cells/mm<sup>3</sup>.<sup>128</sup> Issues related to GVHD in bone marrow transplant patients are covered in a separate chapter. The management of secretory diarrhea caused by neuroendocrine tumors has been greatly enhanced with somatostatin, which has become the standard of care and has been summarized in review articles on this topic.<sup>129-131</sup> In the case of secretory diarrhea, fecal electrolytes account for most of the osmolality, whereas osmotic diarrhea is characterized by an osmotic gap that exceeds 50 to 100 mOsm/kg.<sup>132</sup> Taking a careful medication history, including the use of over-the-counter and alternative medications, determining if diarrhea persists during fasting, considering the common causes of nosocomial diarrhea, establishing risk factors for the probability of infectious diarrhea, performing stool examinations when symptoms are severe and/or pus and blood are present, doing diagnostic sigmoidoscopy when symptoms are persistent and colonoscopy if diarrhea is indeterminate in a patient with immune deficiency, establishing if malabsorption is present, and providing fluid and electrolyte repletion and symptomatic treatment for diarrhea will collectively facilitate management of this common problem..

## Summary

In summary, recognition of important principles in the management of common gastrointestinal disorders can greatly facilitate care of the cancer patient. Some of these principles include (1) recognizing the value of supportive care and importance of enteral feedings in patients with SBS; (2) understanding the potential for malabsorption of specific nutrients and the probability of small bowel pathology when nutritional deficiencies are encountered; (3) providing exocrine pancreatic enzyme supplements in the presence of pancreatic disease; (4) knowing pharmacotherapy options in the management of nausea and vomiting; (5) appreciating the importance of constipation and the value of prevention and therapeutic options; and (6) recognition of the likely cause of diarrhea in various clinical settings and the

importance of CDAD in the cancer patient. It is hoped that by applying basic principles, symptoms can be attenuated and cancer patient care can be enhanced.

**Table 6** Diarrhea: Classification and Conditions Common to Cancer Patients

Osmotic
Laxative use
Carbohydrate malabsorption
Maldigestion
Pancreatic insufficiency
Resection
Ductal obstruction
Bile acid insufficiency (see below)
Bacterial overgrowth
Malabsorption
Short bowel
Celiac disease
Bacterial overgrowth
Bile acid insufficiency
Ileal disease
Ileal resection
Radiation therapy
Inflammatory
Infectious nosocomial
<i>Clostridium difficile</i>
Infectious non-nosocomial (immunodeficiency associated)
Bacterial
<i>Salmonella</i>
<i>Shigella</i>
<i>Escherichia coli</i> 0157
<i>Yersinia</i>
Parasitic
Amebiasis
Strongyloides
Ulcerative viral
Cytomegalovirus
Herpes
Other
Tuberculosis
Bone marrow transplant
GVHD
Opportunistic infection
Inflammatory bowel disease
Ulcerative colitis
Crohn's disease
Microscopic colitis
Postoperative
Pancreatic insufficiency
Unmasked celiac
Postvagotomy/dumping syndrome
Short or bypassed bowel
Secretory
Neuroendocrine
Gastrinoma
VIPoma
Carcinoid
Medullary cancer of the thyroid
Somatostatinoma
Endocrine
Hyperthyroidism
Addison's disease

**Table 6** Continued

Primary neoplastic
Colon cancer
Rectal villous adenoma
Lymphoma
Pseudodiarrhea
Fecal impaction
Anorectal obstruction
Mixed inflammatory/secretory
Chemotherapy induced
Non-chemotherapy related
NSAIDs
Colchicine
$\beta$ -Adrenergic antagonists
GVHD = graft-versus-host disease; NSAID = nonsteroidal anti-inflammatory drug

# Graft Versus Host Disease and the Immunologic Complications of Cancer

William A. Ross, MD, MBA

A wide spectrum of immunologic derangements are associated with cancer and its treatment. They range from immunosuppression to enhanced, albeit dysfunctional, performance. This chapter focuses on one such manifestation of immunologic dysfunction, namely graft-versus-host disease (GVHD) following allogeneic hematopoietic stem cell transplantation (HSCT). A brief discussion of three other dysfunctional immune responses concludes the chapter. The conditions discussed include two examples of constant antigenic stimulation resulting in cancer and an example of tumor-associated autoantibody production.

## Graft-versus-Host Disease

GVHD is a frequent major complication of allogeneic HSCT. The likelihood of occurrence is directly related to the degree of human leukocyte antigen (HLA) incompatibility between donor and recipient. The pathogenesis is discussed in detail in Chapter 62. Briefly, three conditions must exist for GVHD to occur: (1) competent T cells are introduced with the graft, (2) antigenic differences between the host and the graft are sufficient to activate the donated T cells, and (3) the host immune response is insufficient to reject the graft.<sup>1</sup> GVHD prophylactic regimens are designed to suppress the donor-derived immune response without endangering the survival of the graft or putting the patient at too great a risk of infectious complications.<sup>2</sup> In addition, some aspects of the donor immune response manifesting as GVHD also account for the beneficial graft-versus-tumor effect seen after allogeneic HSCT.<sup>3</sup> The graft-versus-tumor effect probably accounts for the improved survival in patients with mild GVHD compared with those with no GVHD after allogeneic HSCT.<sup>4</sup> So a fine balancing act is required between donor and recipient immune systems as well as graft response to host-versus-tumor antigens.

Gastrointestinal (GI) tract damage during pretransplantation conditioning regimens plays a key role in GVHD development by creating a

proinflammatory environment into which donor T cells are introduced.<sup>5</sup> The inflammatory cytokines activate donated T cells and stimulate them to multiply. These cells are attracted preferentially to the three organs that are involved in acute GVHD: the skin, liver, and gut. Acute GVHD is traditionally defined as onset in the first 100 days after transplantation. Chronic GVHD, traditionally defined as onset after the first 100 days, has a more diffuse organ system involvement. Whereas liver and oral cavity involvement is prominent in chronic GVHD, GI involvement is not.<sup>6</sup> Skin GVHD is discussed in Chapter 62. The focus of this chapter is on manifestations of GVHD in the liver, gut, and oral cavity.

Clinically significant acute GVHD is seen in 20 to 50% of patients following HLA-matched sibling HSCT. If the donor is unrelated or an HLA-mismatched sibling, then the incidence of significant GVHD increases to 60 to 80%.<sup>7</sup> The skin is the most commonly involved organ in acute GVHD, seen in 80 to 85% of patients.<sup>8</sup> GI tract involvement is seen in more than 50% of GVHD patients and is being increasingly recognized with more liberal use of endoscopy to evaluate GI complaints.<sup>9</sup> Liver involvement is seen in half of patients. Although initially felt to be rare in the absence of skin involvement, both gut and hepatic GVHD can present in lieu of any other organ involvement. Symptoms of GI involvement include diarrhea, abdominal pain, bleeding, nausea, and vomiting. Liver involvement is manifested primarily by cholestasis, with minimal hepatitis. Onset of acute GVHD is typically in the first 2 months post-transplantation. The differential diagnosis is extensive for both GI symptoms and abnormal liver function tests, with the after-effects of the conditioning regimen being a major concern, particularly in the first 2 or 3 weeks post-transplantation. Infections are high on the list owing to the neutropenic state that exists prior to engraftment and the frequent use of immunosuppressive therapy through the post-HSCT period. Drug toxicity remains on the differential diagnosis throughout the post-transplantation period.

## Gastrointestinal GVHD

GI GVHD is readily diagnosed with endoscopic biopsy. The sine qua non is apoptosis, with an intracyptal location being the most specific.<sup>10,11</sup> However, apoptosis is not unique for GVHD and is associated with a number of drugs and infections common after HSCT. In the first 3 weeks post-HSCT, the conditioning regimen can account for apoptosis and complicate the evaluation in this early phase.<sup>12</sup> Cytomegalovirus can also cause apoptosis; however, its clinical significance has been much reduced with prophylactic use of antivirals.<sup>13–15</sup> More recently, *Cryptosporidium* has been described as causing apoptosis in an HSCT patient.<sup>16</sup> Drugs described as inducing apoptosis include cyclosporine, mycophenolate mofetil, ticlopidine, and nonsteroidal anti-inflammatory drugs.<sup>17–20</sup>

## Diagnosis

There is some disagreement in the endoscopic literature as to what portion of the gut to biopsy for the highest diagnostic yield. Some argue that GVHD involves the entire gut and that the site of biopsy is not critical. The traditional approach has been to perform rectal biopsies. Early reports suggested good correlation with symptoms and more proximal intestinal disease.<sup>21</sup> However, later reports touted the utility of gastric biopsies even in those patients presenting with diarrhea.<sup>22</sup> The concept that GVHD represented a panintestinal process was challenged by data showing a lack of congruence between simultaneous rectal and gastric biopsies in 28% of patients.<sup>23</sup> Unlike early studies, endoscopic impressions and symptoms were found to correlate poorly with histology.<sup>23</sup> Although gastric biopsies were touted as the best approach, data existed suggesting a potential to underestimate the severity of more distal disease.<sup>24</sup> Reports of duodenal hematomas after biopsy in thrombocytopenic post-HSCT patients led to reluctance to biopsy the duodenum despite its endoscopically more impressive involvement.<sup>22,24</sup> However, others feel that duodenal biopsies produce the highest yield and are safe.<sup>25,26</sup>

Finally, some feel that the traditional approach to biopsy the rectum remains adequate.<sup>27</sup> The result is that no standard endoscopic approach to diagnosing gastrointestinal GVHD exists.<sup>28</sup> Our approach at The University of Texas M. D. Anderson Cancer Center is to biopsy the rectum, stomach, and duodenum in those patients referred for suspected GI GVHD.

The safety of endoscopic evaluation in this patient population has not been evaluated in a systematic fashion. Procedure-related mortality has been reported to be as high as 1.8%.<sup>29</sup> Our experience would argue for a much lower procedural mortality risk. Yet an ongoing concern in these frequently thrombocytopenic patients is bleeding from endoscopic biopsy. Reports on severe gastrointestinal bleeding following HSCT do not include any related to endoscopic biopsy.<sup>30,31</sup> However, colon perforation and duodenal hematomas have been described.<sup>29,32</sup> A platelet count of at least 50,000/cu mm is recommended by some authors prior to endoscopic biopsy.<sup>24</sup> Others feel that this threshold may be excessive, entailing unnecessary use of valuable blood products, and that a lower threshold would be equally efficacious.<sup>28</sup> There are few firm data to provide guidance. An ongoing review of our experience at M. D. Anderson may provide some insight on this question. Finally, the risk of infection in light of the prevalent neutropenia, particularly early after HSCT, is a concern. Again, the available published data are scanty and contradictory, with some reports showing increased risk of bacteremia and others finding none.<sup>33,34</sup> No specific recommendations regarding antibiotic prophylaxis for endoscopy exist for immunosuppressed patients, let alone those following HSCT.<sup>35</sup>

### Clinical Manifestations

Diarrhea is a prominent symptom of gastrointestinal GVHD, and stool volume is the main parameter by which GI GVHD is graded (Table 1).<sup>36</sup> GVHD is the most frequent cause of diarrhea in

allogeneic HSCT patients after the first 20 days post-transplantation.<sup>22,37</sup> The diarrhea is secretory and frequently refractory to antidiarrheals. Octreotide has been reported to be of benefit in some patients.<sup>38</sup>

Although GI complaints are frequent in patients with chronic GVHD, direct involvement of the gut by isolated chronic GVHD is felt to be rare.<sup>6</sup> Unresolved or recurrent acute GI GVHD accounts for the bulk of GI symptoms.<sup>6</sup> Some patients will develop de novo acute GI GVHD after day 100.<sup>39</sup> Other factors to consider are pancreatic insufficiency and infections in these immunosuppressed patients.<sup>40</sup> Weight loss and malnutrition are common in chronic GVHD patients, with 41% having a greater than 10% weight loss and 14% with a body mass index less than 18.5.<sup>41,42</sup> However, weight loss was not associated with gut GVHD, abdominal pain, dysphagia, or oral sensitivity. Weight loss and malnutrition were more likely in those patients with active chronic GVHD. Patients with extensive chronic GVHD have been shown to have increased resting energy expenditure compared with normal controls, which may contribute to weight loss.<sup>43</sup> The situation may be comparable to the cachexia seen in other chronic nonmalignant conditions and may not be related to gut dysfunction induced by GVHD.<sup>44</sup>

### Oral GVHD

Oral mucositis occurs in two-thirds of patients in the first weeks following HSCT.<sup>45</sup> This early injury is secondary to the pretransplantation conditioning regimen, particularly if total-body radiation is employed.<sup>45,46</sup> Although allogeneic HSCT is a risk factor for oral mucositis in some reports, there appears to be no association between mucositis and subsequent acute GVHD.<sup>45</sup> Resolution is rapid and coincides with engraftment. If mucositis persists despite neutrophil counts exceeding 500/cu mm, then acute oral GVHD must be considered, although this is rare.<sup>47</sup>

However, oral lesions are a very frequent manifestation of chronic GVHD and are a major complaint of post-HSCT patients.<sup>48-50</sup> A composite score of oral abnormalities was correlated with decreasing performance status.<sup>51</sup> Some 60 to 80% of chronic GVHD patients will have oral involvement, with the skin being the only site more frequently involved.<sup>49,50</sup> The history and physical examination can be suggestive but are not diagnostic. Lichenoid lesions have a sensitivity of 61% and a specificity of 53%.<sup>52</sup> Salivary flow rates are diminished in chronic oral GVHD, but subjective xerostomia is a common complaint in HSCT patients with or without GVHD.<sup>52,53</sup> The histology of buccal mucosa or labial salivary glands is suggestive but not diagnostic.<sup>52</sup>

The best treatment is successful systemic therapy.<sup>54</sup> Case reports of resolution with various topical agents have appeared.<sup>55</sup> Long term, the risk of subsequent oral cancers is increased.<sup>56</sup>

### Hepatic GVHD

GVHD involving the liver is just one of a number of potential etiologies of liver dysfunction following HSCT. The gambit of diseases was recently reviewed.<sup>57</sup> Acute hepatic GVHD typically presents as cholestasis, with very modest transaminase elevations in the first month or so after HSCT. However, abnormal liver function tests are very common after HSCT, being seen in up to 80% of patients.<sup>57</sup> The timing after HSCT can give some guidance as to probable etiologies. In the first few weeks following HSCT, the after-effects of the conditioning regimen must be considered. The first 3 weeks after HSCT is also prime time for veno-occlusive disease (VOD), which usually presents as cholestasis and right upper quadrant pain. After the initial 20 days of GVHD, drug toxicity and sepsis are the primary causes of abnormal liver tests.<sup>58,59</sup> In some patients, the cholestasis is multifactorial, with GVHD being the most prevalent in allogeneic HSCT and drug toxicity being the most common etiology after autologous HSCT.<sup>58,60</sup> The ability to test for hepatitis C virus (HCV) has simplified the picture by reducing its prevalence in HSCT patients.<sup>60</sup>

Cholestasis in the first few weeks associated with right upper quadrant pain, hepatomegaly, weight gain, and/or ascites makes VOD a prime consideration. Unfortunately, clinical criteria are not specific unless adhered to strictly, which decreases sensitivity to 56%.<sup>61</sup> Owing to the varying means of defining the diagnosis, the incidence is reported to be as low as 1% and up to 54%.<sup>62-64</sup> More recent reports tend to be at the lower end of this range.<sup>65</sup> Approximately one-quarter of affected patients will have severe VOD and be at high risk of fulminant hepatic failure.<sup>63,65</sup> Biopsy is useful in establishing a diagnosis, but thrombocytopenia early after HSCT dictates a transjugular approach.<sup>61</sup> The prognosis is dismal for severe

Table 1 Grading System for Acute Graft-versus-Host Disease

Stage	Skin	Liver	GI	
1	<25% BSA	Bilirubin 2–3 mg/dL	Diarrhea 500–1,000 cc/d or persistent nausea	
2	25–50% BSA	Bilirubin 3–6 mg/dL	Diarrhea 1–1.5 L/d	
3	Generalized Erythroderma	Bilirubin 6–15 mg/dL	Diarrhea > 1.5 L/d	
4	Desquamation	Bilirubin > 15 mg/dL	Severe abdominal pain or ileus	
Grade	Severity	Skin	Liver	Gut
0	None	0	0	0
I	Mild	1–2	0	0
II	Moderate	3 or	1 or	1
III	Severe		2–3 or	2–3
IV	Life-threatening	4 or	4 or	4

BSA = body surface area; GI = gastrointestinal.

disease as effective therapeutic options are limited. Transjugular intrahepatic portosystemic shunt can reduce portal pressure but has not been shown to improve survival.<sup>66</sup> Defibrotide, a single-stranded polydeoxyribonucleotide with fibrinolytic, antithrombotic, and anti-ischemic properties, has some promise to help patients with severe VOD.<sup>67</sup>

Complicating the diagnosis of hepatic GVHD in some patients is the atypical presentation as an acute hepatitis.<sup>59</sup> In US reports, this presentation tends to be seen when immunosuppressive therapy is being tapered<sup>68</sup> or after donor lymphocyte infusions.<sup>69</sup> A different form was reported in a large series from Hong Kong, where 36% of all liver GVHD patients presented with an acute hepatitis picture.<sup>59</sup> There was no association with changes in immunosuppression or donor lymphocyte infusions as the onset of abnormal liver function tests was within days of that seen with the classic cholestasis picture. Peak bilirubin was the same in both types. However, mean peak transaminase levels were three to four times that seen in classic hepatic GVHD. Resolution with therapy took longer with the acute hepatitis-type presentation. Pathology shows more lobular hepatitis, with hepatocyte necrosis and acidophil bodies. Cholestasis and bile duct injury are less marked.<sup>59,69</sup>

A liver biopsy may clarify the situation in evaluating the HSCT patient with abnormal liver function tests, but it is rarely diagnostic in isolation and must be considered, along with clinical data. Many of the classic reports on liver pathology in HSCT were done prior to the ability to test for hepatitis C.<sup>70,71</sup> Retrospective analysis showed that HCV had a pretransplantation prevalence in a US center of 17%, which increased to 32% post-transplantation.<sup>72</sup> So some of the patients in these early reports on the pathology of hepatic GVHD probably had underlying HCV as well, making it difficult to distinguish the histologic changes unique to GVHD. Still, certain features are felt to be very suggestive of GVHD. These include prominent bile duct atypia with pleiomorphism and, in advanced cases, bile duct dropout. Endothelialitis was felt in early reports to be very suggestive of GVHD but not so in others.<sup>70,71</sup> Inflammatory infiltrates tend to be modest at this early stage of bone marrow reconstitution, and piecemeal necrosis is rare.<sup>73</sup> These changes take time to develop, so early biopsy, within 4 weeks of transplantation, can be unhelpful in establishing a diagnosis of GVHD.<sup>70,71</sup> If GVHD-induced jaundice has been present for 2 weeks or more, liver biopsy should contain findings suggestive of GVHD.<sup>73,74</sup> Unlike with early skin or gastrointestinal biopsies, there is no confusion with the hepatic effects of the preconditioning regimen.<sup>75</sup>

Chronic hepatic GVHD shows more extensive cholestasis with bile duct dropout and an increasing amount of periductal inflammatory

infiltration as bone marrow function improves.<sup>74</sup> Portal fibrosis can be seen, but progression to cirrhosis is rare unless another disease process intervenes.<sup>75</sup> Changes among the hepatocytes are minimal.<sup>73</sup> Early surveys put liver involvement in chronic GVHD at 40 to 60%, but these may include chronic HCV patients.<sup>49</sup> More recent reports put the prevalence in the 30 to 40% range.<sup>6,50</sup> Although reports of development of cirrhosis in the setting of chronic GVHD exist, these are mostly prior to the ability to test for HCV.<sup>76</sup> So it is unclear if the cirrhosis is truly due to GVHD or from HCV. Another potential confounding factor is the high prevalence of iron overload in HCST patients owing to their transfusion requirements.<sup>77</sup> A report on 31 cases of cirrhosis in 3,721 HSCT patients who survived at least 1 year found no association with GVHD.<sup>78</sup> Data were collected from 1969 to 1995, when full viral serologic testing was available only in the later years. As a result, the hepatitis viruses played predominant roles in patients with cirrhosis. Twenty-five of the 31 cases had HCV, and 5 of these had hepatitis B virus coinfections. One case each could be attributed to autoimmune hepatitis and drug toxicity. Only one case had GVHD as the sole risk factor for liver disease. The authors felt that GVHD could accelerate liver injury in a patient with HCV but that GVHD alone was an extremely rare cause of cirrhosis.

### Treatment for GVHD

The best management strategy is to minimize conditions that foster GVHD, namely HLA incompatibilities between donor and recipient. More sophisticated matching techniques have the potential to make unrelated donors as useful a source of stem cells as matched siblings.<sup>79</sup> Adding methotrexate to the prophylactic regimen with cyclosporine has helped reduce the incidence of GVHD.<sup>80</sup> Use of antithymocyte globulin (ATG) as part of the pretransplantation conditioning regimen in unrelated donor transplants can reduce both acute and chronic GVHD to levels seen with match-related donor transplants undergoing standard non-ATG containing preconditioning.<sup>81</sup> Despite the reduced incidence of GVHD, increases in long-term survival rates have been more difficult to demonstrate with prophylactic ATG.<sup>82–84</sup> This failure reflects a higher incidence of relapse and infectious complications at doses of ATG 10 mg/kg and greater.<sup>84</sup> However, too low a dose of ATG (eg, 4 mg/kg) has no effect on GVHD incidence. The question of the most appropriate dose was debated in recent reports.<sup>85</sup>

Systemic steroids are the first-line therapy for GVHD. Unfortunately, only half of patients respond, and there is no standard second-line therapy.<sup>8</sup> Acute hepatic GVHD is more refractory to treatment than skin or gut disease, with more patients progressing on therapy than

responding.<sup>8</sup> This relative refractoriness for hepatic GVHD persists with second-line therapies as well.<sup>86,87</sup>

Although a wide range of agents have been tried in steroid-refractory GVHD, only recent reports are reviewed here. ATG has also been reported as a second-line therapy, with some series going back decades.<sup>86,88</sup> The results are mixed, with the group from Johns Hopkins University reporting extremely poor results, whereas the University of Minnesota group reported more favorable results.<sup>88,89</sup> Timing of the ATG administration may partially explain the disparity in the results as initiation soon after the diagnosis is associated with a better response.<sup>90</sup> The best long-term survival rate reported is 32%, with half of the survivors suffering from chronic GVHD.<sup>89</sup> Although the long-term survival rate was better in responders than nonresponders, the difference did not reach statistical significance. Two randomized trials in Italy compared 7.5 and 15 mg/kg of rabbit ATG with placebo.<sup>82</sup> The low-dose ATG group showed no reduction in GVHD, and survival was comparable to that of controls. The high-dose ATG group showed a significant decrease in GVHD, particularly grades III and IV. However, an increase in lethal infections and deaths from relapse negated any survival benefit. So ATG failed to show benefit in transplant-related mortality, relapse, or overall survival. Chronic GVHD was seen at comparable rates in the low-dose group and controls. Even when data were pooled from both dosage groups, the ATG group had a significantly lower incidence of chronic GVHD: 39% versus 62%. The authors recommended the use of low-dose ATG in pretransplantation GVHD prophylaxis and early post-transplantation use, almost preemptively, in patients at high risk of GVHD. A report from the same group found that blood urea nitrogen >21 mg/dL and total bilirubin >0.9 mg/dL on day 7 post-transplantation stratified patients into low- and high-risk groups for transplant-related mortality.<sup>91</sup> Using data such as these could potentially identify groups most likely to benefit from early intervention. Unfortunately, ATG is a double-edged sword, with its immunosuppressive effects decreasing GVHD but increasing the risk of infection. Transplant-related mortality in the patients treated with ATG is divided almost evenly among GVHD, infection, and other etiologies (eg, multiorgan failure and leukemia).<sup>82</sup> This compares with controls, in whom GVHD accounts for two of every three deaths.

Infliximab, a monoclonal antibody to tumor necrosis factor, has been shown to lead to complete responses in 62% of 21 patients with steroid-resistant acute GVHD.<sup>87</sup> The responses in GI GVHD are particularly striking. However, the incidence of infectious complications was very high, with 81% having a bacteria infection, 90% a viral infection, and half a fungal infection. Only

one death was attributable to infection, but eight patients died of chronic GVHD, in whom infections frequently contribute to death. The survival rate at 30 months was 35%, with all survivors suffering from chronic GVHD. Basiliximab, a monoclonal antibody to the alpha chain of the interleukin-2 receptor, has been shown to lead to complete response in over half of 17 patients with steroid-resistant GVHD.<sup>92</sup> Most patients went on to develop chronic GVHD. However, no bacterial or fungal infections were reported. CMV reactivation was seen in five. One-third of patients had survived for more than 1 year at the time of the report. Whereas the response to infliximab was not associated with survival, the response to basiliximab was strongly associated with survival.

Combining tacrolimus with ATG was reported in a series of 20 patients with steroid-resistant or -dependent acute GVHD.<sup>93</sup> There were complete responses in 40% and partial responses in another 30%. Infectious complications were seen in 80% despite viral and fungal prophylaxis. Infections were directly responsible for deaths in 15% and contributed to deaths in an additional 10%. The long-term survival rate was 35% and was associated with a response to tacrolimus and ATG.

Oral budesonide has been reported to be beneficial in patients with acute GI GVHD.<sup>94,95</sup> For difficult to treat hepatic GVHD, intra-arterial administration of methotrexate with steroids has been employed, with mixed results.<sup>96,97</sup>

Management of chronic hepatic GVHD involves long-term steroids that can be supplemented with cyclosporine.<sup>57</sup> Ursodeoxycholic acid can improve laboratory parameters, but the effect on outcomes is unclear.<sup>57</sup> Gastrointestinal complaints in long-term survivors should prompt evaluation for recurrent acute GVHD and other etiologies, such as pancreatic insufficiency or infections.

## Other Tumor-Associated Immunologic Complications

### *Helicobacter pylori* and Mucosa-Associated Lymphoid Tissue Lymphoma

*Helicobacter pylori* infection induces formation of mucosa-associated lymphoid tissue (MALT), a structure not normally found in the stomach. Part of this lymphoid tissue formation is the development of B-lymphocyte clones and increasing number of T helper cells.<sup>98,99</sup> The B-cell expansion is polyclonal and T cell dependent. In a small subset of patients, a single B-cell clone will expand and cause destruction of surrounding glands, forming the characteristic lymphoepithelial lesions of MALT lymphoma.<sup>100</sup> The mechanism

causing migration from a polyclonal to a monoclonal B-cell response is unclear. Attempts to correlate MALT lymphoma with bacterial virulence factors have not been fruitful.<sup>101,102</sup> The monoclonal expansion is initially dependent on T cells, and helper T cells are frequently seen infiltrating the tumor.<sup>103</sup> The type of T-cell response to *H. pylori* infection may dictate whether the outcome is chronic gastritis, peptic ulcer, or lymphoma.<sup>104</sup> Curiously, the expanding B-cell clone produces antibodies that are not reactive to *H. pylori* but rather act on various autoantigens of the gastric mucosa.<sup>105</sup> So this clonal expansion is not a functional response to the infection. Rather, the constant antigenic stimulation brings about a T cell-mediated dysfunctional immunologic response, leading to a B-cell malignancy in a subset of infected patients. Withdrawal of the antigen by eradication of the *H. pylori* can eliminate the MALT lymphoma but frequently not the MALT or B-cell clonal population.<sup>99,106</sup> In about half of patients with remission, the monoclonal tumor cells persist for years without histologic evidence of disease.<sup>107</sup> With time, these cells may disappear, but their persistence readily explains recurrence of lymphoma with reinfection by *H. pylori*.<sup>108</sup> Follow-up studies also document recurrence of MALT lymphoma without the need for reinfection with *H. pylori*.<sup>109</sup>

In a subset of MALT lymphomas, their expansion becomes independent of *H. pylori* and antibiotics fail to induce remission. Pretreatment endoscopic ultrasonography can help identify patients not likely to completely respond to eradication alone.<sup>110</sup> Lymphoma extending beyond the submucosa is unlikely to respond to antibiotics.<sup>108</sup> Whereas the optimal therapy remains unclear for those refractory to eradication of *H. pylori*, overall survival remains impressive with the various modalities employed.<sup>105,111</sup> For those patients who respond to eradication, follow-up is for an indefinite period as histologic demonstration of complete remission with biopsy material alone is problematic<sup>108,112</sup> and the significance of the persisting monoclonal populations remains unclear.<sup>113</sup> Finally, there is a risk of early gastric adenocarcinoma in patients after *H. pylori* eradication.<sup>114</sup>

Some MALT lymphomas can transform into a high-grade lymphoma that is histologically indistinguishable from a diffuse large B-cell lymphoma. There is molecular genetic evidence that the high-grade lymphoma evolves from a low-grade state.<sup>115</sup> MALT lymphomas with synchronous low- and high-grade components have been described with some frequency.<sup>116</sup> The exact mechanism of transformation is not defined. However, factors felt to be important for promoting growth in low-grade MALT, such as tumor-associated T cells and autoantibodies, are felt to play a diminished role as the tumor transforms

into a high-grade state.<sup>105,117</sup> The driving force behind the transformation appears to be the cumulative effect of various genetic abnormalities.<sup>117</sup> The average age of patients with high-grade lesions is 8 years older than that of those with low-grade lesions, suggesting a long course of evolution from one form to another.<sup>118</sup> Isolated case reports of a complete response to *H. pylori* eradication exist for high-grade lesions.<sup>119,120</sup> So for the patient with *H. pylori* infection, eradication should be a component of therapy.<sup>99</sup>

### Enteropathy-Type Intestinal T-Cell Lymphoma

Constant antigenic stimulation from gluten in the diet leads to a fivefold increase in intraepithelial lymphocytes (IELs) in patients with celiac disease (CD).<sup>121</sup> In some patients, the usual polyclonal increase may evolve in which a single clone predominates. This is commonly seen in the rare entities refractory sprue and ulcerative ileojejunitis.<sup>122</sup> Curiously, the monoclonal population has different immunophenotypic markers from IELs in normal small bowel or those in other CD patients.<sup>123</sup> The same aberrant monoclonal type is seen in enteropathy-type intestinal T-cell lymphoma (EITCL), as well as in nonlymphomatous intestinal mucosa in EITCL patients.<sup>124</sup> This led to the proposal that these aberrant monoclonal cells represent a cryptic lymphoma in refractory sprue and ulcerative ileojejunitis.<sup>125,126</sup> As in *H. pylori*-induced MALT lymphoma, the immunologic response is dysfunctional, with expansion of a monoclonal population with no role in the response to the original inciting antigen.

Although the overall incidence of non-Hodgkin's lymphoma (NHL) is increasing, its presentation in extranodal sites, such as the GI tract, is increasing at an even faster rate.<sup>113</sup> The stomach is the most common extranodal site, with the small bowel being the primary site in less than 2% of NHL patients. Most gastrointestinal NHLs, like MALT lymphomas, are B cell derived, with the number of T-cell lymphomas making up only 12% of the total.<sup>127</sup> Patients with celiac sprue make up only 1% of NHL patients, and not all of their lymphomas are EITCL.<sup>128</sup> Conversely, although most patients with T-cell intestinal lymphoma have celiac sprue, it is not a universal finding.<sup>129</sup> The increased cancer risk in CD patients is almost exclusively due to NHL.<sup>130</sup> CD patients have an odds ratio of 3.1 for NHL, 16.9 for GI involvement, and 19.2 for T-cell lymphoma. CD patients have a mortality rate that is twice the expected rate in the first 3 years after diagnosis, and this is primarily due to NHL.<sup>130</sup> These deaths are primarily in patients with signs of malabsorption and not those with milder forms of the disease.

For EITCL, the lymphoma most specific to CD, the prognosis is poor. The EITCL is usually

diagnosed prior to the CD.<sup>131</sup> The patients frequently present with major complications of the EITCL, such as obstruction or perforation.<sup>131,132</sup> Chemotherapy is complicated by poor nutritional status in many patients. The actuarial 5-year survival rate is 19.7%, but the disease-free survival rate is only 3.2%.<sup>131</sup> This limited prognosis is seen in intestinal T-cell lymphoma in a nonenteropathy setting as well.<sup>132</sup> Preliminary results with high-dose chemotherapy followed by autologous stem cell transplantation for EITCL have been disappointing, with high transplant-related mortality and universal relapse.<sup>133</sup> Other reports in abstract form are slightly more sanguine.<sup>134</sup>

## Autoantibodies

The interactions between the immune system and cancer are complex. Although immunosuppressed states are associated with an increased risk of cancer development, cancer itself can induce immunologic dysfunction. This may take the form of immunosuppression or enhanced, albeit misdirected, function.<sup>135,136</sup> One manifestation of the latter is the formation of autoantibodies associated with cancer. These are felt to be antibodies directed at a tumor antigen that is shared by other tissues, usually neurologic.<sup>137</sup> They are associated with a number of solid tumors, especially lung cancer, but their clinical significance for the most part remains unclear.<sup>138</sup> A handful of autoantibodies are associated with various paraneoplastic neurologic syndromes (see Chapter 44 for further discussion).<sup>139</sup> Some are directly implicated in the pathogenesis of the neurologic syndrome and tend to be directed at peripheral nervous system antigens. Examples are myasthenia gravis and Eaton-Lambert syndrome. However, there are an increasing number of autoantibodies to central nervous system sites being described associated with many neurologic paraneoplastic syndromes that have an unclear role in pathogenesis.<sup>140</sup> Their number seems even larger as they are referred to in the literature by two parallel sets of nomenclature (Table 2).<sup>141</sup> These autoantibodies are most commonly seen with the following malignancies: small cell lung, breast, and ovarian cancers; Hodgkin's disease; and

thymoma.<sup>142</sup> Their presence or absence is not very sensitive or specific for any given neurologic syndrome or tumor type. Although some correlations exist, any given antibody can be associated with a number of different tumor types and neurologic syndromes. Conversely, a neurologic syndrome, such as cerebellar degeneration, can be associated with as many as nine different autoantibodies.<sup>143</sup> With no as yet defined role in pathogenesis, these autoantibodies may simply be an epiphenomenon and not involved in target tissue injury.<sup>142</sup>

The most common central nervous system autoantibody is anti-Hu (antineuronal nuclear antibody type 1 or ANNA-1). Anti-Hu is associated with multiple neurologic presentations, usually in patients with small cell lung cancer. Usually, the neurologic symptoms precede the diagnosis of the cancer. Cancer is ultimately diagnosed in 80 to 90% of patients with high titers (greater than 1:1,000 titers).<sup>144</sup> Low-titer anti-Hu is found in 16% of patients with small cell lung cancer without neurologic symptoms.<sup>141</sup> Although small cell lung cancer accounts for 90 to 95% of the associated cancers, cases are described with prostate, breast, GI, pancreatic, and bladder cancers; lymphomas; and thymomas and other lung cancers.<sup>144-146</sup> The most commonly associated neurologic symptoms are sensory neuropathy, limbic encephalitis, and cerebellar degeneration.<sup>144</sup> The antibody is also frequently found with paraneoplastic gut dysmotility most frequently associated with small cell lung cancer.<sup>147</sup> Gut dysmotility is the presenting symptom in up to 12% of anti-Hu patients.<sup>145</sup> The Hu antigen is made up of four different ribonucleic acid binding proteins, three of which are neuron specific. Antibodies to one of these, Hu-D, have been shown to induce apoptosis in neurons, suggesting that the antibody plays a direct role in the pathogenesis.<sup>139</sup>

## Conclusions

The interactions between the graft and the host, dietary protein and the gut, bacteria and the stomach, and the tumor and the immune system described above demonstrate detrimental

immunologic responses. Our focused view has ignored other factors, such as the environment, that add to the milieu that influences the nature and outcome of immunologic response.<sup>148</sup> However, a better understanding of the immunologic role in pathogenesis helps explain various facets of the conditions under study and points the way to more effective prophylaxis of GVHD, control of *H. pylori*'s oncogenesis, treatment for CD, and limits on paraneoplastic syndromes.

**Table 2** Autoantibodies for Neurologic Paraneoplastic Syndromes

Traditional Name	Alternate Name	Antigen Function	Associated Cancers
Anti-Hu	ANNA-1	RNA binding	SCLC
Anti-Ri	ANNA-2	RNA binding	Breast
ANNA-3		Unknown	SCLC
Anti-Yo	PCA-1	DNA binding	Breast, ovarian
Anti-PCA2		Unknown	Lung
Anti-CRMP5	Anti-CV2	Neuronal development	SCLC, thymoma
Anti-Ma		Unknown	Various
Anti-Tr	PCA-Tr	Unknown	Hodgkin's disease

ANNA = antineuronal nuclear antibody; DNA = deoxyribonucleic acid; RNA = ribonucleic acid; SCLC = small cell lung cancer.

# Interventional Gastroenterology

Jeffrey H. Lee, MD  
William A. Ross, MD, MBA

Gastrointestinal malignancies are leading causes of cancer death throughout the world, and cure is largely dependent on surgical resection. Selection of appropriate treatment options depends on accurate diagnosis and staging. Recent developments in endoscopic technology have contributed to major improvements in early diagnosis and accurate staging. In addition, endoscopy plays an increasing role in the treatment and palliation of gastrointestinal malignancies. This chapter reviews advances in interventional endoscopy.

## Endoscopic Ultrasonography

### Endoscopic Ultrasonography in Esophageal Cancer

Adenocarcinoma of the esophagus has the highest increase in incidence of any cancer in the United States. It is a disease predominantly of white males with long-standing gastroesophageal reflux. The recognition of specialized columnar mucosa in Barrett's esophagus as a precursor for esophageal adenocarcinoma has provided a means to identify a patient group that may benefit from periodic endoscopic surveillance. Such surveillance leads to identification of lesions at an earlier asymptomatic stage. Accurate staging is critical in selecting the most appropriate therapy.

Evaluation by endoscopic ultrasonography (EUS) is an excellent tool to assess the depth of tumor (T) invasion and the status of regional lymph nodes (N) in patients with esophageal cancer. It also serves as a complementary imaging modality to assess the sites of distant metastases (M) of esophageal cancer (Table 1 and Figure 1). During an EUS examination, fine-needle aspiration (FNA) can be performed, using a 19- or 22-gauge needle, into the regional and/or celiac lymph nodes under ultrasound guidance with few risks of complication. All of these can be performed under conscious sedation.

Vazquez-Sequeiros and colleagues reported that helical computed tomographic (CT) scans with 5 to 7 mm cuts provide T-staging accuracy of 72% compared with 86% by EUS. For N staging, the accuracy of CT, EUS, and EUS-FNA was 61%, 81%, 87%, respectively.<sup>1</sup> EUS features of lymph nodes can help distinguish whether they

**Table 1** System for Staging Esophageal Cancer

<i>Primary Tumor (T)</i>	
Tx	Tumor limited to mucosa and muscularis mucosa
T0	Tumor limited to submucosa
T1	Tumor limited to muscularis propria
T2	Tumor infiltration to adventitia
T3	Tumor infiltration to adjacent organ
T4	Regional lymph nodes cannot be assessed
<i>Regional Lymph Nodes (N)</i>	
Nx	No regional lymph node metastasis

<i>Distant Metastasis (M)</i>	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

The American Joint Committee on Cancer (AJCC), Manual for Staging of Cancer, 4<sup>th</sup> ed. 1992.

are benign or malignant. A modified set of seven EUS criteria for malignancy were described as hypoechoic, smooth border, round shape, width  $\geq 5$  mm, lymph node in celiac location, more than five lymph nodes identified, and T3 or T4 tumor on EUS. When three or more of the seven criteria were present, the accuracy of predicting malignancy was 88%. The presence of six or more criteria had a positive predictive value for malignancy of 100%.<sup>2</sup>

For patients who receive preoperative chemotherapy, repeat EUS staging is usually performed

before planned surgery. In the postchemoradiation setting, however, the accuracy of EUS for T staging drops to 51% and for N staging to 49%.<sup>3</sup> Therefore it is necessary to sample the treatment site by endoscopic biopsy. When a suspicious lymph node is seen, FNA of the node should also be done to improve the accuracy of post-treatment staging.

## EUS in Solid Tumors of the Pancreas

Eighty percent of pancreatic cancers present with metastatic disease. Only a subset of the remainder are felt to be true surgical candidates with resectable and, therefore, potentially curable disease. Given a 5-year survival rate of 4%, the emphasis has been on early detection and prompt management.<sup>4</sup> With improved imaging modalities such as helical CT and EUS, preoperative evaluations are more accurately staging patients, allowing a more select group of patients to undergo surgery. Pancreatic cancers can arise from both the exocrine and endocrine portions of the pancreas. Of pancreatic tumors, 95% develop from the exocrine portion of the pancreas, including the ductal epithelium, acinar cells, connective tissue, and lymphatic tissue. When a pancreatic mass is seen on a CT scan, the next step should be performing EUS-FNA to obtain local tumor staging and a tissue diagnosis (Table 2 and Figures 2 and 3). For pancreatic masses, the accuracy of EUS-FNA was reported to be 88%, with a sensitivity of 86%, a specificity of 94%, a positive

**FIGURE 2** Endoscopic ultrasonographic view of a pancreatic head mass abutting the confluence of the portal vein and the superior mesenteric vein. PV=portal vein; SMV=superior mesenteric vein; T=tumor.

**FIGURE 3** Fine-needle aspiration of pancreatic carcinoma: cytologic smear showing a fragment of ductal epithelium that displays atypical nuclear features that include focal enlargement, irregularity, hyperchromasia, crowding, and overlap. Nuclei are not evenly spaced, size (volume) ratios differ significantly from one nucleus to another, and areas of three-dimensionality are seen. These features taken together allow for a malignant diagnosis (Papanicolaou stain, medium power).

predictive value of 100%, and a negative predictive value of 86%.<sup>5</sup> When a mass is not visible on CT or magnetic resonance imaging (MRI) in patients presenting with obstructive jaundice, however, the sensitivity, specificity, positive predictive value, and negative predictive value of EUS-FNA are 47%, 100%, 100%, and 50%, respectively. In this setting, detection of mass, an irregular bile duct wall, or common bile duct wall thickness greater than 3 mm by EUS provides much improved sensitivity over FNA.<sup>6</sup>

The ability to detect pancreatic endocrine tumors (PENs) by conventional imaging studies such as transcutaneous ultrasonography, CT, and MRI is highly dependent on the size of the tumor. CT and MRI can localize fewer than 10% of PENs less than 1 cm in diameter, 30 to 40% of PENs 1 to 3 cm in size, and more than 50% of those more than 3 cm in diameter.<sup>7-12</sup> Intra-arterial secretin injection with portal venous sampling was shown in one study to have high positive and negative predictive values for the identification of gastrinoma.<sup>13</sup> However, this procedure is highly invasive and does not provide a tissue diagnosis. Zimmer and colleagues, however, reported a higher accuracy for EUS for localization of gastrinoma (79%) and insulinoma (93%).<sup>14</sup> In another study of 30 patients with suspected PEN, EUS-FNA had a sensitivity of 82.6%, a specificity of 85.7%, an accuracy of 83.3%, a positive predictive value of 95.0%, and a negative predictive value of 60.0%.<sup>15</sup>

EUS in a Billroth II operation was once considered to be contraindicated. It is difficult to orient the anatomy owing to resection of the antrum and duodenal bulb and reconstruction. However, Pancreatic EUS following a Billroth II operation was once considered to be contraindicated. It is difficult to orient the anatomy owing to resection of the antrum and duodenal bulb and reconstruction. Linear-array echoendoscopes provide a more complete examination than radial echoendoscopes. Of note, the pancreatic neck may be difficult to visualize.<sup>16</sup>

When subtle pathologic conditions of the bile duct or pancreatic duct are suspected, intraductal ultrasonography can be performed by using a 12, 15, or 20 MHz, radial scanning ultrasound catheter probe (UM R-series, Olympus Optical Co, Tokyo, Japan). This requires cannulating either or both ducts using a duodenoscope and the probe.

### EUS in Cystic Tumors of the Pancreas

Owing to better and more frequently used imaging studies, there has been an increase in the detection of cystic lesions in the pancreas. Cystic lesions represent less than 10% of pancreatic neoplasms. The most common pancreatic cystic lesion is a pseudocyst. When a pseudocyst is suspected, it is important to ask the patients whether they have a history of pancreatitis as

pseudocysts follow an episode of acute pancreatitis or occur in the setting of chronic pancreatitis. Cystic tumors could be benign, as in serous cystadenoma and pseudocyst, or malignant (or with malignant potential), as in mucinous cystic adenoma, intraductal mucinous papillary neoplasm (IPMN), or mucinous cystadenocarcinoma. EUS-FNA not only provides images to help distinguish benign from malignant cysts, it also allows aspiration of cystic content for fluid analysis (Figure 4). The benign EUS features include sunburst calcification with numerous microcysts resembling a honeycomb appearance, which suggests serous cystadenoma. The worrisome EUS features include intracystic growth or a solid mass associated with the cyst. The aspirated fluid is usually sent for cytology, carcinoembryonic antigen (CEA), cancer antigen (CA) 19-9, CA 125, CA 72-4, and amylase (Table 3). In a study by Brugge and colleagues, CEA was the most specific tumor marker for malignancy.<sup>17</sup> Using the CEA value of 192 ng/mL, the sensitivity for diagnosis of a mucinous cyst was 75%, with a specificity of 84% and an accuracy of 79%. In comparison, the accuracy of EUS morphology was 51% and cytology was 59%.

EUS can further characterize IPMN by visualizing the papillary growth along the duct. FNA enables obtaining tissue from the papillary growth and aspirating ductal contents for the presence of mucin and other studies.

### EUS in Rectal Cancer

In a review of EUS accuracy in staging rectal cancer, in all published data between 1985 and 2003, EUS T-staging accuracy was reported in 40 studies and N-staging accuracy in 27 studies.<sup>18</sup> In 4,118 subjects, an overall mean T-staging accuracy was 85.2% (median 87.5%) and N-staging accuracy was 75.0% (median 76.0%). EUS staging of rectal cancer can facilitate appropriate employment of preoperative neoadjuvant therapy in those patients with advanced disease. However, EUS tends to overstage rectal cancers because

**FIGURE 4** Endoscopic ultrasonography-fine-needle aspiration of a cystic lesion of the pancreas.

**Table 3** Tumor Markers in Cystic Fluid in the Various Pancreas Cysts

Tumor Marker	SCA	MCA	MCAC	IPMN	Pseudocyst
CEA	Low	High	High	Variable	Low
CA 19-9	Variable	Variable	Variable	Variable	High
CA 15-3	Low	High	High	Low	Low
CA 72-4	Low	High	High	High	Low
CA 125	Low	Variable	Variable	Low	Low
Amylase	Low	Low	Low	High	High
Viscosity	Low	High	High	High	Low
Cytology	Glycogen	Mucin	Mucin	Mucin	Inflammatory

CA = cancer antigen; CEA = carcinoembryonic antigen; IPMN = intraductal papillary mucinous neoplasm; MCA = mucinous cystic adenoma; MCAC = mucinous cystadenocarcinoma.

high-resolution ultrasonography can detect, but not separate, hypoechoic inflammation around the malignancy from the tumor itself.<sup>19</sup>

### EUS in T4 Lung Cancer

Nearly 30% of patients with lung cancer harbor mediastinal disease at presentation. Through the esophageal wall, EUS provides excellent access to the posterior mediastinum. In patients with lung cancer and posterior mediastinal adenopathy on CT, EUS-FNA was reported to be superior to CT for detection of malignancy, with a sensitivity of 90% and a specificity of 100%.<sup>20-23</sup> Although ultrasonography cannot penetrate air-filled structures such as the lungs, invasion of the mediastinum by lung cancer is suspected when there is a loss of interface between the mass and the soft tissue of the mediastinum, heart, great vessels, trachea, esophagus, or vertebral body. In a study of 175 patients with lung cancer who underwent EUS evaluation of the mediastinum, structures in the lateral mediastinum, such as upper paratracheal (2L/R) and lower paratracheal (4L/R) lymph nodes, were routinely imaged and sampled by EUS-FNA without difficulty. For detection of mediastinal invasion by lung cancer, EUS had a sensitivity of 87.5%, a specificity of 98%, a positive predictive value of 70%, and a negative predictive value of 99%, with no procedure-related complication.<sup>24</sup> Therefore, EUS-FNA is an accurate, safe, and cost-effective means of screening patients with lung cancer with possible mediastinal metastasis. However, T4 staging should be made by EUS only when invasion of great vessels or mediastinal organs (heart, spine, esophagus) is clearly evident or EUS-FNA confirms malignant pleural effusion. Loss of interface between the tumor and mediastinum detected by EUS should be further evaluated by other modalities before the tumor is considered unresectable.

### Endoscopic Retrograde Cholangiopancreatography and Pancreatoscopy

The most common presenting symptom and sign of pancreatic cancer involving the head of the pancreas is painless obstructive jaundice. There

are many possible etiologies for obstructive jaundice, including benign and malignant conditions; among them are primary sclerosing cholangitis, chronic pancreatitis, cholangiocarcinoma, and pancreatic malignancies, including both solid and cystic tumors of the pancreas. The first step in management of obstructive jaundice in a suspected malignancy is obtaining a CT scan of the abdomen. If ascending cholangitis is suspected owing to biliary obstruction, the patient should be admitted for intravenous hydration and antibiotics. Charcot's triad of jaundice, fever, and right upper quadrant abdominal pain is seen in approximately 70% of the patients with ascending cholangitis. The antibiotics should be able to cover a broad spectrum, including *Escherichia coli*, *Enterococcus*, *Klebsiella*, and anaerobes. Following this, at the earliest possible time, endoscopic retrograde cholangiopancreatography (ERCP) should be performed to establish drainage of bile and pus. In severe ascending cholangitis, a plastic biliary stent may not be sufficient to drain the large amount of viscous pus. A nasobiliary drainage that allows lavaging of the bile duct would be more effective in this setting. If ERCP is unsuccessful for technical or anatomic reasons, percutaneous drainage by an interventional radiology service should be performed.

In suspected pancreatic exocrine tumor presenting with obstructive jaundice, ERCP can be performed immediately following EUS-FNA to alleviate the symptoms of obstructive jaundice. During ERCP, the confirmation on tissue diagnosis on the cytology specimen obtained by EUS-FNA can be made by a cytopathologist. For biliary decompression in patients with resectable pancreatic cancers, traditionally, plastic stents were used for various presumed advantages over the metallic stents. However, Wasan and colleagues reported data on the utility of metal stents on resectable pancreatic cancer.<sup>25</sup> During the preoperative course, the incidence of cholangitis or cholecystitis was 15% in the metal stent group and 92% in the plastic stent group. In both groups, there were no stent-related intra- or postoperative complications. For both groups,

the intraoperative time per patient was approximately 7 hours, with an intraoperative blood loss of 650 mL and length of hospital stay of 10.5 days. Overall, for the metal group, significantly fewer ERCP sessions were required, which more than compensated for the higher initial stent costs.<sup>26</sup>

For IPMN, the most common presenting symptom is abdominal pain. On ERCP, visualization of thick mucin extrusion from the widely open papilla is diagnostic of IPMN (Figure 5). Magnetic resonance cholangiopancreatography is a noninvasive imaging study that allows evaluation of the pancreatic duct, the presence or absence of a cyst, communication of cystic dilation with the main pancreatic duct, and the presence of side-branch IPMNs with minimal risk. A pancreatogram will frequently show multiple filling defects, ductal dilation, and, at times, cystic dilation of side branches. ERCP brushing and biopsy are not very sensitive, but intraoperative pancreatoscopy is highly sensitive and specific. Intraoperative pancreatoscopy also enables precise location of resection for clear surgical margins so that repetitive resection would not be needed.

### Endoscopic Mucosal Resection

For selected patients with early esophageal or gastric cancer (T1a) who are poor or reluctant surgical candidates, endoscopic mucosal resection (EMR) should be considered. The first step in EMR is a conventional endoscopy to mark the periphery of the lesion and to inject saline solution into the submucosa. Next, the EMR cap (Olympus Optical Co., Ltd., Tokyo, Japan) is fitted at the tip of the endoscope. A crescent-shaped snare is then prelooped into the groove of the rim of the cap. The lesion is suctioned into the cap, and snare resection is performed. The two most common complications of EMR are perforation and bleeding. Most bleeding occurs within 24 hours, and the patients should be closely followed during this time. Bleeding occurring during EMR can usually be treated using a heater

**FIGURE 5** Mucin extrusion from a widely open papilla, diagnostic of intraductal mucinous papillary neoplasm.

probe, hemoclips, or other modalities. When the perforation is small and the patient is clinically stable, attempts to seal the perforation by endoscopic hemoclippling should be made if the area of perforation is easily accessible. When EMR is being considered rather than surgical resection for T1 lesions, it is important to be able to distinguish T1a (only mucosal and muscularis mucosal involvement) from T1b (submucosal involvement) by EUS as there is a higher rate of lymphatic invasion with T1b than with T1a. Post-EMR, close surveillance should be routine for early detection of recurrence. In the study published by Scotinotis and colleagues, T1a could be separated from T1b with a sensitivity of 100%, a specificity of 94%, and a negative predictive value of 100% by EUS.<sup>27</sup> Kume and colleagues published new techniques of EMR using a soft, irrigation-prelooped hood. This technique allows effective irrigation, thus providing better visualization of the field. In this study, 15 patients (4 with early esophageal cancer, 11 with early gastric cancer) underwent successful EMR; the complications mentioned included 4 patients with limited bleeding, which was easily treated by endoscopic therapy. No perforation was observed.<sup>28</sup>

### Endoscopic Ampullectomy

Patients with an ampullary adenoma frequently present with nondescript upper abdominal pain, jaundice, and/or gastrointestinal bleeding. Patients with familial adenomatous polyposis (FAP), including Gardner's variant, have an increased likelihood of papillary neoplasm and thus should undergo endoscopic surveillance.<sup>29,30</sup> CT is not sensitive for detection of ampullary tumors. To optimally visualize the ampulla, a side-viewing scope should be employed as the straight-viewing scope does not provide an accurate assessment of the ampulla. During the evaluation of the ampulla, biopsy specimens should be obtained from the ampulla if adenoma is suspected or routinely in the patients with FAP as an adenoma may be grossly evident or the ampulla may appear to be completely normal. If jaundice is present, ERCP should be performed with a biliary sphincterotomy to establish drainage and obtain biopsy specimens from the inner segment of the ampulla and a biliary stent should be placed if the stricture is still shown with poor drainage following biliary sphincterotomy. A cholangiogram should be obtained with brushing of the stricture. When the pathology results of ampullary biopsy confirm that it is an adenoma rather than a carcinoma, then EUS should be performed to stage the adenoma. The standard management for papillary neoplasms continues to be surgery, either local excision or pancreaticoduodenectomy. If an ampullary adenoma is

confined within the mucosal or submucosal layer (confirmed by EUS), snare ampullectomy could be considered. Endoscopic ampullectomy can be performed in two ways. First, the ampulla can be snared off in one cut. The pancreatic duct needs to be found first so that it can be stented postampullectomy to prevent post-ERCP pancreatitis as the papillary edema could result in temporary blockage of the duct. Also, to prevent cholangitis, the bile duct should be cannulated and biliary sphincterotomy (with or without biliary stent placement depending on efficiency of bile drainage after sphincterotomy) should be performed. For ampullary tumors greater than 2 cm in size, alternatively, a pancreatic ductal stent can be inserted first and piecemeal ampullectomy can be performed. In this method, after ampullectomy is completed, thermal ablation of the base of the tumor could result in lower incidents of recurrence.

Only five studies have critically evaluated endoscopic ampullectomy. The success rates ranged from 60 to 90%, with complication rates ranging from 9.7 to 27%. The complications included acute pancreatitis, bleeding, cholangitis, duodenal perforation, and late papillary stenosis. Among all patients in reported series, there was only one death, which occurred as a result of severe necrotizing pancreatitis.<sup>31–35</sup> The largest one of the five studies had 103 patients. The long-term success rate was 80%, with a complication rate of 9.7%; complications included acute pancreatitis (5%), bleeding (2%), and late papillary stenosis (3%). By multivariate logistic analysis, predictors of successful endoscopic resection included age greater than 48 years ( $p < .001$ ), lesion size of 24 mm or less ( $p = .001$ ), and male gender ( $p < .05$ ). Acute pancreatitis occurred more frequently in patients without pancreatic duct stents (17% vs 3.3%), and papillary stenosis also occurred more frequently in patients without pancreatic duct stents (8.3% vs 2.2%). The recurrence rate for papillary adenoma after ampullectomy was 20%. Significant risk factors for recurrence were larger size, genetic predisposition, younger age, and absence of adjuvant thermal ablation at the initial ampullectomy. For patients who have adenomas removed completely, endoscopic surveillance at 6-month intervals for a minimum of 2 years is recommended. For patients with FAP, more vigilant surveillance would be prudent.<sup>35</sup>

If the neoplasm is not completely removed at the initial procedure, ampullectomy and thermal ablation should be repeated at 2- to 3-month intervals until ablation is complete.

### Photodynamic Therapy

Photodynamic therapy (PDT) with porfimer sodium has been used to treat patients with high-grade dysplasia (HGD) and early-stage esophageal cancer (T1). Patients receive an

intravenous injection (2 mg/kg) of porfimer sodium (Photofrin, Axcan Pharma, Mont-Saint-Hilaire, QC). Three days after drug injection, 630 nm light from a potassium titanyl phosphate dye laser (Laserscope, San Jose, CA) is delivered by using a cylindrical diffuser inserted in a 20 nm-diameter reflective esophageal PDT balloon (Wilson-Cook Medical Inc., Winston-Salem, NC). Esophageal strictures can occur in 18 to 37% of patients after PDT for HGD in Barrett's esophagus.<sup>36–39</sup> Strictures occur within 3 to 4 weeks and require serial dilations. When different light doses were employed, the efficacy and stricture rate were different among them. In a study of 113 patients with Barrett's esophagus with HGD or T1 disease, residual HGD or T1 disease. After one treatment was seen in 17% of patients with a light dose of 115 J/cm, 33.3% with a light dose of 105 J/cm, 29.4% with a light dose of 95 J/cm, and 31.6% with a light dose of 85 J/cm. Complete ablation of Barrett's mucosa and total replacement of the treated area with squamous mucosa were achieved in 40.7% treated with a light dose of 115 J/cm, 35.3% of patients treated with a light dose of 105 J/cm, 33.3% of patients treated with a light dose of 95 J/cm, and 21% of patients treated with a light dose of 85 J/cm. Although the overall rate of stricture formation was not directly correlated to the light dose, severe strictures requiring more than six dilations were seen in 15.3% with a light dose of 115 J/cm, 5.6% with a light dose of 105 J/cm, 5.9% with a light dose of 95 J/cm, and 5.3% with a light dose of 85 J/cm. Thus, decreasing the light dose below 115 J/cm reduced the rate of the stricture at the expense of efficacy. The optimal dose for treatment with PDT is yet to be established.<sup>40</sup>

## Endoluminal Stenting

### Esophageal Stents

Most esophageal cancer patients will present with unresectable disease, and treatment is limited to palliation.<sup>41</sup> Relief of dysphagia is a major focus, and this can be addressed with endoscopic measures, primarily self-expanding metallic stents (SEMSs). A subset of patients will develop tracheoesophageal fistulae (TEF) and be good candidates for a SEMS. Although other endoscopic modalities have been used in the past to reestablish esophageal lumen, SEMSs have become the primary endoscopic measure since their introduction in the early 1990s. Early studies showed a clear advantage over plastic stents.<sup>42</sup> Advantages over recanalization by laser therapy have been difficult to demonstrate.<sup>43,44</sup> PDT has not been shown to be more effective or safer than SEMSs.<sup>45,46</sup> Concerns about the high cost of SEMSs have been tempered by studies showing no cost disadvantage despite the high initial expense as patients palliated with SEMSs need fewer interventions than laser and have fewer complications than plastic stents.<sup>47,48</sup>

Placement of a SEMS is done with fluoroscopy and at some centers is performed by interventional radiology. A previous definition of the esophageal anatomy is desirable but not essential. The presence and location of a TEF should be confirmed by previous imaging or contrast injection at the time of stent placement. Most commercially available stents have a coating covering most, if not all, of the stent. Available lengths are typically 10 to 15 cm. The diameter of the delivery systems precludes through-the-scope placement. However, the relatively slim profile of some stents, such as the 18F diameter Wallstent II (Boston Scientific, Natick, MA), makes negotiation of strictures possible with little to no dilation. Antireflux valves are available with some stent designs for those patients prone to gastroesophageal reflux disease. Dilation of the stricture should be avoided or kept to a minimum to reduce the risk of perforation.<sup>49</sup> We use a small-caliber 5 mm in diameter scope (Pentax 1540, Pentax Inc. Montvale, NJ 1540) to facilitate passage through the stricture. A wire is placed into the stomach, and the scope is withdrawn after stricture length is determined. External metal markers are used to delineate the proximal and distal margins of the stricture. Alternatively, contrast material can be injected via a sclerotherapy needle into the submucosal layer at the margins. A stent length is chosen that will readily bridge the stricture, leaving 1 to 2 cm at either end to accommodate stent foreshortening and to avoid having the uncovered ends within the stricture. The stent is passed over the wire and into position. An endoscope can be introduced alongside to check proximal positioning. The stent is deployed slowly to allow an opportunity to make final adjustments in position prior to full release. The small-caliber endoscope is then reintroduced to assess stent patency and placement. Patients are allowed a liquid diet and are to advance their diet as tolerated as the stent expands over the next 48 hours. Proton pump blockers are routinely prescribed for those with a stent bridging the esophagogastric junction.

Dysphagia will improve in 80 to 90% of patients, although this may be modest.<sup>50</sup> At least 80% of TEF will close at least temporarily.<sup>49,51</sup> Despite less dysphagia, improvement in quality of life is not readily demonstrated.<sup>44,52</sup> Although the mainstay of endoscopic palliation, placement of a SEMS is a procedure plagued by a high complication rate.<sup>53,54</sup> A quarter to half of patients will suffer a major complication requiring another stent, endoscopy, admission, or a percutaneous endoscopic gastrostomy tube.<sup>55-57</sup> In addition, the operative mortality is 1 to 2%. Patient selection for SEMSs should be based on several factors. The presence of a TEF is the most clear-cut indication. The best timing of stent placement relative to other therapeutic interventions is debated. Whereas early reports suggested a higher

complication rate in those patients who have received chemoradiation, our experience and that of others have not shown such an increased risk.<sup>58,59</sup> On the other hand, there are reasons to defer stent placement prior to chemoradiation. First, chemoradiation may lead to improvement in dysphagia and that tumor regression can result in stent migration. In most cases of migration, the stents remain in the stomach, although some travel distally and can obstruct.<sup>60,61</sup> Stents designed for easy removal from the esophagus or stomach as chemoradiation is completed would effectively deal with this concern.<sup>62</sup> However, removal of a SEMS requires substantial technical expertise, with associated risk of bleeding and perforation.<sup>63</sup> Second, very high complication rates have been reported in patients with SEMSs who subsequently undergo radiation therapy.<sup>64</sup> High cervical lesions are problematic as there may be insufficient room proximally for stent placement without encroaching on the hypopharynx, and palliative benefit is limited.<sup>65</sup> Stents for tumors involving the esophagogastric junction can lead to reflux symptoms and have a higher rate of migration in some studies.<sup>50</sup> A stent with an antireflux valve is an option, although experience with them is mixed and the number of patients not responding to acid-suppressive therapy is small.<sup>54,55,66,67</sup>

So ideal timing of SEMS placement in the course of the patient's illness is unclear. Some authors argue for deferring SEMS placement until dysphagia proves refractory to all other modalities.<sup>52</sup> Prolonged patient survival with SEMS is associated with a higher risk of stent dysfunction.<sup>68</sup> Yet others argue that SEMSs should be reserved only for those with longer life expectancies.<sup>43</sup> The use of SEMSs has decreased over the years at our institution despite increasing numbers of esophageal cancer patients.<sup>49,69</sup> The limited benefits that SEMSs can offer, as well as an appreciation of their complication risks, have contributed to this decline. Other endoscopic modalities have not been substituted, nor are other services deploying SEMS. Rather, we have adopted a position of allowing sufficient time after chemoradiation for its benefits to be defined. In those patients who are not candidates for chemoradiation or who have completed radiation with recurrent dysphagia, SEMSs are placed if there is a reasonable life expectancy measured in weeks or months and the anatomy permits.

### Enteral Stents

Gastric outlet obstruction can result from a primary or metastatic malignant process involving the distal stomach, duodenum, or periampullary region. The most common etiology is pancreatic adenocarcinoma.<sup>70</sup> The traditional approach has been surgical bypass, but SEMSs offer an alternative, with less morbidity and a faster return

to oral intake at a lower cost.<sup>71-73</sup> No control trials comparing the two approaches exist.

The technique is basically similar to that of esophageal stents, with the advantage that the slim delivery catheter allows through-the-scope placement. Previous barium studies are helpful to define the anatomy and to rule out additional distal strictures but are not necessary or at times possible owing to complete obstruction. Attempts at a barium study may complicate stent placement owing to retained barium hampering endoscopic and fluoroscopic views. A small-caliber scope may facilitate wire placement across the stricture. If the stricture is too tight for a scope, then advancing a biliary catheter into the stricture under fluoroscopy with intermittent injection of contrast can facilitate wire placement. A floppy wire may be required to traverse the stricture initially and can be replaced with a stiffer wire through the biliary catheter. The distal margin of the stricture should be carefully marked externally or, if possible, by an endoclip or submucosal injection of contrast. A typical stent has a delivery system 10F in diameter and can readily go through a 3.8 mm channel. Owing to its small caliber, dilation of the stricture is rarely required. If stent passage requires dilation, this should be kept to a minimum to attenuate the risk of perforation. Diameters of expanded stents are 20 to 22 mm, with lengths of 60 and 90 mm. Covered versions were found to migrate too readily and are no longer available.

Biliary ductal patency is a concern, and placement of a SEMS in the biliary tree prior to deployment of duodenal stents is desirable. The stents can be placed during the same procedure if the duodenoscope can be introduced.<sup>74</sup> However, a high failure rate has been reported in this setting even with stricture dilation to facilitate passage of the duodenoscope.<sup>75</sup> Dilation in this setting carries a 6% risk of perforation.<sup>75</sup> If biliary drainage cannot be achieved endoscopically, then a percutaneous approach with placement of the biliary SEMS through the sidewall of the duodenal SEMS is possible.<sup>72</sup>

Stricture length dictates placement of more than one stent in 7 to 18% of patients.<sup>72,75-77</sup> Two recent reviews found that technically adequate stenting is achieved in 94 to 97% of patients.<sup>70,78</sup> However, clinical success is not seen in 7 to 11% of those with adequate stent placement owing to dysmotility or distal disease.<sup>70,78</sup> As a result, the overall success rate is 87%. Data from five recent series show that resumption of a normal or soft diet is possible in 70% of patients.<sup>71,72,75-77</sup> Ten to 17% of stents will obstruct, usually with tumor ingrowth.<sup>70,78</sup> This compares with 10% of patients after bypass gastrojejunostomy who develop recurrent obstructive symptoms.<sup>79</sup> Migration is seen with 2.7% of uncovered stents.<sup>78</sup> Abdominal pain occurs in 2.5%.<sup>70</sup> Bleeding and perforation

are seen in 1%.<sup>70,78</sup> Procedural mortality is not reported.<sup>70</sup> The median survival rate reported ranges from 7 to 14.5 weeks.<sup>75–78,80</sup> No improvement over historical median survival after surgical bypass is seen.<sup>71</sup>

In patients with incurable disease causing gastric outlet obstruction, SEMSs represent the best option for palliation, with an 87% likelihood of relieving symptoms and a 70% chance of resumption of a nearly normal diet. This intervention requires little, if any, hospital time versus a postgastrojejunostomy bypass recovery period of a median 14 to 17 days in patients with an average survival of only a few months.<sup>73,79,81</sup> The timing of stent placement should be dictated by symptoms, functional status, and available therapeutic options. Chemoradiation therapies should have been exhausted or have a low likelihood of producing major tumor regression to minimize the chances of distal migration or stent-induced perforation.<sup>75</sup>

### Colonic Stents

Colonic obstruction can be the initial presentation of colon cancer or develop with recurrent or progressive disease. SEMSs offer an alternative to surgery for relieving the obstruction. As with enteral stents, no controlled trials comparing the two approaches exist.<sup>82</sup> A recent review involving 1,198 patients provides some perspective as to the role of SEMSs in this setting.<sup>83</sup> Two-thirds of stents were placed for palliation of recurrent or unresectable disease. The other third were placed for bridging the acutely obstructed patients to definitive resection, thereby forgoing an emergent decompressive colostomy. Eighty-six percent of the stents were for rectosigmoid disease. Eleven percent were for left colon obstruction. Two percent were deployed in the transverse colon and 0.5% in the ascending colon. Technical success is seen in 93% of patients, although this does not always equate with clinical success, which is seen in 88%.<sup>83</sup> Facilitating a single-stage surgery was possible in 72% in the “bridge to surgery” indication group. Migration is seen in 12%, with most occurring in the first week after deployment. The more proximal the stent, the higher the migration rate. Perforation is seen in 2.8% of patients not previously dilated. The perforation rate in those patients whose strictures were dilated prior to stent placement was almost six times higher. Perforations were responsible for five of seven procedure-related deaths, and procedure-related mortality was 0.58%. Reobstruction occurred in 7.8% of uncovered stents at a median time of 24 weeks. Additional complications seen are bleeding and migration in 5 and 10% of patients, respectively.<sup>82</sup> The need for surgical intervention for complications can be as high as 12.5%.<sup>84</sup> It is unclear if previous radiation therapy alters complication rates.<sup>82</sup>

As with other SEMSs, contrast studies are of limited utility in the acute setting and attempts at opacification can hinder subsequent endoscopic and fluoroscopic evaluation. Imaging studies such as CT or abdominal plain films to rule out perforation and give approximate location of stricture are vital. Colonoscopic evaluation of the stricture and its anatomy follows. A small-caliber scope can be critical to facilitate negotiation of the stricture and place a wire proximally. In those patients in whom endoscopic advance through the stricture is not possible, fluoroscopic guidance is sufficient for stent placement. Fluoroscopic images are easier to interpret with the patient in the supine position than the patient in the left lateral decubitus position. A biliary catheter can help with passage of the wire in those strictures too tight even for the small-caliber scopes. A wire with a floppy tip can help with initial passage. The biliary catheter can then be advanced through the stricture and a stiffer wire substituted to facilitate stent passage. Stents are identical to those used in the duodenum or are available from some vendors with slightly large diameters. Delivery catheter size in some versions allows passage through a therapeutic scope accessory channel, simplifying placement, particularly for proximal lesions.<sup>82</sup> All commercially available stents are uncovered owing to high migration rates with early covered versions. In those patients with fistulae, a covered esophageal stent can be deployed.<sup>85</sup> Pre-stent dilation is not advised as perforation rates are sharply increased. Prophylactic antibiotics are not routinely recommended yet may have a role in those patients with complete obstruction and marked colon dilation.<sup>82</sup>

Patients are advised to comply with a low-residue diet and adopt a bowel management regimen to avoid stool impaction in the stent.<sup>82</sup>

A small, randomized trial of left-sided partial obstruction treated with a SEMS versus colostomy showed better quality of life in the stent group, with comparable costs.<sup>86</sup> Using historical controls, Johnson and colleagues found comparable outcomes after SEMSs, despite a patient population with poorer performance status than surgical controls.<sup>87</sup> In an analysis of the bridge to surgery presentation, Targownik and colleagues found in a decision analysis that SEMSs followed by elective surgical resection had better outcomes at lower cost compared with emergent surgery with stoma formation or primary resection.<sup>88</sup> Stent placement in acute obstruction has no adverse effects on long-term prognosis compared with initial surgical decompression.<sup>89</sup>

### Future in Interventional Gastroenterology

With ongoing development of new tools and technology, the future of endoscopic therapy of gastrointestinal malignancies has promising

potential. Ideas that have been considered include EUS-guided radiofrequency ablation, EUS-guided PDT with probe insertion, EUS-guided alcohol injection into the solid tumors, including pancreatic cancer, and endoscopically delivered chemotherapy. We look forward to the results of further research in this exciting area.

# Nutritional Issues in Cancer Patients

Yakir Muszkat, MD

Genetic predisposition and environmental factors play major roles in the etiology of cancer.<sup>1,2</sup> Dietary factors are among the most important environmental factors implicated in cancer development.<sup>3</sup> It has been estimated that approximately 35% (10–70%) of all cancers are attributable to diet.<sup>4</sup> Cancer is a multistage process that involves activation of a precarcinogen to an ultimate carcinogen, initiation of a tumor cell through oncogene expression, and, finally, promotion to clinical cancer. Nutritional factors can interact in all of these steps, both positively and negatively. Therefore, nutrients such as vitamins, minerals, or other food constituents may also function as chemopreventive agents that may help reverse, suppress, or prevent progression to invasive cancer.<sup>5</sup>

Although the role of diet in health and disease has been known since ancient times,<sup>6</sup> many of the current recommendations are based on evidence that is derived from more recent epidemiologic studies.<sup>7</sup> However, for a number of nutrients, well-designed dietary intervention studies have failed to demonstrate the anticipated protection against cancer.<sup>8</sup> A novel approach to understanding this discrepancy has been to study the response to a specific nutrient as determined by an individual's genotype. The great variability in the responses of subjects in nutritional intervention studies may be due to differences in study participants' genetic polymorphisms. This has led investigators to further define the role that nutrients play in influencing genetic processes involved in carcinogenesis, such as those that determine cellular metabolism, differentiation, and apoptosis. Therefore, even though genetic factors cannot be altered, making beneficial changes in nutritional habits may potentially decrease the risk of cancer substantially.<sup>9</sup>

Once cancer is diagnosed, up to 80% of patients will develop weight loss and malnutrition during the course of their illness.<sup>10</sup> Malnutrition in patients with cancer has been associated with longer hospital stays,<sup>11</sup> diminished tolerance of and responsiveness to both chemotherapy and radiotherapy,<sup>10</sup> increased perioperative morbidity,<sup>12</sup> increased cost,<sup>13</sup> worse performance status and quality of life, and decreased survival.<sup>11</sup> The etiology of malnutrition in such patients is

multifactorial. The causes can be classified into two major categories: (1) anorexia, factors related to decreased food intake, and gastrointestinal dysfunction and (2) metabolic disturbances.<sup>14,15</sup> Although numerous techniques are available for the nutritional assessment of these patients, most of these methods are difficult to interpret in clinical practice and are poor indicators of response to therapy in patients with malignancy.<sup>16</sup>

Oral dietary therapy, oral supplements, and enteral or parenteral nutrition are all forms of nutritional therapy that can be used depending on the clinical circumstances.<sup>17</sup> It is important to clearly define the goals and objectives of therapy prior to initiating nutritional support and to limit the decision to initiate nutritional therapy to clinical situations in which the benefits outweigh the risks.<sup>18</sup> Cancer survivors may have persistent gastrointestinal failure secondary to the effects of previous radiation therapy or multiple surgical resections and may require long-term home enteral or total parenteral nutrition (TPN).<sup>14</sup>

## Dietary Factors and Cancer

During the last few decades, increasing attention has been paid to various foods, nutrients, and dietary lifestyles as modifiers of cancer risk. Many hypotheses describing the effects of diet on cancer risk have been derived by analyzing the dietary patterns and cancer rates in different populations around the world. It was noted in the 1970s that developed Western countries have diets high in animal products, fat, and sugar and high rates of cancer of the colorectum, breast, and prostate. In contrast, developing countries typically have diets based on one or two starchy staple foods, low intakes of animal products, fat and sugar, low rates of 'Western'-type cancers, and higher rates of cancer of the esophagus, stomach, and liver. The international variations in diet and cancer rates suggest that diet is an important risk factor for many common cancers; therefore, cancer may be partially preventable by dietary changes.<sup>19</sup>

## Epidemiologic Evidence

The great interest in diet and human cancer in the last several decades derives from the large variations in the rates of specific cancers among

countries, changes in the incidence of certain types of cancer over a relatively short time span, and dramatic changes in cancer incidence among populations emigrating to regions with different cancer rates. More than 50 years ago, Burkitt and his associates noted a negligible risk of colon cancer among the indigenous populations of many African countries. The diets in these countries were quite similar: low in calories, low in fat and animal protein, high in fiber, and rich in vegetables, fruits, and cereal grains. Furthermore, over the past several decades, the incidence of stomach cancer in the United States has progressively declined. Similarly, 50 years ago, stomach cancer was the most prevalent malignancy in Japan and colorectal cancer was quite rare. Today, the incidence of stomach cancer is declining, whereas the rate of colon cancer is increasing. Finally, the incidence of breast cancer in Japan is much lower than in Japanese women from Hawaii. However, in one generation, Japanese women who move to Hawaii increase their risk of developing breast cancer, and in two generations, they develop the same risk as native-born Hawaiians.<sup>1</sup>

More recent studies have focused on the diet of individuals and the role of specific nutritional factors and the risk of developing cancer. The evidence linking nutritional factors to cancer is derived from many different lines of evidence of varying strengths. In vitro animal and epidemiologic studies have all contributed to understanding the relationship between nutrition and cancer. In vitro studies provide data on cellular mechanisms involving individual nutrients. Animal studies can test hypotheses and contribute causal inferences, but these may not be directly relevant to humans.<sup>5</sup> Epidemiologic studies such as case-control and prospective, observational studies have also greatly contributed to identifying risk factors and generating hypotheses, but these have their limitations. Case-control studies are useful for searching for possible dietary effects but cannot be relied on to establish moderate dietary associations because they are susceptible to both recall and selection bias. Accurate assessment of dietary intake through food records, food frequency questionnaires, and dietary recall can be problematic. Another limitation of case-control

Table 1 Dietary and Nutritional Factors and Cancer Risk<sup>2,19</sup>

Cancer Site	Probable		Possible	
	Harmful	Protective	Harmful	Protective
Oral cavity, pharynx, esophagus	Alcohol Obesity Hot drinks and food	Fruits and vegetables		Riboflavin Folate Vitamin C Zinc
Nasopharyngeal	Chinese style salted fish			
Stomach	Salted fish and meat Pickled vegetables Smoked foods High salt intake	Fruits and vegetables Vitamin C		$\beta$ -carotene Vitamin E Selenium
Colorectal	Obesity Red meat Smoked, salted & processed meat Total fat Saturated fat	Physical activity Folate Calcium		Fruits and vegetables Fiber
Liver	Alcohol Aflotaxin			
Pancreas	Obesity		Red meat	Vegetables
Lung	High intakes of $\beta$ -carotene			Fruits and vegetables
Breast	Obesity Alcohol	Physical activity		
Endometrium	Obesity		Total fat Saturated fat	Fruits and vegetables
Cervix				Folate Carotenoids Fruits and vegetables
Prostate	Red meat Total fat	Physical activity Lycopene		Vitamin E Selenium Vegetables
Bladder				Fruits and vegetables
Kidney	Obesity		Meat and dairy products	Vegetables

studies is that healthy controls may not be fully representative of the base population. Although prospective cohort studies eliminate recall and selection bias, measurement errors and confounding factors must be considered when interpreting the results of these studies. In particular, it is difficult to sort out the independent effects of specific nutrients or foods among a myriad of potential confounders.<sup>19,20</sup>

In an ideal situation, dietary recommendations should be based on data from the most well-designed type of study, namely the randomized controlled trial. Randomized controlled trials eliminate both the biases and the confounding that can affect observational studies, and the results can therefore be confidently interpreted in terms of cause and effect. Within the field of diet and cancer, however, trials are limited by the difficulty of randomizing at the level of foods and by the constraints that only a small number of nutritional factors can be tested in each trial, usually for only a short period. In cases in which these trials do not show the desired effect, it remains

possible that an effect would have been seen at a different dose, at a different time in life, or if the duration of the trial had been longer. Another point that should be considered when interpreting the results of randomized controlled trials is the possibility that the effect of a dietary component on cancer risk may differ according to the characteristics of the population studied. For example, the effects of a multinutrient supplement could be more marked in a population with a low dietary intake of micronutrients than in a population with a high dietary intake of micronutrients.<sup>19</sup>

### Energy Balance

Excessive energy intake in relation to requirements to maintain a normal body weight increases the risk of developing several common cancers.<sup>21</sup> Many studies, including retrospective and prospective studies, have found that a higher body mass index (BMI) is associated with an increased risk of colon cancer. An approximately twofold higher risk is typically observed in the 20% of

individuals with the highest BMI relative to those with the lowest 20%.<sup>22</sup> More recent evidence indicates that a tendency for central distribution of adiposity, also called visceral adiposity, increases the risk independently of the BMI.<sup>23</sup> A relationship also exists between positive caloric balance and the development of cancers of the esophagus, endometrium, kidney, and gallbladder.<sup>21</sup> The relationship between body adiposity and breast cancer is more complex. Prior to menopause, women with greater body fat have reduced risks of breast cancer, probably because of more anovulatory menstrual cycles in heavier women. After menopause, a positive, weak overall association with adiposity is seen, which is stronger for women who never used a hormone replacement.<sup>21</sup>

Whereas excess caloric intake appears to increase the risk of developing cancer, physical activity has been associated with a decrease in risk. Physical activity appears to decrease the risk of all-cancer mortality in men and women.<sup>24</sup> Colon cancer has been the most extensively

Table 2 Current Guidelines on Diet, Nutrition, and Cancer Prevention<sup>2,19,21,35,59</sup>

- Maintain BMI between 18.5-25 kg/m<sup>2</sup>.
- Keep physical activity to moderate intensity for at least 30 minutes on most days of the week.
- Limit consumption of alcoholic beverages.
- Minimize exposure of aflatoxin in foods.
- Chinese style salted fish and other salt-preserved foods and salt should be consumed in moderation.
- Eat at least 5 servings of fruits and vegetables daily.
- Eat plenty of whole grain and fiber rich foods; 20-30 g of fiber daily-wheat bran preferred.
- Limit red meat and preserved meat consumption.
- Reduce total fat intake to less than 25-30% of total calories and saturated fat to less than 10% of total calories.
- Do not consume foods or drinks when they are at a very hot temperature.

However, in prospective studies, little or no relationship has been observed between fiber intake and the risk of breast cancer.<sup>34</sup>

### Vitamins, Minerals, and Trace Elements

Acute deficiencies of micronutrients are rare in developed countries, but suboptimal nutrient intake remains a widespread problem. Deficiencies in one aspect of the metabolic network can cause repercussions in many systems. Evidence of a link between various micronutrient deficiencies and deoxyribonucleic acid (DNA) damage has been accumulating in recent years. Optimizing vitamin and mineral intake by encouraging dietary change and multivitamin and multimineral supplementation when appropriate and fortifying foods might therefore help prevent cancer.<sup>20</sup>

### Antioxidants

Antioxidants are compounds used by aerobic organisms for protection against oxidative stress induced by free radicals and active oxygen species. They exert their protective action either by suppressing the formation of free radicals or by scavenging free radicals. A wide range of biologic effects, established experimentally, may inhibit carcinogenesis. These include effects on tumor initiation, promotion, and progression; cell proliferation and differentiation; and DNA repair, cell membrane stability, and immune function. Diet-derived antioxidants such as carotenoids, vitamin C, vitamin E, and selenium have received much attention as potential cancer chemopreventive agents.<sup>35</sup>

Carotenoids are fat-soluble compounds classified as xanthophylls, carotenes, or lycopenes. Over 600 carotenoids occur in nature, and among them, the most commonly available in the human diet is  $\beta$ -carotene.  $\beta$ -Carotene is a naturally

occurring precursor of vitamin A found in leafy green and yellow vegetables, carrots, and a variety of fruits. It has potent antioxidant properties and has been postulated to inhibit the process of carcinogenesis by preventing DNA damage directly induced by free radicals or by interfering with the metabolic activation of chemical carcinogens. Additionally,  $\beta$ -carotene is converted to vitamin A in the human body. The hormone-like effects of vitamin A on epithelial tissue cell growth and differentiation may antagonize the promotional stages of cancer development.  $\beta$ -Carotene and vitamin A both have immunomodulatory effects; increases in the humoral and cell-mediated immune response could potentially enhance immunosurveillance in carcinogenesis. Finally,  $\beta$ -carotene may modify enzymatic activation of carcinogens and enhance gap junction communication. Enhanced cell-to-cell communication would restrict clonal expansion of initiated cells, decreasing the likelihood of cancer occurring.<sup>36</sup>

Observational epidemiologic studies have indicated a protective effect of carotene-rich vegetables or  $\beta$ -carotene on cancers of the lung, esophagus, stomach, colorectum, cervix, oropharynx, and prostate. On the other hand, findings from several randomized clinical trials do not support the promising findings of observational studies. In three large randomized trials,  $\beta$ -carotene supplements did not reduce the risk of lung or other cancers.<sup>21</sup> Indeed, in two of these trials, the incidence of lung cancer was actually increased among those receiving  $\beta$ -carotene (in one of these studies,  $\beta$ -carotene was given in combination with vitamin A).<sup>37,38</sup>

Chemoprevention using vitamin A-related compounds in patients with oral leukoplakia, a precancerous lesion, has shown promising results. Trials using retinoic acid, isotretinoin, and vitamin A have reported decreased size or remission in patients assigned to these treatments compared

with placebo. Studies using  $\beta$ -carotene have not shown as favorable results on leukoplakia.<sup>5</sup>

Lycopene is a carotenoid found primarily in tomatoes and tomato products; however, other sources include watermelon, pink grapefruit, and Japanese persimmons. Several studies have demonstrated a significant inverse association between the dietary intake of tomatoes and blood lycopene levels and the risk of prostate cancer. Lycopene is significantly taken up by prostate tissue and is associated with a reduction in DNA damage in both leukocytes and prostate epithelial cells. Lycopenes may exert protection against prostate cancer by decreasing plasma insulin-like growth factor 1 levels by a currently unknown mechanism.<sup>39</sup> In a prospective study of the biologic effects of lycopene in men with localized prostate cancer who subsequently underwent prostatectomy, men who received dietary lycopene supplementation after prostatectomy and over the 3-week period following prostatectomy had significantly smaller tumors, less involvement of the surgical margins, less diffuse involvement of the prostate by high-grade intraepithelial neoplasia, and lower serum mean prostate-specific antigen levels compared with men in the control group who did not receive lycopene supplementation.<sup>40</sup>

Vitamin C is another potent, naturally occurring antioxidant found in many fruits and vegetables. It is an important free radical scavenger in plasma and acts to regenerate active vitamin E in lipid membranes. Another postulated protective mechanism is the prevention of mutagenic nitrosamines in the stomach. In addition, vitamin C may also play an immune-enhancing role.<sup>36</sup>

Although several different factors in fruits and vegetables act jointly, the epidemiologic and biochemical evidence indicates an important role for vitamin C. The evidence for a protective effect of vitamin C is strongest for cancer of the stomach and upper aerodigestive tract and weaker for other forms of cancer.<sup>21</sup> However, randomized trials for vitamin C alone in the primary prevention of cancer are lacking. Another limitation in studying the relationship between vitamin C and cancer is that, in the absence of special preservation, vitamin C deteriorates rapidly during frozen storage. Thus, reliable assessments of blood vitamin C levels may be made only on fresh specimens or on samples that have been acid stabilized at  $-70^{\circ}\text{C}$ .<sup>36</sup>

Vitamin E, a fat-soluble vitamin, is the major lipid-soluble antioxidant of the cell membrane. It acts as a free radical scavenger and inhibits peroxidation. It has also been postulated to be related to improved host immunity, inhibition of tumor initiators and promoters, activation of the *TP53* tumor suppressor gene, inhibition of tumor angiogenesis, reduction in DNA damage, alteration of in vitro cell signaling systems, and reduction in the effect of environmental carcinogens.

**FIGURE 2** In cancer anorexia, increased expression of cytokines such as interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) prevents the hypothalamus from appropriately responding to peripheral signals, causing hyperactivation of the pro-opiomelanocortin (POMC) system and inhibition of the neuropeptide Y (NPY) neuronal pathway. This leads to a strong negative influence on energy intake. Adapted from Laviano A et al.<sup>65</sup>

Reduction of the effect of carcinogens may occur through prevention of nitrosamine formation in the stomach, more rapid carcinogen metabolism, and prevention of conversion of carcinogens to their active form.<sup>41</sup> Rich sources of vitamin E include vegetable oils, margarine, nuts, seeds, cereal grains, and vegetables. Animal products such as milk fat, meat, poultry, and eggs also contain smaller amounts of this vitamin.<sup>36</sup>

In single studies, vitamin E supplements were associated with a reduced risk of oral cancer and colon cancer. In a large randomized trial conducted in Finland ( $\alpha$ -Tocopherol,  $\beta$ -Carotene Cancer Prevention Study), men receiving vitamin E (50 IU/d) experienced reduced risk of prostate cancer.<sup>37</sup> Although statistically significant, this finding needs to be reproduced because it was not a previous hypothesis and many specific cancers were examined; chance remains a possible explanation.<sup>21</sup> In the Chinese Cancer Prevention Study, a randomized trial conducted in a region of China with very low consumption of fruits and vegetables, a supplement containing  $\beta$ -carotene, vitamin E, and selenium reduced the incidence of stomach cancer. Benefits began to emerge 1 to 2 years following initiation of vitamin supplementation.<sup>42</sup> A second randomized controlled trial also conducted in Linxian, China, compared a regimen of multiple vitamin-mineral supplementation that included vitamin E (as 60 IU/d of DL  $\alpha$ -tocopherol acetate) with placebo in patients with esophageal dysplasia, a precursor of esophageal cancer. However, this trial failed to demonstrate a significant reduction in the incidence of stomach cancer, esophageal cancer, or cancer overall, and a reduction in cancer-specific mortality was not seen.<sup>43</sup>

Selenium is a trace element discovered by Berzelius in 1817. For a long time, selenium was considered more as an intriguing element in biochemistry rather than a truly relevant element in

human biology. It is now recognized as an important essential micronutrient with the potential for chemoprevention.<sup>44</sup> Selenium appears to have two anticarcinogenic roles. When taken in doses of recommended dietary intake, selenium functions as an essential nutrient providing the catalytic centers of antioxidant enzymes such as glutathione peroxidase, thioredoxin reductase, iodothyronine 5'-deiodinase, and others. However, at supranutritional intakes, achievable only with dietary supplementation, certain chemical forms of selenium are metabolized to selenodiglutathione, hydrogen selenide, and methylselenol. These metabolites can directly affect tumorigenesis. Therefore, in selenium-deficient populations, the protective effect of selenium against cancer is derived mainly from its antioxidant activity through glutathione peroxidase and other selenoenzymes. On the other hand, in areas of supranutritional selenium exposures, the anticancer effects of selenium and its metabolites include enhancement of immune function, alteration in the metabolism of carcinogens, inhibition of tumor cell proliferation, enhancement of apoptosis, activation of the DNA repair response, and inhibition of tumor angiogenesis during tumor growth.<sup>45</sup>

Blood and tissue levels of selenium are often lower in cancer patients than in control subjects. However, this may be secondary to the malnutrition frequently seen in these patients.<sup>46</sup> There is also evidence from epidemiologic studies that high dietary selenium intakes and high selenium status in people are associated with lower cancer mortality.<sup>46</sup> A new impetus for the relationship between the dose and chemical form of selenium and cancer risk was provided by Clark and colleagues' study in 1996.<sup>47</sup> In a prospective, placebo-controlled, double-blind study conducted over about 4.5 years with more than 1,100 participants selected for a previous history of skin cancer,

these authors observed that selenium supplementation with 200  $\mu$ g/d in the form of enriched yeast resulted in significantly lower incidences of various types of cancer (mainly of the lungs, prostate, and colorectum) and lower overall cancer mortality.

The selenium content of plants is dependent on the region of growth. For example, China has regions with both the lowest and the highest selenium-containing soil in the world.<sup>44</sup> Dietary selenium consists mainly of selenoamino acids and analogues such as L-selenomethionine from cereal grains or animal proteins or L-selenocysteine from animal meats, poultry, fish, and dairy products, with trace amounts of other selenium compounds, such as L-selenomethylcysteine. Alternatively, selenium supplements are available in both inorganic (selenite and selenate) and organic formulations, such as L-selenomethionine and selenium-enriched yeast, a less well-defined form of selenium. The adequate dose and optimal chemical form of selenium for nutritional or preventive and therapeutic purposes continue to be intensively investigated in a number of ongoing trials.<sup>48</sup>

### Other Vitamins and Minerals

1,25-Dihydroxyvitamin D<sub>3</sub> is the active form of the fat-soluble vitamin D. Major dietary sources of vitamin D include liver, fatty saltwater fish, eggs, and fortified milk. Vitamin D functions in the regulation of calcium homeostasis. Vitamin D also inhibits proliferation and DNA synthesis, alters expression of several oncogenes, reduces lipid peroxidation and angiogenesis, and induces differentiation. Epidemiologic studies support an inverse relationship between vitamin D intake and colorectal cancer risk and have also shown that vitamin D<sub>3</sub> deficiency and low plasma levels of 1,25-dihydroxyvitamin D<sub>3</sub> increase the risk of prostate cancer. The overall evidence, however, remains insufficient.<sup>35</sup>

Several hypotheses have focused on the potential benefits of dietary calcium. Calcium has been proposed to reduce colorectal cancer risk by binding secondary bile acids and ionized fatty acids in the colonic lumen, thereby reducing the proliferative stimulus of these compounds on mucosal cells. Alternatively, calcium may have a direct beneficial influence on the proliferative activity of the colonic mucosa.<sup>22</sup> In a recently reported randomized trial, calcium supplements modestly reduced the recurrence of colonic adenomas.<sup>49</sup> However, in large prospective studies, only weak and nonsignificant inverse associations have been seen between calcium intake and the risk of colon cancer.<sup>21</sup> Calcium supplement use was also positively associated with the risk of prostate cancer in one study. Thus, avoidance of low intakes of calcium may be prudent, but the data do not currently support very high intakes of calcium for the purpose of cancer prevention.<sup>21</sup>

Table 3 Four-Step Pharmacologic Management for Cancer Anorexia and Cachexia<sup>15,64</sup>

History	Physical
<ul style="list-style-type: none"> <li>● Weight change over past 6 months</li> <li>● Dietary intake and change relative to usual intake</li> <li>● Gastrointestinal symptoms persistent for at least 2 weeks</li> <li>● Functional capacity</li> <li>● Metabolic demand of underlying disease process</li> </ul>	<ul style="list-style-type: none"> <li>● Loss of subcutaneous fat</li> <li>● Muscle wasting</li> <li>● Ankle or sacral edema</li> <li>● Ascites</li> <li>● Mucosal lesions</li> <li>● Cutaneous and hair changes</li> </ul>

Folate, a water-soluble B complex vitamin, is a major participant in the formation of purine and pyrimidine nucleotide precursors for DNA and ribonucleic acid, as well as in the formation of methionine, which is itself transformed to S-adenosylmethionine, a coenzyme needed for more than 100 transmethylation reactions in cells.<sup>50</sup> The richest sources of folate are green, leafy vegetables and, in the United States, fortified flour, cold cereal, and orange or grapefruit juice.<sup>20,21</sup>

There is much epidemiologic evidence indicating that low folate status increases the risk of many types of cancer.<sup>20</sup> The data are strongest for colorectal cancer. An increased occurrence of colorectal adenomas, precursors of colorectal cancer, has been observed fairly consistently among individuals with low circulating folate concentrations. In general, prospective studies also support an inverse association between low folate intake or circulating level and colon cancer risk.<sup>22</sup> Furthermore, a recent report indicated that the excess risk of colon cancer among women with a positive family history of colorectal cancer could be substantially reduced if they had high intakes of folate or took a multivitamin supplement.<sup>51</sup> Low folate status may be deleterious either by causing misincorporation of uracil into DNA and increased frequency of chromosomal breaks or by contributing to DNA hypomethylation.<sup>52</sup> Site-specific DNA methylation appears to control gene expression, and DNA hypomethylation can lead to dysregulated activation of proto-oncogenes involved in carcinogenesis. The finding that homozygotes with a variant form of methylenetetrahydrofolate reductase (MTHFR), the enzyme that regulates the conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, are at reduced risk of colon cancer further supports a role for folate. However, the protective effect of this genetic polymorphism may be lost in patients with a dietary deficiency of folate or with high alcohol consumption, which

effectively impairs the absorption and use of folate.<sup>53</sup> Higher intakes of folic acid may also mitigate the elevated risks of breast cancer seen with daily alcohol consumption.<sup>21</sup>

### Other Dietary Factors

There is considerable interest in the prevention of cancer by chemicals present in food plants that play no known nutritive role. These chemicals are often referred to as phytochemicals or nutraceuticals.<sup>54</sup> A number of animal studies have demonstrated that tea polyphenols can prevent induction of cancer of the lung, colon, esophagus, pancreas, and liver.<sup>35</sup> Epidemiologic studies suggest that soy proteins containing the isoflavone genistein can inhibit the growth of androgen-dependent and androgen-independent cell lines of prostate cancer. Genistein can also induce apoptosis, inhibit angiogenesis, and regulate transcription of the estrogen receptor.<sup>35</sup> A lot of evidence also suggests that soy consumption may decrease breast cancer risk; however, conflicting information that soy may be harmful for women with a history of breast cancer or who are at high risk makes it difficult to recommend soy consumption at this time.<sup>55</sup>

Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit the enzyme cyclooxygenase (COX) involved in the metabolism of arachidonic acid and the production of prostaglandins. There are two recognized isoforms of COX. COX-1 is a constitutive isoform involved in a range of physiologic functions, whereas COX-2 is an inducible isoform expressed at sites of inflammation. There is growing evidence that the COX-2 isoform plays a key role in the early stages of intestinal polyp formation. A number of natural substances have been identified with COX-2 inhibitory properties. The natural COX-2 inhibitors identified include curcumin (the natural yellow pigment in tumeric), resveratrol (a phytochemical found in grape skin), and the omega-3

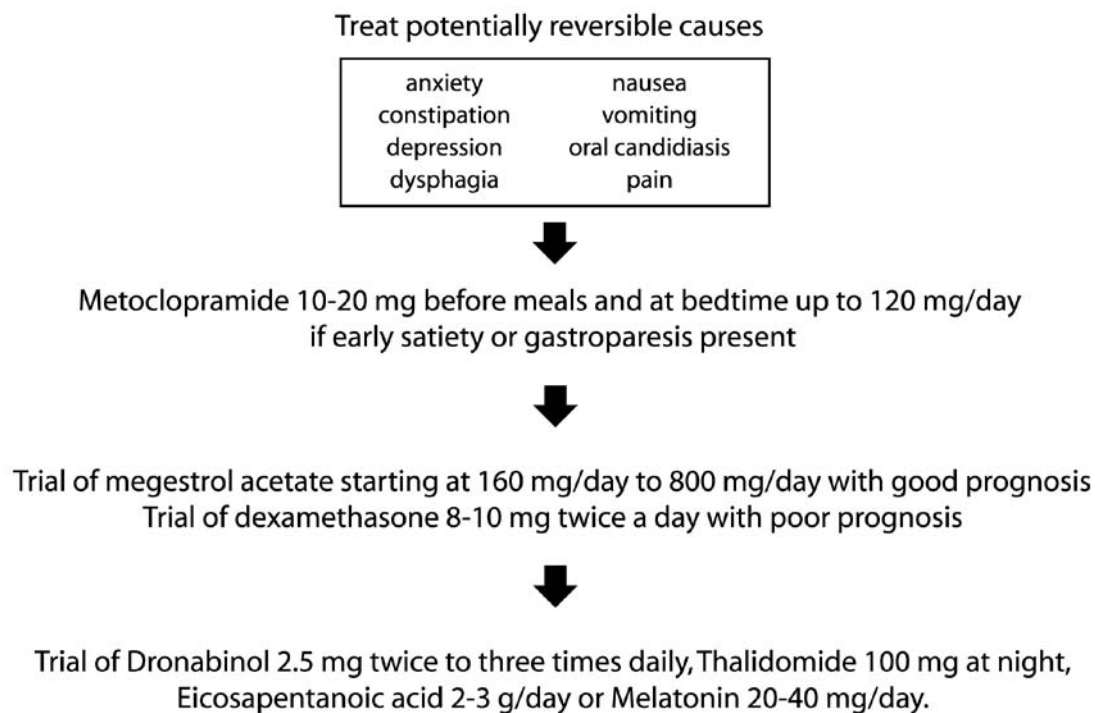

fatty acids found in fish oil. Dietary supplementation with omega-3 fatty acids has been evaluated in several clinical trials, and the results suggest some benefits for cancer patients.<sup>55</sup>

On the other hand, some food substances and eating habits increase the risk of cancer. Aflatoxin in food causes liver cancer. Chinese-style salted fish increases the risk of nasopharyngeal carcinoma. Salt-preserved foods and high salt intake probably increase the risk of stomach cancer. Alcohol causes cancers of the oral cavity, pharynx, esophagus, and liver and a small increase in the risk of breast cancer. Very hot drinks and foods probably increase the risk of cancers of the oral cavity, pharynx, and esophagus; drinks and foods should not be consumed when they are scalding hot.<sup>19</sup>

### Genetics and Nutrition

Inconsistencies between epidemiologic studies and randomized clinical trials have led to the development of a new discipline called nutritional genomics. Transforming nutrition and cancer research from a predominantly observational to a molecular approach offers exciting opportunities for truly identifying those who will and those who will not benefit from dietary intervention strategies.<sup>8,56</sup> Nutrients and genes can interact at two levels. Nutrients can induce gene expression, thereby altering individual phenotype. Conversely, genetic polymorphisms, in a range of genes important in inflammation and lipid metabolism, alter the bioactivity of important metabolic pathways and mediators and influence the ability of nutrients to interact with them.<sup>57</sup> Therefore, one can appreciate that the fundamental action of a nutrient is to serve as a regulator of gene expression and/or modulator of a gene product. Nutrients have specific sites of action, which can best be described as molecular targets. There is evidence that genetic polymorphisms can influence the dynamics between nutrients and molecular targets and thus contribute to the variation in response among individuals.<sup>9</sup> Current study of nutrient-modulated carcinogenesis involves exploring the effect of nutrients on DNA damage and repair mechanisms; DNA methylation, which influences gene expression and cellular phenotypes; antioxidant rearranging and oxidative stress; target receptors and signal transduction pathways; cell cycle controls and checkpoints; apoptosis; and antiangiogenic processes. The generation of this new knowledge on nutrient-gene interactions provides the justification for a research framework for diet and cancer prevention that is focused on identifying and developing new biomarkers as well as a novel and contemporary paradigm for dietary intervention.<sup>58</sup>

Table 4 Essential Features of the Subjective Global Assessment<sup>77,78</sup>

### Current Dietary Recommendations

Dietary suggestions for cancer prevention by nutritional means should be based on the best available scientific research. Although many data have been presented, few dietary influences on cancer risk have been firmly established. Avoiding obesity, maintaining an ideal body weight, limiting alcohol intake to one drink a day for women and two drinks a day for men, and increasing physical activity to moderate to vigorous intensity for 30 minutes on most days will reduce cancer risk. Limiting consumption of Chinese-style salted fish and minimizing dietary exposure to aflatoxin will also reduce cancer risk in populations in which these dietary factors are important. Risk will probably be decreased by increasing the average intake of fruits and vegetables to five servings per day and by limiting the intake of preserved and red meat, salt-preserved foods and salt, and very hot drinks and foods. Consuming cereal products in a minimally refined whole-grain form and taking a multiple vitamin containing folic acid may also be of benefit.<sup>2,3,5,19,21,59</sup>

### Malnutrition and Cancer

Nutritional decline is often accepted as part of the natural history of cancer and its treatment. The prevalence of weight loss and malnutrition in patients depends on the tumor type and stage, the organs involved, and the anticancer therapy. Weight loss and malnutrition in patients have been reported to range from 9% in breast cancer to 80% in patients with esophageal cancer. In addition, as many as 20% of patients with cancer

die from the effects of malnutrition rather than the malignancy.<sup>12</sup> Patients with cancer of the pancreas, esophagus, or stomach have the highest frequency and severity of weight loss, whereas patients with breast cancer, leukemia, sarcoma, and lymphoma have the lowest risk of weight loss. Intermediate frequency of weight loss occurs in patients with colon, prostate, and lung cancers.<sup>14</sup> Among surgical patients in a Veterans Administration Hospital, 39% of those undergoing a major operation for cancer were malnourished, as judged by either a nutrition risk index or a combination of weight loss and low serum proteins.<sup>60</sup>

The presence of malnutrition in cancer patients has major prognostic significance. In a review of more than 3,000 cancer patients, DeWys and colleagues found better survival rates in those patients without weight loss compared with patients who had lost just 6% of their body weight.<sup>61</sup> Malnutrition not only affects morbidity and mortality but can also lead to a diminished quality of life and poor performance status.<sup>10</sup> Increased hospital stays,<sup>11</sup> unplanned hospitalizations, readmissions, and a greater incidence of postoperative complications result in higher health care costs.<sup>13</sup> Furthermore, the malnourished cancer patient has a poor response and diminished tolerance to antineoplastic treatments such as chemotherapy, radiotherapy, and surgery.<sup>12</sup> This highlights the need for early identification and treatment of malnourished cancer patients who could potentially benefit from nutritional intervention.

### Etiology of Malnutrition

The cancer anorexia-cachexia syndrome results from progressive nutritional deterioration and is among the most debilitating and life-threatening aspects of cancer. Lean body mass wasting accounts for up to 30% of cancer-related deaths.<sup>15</sup> Cancer cachexia is clinically characterized by anorexia, early satiety, wasting, weight loss, anemia, weakness, fatigue, poor mental and physical performance, decreased capacity for wound healing, impaired immunologic function, and a compromised quality of life.<sup>62</sup> Cachexia should be expected if an involuntary or unexpected weight loss of greater than 5% has occurred within the previous 6-month period, especially when combined with muscle wasting. A weight loss of 10% or more indicates more severe depletion.<sup>17</sup>

Attempts to provide energy in patients with cancer cachexia often do not result in weight gain. One possible explanation is that the weight loss observed in cachexia is different from that seen in simple starvation or anorexia. The patient with cancer cachexia exhibits features of both starvation and injury. In cachexia, there is an accelerated loss of skeletal muscle in relation to adipose tissue. This contrasts with simple starvation, in which fat replaces glucose as the preferred fuel to spare lean body mass.<sup>63</sup>

The etiology of malnutrition in patients with cancer is multifactorial.<sup>14</sup> The causes can be classified into two major categories: (1) anorexia, factors related to decreased food intake, and gastrointestinal dysfunction and (2) metabolic disturbances.<sup>15</sup>

### Pathophysiology of Anorexia

Appetite loss or anorexia is a substantial contributing factor to the malnutrition seen in cancer patients.<sup>17</sup> It can be caused by localized effects induced by the tumor itself or by systemic effects caused by metastasis or humoral factors produced by tumor cells.<sup>12</sup> Cancer patients may experience mechanical gastrointestinal obstruction, pain, constipation, maldigestion, malabsorption, debility, and the side effects of therapy, any of which can lead to decreased food intake. In some cases, the loss of appetite is due to depression or psychological stress.<sup>64</sup> Cancer patients may also develop anorexia secondary to food aversion learning after treatment with radiochemotherapy regimens.<sup>65</sup>

The pathogenesis of cancer-associated anorexia is related to disturbances of the central physiologic mechanisms controlling food intake. Convincing evidence suggests that cancer anorexia is brought about by the derangement of the hypothalamic system transducing peripheral signals into neuronal responses. Under normal conditions, peripheral signals (such as the hormone leptin produced by adipocytes exerting a strong

Adapted from Shike M.<sup>14</sup>

negative influence on food intake) interact with two separate neuronal populations within the arcuate nucleus of the hypothalamus, the neuropeptide Y neurons and the pro-opiomelanocortin neurons. These neurons constitute two pathways, the former stimulating and the latter inhibiting energy intake. In cancer anorexia, it appears that the hypothalamus is unable to respond appropriately to consistent peripheral signals owing to hyperactivation of the melanocortin system. Increased expression of cytokines by the tumor itself during tumor growth or by the host in response to the tumor inhibits the hypothalamus to appropriately respond to peripheral signals by persistently activating the melanocortin system and inhibiting the neuropeptide Y neuronal pathway.<sup>65</sup> Several cytokines have been proposed as possible mediators of the cachectic process. Elevated serum levels of tumor necrosis factor  $\alpha$ , interleukin-1, and interleukin-6 have been found in some, but not all, cancer patients, and the serum levels of these cytokines seem to correlate with the progression of the tumor.<sup>66</sup> These cytokines and others may also produce long-term inhibition of appetite and feeding by stimulating the production and release of leptin and/or by mimicking the hypothalamic effect of excessive negative feedback signaling from leptin, leading to normal compensatory mechanisms for decreases in food intake and body weight.<sup>15</sup>

Another possible cause of anorexia is the increased serotonergic activity within the central nervous system of patients with cancer cachexia, attributed to the enhanced availability of tryptophan to the brain. The fact that uptake of tryptophan into the brain is competitive with uptake of branched-chain amino acids has

suggested the use of branched-chain amino acids to decrease the incidence of anorexia in cachectic cancer patients.<sup>64</sup>

## Gastrointestinal Dysfunction

Malignant disease and its treatment often lead to abnormalities in the mouth and elsewhere in the gastrointestinal tract and may interfere with the ingestion of food.<sup>15</sup> Altered taste and smell have been documented in about half of these patients. Changes in the recognition of sweet taste occur in approximately one-third of patients, whereas bitterness (responsible for meat aversion), sourness, and saltiness are less frequently affected. Many patients undergoing dose-intensive radiation and/or chemotherapy regimens experience reduced taste (hypogeusia) or altered taste (dysgeusia), which may have a significant impact on quality of life.<sup>17</sup>

Antineoplastic drugs that have been associated with taste changes include cisplatin, carboplatin, cyclophosphamide, doxorubicin, 5-fluorouracil, levamisole, and methotrexate.<sup>67</sup> In a study reported by Mattson and colleagues, 10 patients evaluated had dysgeusia during the aplastic phase of hematopoietic cell transplantation; the threshold for salt was most profoundly affected.<sup>68</sup> However, 1 year after transplantation, it was found that in 80% of them, taste acuity had normalized by the end of the year. Therefore, it seems that taste receptors have the capacity to regenerate and function can recover following injury.

Chemotherapy itself can also have an immediate effect on taste. Some patients will complain of a bitter or metallic taste during administration of the cytotoxic drug. This may occur because drugs pass into the saliva; hence, these drugs can be tasted or smelled once they enter the oral or nasal cavity. The etiology of taste disorders in the setting of chemotherapy is probably multifactorial and not merely due to damage to the taste receptors.<sup>67</sup> There have been reports in the literature linking hypogeusia to zinc deficiency. Some drugs that cause hypogeusia have a sulfhydryl group in their structures; the sulfhydryl group is known to bind and chelate heavy metal ions, including zinc.

Nonetheless, zinc supplementation rarely impacts on taste in these patients.<sup>69</sup>

Other drugs, such as some antibiotics, analgesics, bisphosphonates, antihypertensives and cardiac medications, bronchodilators, muscle relaxants, antidepressants, and anticonvulsants, can also alter taste. Agents that effect hormonal changes, such as tamoxifen, may also affect taste. Xerostomia is also a possible side effect of a number of medications, including antiemetics, antidepressants, and antihypertensives, and may contribute to taste changes. Damage to salivary glands may reduce the flow of saliva so that

tastants do not reach the receptor, rendering food tasteless. Changes in the oral flora; bacterial, viral, or fungal infections of the nasal or oral cavity; diseased teeth; dental caries; poor oral hygiene; and gastroesophageal reflux may also lead to altered taste.<sup>68</sup>

Considerable taste change also occurs during radiotherapy; however, unlike taste changes associated with chemotherapy, pretreatment taste sensation is usually not recovered. These taste complaints may be due to direct damage to taste receptors and to reduced saliva production and xerostomia, resulting in secondary infection and reduced delivery of tastants to receptor sites.<sup>67</sup>

Patients undergoing chemotherapy may also complain of smells during or after the administration of the drug, and some patients have a heightened sensitivity to odors. Olfactory hallucinations have also been reported, in which a patient may experience a chemical odor even when just thinking about previously administered therapy. Olfactory loss may also result from the direct toxic effects of radiation therapy; such effects may take over 6 months to resolve.<sup>67</sup>

Dysphagia and odynophagia are particularly marked in head and neck and esophageal cancer. Tumors elsewhere in the gastrointestinal tract and the hepatobiliary tract and metastatic tumors (such as ovarian cancer) causing extrinsic compression often lead to nausea, vomiting, and early satiety. Malabsorption with severe atrophy of the small bowel mucosa and exudative enteropathy have also been described. Furthermore, gastrointestinal dysmotility can lead to a sensation of early satiety, delayed digestion, and weight loss.<sup>17</sup>

Anticancer therapies are also a major cause of anorexia and weight loss.<sup>14</sup> Chemotherapy can cause nausea, vomiting, abdominal pain, mucositis, adynamic ileus, and malabsorption.<sup>17</sup> Surgery involving a segment of the gastrointestinal tract, such as the pharynx, esophagus, or stomach, can decrease the ability to ingest food. Extensive resections of the small bowel result in the short bowel syndrome characterized by malabsorption of nutrients and fluids. Pancreatic resections can result in pancreatic exocrine and endocrine insufficiency, creating major nutrition problems, such as steatorrhea and hyperglycemia. Major hepatic resections cause metabolic abnormalities in the immediate postoperative period.<sup>12</sup> Radiotherapy can induce acute and chronic complications that can interfere with the ingestion and absorption of nutrients. Edema and mucositis of the oropharynx and radiation esophagitis cause severe dysphagia and odynophagia, further compounding the swallowing difficulties imposed by the cancer itself. In the acute setting, patients receiving radiotherapy to the abdomen frequently experience self-limited nausea, vomiting, and diarrhea. However, chronic severe radiation enterocolitis is complicated by fistulae, complete obstruction

**FIGURE 3** Patient with head and neck cancer on long-term enteral nutrition using a 24F 3.4 cm button gastrostomy tube. A, Feeding tube with extension tube attached; B, the closed feeding tube flap lies close to the skin and is less cumbersome between feedings.

secondary to strictures, or peritonitis, which may lead to prolonged nutritional support. Improved fractionation of radiation therapy and protective shielding of the intestines have considerably reduced such complications.<sup>14</sup>

### Metabolic Disturbances

Inability to gain or maintain weight despite seemingly adequate nutrient intake may be due to increased metabolic needs generated by the accentuated nutritional demands of the semiautonomous tumor, generalized increased energy expenditure in the cancer patient, and failure of the cancer patient's host tissues to use the nutrients available in an efficient and effective manner to satisfy the energy requirements of the body.<sup>14</sup>

Malignant tumors are characterized by a high rate of growth. The tumor escapes all of the normal mechanisms of metabolic control. Most tumor tissue develops whatever the host's nutritional status and maintains a high level of metabolic activity at the expense of the host. Malignant cells have a high degree of anaerobic glycolysis and produce large amounts of lactate. An investigation of amino acid metabolism also showed net uptake of amino acids by human tumor tissue, suggesting that cachexia is at least partially caused by increased metabolic demands of the tumor.<sup>17</sup>

An increase in energy expenditure has been widely but not universally found in cancer patients.<sup>14</sup> Patients with newly diagnosed small cell lung cancer were shown to have a mean 37% increase in resting energy expenditure. Their food intake was not sufficient to meet the demands of the increased metabolic rate, resulting in a negative energy balance and weight loss. The high metabolic rate declined in patients who responded to chemotherapy.<sup>70</sup> Similar elevations in resting energy expenditure were reported in patients with gastric cancer,<sup>71</sup> sarcoma,<sup>72</sup> and a variety of other tumors.<sup>73</sup>

Maladaptive metabolism in cancer patients is associated with widespread metabolic derangements that decrease the efficiency of nutrient use and can affect the metabolism of carbohydrate,

fat, protein, vitamins, and minerals.<sup>74</sup> Alterations in carbohydrate metabolism include the activation of low-efficiency biochemical cycles such as the Cori cycle, where lactate is converted to glucose in the liver, an increase in endogenous glucose production from alanine, glucose intolerance, and peripheral tissue insulin resistance.<sup>63</sup> The most consistent abnormalities of lipid metabolism involve increased mobilization of peripheral fat and excessive oxidation of fatty acids. This increase in endogenous lipolysis eventually leads to the depletion of lipid stores. Increased plasma concentrations of glycerol and free fatty acids reflect the mobilization of lipid stores and usually occur only in patients with malignant disease who develop weight loss. In healthy patients, a glucose infusion suppresses lipolysis but does not suppress lipolysis in cancer patients. Ultimately, the cancer patient depletes fat stores, develops hypertriglyceridemia, and manifests decreased lipoprotein lipase levels.<sup>64</sup> Protein metabolism is also altered in cancer patients. This is manifested by an increase in protein turnover, a reduction in muscle protein synthesis, an increase in inflammatory hepatic protein synthesis, increased muscle catabolism, and a progressive loss of body nitrogen with a negative nitrogen balance.<sup>17</sup> The cytokines tumor necrosis factor  $\alpha$  and interleukin-1 produced by macrophages and interleukin-6 released by macrophages or by the tumor itself play important roles in the development of these metabolic disturbances.<sup>65</sup>

All of these metabolic abnormalities that occur in the cancer patient with cachexia point to a wasteful and inefficient metabolism in which the nutritional requirements of the tumor are selectively favored over those of the host. This makes it quite difficult to reverse malnutrition even with the highly sophisticated nutritional support techniques currently available.<sup>14</sup>

### Diagnosis of Malnutrition

Nutritional assessment of the cancer patient is important to identify the subsets of patients who

can potentially benefit from dietary counseling by a dietitian or other forms of nutritional intervention, as well as to determine the severity and causes of malnutrition, to identify patients at risk of complications from anticancer therapies, and to assess the efficacy of nutritional support.<sup>17</sup> Although many nutritional assessment techniques are available, each has its limitations.<sup>75</sup> Furthermore, the use of a single measurement in time provides an inaccurate assessment of an individual's nutritional status.<sup>16</sup> Therefore, an ideal evaluation for the clinician has been to shift nutritional assessment from a diagnostic to a prognostic instrument to identify patients who can benefit from nutritional therapy by decreasing the risk of malnutrition-associated medical complications.<sup>76</sup>

Nutritional status has been traditionally defined by body composition and anthropometric measurements, plasma protein concentrations, immunocompetence, and multivariate analysis of certain parameters.<sup>62</sup> Body composition analysis requires sophisticated equipment and is not always readily available.<sup>77</sup> Recent weight change is generally a good indicator of nutritional deficit. A weight loss of 10% or more within the previous 6 months or 5% or more within the previous month indicates severe malnutrition. However, weight changes do not always reflect nutritional deficits but can also occur secondary to changes in body fluid balance.<sup>78</sup> Subscapular and triceps skinfold thickness and midarm muscle circumference provide an estimate of body fat and fat-free mass, but values may vary with hydration status and are based on a standard that has not been validated in cancer patients. In addition, interobserver reproducibility is poor, even after several weeks of special training.<sup>16</sup> A strong relationship has been found between low albumin concentrations and poor outcome in cancer patients. However, many clinical conditions found in cancer patients can interfere with measurements of plasma protein concentrations. Serum albumin has a long half-life of 18 to 20 days and is severely depressed during stress, illness, infection, and states of overhydration and with hepatic and renal dysfunction. The use of other proteins with shorter half-lives, such as prealbumin, transferrin, and retinol binding protein, is also limited because those proteins are also affected by illness and hydration status.<sup>77</sup> Tests of immunocompetence, such as delayed cutaneous hypersensitivity, may indicate malnutrition but are also affected by infection, illnesses, medications, and medical procedures.<sup>76</sup> Absolute lymphocyte counts may be affected by infection and hematologic malignancy.<sup>62</sup> Creatinine height index measurements require accurate urine collections and are affected by alterations in protein intake, renal failure, sepsis, trauma, exercise, and

steroid therapy.<sup>76</sup> Calculating nitrogen balance by obtaining a 24-hour urinary total or urea nitrogen has been used to determine the degree of protein catabolism present. However, many factors can affect this measurement, including the adequacy of collection, diuretics, renal function, and protein intake, so this test needs to be interpreted carefully.<sup>79</sup> Discriminant functional analysis of multiple nutritional parameters has been used by Buzby and colleagues to develop the prognostic nutrition index, which has been shown to provide a quantitative estimate of postoperative complications when applied prospectively to patients undergoing gastrointestinal surgery.<sup>77</sup> More recently, hand-grip strength and adductor pollicis relaxation rate have been shown to correlate with postoperative complications. Muscle function testing measures physiologic changes in malnutrition even before changes in body nitrogen or plasma protein concentration occur.<sup>76</sup> Bioelectrical impedance has also been used to evaluate nutritional status and to follow the effectiveness of nutrition support but requires specialized equipment and training.<sup>78</sup>

A clinical nutritional assessment was first developed by the Toronto group and has been termed subjective global assessment (SGA). The SGA combines elements from the history and physical examination and defines malnourished patients as those who are at increased risk of medical complications and who will presumably benefit from nutritional therapy. The SGA integrates five history and four physical examination findings to define nutritional status: weight loss pattern, change in dietary intake, gastrointestinal symptoms, the patient's functional status, the metabolic demand of the underlying disease, subcutaneous fat thickness, muscle wasting, the presence of edema and ascites, mucosal lesions, and skin and hair changes. The findings of the history and physical examination are used to categorize patients as well nourished (category A), moderately malnourished (category B), and severely malnourished (category C).<sup>63,78</sup> The SGA correlates closely with objective parameters, such as anthropometric measurements and serum protein levels, and accurately predicts clinical outcome after major surgery with 82% sensitivity and 72% specificity. Interobserver variability and reproducibility are satisfactory after a training period of a few days.<sup>80</sup>

In summary, the nutrition assessment of the cancer patient should initially include a careful history, a physical examination, and the SGA to identify patients who are at increased risk of malnutrition-associated complications, followed by appropriate laboratory testing to further evaluate considerations raised during the clinical examination. This will identify the patients who will most likely benefit from nutritional support.

## Treatment of Malnutrition

Clearly, the most important treatment for the malnourished cancer patient would be the development of antineoplastic therapies that target and cure the underlying disease process. Until that goal is achieved, the adjunctive and palliative use of pharmacologic agents and unique nutritional formulations and therapies in an attempt to alter the course of progressive nutritional deterioration play significant roles in the treatment of the malnutrition frequently seen in cancer patients.<sup>64</sup>

## Pharmacologic Treatment

Drugs that are directed toward improving functional status and quality of life in cancer patients have become an integral part of antineoplastic therapy. Symptomatic control of nausea, vomiting, mucositis, and gastrointestinal dysmotility can usually be accomplished. Several types of drugs have also been employed in an attempt to improve appetite, food intake, a sense of well-being, and body weight gain. These and other agents represent a new approach to management of the cancer anorexia-cachexia syndrome and an opportunity for combined therapeutic endeavors to improve the quality of life of these patients.<sup>63</sup>

Improvement of appetite in cancer patients also calls for treatment of other symptoms, such as pain, mucositis, depression, and the side effects of oncologic treatments.<sup>17</sup> Ondanestron and granisetron, which are often used as antiemetics during chemotherapy, are serotonin receptor antagonists that have also been used in cancer cachexia as antagonists to the satiating effects of serotonin. Although these agents failed to promote weight gain, treatment did improve the ability of patients to enjoy food. Cyproheptadine, another antiserotonergic drug useful as an appetite stimulant in anorexia nervosa, also failed to prevent progressive weight loss in cancer patients. Metoclopramide has been used to ameliorate the emesis associated with chemotherapy and to treat patients with early satiety, delayed gastric emptying, and gastroparesis seen in advanced cancer.<sup>64</sup>

Megestrol acetate and medroxyprogesterone acetate are first-line therapy for cancer cachexia. Many randomized controlled trials have confirmed that progestational drugs can stimulate appetite, food intake, energy level, and significant weight gain in cancer patients.<sup>81</sup> The effect of megestrol acetate is dose related, ranging from 160 to 1,600 mg, with an optimal dose of 800 mg/d. In general, patients are started on the lowest effective dosage (160 mg/d) and the dose is increased according to the clinical response of the patient. The dose of medroxyprogesterone acetate is 500 mg twice daily.<sup>63</sup> Most of the weight gain obtained with progestational agents consists of fat

rather than lean body mass.<sup>66</sup> The effect of these drugs on appetite appears to be mediated by a down-regulation of the synthesis and release of cytokines, leading to an increase in neuropeptide Y hypothalamic levels.<sup>65</sup> The side effects of progestational agents include induction of thrombosis and thromboemboli, breakthrough uterine bleeding, hypertension, hyperglycemia, peripheral edema, alopecia, Cushing's syndrome, adrenal suppression, and adrenal insufficiency.<sup>64</sup> Side effects were seen in 10 to 30% of patients in clinical trials.<sup>17</sup> Caution must be taken in administering these drugs to patients with known thromboembolic disease, heart disease, or a high risk of fluid retention. Progestational agents are contraindicated in hormone-dependent tumors.<sup>65</sup>

Corticosteroids are frequently used as appetite stimulants in cancer patients. Although treated patients report an increased sense of well-being, there is no long-term benefit since any benefit is lost within a month of treatment. Dexamethasone's ability to stimulate appetite is equivalent to that of megestrol acetate but does not produce weight gain.<sup>15</sup>

The use of anabolic steroids in healthy people and athletes increases muscle mass, but this benefit has not been shown to occur in patients with gastrointestinal cancer. Only one small trial in lung cancer patients treated with nandrolone decanoate suggested benefit in attenuating weight loss.<sup>82</sup> Anabolic steroids are associated with some severe side effects, such as hepatotoxicity and endocrine effects.<sup>74</sup>

The metabolic inhibitor hydrazine sulfate inhibits an integral enzyme in gluconeogenesis, thereby interrupting the Cori cycle and normalizing carbohydrate metabolism. Unfortunately, several large studies have shown no significant impact on weight gain in cancer patients.<sup>64</sup>

Dronabinol, a commercially available cannabinoid, is an appetite stimulant that can promote minimal improvement in overall body weight. The usual dosage is 2.5 mg two to three times a day. Adverse effects include somnolence, confusion, and perceptual disturbances.<sup>15</sup>

Pentoxifylline is a methylxanthine-derived phosphodiesterase inhibitor that has been shown to decrease tumor necrosis factor  $\alpha$  synthesis in cancer patients by decreasing gene transcription. In a randomized controlled trial in patients with advanced cancer, it failed to cause better appetite or body weight than placebo.<sup>83</sup>

Melatonin stimulates host immune defenses and inhibits tumor growth factor production. Studies in cancer patients using a dosage of 20 mg daily significantly lowered the percentage of treated patients who experienced a greater than 10% weight loss. More trials are needed before the widespread use of melatonin is recommended.<sup>84</sup>

$\beta_2$ -Adrenergic receptor agonists can prevent muscle protein wasting in tumor-bearing rats. Tumor-bearing rats have an anabolic response with increases in muscle mass while receiving salbutamol, salmeterol, and clenbuterol. However, no controlled trials have been reported using these agents in cancer patients.<sup>15</sup>

Growth hormone increases lean body mass and protein synthesis and reduces urinary nitrogen excretion in patients in catabolic states. The use of recombinant growth hormone has not been studied in cancer cachexia.<sup>64</sup>

Eicosapentanoic acid, a polyunsaturated fatty acid, and NSAIDs inhibit COX. Diets rich in eicosapentanoic acid attenuate weight loss in patients with advanced pancreatic cancer.<sup>85</sup> Ibuprofen was shown to normalize protein kinetics in cachectic patients with colorectal cancer and stabilize weight while reducing resting energy expenditure and increasing quality of life in patients with pancreatic cancer.<sup>86,87</sup> Gastrointestinal side effects limit the use of NSAIDs.<sup>54</sup>

Thalidomide is a potent suppressor of tumor necrosis factor  $\alpha$  production. It has been shown to improve insomnia, restlessness, and nausea in advanced cancer patients while improving appetite and a sense of well-being in a majority of patients studied. Side effects of thalidomide include fever, skin rash, and peripheral neuropathy in addition to its well-known teratogenic effect.<sup>88</sup>

A four-step pharmacologic management model has been proposed for the treatment of cancer cachexia. The first step includes the treatment of potentially reversible causes of anorexia, such as anxiety, constipation, depression, dysphagia, nausea, vomiting, oral candidiasis, or pain. If a patient has reduced appetite associated with early satiety or evidence of gastroparesis, a trial of metoclopramide 10 to 20 mg before meals and at bedtime up to 120 mg/d is a reasonable second step. If this fails, then a trial of megestrol acetate starting at 160 mg/d and increasing the dose up to 800 mg/d for patients with a relatively good prognosis or the use of dexamethasone 8 to 10 mg twice daily in patients with a poor prognosis is indicated. Megestrol acetate should not be combined with other chemotherapy agents. The fourth step is based on emerging evidence from clinical trials for dronabinol, thalidomide, eicosapentanoic acid, and melatonin. Dronabinol should be used 2.5 mg twice to three times daily, thalidomide at 100 mg per night, eicosapentanoic acid at 2 to 3 g/d, and melatonin at 20 to 40 mg/d.<sup>15,64</sup>

### Use of Dietary Supplements during Cancer Therapy

Many cancer patients take nutritional supplements and herbs or start a special diet during or after conventional cancer treatment hoping to

enhance the benefits of treatment, to alleviate side effects, and to maintain or improve general health and well-being.<sup>89</sup> Unfortunately, the use of dietary supplements during cancer treatment remains controversial.<sup>56</sup> Physicians should routinely ask their patients if they are taking any nutritional supplements or herbs, especially since patients often fail to inform their physician of their supplement use. Patients should also be cautioned not to substitute vitamin and mineral supplements for established medicine.<sup>90</sup>

Supplemental antioxidants remain one of the more popular nutritional supplements taken by cancer patients, often at doses higher than the recommended dietary allowances. The rationale for this practice is that antioxidants may improve the efficacy of cytotoxic therapies by selectively inhibiting the growth of tumor cells, inducing cellular differentiation, or altering the intracellular redox state.<sup>91</sup> Many oncologists, on the other hand, are reluctant to recommend antioxidant supplementation during treatment for fear that it will interfere with conventional therapy. Antioxidants may interfere with the oxidative breakdown of cellular DNA and cell membranes necessary for the agents to work. Furthermore, there is evidence to suggest that apoptotic breakdown of tumor cells is selectively increased by the presence of reactive oxygen species within the tissue. This cytotoxic process would most likely be slowed by an antioxidant-replete diet.<sup>56</sup> The American Institute for Cancer Research has concluded, based on current evidence, that supplementation of the diets of cancer patients undergoing active treatments with individual or combined antioxidants above their dietary reference intakes cannot be recommended as safe or effective. However, adding a daily multivitamin containing supplements at levels of the dietary reference intake can be done safely as part of a program of healthy nutrition including 5 to 10 servings of fruits and vegetables daily.<sup>56</sup>

The use of nonantioxidant supplements such as soy protein and isoflavones, herbal supplements, and special diets is not currently supported by substantial evidence. Potential drug interactions with other supplements, medications, and anticancer therapy and overlooking or misinterpreting the side effects of herbal supplements and possible contaminants can have serious consequences. It is important to establish efficacy, dosing timing, and duration of supplementation prior to recommending patient use. Recommendations should be based on sound scientific evidence.<sup>90</sup>

### Nutritional Therapies

Nutrition screening should be performed as part of the initial assessment at the time of diagnosis. Options for nutrition intervention include oral supplements, hydration solutions, and dietary

recommendations; enteral feeding with polymeric, monomeric, or specialized formulas; and TPN. Treatment should be individualized according to the needs of the patient.<sup>17</sup> It is important to define the goals of nutrition support on initiation of treatment. Nutritional therapy can be used as adjuvant treatment and support during anticancer therapy or as a means to provide long-term nutrient supplementation to patients with severely impaired gastrointestinal function who would not survive without intervention.<sup>14</sup>

### Oral Dietary Therapy

Oral dietary therapy can improve nutrition in patients who are able to eat but require special diets because of gastrointestinal dysfunction. Simple dietary recommendations can significantly increase oral protein-energy intake by cancer patients in the course of treatment or in palliative care. Successful implementation of a diet requires instruction of the patient and family by a dietitian.<sup>14</sup> The dietitian should intervene as soon as possible after the diagnosis of cancer is made. The dietitian's role is to calculate food consumption and caloric requirements, develop meal plans, evaluate nutritional status, and anticipate the nutritional risks of both the cancer and its treatment. Regular monitoring and follow-up and close coordination with staff involved in patient care are important to alert the physician to the need for enteral or parenteral support.<sup>17</sup>

In addition to the diet, a variety of oral nutritional supplements are available. They vary according to the type of proteins, energy density, osmolarity, lactose, gluten and fiber content, commercial formulation (eg, liquid, powder, pudding, bar), and the range of flavors.<sup>17</sup> The main problem with the use of oral supplements is taste fatigue.<sup>14</sup> Nevertheless, such formulations can be an important source of nutrients in patients who are able to reach their caloric goals with oral intake alone.

### Enteral Nutrition

Enteral feeding delivers nutrients to the gastrointestinal tract through tubes.<sup>92</sup> The enteral route is preferred over parenteral nutrition in the setting of a functional gastrointestinal tract.<sup>93</sup> Enteral feeding is more physiologic, preserves the gastrointestinal architecture, and prevents bacterial translocation from the gut.<sup>75</sup> Enteral nutrition solutions are easier to administer, have fewer complications, and are more cost effective. The rate of enteral feeding can be regulated to be delivered as a bolus or as a slow, continuous infusion to permit the optimal use of a limited small intestinal absorptive capacity. Enteral nutrition can bypass proximal obstruction or defects, overcome oropharyngeal dysphagia, or allow a gastrointestinal tract that has a limited absorptive capacity to be constantly bathed in nutrients.<sup>11</sup>

Once it has been decided to initiate enteral nutrition support, a choice of enteral access device must be made. Tubes may be placed through the nose or percutaneously, and the tip terminates in the stomach or small intestine. For patients for whom the anticipated duration of enteral support is less than 30 days, a nasogastric or nasoenteric tube is the best choice. These tubes are also useful to test for tolerance to enteral feeding before committing a patient to a percutaneous tube. Tubes typically range from 8F to 12F and have a mean durability of less than 10 days before they get clogged or dislodged.<sup>11</sup> A serious complication of transnasal tube placement is inadvertent placement into the lung or pleural cavity and the development of a pneumothorax. Radiographs or direct endoscopic visualization should be used to confirm the location of the tube prior to initiation of feeding.<sup>93</sup>

For patients who will require enteral nutrition for more than 4 weeks, a percutaneous feeding tube is indicated.<sup>94</sup> Surgical, radiologic, and endoscopic methods have been successfully used to place percutaneous feeding tubes in the stomach and small intestine.<sup>92</sup> Success rates of up to 99% with major complication rates of only 1.3% have made the placement of percutaneous endoscopic gastrostomy (PEG) tubes the most popular.<sup>95</sup> Commercially available PEG tubes are typically made of silicone or polyurethane and come in sizes ranging from 15F to 28F. These larger-bore tubes are associated with less frequent clogging than nasal tubes. With proper care, the average tube will last 1 to 2 years. In patients with cancer, PEG tubes have been shown to safely provide long-term enteral access, with few major complications. Complications of PEG placement include peritonitis, perforation, hemorrhage, and fasciitis.<sup>11</sup> In patients with head and neck cancer, metastases to the PEG stoma have been described. This may occur secondary to direct seeding of the stoma during PEG placement or by hematogenous or lymphatic spread.<sup>96</sup>

In general, gastric feeding is preferred. However, jejunal feeding is indicated in the presence of gastric outlet obstruction, gastroparesis, or proximal fistula or leak or if there is suspicion of aspiration of gastric contents.<sup>97</sup> Surgical jejunostomies are associated with significant morbidity and mortality, including intestinal obstruction and necrosis and the development of abscesses and fistulae, and carry a mortality rate of up to 10%.<sup>98</sup> Radiologically placed gastrojejunostomy tubes are safe and well tolerated.<sup>99</sup> There are two types of endoscopically placed jejunostomies: the jejunal extension tube (JET-PEG) and the direct percutaneous endoscopic jejunostomy (DPEJ). The JET-PEG is essentially a small-bore tube that is placed through a larger-bore PEG tube and endoscopically advanced to the jejunum. The small-bore extension tube often clogs or migrates

back into the stomach.<sup>11</sup> The placement of a DPEJ tube uses the same technique as PEG placement and has been performed by experienced endoscopists with success rates of 88% and complication rates of 3 to 7%.<sup>100,101</sup> DPEJ is particularly useful in patients who have had a previous esophagectomy or gastrectomy. Successful DPEJ placement has been shown to decrease dependence on TPN and simplify hospital discharge.<sup>102,103</sup> DPEJ tubes also last for 1 to 2 years before needing to be changed and can be safely used for long-term nutritional support if necessary. Whenever delivering nutrient solutions directly into the small intestine, a continuous infusion via a pump must be used. Bolus feedings are contraindicated. However, infusion rates of up to 180 mL/h are safe and can be tolerated.<sup>11</sup>

More than 100 different enteral feeding formulas are currently available. Formulas are classified as polymeric, monomeric, and disease specific. Polymeric formulas contain intact carbohydrate polymers, proteins, and triglycerides. They can be used safely in most patients. Monomeric formulas contain nutrients that have been partially or completely hydrolyzed and are therefore more easily absorbed if digestion is impaired. Proteins are present as short peptide chains or free amino acids, carbohydrates as oligosaccharides or maltodextrin, and fat as a mixture of long- and medium-chain triglycerides. They are indicated in patients with malabsorption. Disease-specific formulas are targeted toward patients with specific underlying conditions. Formulas have been developed for patients with diabetes mellitus, renal insufficiency, pulmonary insufficiency, and hepatic encephalopathy. Immune-enhancing formulas are also available for use in patients with acquired immune deficiency syndrome (AIDS), severe traumatic injury, or critical illness, as well as in cancer patients.<sup>92</sup>

There is no evidence to support the routine use of enteral feeding in well-nourished patients undergoing anticancer therapy.<sup>62</sup> On the other hand, patients with head and neck cancer represent a group of patients who benefit the most from placement of a PEG tube prior to the initiation of radiotherapy.<sup>104</sup> Enteral nutrition in these patients has been shown to prevent weight loss, treatment interruption, and hospitalization for dehydration. For malnourished patients undergoing resection of their tumor, 7 to 10 days of preoperative enteral nutrition support is associated with a 10% reduction in morbidity and improved quality of life.<sup>105</sup> In a prospective study of patients with esophageal cancer undergoing chemoradiation, enteral nutrition effectively prevented weight loss during therapy.<sup>106</sup> Placement of DPEJ tubes is useful in the management of complications after esophagectomy. Most patients will regain their ability to eat and can have the feeding tube removed. However, a

significant minority will become dependent on enteral nutrition and can be fed long term via a PEG tube, percutaneous endoscopic jejunostomy tube, or a button (skin level, low profile) gastrostomy or jejunostomy device with few complications.<sup>11</sup>

Immune-enhancing formulas contain substantial amounts of arginine, n-3 polyunsaturated fatty acids, nucleotides, and glutamine.<sup>107</sup> Studies using these specialized formulas in patients undergoing elective surgery for upper gastrointestinal or pharyngeal cancer show a consistent trend toward reduced infectious complications; however, none of them has demonstrated a statistically significant survival benefit. Furthermore, many of these studies have design flaws.<sup>108</sup> On the other hand, more recent evidence suggests that if an adequate volume of immunonutrition is delivered in advance of surgical insult, more impressive benefits can be appreciated. In a clinical trial by Braga and colleagues, 150 malnourished patients who were candidates for major elective surgery for malignancy of the gastrointestinal tract were randomly assigned to receive either postoperative enteral nutrition with a standard formula, 1 L/d for 7 days of immunonutrition formula preoperatively and standard enteral formula postoperatively, or immunonutrition formula 1 L/d for 7 days preoperatively and continued postoperatively.<sup>109</sup> Statistically significant reductions in infectious complications and in postoperative length of stay were noted in the groups receiving immunonutrition compared with the control group. Although more studies are needed before the routine use of immunonutrition is advocated, some practical strategies to maximize the success of these formulas have been suggested. Arginine should be at least 12 g/L; the duration should be at least 3 days; feeding goals should approach 25 kcal/kg and at least 800 mL/d; and enteral nutrition protocols should be more aggressive in feeding patients preoperatively and reaching enteral goals postoperatively.<sup>108</sup>

### Total Parenteral Nutrition

TPN is an effective means of delivering hypertonic nutrient solutions via the central venous system into the general circulation and bypassing the gastrointestinal tract. In patients unsuitable for enteral nutrition support, parenteral nutrition remains an important option. Catheter-related complications include pneumothorax, venous thrombosis, arterial trauma, and sepsis. Metabolic and electrolyte abnormalities such as hypokalemia, hypophosphatemia, glucose intolerance, and nonketotic hyperosmolar coma can also occur.<sup>75</sup> Many prospective randomized controlled studies have examined the role of TPN in the management of cancer patients. A clear benefit from nutritional support appears to be limited to a specific group of patients.<sup>14</sup>

Most studies reveal no benefits of specialized nutrition support during chemotherapy or radiation with regard to treatment tolerance, antitumor therapy side effects, or survival.<sup>62</sup> Furthermore, patients who receive TPN while undergoing chemotherapy have more infectious complications. However, in some of these studies, patients were not necessarily malnourished, and some had adequate oral intake and gastrointestinal function.<sup>14</sup> Therefore, patients who are severely malnourished or who develop prolonged gastrointestinal toxicity with treatment may be candidates for TPN.

A group of patients for whom prolonged gastrointestinal toxicity during treatment and poor tolerance to oral or enteral nutrition support is extremely common is in the setting of bone marrow transplantation.<sup>62</sup> The use of TPN has become routine practice to maintain body cell mass. Prophylactic TPN decreases the incidence of malignant relapse and improves survival in patients receiving bone marrow transplantation.<sup>110</sup> Studies using glutamine-supplemented parenteral nutrition solutions in bone marrow transplant recipients have also demonstrated a significant reduction in the incidence of clinical infections and the duration of hospital stay compared with those patients receiving standard TPN. However, there was no significant difference in the severity of mucositis, the incidence or severity of graft-versus-host disease, or inhospital mortality.<sup>111,112</sup> The role of glutamine-supplemented TPN needs more study prior to recommending its routine use.

The use of TPN during the perioperative period in malnourished cancer patients undergoing surgery has also been recommended.<sup>10</sup> Patients with gastrointestinal cancer who received TPN for 10 days before surgery had lower rates of postoperative wound infection, pneumonia, major complications, and mortality compared with patients on a regular hospital diet.<sup>113</sup> The Veterans Affairs Cooperative Study Group, in one of the largest clinical trials, randomly assigned 395 malnourished patients prior to surgery to receive TPN before and after surgery or no perioperative TPN. Approximately two-thirds of these patients had malignant disease. Although the overall incidence of infectious complications was higher in the group receiving TPN, the small subgroup of patients who were categorized as severely malnourished receiving TPN had fewer noninfectious complications and no concomitant increase in infectious complications compared with the control group.<sup>60</sup> The use of perioperative TPN in patients undergoing hepatectomy for hepatocellular carcinoma was also associated with a reduction in overall postoperative morbidity and diminished deterioration in postoperative liver function.<sup>114</sup> However, not all studies have demonstrated a clear benefit for the use of perioperative

TPN in cancer patients. In a randomized trial of 117 patients with pancreatic cancer who underwent major pancreatic resection, complications were significantly greater in the group receiving TPN postoperatively and were associated with an increase in the rate of intra-abdominal abscesses. The overall mortality rates were similar in the TPN and the control groups.<sup>115</sup> In a recent consensus conference sponsored by the National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society of Clinical Nutrition, 33 prospective randomized controlled trials, involving more than 2,500 surgical patients, were reviewed to evaluate perioperative nutrition support. The panel came to the following conclusions: (1) TPN given to malnourished patients (defined by weight loss, plasma proteins, or prognostic indices) with gastrointestinal cancer for 7 to 10 days before surgery reduces postoperative complications by 10%, (2) routine use of early postoperative TPN in malnourished general surgical patients who did not receive preoperative TPN increases postoperative complications by approximately 10%, and (3) postoperative nutritional support is necessary for patients unable to eat for prolonged periods after surgery (within 5 to 10 days after surgery) to prevent the adverse effects of starvation.<sup>10</sup>

### Home Nutrition Support

Long-term home enteral nutrition and parenteral nutrition are tools that can be used by physicians in the appropriate clinical setting. Patients requiring home nutrition support fall into three general categories. The first group of patients are cancer survivors or patients with stable disease who develop gastrointestinal failure during the course of treatment. The second group of patients are moderately to severely malnourished and undergoing a defined curative or palliative oncologic intervention with anticipated side effects. The third group of patients are those with widely metastatic disease and little hope for cure who are being considered for palliative nutritional support.<sup>62</sup>

Patients with severe gastrointestinal failure secondary to massive small bowel resection or severe radiation enteritis usually require long-term home TPN.<sup>14</sup> In a published report, patients with intestinal failure secondary to therapy for malignancy received home TPN for an average of  $1,092 \pm 867$  days.<sup>116</sup> Survival rates and TPN-related complications in such patients are comparable to those seen in patients with benign disease who require home TPN. Most deaths in patients on home TPN are secondary to progression of the primary disease process rather than TPN-related complications.<sup>117</sup>

In malnourished cancer patients with a defined treatment plan who are at high risk of

progressive nutritional deterioration secondary to therapy, enteral nutrition is the preferred treatment. Parenteral nutrition should be reserved for patients in whom enteral nutrition is contraindicated or not tolerated.<sup>62</sup> A review of the North American registry showed that 30% of patients on home enteral nutrition were able to resume oral intake and discontinue enteral feeding during the first year and 36% of all cancer patients on home enteral nutrition were alive after 1 year.<sup>118</sup> Home enteral nutrition is safe, with a hospitalization rate for complications owing to home enteral nutrition of fewer than 0.4 hospitalizations per patient per year.<sup>118</sup> Outpatient follow-up and repeated evaluations are necessary to determine whether patients enrolled in a home nutrition program require indefinite nutrition support or if they can eventually be transitioned to oral intake.<sup>11</sup>

Among patients with progressive disease despite specific treatments, home TPN offers little benefit.<sup>14</sup> Nevertheless, in the United States, cancer patients represent about one-third of patients receiving home TPN compared with about half in Italy. In addition, 50 to 75% of these patients have locoregional and/or metastatic progressive disease.<sup>17</sup> The 1-year survival rate in these conditions was 32% in the 1995 American survey, with preservation of satisfactory social and/or professional activity in 25% of the cases during the first year.<sup>117</sup> In the Italian study, the improvement in quality of life depended on functional status. Among patients with a Karnofsky index lower than 40, the average survival time was less than 3 months, and an improvement in the quality of life was found in only 9% of cases.<sup>119</sup> On the other hand, some investigators have advocated the use of selected immunonutrient formulas in palliative care. Significant weight gain and increases in oral food intake and functional status have been noted.<sup>120</sup> However, patients with widely metastatic disease usually already have available central access and are often reluctant to have a nasogastric tube or more permanent tube placed. They may also be intolerant of enteral feedings because of partial or complete bowel obstruction secondary to carcinomatosis and extrinsic compression.<sup>17</sup> The decision of whether to initiate home nutrition support in this clinical situation should also take into account patients' perceptions so that quality of life can be improved.<sup>121</sup> In a study aimed at assessing the life experience of patients with malignant bowel obstruction, it was determined that at that time, the most important issues confronting the patient were the inability to eat, alteration in physical activities, deterioration in mental abilities, social isolation, waiting for bowel movements to occur, and a lack of direction and personal inner reflection. However, if the patient had a goal, it meant that something was being done; regardless of whether that goal

was palliative or active treatment, doing something appeared to be a way of maintaining hope, and doing nothing was seen as abandonment or desertion.<sup>122</sup>

Ultimately, the decision to initiate home nutrition support needs to be based on the ability of nutrition support to improve patients' clinical outcome and ethical principles that need to be interpreted and appropriately applied to each individual case. It is vital to maintain an open and honest relationship with patients and their families and to address these issues in a forum in which all parties concerned can effectively communicate their feelings, anxieties, and ethical principles.<sup>121</sup>

Home nutrition is no longer appropriate when a patient enters the terminal stages of the disease. Such patients usually have severely restricted oral intake or are dehydrated. Fluids or small amounts of food should be administered to alleviate hunger or thirst.<sup>14,17</sup>

## Summary

The exact role that nutrients, dietary factors, and lifestyle changes play in cancer prevention remains elusive. However, as clinical breakthroughs are made with the performance of collaborative research involving larger and more well-designed studies and the development of the discipline of nutritional genomics, a deeper understanding of pathophysiologic mechanisms and nutrient-gene interactions can be achieved. Inevitably, this will lead to dietary and lifestyle recommendations based on a solid foundation of scientific evidence.

Malnutrition in cancer patients needs to be addressed early so that patients have the best chance of responding to anticancer therapy. Symptom control, pharmacologic therapies to improve appetite and food intake, dietary therapy, enteral and parenteral nutrition, and home nutrition support provide valuable adjuncts to treatment of the cancer patient. The study and development of immune-enhancing formulas for enteral and parenteral use and the role they have in preventing malnutrition-associated complications remain the focus of continued research in cancer patients.

# Oral and Orofacial Considerations in Oncology

Mark S. Chambers, DMD, MS

Adam S. Garden, MD

Jack W. Martin, DDS, MS

Merrill S. Kies, MD

Randal S. Weber, MD

James C. Lemon, DDS

The care of cancer patients requires the combined efforts of a multidisciplinary team of health care providers whose collective goal is not only to cure patients of malignant disease but also to treat or prevent the morbid sequelae of oncologic treatment. In most cancer patients, problems in the oral cavity mirror those in the general population: moderate to advanced periodontal disease, poorly restored dentition, and associated soft tissue pathologies associated with tobacco use, alcohol use, nutritional neglect, general hygiene neglect, or a combination of these factors.<sup>1,2</sup> Evaluation, treatment, and prevention of any oral and dental preexisting pathology are important aspects of the overall treatment outcome for cancer patients.<sup>1,2</sup> Patients undergoing aggressive anticancer treatment encounter preventable, if not treatable, oral mucosal and dental sequelae that could produce morbid events.<sup>3</sup> Complications vary with each patient, depending on the individual's oral and dental status, the type of malignancy, and the therapeutic approach (ie, surgery, radiation therapy, chemotherapy, or a combination of these treatments).<sup>4</sup> Common and frequent treatment-limiting toxicities, such as mucositis, infection, and bleeding, can be minimized and in some cases eliminated if evaluated and treated early by an involved, trained dental health care team.

An oral and dental consultation before chemotherapy, radiation therapy, or head and neck surgery is extremely important in the oral management of cancer patients.<sup>1,5-8</sup> For patients receiving a tumor-ablative procedure involving the oral cavity, the treating physician should aim to control oral and dental problems before adjunct therapy and during the recovery phase. In the

immediate postsurgical planning, the oral cavity should be prepared for appropriate prosthetic rehabilitation to correct postsurgical deficits. If radiation therapy, chemotherapy, or both are planned, the treating dental specialist should be aware that the resultant oral complications may be devastating; furthermore, the degree and type of oral sequelae may affect the patient's compliance with or continuance of cancer treatment.<sup>9-12</sup> Such complications may arise during cancer therapy and may result either from treatment (eg, chemotherapeutic complications related to myelosuppression, immunosuppression, or the direct cytotoxic effects of chemical agents on oral tissues) or from the malignant disease process.

A head and neck evaluation, an oral and dental clinical examination, and an intraoral radiologic evaluation should all be performed during the initial visit.<sup>1</sup> Selected dental radiographs are essential in evaluating potential areas of infection that are not obvious on clinical examination (eg, periodontal-periapical tooth pathology, residual cysts, and impacted or partially erupted exfoliating teeth). In addition, the oral health care provider should gather and record the patient's history of present illness, medical and dental histories, social history, review of systems, current medications, adverse drug reactions, and the anticipated cancer treatment plan. From this information, the dentist can plan oral treatment to control immediate needs. However, treatment of disease must always take priority over treatment of complications.<sup>1,13</sup> Dentists should communicate with the treating physicians to be aware of the diagnosis and staging of malignant disease, the goals of proposed therapy, the patient's prognosis, the type and dose of therapy

to be administered, and the timing of treatment. If radiation therapy is to be used in the head and neck area, the dentist must know the volume of tissue to be radiated, treatment schedule, dosimetry, fractionation scheme, method of administration (eg, external beam radiation therapy or brachytherapy), type of energy (eg, photon, electron, or mixed beam), and total dose to be administered.<sup>5,7,14-17</sup>

The dentist's initial examination and early treatment of the patient are directed at documenting and reversing any preexisting acute or chronic pathologic conditions—such as dental abscesses, advanced periodontal disease, dental calculus causing gingivitis, partially erupted teeth with the potential for pericoronitis, or soft tissue tooth trauma—that may be factors in the selection of an overall cancer treatment strategy by the treating physician.<sup>1,4</sup> Even if the planned cancer treatment is not toxic to the mucosa and is not myelosuppressive (eg, hormonal therapy), the potential for infection remains even under “normal” circumstances. Additionally, the cancer may eventually progress, necessitating prompt and aggressive therapy; hence, the oral and dental status should be optimal to ensure minimal predictable complications. The periodontal status and degree of tooth decay are evaluated during the initial examination, as are the patient's ability and initiative to maintain optimal oral hygiene.<sup>18</sup> Patients must modify their oral care and hygiene techniques, if possible, to minimize the mucosal and gingival complications that are associated with their specific treatment.<sup>10-20</sup> Caries is another adverse condition resulting from increased caries-forming organisms and is in itself an important consideration in patients with drug- or

radiation-induced xerostomia owing to potential pulpal involvement and subsequent periapical abscess formation.<sup>4,18,21</sup>

## Oral Complications

Complications resulting from therapeutic administration of ionizing radiation to the head and neck and cytotoxic agents as treatment for cancer can be categorized as either acute (eg, mucositis, infectious stomatitis, alteration in taste or smell acuity, dermatitis, pain, inflammation, and difficulty swallowing) or chronic (eg, xerostomia, caries, abnormal development, fibrosis, trismus, photosensitivity, osteoradionecrosis [ORN], and pain).<sup>1,21,22</sup> The severity of treatment-induced morbidity depends on multiple factors, such as the radiation dose, volume of tissue treated, myelosuppressive treatment, pretreatment performance status, and pretreatment oral condition.<sup>23</sup> Complications arise primarily in three anatomic sites: the mucosa, periodontium, and teeth.<sup>4</sup>

The following is a discussion of five key oral complications: mucositis, xerostomia, ORN, oral infections, and caries. Included is a definition of each condition and information about the incidence and risk, etiology and pathophysiology, clinical features, and management of each entity.

## Mucositis

### Definition

The National Cancer Institute defines mucositis as a complication of some cancer therapies in which the lining of the digestive system becomes inflamed and, hence, sores develop in the mouth.<sup>24</sup> “Oral mucositis” generally indicates a nonhematologic complication of the aerodigestive tract secondary to chemotherapy or head and neck radiation therapy (Figure 1). The complicated sequelae of mucositis can be associated with odynophagia, dysphagia, infection, dehydration, malnutrition, dysgeusia, and other quality of life

**FIGURE 1** A patient undergoing external beam radiation therapy with localized backscatter mucositis.

challenges. This condition can be a significant risk factor for systemic infection, particularly for pancytopenic patients, and can result in increased therapeutic expenses.<sup>25,26</sup> In a study by Sonis and colleagues, severe mucositis was associated with increased fever and infection ( $p < .01$ ), increased analgesia therapy ( $p < .001$ ), a fourfold increase in mortality risk, and higher hospital charges, especially with ulcerative mucositis.<sup>27</sup>

The economic and clinical burden of mucositis was examined by Elting and colleagues reviewing a cohort of 599 patients with solid tumors or lymphoma who had a total of 1,236 chemotherapy cycles from 1994 to 1996 with reported thrombocytopenia.<sup>25</sup> This retrospective analysis assessed clinical outcomes (ie, hemorrhage, infection, oral and gastrointestinal mucositis, and death) and resource use (ie, hospitalization, emergency room visits, and antibiotic use). Mucositis was identified in 37% of the 1,236 cycles, with 11% representing grade 3 or 4 mucositis. The results of this trial revealed a significant correlation between mucositis and increased dose reduction or dose delay in the chemotherapeutic regimen, as well as increased infection, the need for nutritional support, the use of anti-infectives, hospitalization and opioid use, and mortality linked to infection.

### Incidence and Risks

The incidence and severity of oral mucositis are influenced by the type of antineoplastic treatment administered and by patient-related factors.<sup>26</sup> Oral and gastrointestinal mucositis can affect up to 100% of patients undergoing high-dose chemotherapy and hematopoietic stem cell transplantation and up to 80% of patients with cancer of the head and neck receiving radiation therapy.<sup>28</sup> In one study, patients who had undergone bone marrow transplantation reported oral mucositis as the most debilitating side effect in comparison with nausea and vomiting, weakness, or diarrhea.<sup>29</sup>

The prevalence of oral mucositis is affected by a number of factors, including the patient's age (more common in the young), diagnosis (increased in patients with a hematologic malignancy), and preexisting oral health (increased in patients with poor oral health), as well as the intensity of antineoplastic therapy, that is, concomitant radiation and chemotherapy.<sup>30</sup> Localized oral infections can be transmitted into the bloodstream through the rich capillary beds that perfuse the mucosa with resultant septicemia. Studies have related septicemia to oral infections in up to 54% of neutropenic individuals.<sup>31</sup>

To improve the long-term disease-free survival rates for patients with head and neck cancer, more intensive regimens are being advocated. These include more aggressive radiation schedules and combining chemotherapy and

radiation. This has resulted in an increase in both the incidence of grade 3 mucositis and its duration. Fu and colleagues reported that patients treated with altered fractionation (hyperfractionation or accelerated fractionation) had a higher incidence of Radiation Therapy Oncology Group (RTOG) grade 3 or 4 mucositis versus standard fractionation (47% vs 25%;  $p < .01$ ).<sup>32</sup> More recently, Forastiere and colleagues described the benefit of concurrent chemotherapy and radiotherapy for organ preservation in advanced laryngeal cancer in an RTOG study of 547 patients. With a median follow-up of 3.8 years, patients treated with radiation therapy with concurrent cisplatin had a higher larynx preservation rate but also a higher mucosal toxicity rate (grade 3 or 4; 43%) compared with patients treated with radiation alone or with induction chemotherapy.<sup>33</sup> Two additional phase III trials have demonstrated the benefit of concurrent postoperative radiation and chemotherapy for patients with advanced squamous cell carcinoma of the head and neck. Both randomized trials demonstrated that the addition of concurrent chemotherapy to radiation resulted in a greater disease-free survival but also contributed to higher mucosal toxicity.<sup>34</sup>

Considerable interpatient variability exists in the tolerance to chemotherapy regimens.<sup>35</sup> Treatment factors that influence the frequency and severity of oral mucositis include the chemotherapeutic agent used, dosage, delivery schedule, and combination with radiation therapy.<sup>36</sup> Other factors that may contribute to the severity of mucositis include smoking, use of over-the-counter mouthwashes, and the coexistence of collagen vascular diseases or human immunodeficiency virus (HIV) infection.<sup>36</sup>

### Etiology and Pathophysiology

The etiology of mucositis is related to the direct and indirect effects of oncologic treatment and clinical factors, such as intercurrent illnesses. Mucosal injury is the cumulative result of a number of concurrent and sequential biologic processes. In general, oral mucositis is characterized by functional complaints, such as pain and dysphagia, and anatomic changes, such as edema, erythema, ulceration, pseudomembrane formation, alterations in mucus consistency, and xerostomia.<sup>37</sup>

Sonis and colleagues proposed a five-phase model to explain the pathophysiology of oral mucositis: initiation, up-regulation and message generation, signaling and amplification, ulceration, and healing.<sup>38</sup> Oral mucosal toxicity is initiated by chemotherapy and radiation therapy and is characterized by injury to the submucosal tissues. Early response genes are up-regulated, resulting in changes in the endothelium, connective tissue, and extracellular matrix, all mediated by the reactive oxygen species, ceramide pathway,

and transcription factors.<sup>38</sup> This, in turn, causes a connective tissue breakdown, epithelial thinning, and initiation of a second set of genes, promoting early apoptosis of clonogenic stem cells in the basal epithelium. The molecules specific for signaling are proinflammatory cytokines derived from epithelial cells (ie, tumor necrosis factor [TNF]- $\alpha$ , interleukin [IL]-1 $\beta$ , and IL-6).<sup>38-40</sup> TNF- $\alpha$  causes local tissue damage, whereas IL-1 $\beta$  and IL-6 cause localized inflammation (increased vascularity). In addition, these molecules further amplify up-regulation of transcription factors, resulting in more elaboration of cytokines, tissue injury, and apoptosis. An unbalancing of apoptosis and necrosis exceeds the hyperproliferative rate and results in an ulcerative phase, with resultant mucosal damage.<sup>30,38-40</sup> This stage is complicated by bacterial colonization and intensifies the damage to the underlying submucosa. The ulcers become colonized with gram-negative bacteria that produce endotoxins, which stimulate the release of cytokines and the production of nitric oxide.<sup>38</sup> The cytokines and nitric acid cause further local tissue damage and localized inflammation. Additional local responses are prompted, including angiogenesis. In the last phase, which is healing, epithelial integrity is stimulated by submucosal signaling and regenerative properties.<sup>38</sup>

#### Clinical Features

The most consistent symptom of mucositis is pain. The severity of the pain correlates directly with the severity of the mucositis.<sup>41</sup> The pain is typically constant and is aggravated by drinking, eating, and performance of oral hygiene measures. All intraoral sites may be affected, although nonkeratinized surfaces are most severely affected (mucosa of the lips, cheeks, floor of the mouth, ventral surface of the tongue, and soft palate). Erythema is the initial manifestation, followed by the development of white desquamative patches. Epithelial sloughing and fibrinous exudate lead to the formation of ulceration and a pseudomembrane.<sup>36</sup>

Definitions of the degree and intensity of mucositis vary. Numerous scoring systems, none universally accepted, have been proposed and are used in clinical trials.<sup>28,41,42</sup> The most common are the World Health Organization system, which considers subjective symptoms (dysphagia) into the scores, and the National Cancer Institute Common Toxicity Criteria system (version 3.0), a simple 0 to 4 scale based on the observed degree of mucositis.<sup>1,28</sup> The lack of uniformity in scoring and the question of the validity of these systems, despite their common use, further compound the difficulty in assessing trials exploring mucositis. In particular, the objections to systems that use observer scores alone argue that mucositis is not

a problem but rather the subjective pain and dysphagia it causes, and evidence to correlate objective scores to degrees of subjective symptoms is lacking.

The complications of oral mucositis include dehydration, malnutrition, local infection, systemic infection, local hemorrhage, and interference with the cancer treatment regimen. The latter complication is particularly important because a delay in completing treatment or a reduction in the amount of treatment given may influence the eventual outcome of treatment. Oral mucositis is a self-limiting condition, with recovery occurring around 2 weeks after a course of chemotherapy and approximately 3 to 4 weeks after a course of radiation therapy.<sup>30</sup> Preexisting or predisposing factors that challenge wound healing can affect recovery from oral mucositis (eg, infection).<sup>1,22,30</sup>

#### Management

Mucositis management is primarily targeted to reduce symptomatology. The established or experimental prevention and treatment of oral mucositis focus on locally and systemically applied pharmacologic and nonpharmacologic methods.<sup>26</sup> There are multiple classes of agents for managing mucositis: anesthetics, antimicrobials, antioxidants, antiseptics, chemoprotectants, customized “cocktails,” coating agents, cryotherapy, growth factors, immunomodulators, laser therapy, nutritional supplements, and others.<sup>28</sup> The majority of the agents used today fall into one of four categories: drugs designed to protect against damage to the proliferating cells, anti-inflammatories, antimicrobials, and drugs that provide anesthesia.

No standard therapy is universally accepted to be effective in the prevention of oral mucositis. Cryotherapy was the first mechanism-based therapy for mucositis demonstrating benefit of vasoconstriction.<sup>28</sup> A recent systematic review identified 21 interventions that had been evaluated in randomized controlled trials; only 9 of these interventions showed evidence of benefit.<sup>44</sup> The authors concluded that there was some (“sometimes weak”) evidence to support the use of allopurinol, amifostine, antibiotics, granulocyte-macrophage colony-stimulating factor (GM-CSF), hydrolytic enzymes, ice chips, povidone, and oral care.<sup>44</sup> In many instances, evidence of the effectiveness of an intervention was based on studies performed in a specific patient or treatment groups. Similarly, no standard therapy is effective in the treatment or reversal of oral mucositis. In another systematic review, of six interventions evaluated in randomized controlled trials, evidence of benefit was found for only two.<sup>45</sup> The authors concluded that there was weak (“unreliable”) evidence to support the use of allopurinol mouthwash and vitamin E. Considered together,

these study results show that the primary objective in the treatment of mucositis should be palliation.

Management of pain related to oral mucositis is mainly treated with analgesics. In some cases, topical analgesics will control the pain. Nevertheless, in many cases, topical analgesics need to be supplemented or replaced by systemic analgesics. The principles of pain relief in this condition are the same as the general principles of pain relief in patients with cancer.<sup>46</sup> Patients often require opioids for moderate to severe pain; often these opioids must be given by transdermal administration, with a concomitant breakthrough in pain control.

#### Mucosal Protectors

Amifostine (WR-2721) is a phosphorylated aminothiol prodrug acting as a free radical scavenger (radioprotector).<sup>47</sup> The drug is currently approved by the US Food and Drug Administration (FDA) for the prevention of moderate to severe radiation-induced xerostomia and reducing the cumulative renal toxicity associated with repeated doses of cisplatin in patients with advanced ovarian cancer or non-small cell lung cancer. More recently, investigators have been interested in using this drug to prevent or reduce the severity of mucositis, but its effectiveness remains controversial. In a randomized clinical trial of over 300 patients with xerostomia, mucositis grade  $\geq 3$  occurred in 35% of the amifostine group and in 39% of the radiotherapy-alone patients.<sup>48</sup> The median duration of mucositis was 41 days versus 38 days, respectively.

Several smaller randomized trials have also investigated the role of amifostine for patients with head and neck cancer, with prevention of mucositis as a primary end point. Bourhis and colleagues randomized 26 patients treated with an accelerated course of radiation.<sup>49</sup> Patients randomized to amifostine had a lower incidence of grade 4 mucositis and needed feeding tubes for a shorter duration. Buntzel and colleagues investigated the role of amifostine with concurrent chemotherapy and radiation therapy.<sup>50</sup> Randomizing 28 patients, they reported a significant reduction in mucositis as none of the patients receiving amifostine had grade 3 or 4 mucositis compared with 86% of patients treated with radiation alone.

Growth factors and cytokines can either stimulate or suppress cell proliferation. Some, for example, IL-11,<sup>40,51</sup> transforming growth factor  $\beta_3$ ,<sup>38,51,52</sup> and recombinant human keratinocyte growth factor (rHuKGF),<sup>26,53</sup> through a variety of mechanisms, may reduce mucositis by either interfering with epithelial proliferation or through other effects. Palifermin (rHuKGF) is indicated to decrease the incidence and duration of severe

oral mucositis in patients with hematologic malignancies receiving myelotoxic therapy requiring hematopoietic stem cell support.<sup>54</sup> Keratinocyte growth factor (KGF) is another growth factor speculated to have a role in prevention of mucositis.<sup>26,55</sup> KGF has stem cell stimulatory properties. Clinical use of these agents for radiation-induced mucositis remains highly investigational.

Preclinical data have demonstrated that GM-CSF can influence the proliferation of keratinocytes.<sup>56</sup> Clinical observations that patients receiving GM-CSF with myeloablative chemotherapy for hematologic malignancies appeared to have a lower incidence of grade 3 and 4 mucositis compared with placebo controls<sup>57</sup> have also garnered interest. However, small trials using this agent via a subcutaneous route have been conducted and have not demonstrated a benefit with regard to mucositis reduction.<sup>58,59</sup> Topical administration of GM-CSF is also under investigation. Encouraging results have been reported in single-arm trials testing topical GM-CSF in patients receiving radiation for head and neck cancers.<sup>60</sup> However, a trial randomizing patients receiving chemoradiation to topical administration of GM-CSF or a control solution was discontinued when preliminary results did not demonstrate any benefit.<sup>61</sup>

Sucralfate, an agent that has little systemic absorption and adheres to ulcer bases, has been postulated to be of use in the prevention or amelioration of mucositis.<sup>28</sup> It is believed that the coating action provides some protection from injury and promotes healing. It is approved for the treatment of gastric ulceration. Numerous trials have investigated sucralfate rinses for oral mucositis secondary to radiation injury, and the results have been mixed.<sup>26</sup> However, the majority of studies, including double-blind, placebo-controlled, randomized trials, show little, if any, benefit of sucralfate in reducing radiation-induced oral side effects.<sup>62-69</sup>

#### Anti-inflammatory Agents

Steroid and nonsteroidal anti-inflammatory agents are not routinely used to treat mucositis.<sup>26</sup> Topical prostaglandins are believed to have anti-inflammatory properties that may benefit patients who will develop radiation-induced mucositis. However, both prostaglandin E<sub>1</sub> (misoprostol) and prostaglandin E<sub>2</sub> (prostin) have been evaluated in small trials, and neither has been demonstrated to prevent or reduce the severity of radiation-induced mucositis.<sup>70,71</sup>

Benzydamine hydrochloride is a topical agent that has been studied for preventing or alleviating radiation-induced mucositis. The primary mode of action is believed to be anti-inflammatory, and it has been demonstrated that benzydamine hydrochloride inhibits the production and effects

of inflammatory cytokines, particularly TNF- $\alpha$ .<sup>72</sup> However, the drug has numerous other described properties, including analgesic, antimicrobial, and anesthetic properties.<sup>28</sup>

Epstein and colleagues conducted a randomized trial of nearly 150 patients, studying the efficacy of a 0.15% benzydamine rinse for the prevention of mucositis.<sup>73</sup> For conventionally fractionated radiation up to cumulative doses of 50 Gy, benzydamine significantly ( $p = .006$ ) reduced erythema and ulceration by approximately 30% compared with the placebo and greater than 33% of benzydamine subjects remained ulcer free compared with 18% of placebo subjects ( $p = .037$ ). However, benzydamine was not effective in subjects receiving accelerated radiation doses.

Currently, benzydamine is not approved for use in the United States. A large multicenter randomized trial is under way in the United States and will include patients treated with conventional and altered fractionation and patients treated with radiation alone or concurrent chemoradiation.

#### Decontamination

It has been theorized that the formation of ulcerative mucositis combined with changes in the pH of the oral cavity owing to the effects of radiation on salivary glands creates a favorable environment for microbial contamination and local infections; therefore, decontamination treatment may reduce this postradiation sequelae.<sup>1,26</sup> These infections create additional stress on the tissues and thereby intensify the severity of mucositis. Based on this theory, topical antimicrobials have been studied as a strategy to minimize mucositis. Numerous antimicrobials have been tested.<sup>26,28</sup>

Chlorhexidine, a broad-spectrum rinse effective against both gram-positive and gram-negative bacilli and yeast, has been tested in several randomized trials for preventing or alleviating oral mucositis. No trial has demonstrated it to be efficacious,<sup>74,75</sup> and Foote and colleagues concluded that not only was chlorhexidine not effective in preventing mucositis, it was even detrimental for their patients undergoing radiation for head and neck cancer.<sup>76</sup>

Several centers have studied rinses or pastilles using a combination of agents.<sup>1,26</sup> Typically, the combinations have included an antifungal (amphotericin B or clotrimazole) and antibacterials, particularly those to combat gram-negative organisms. PTA, a combination of polymyxin B, tobramycin, and amphotericin B,<sup>77</sup> has been tested in several centers as an antimicrobial strategy for mucositis prevention. PTA has been formulated into lozenges and administered several times per day during a course of radiation. Several randomized placebo-controlled trials have been conducted, and the results are mixed.

Okuno and colleagues found no differences in objective measures of mucositis in patients treated with an antibiotic lozenge compared with patients using a placebo lozenge, but patient-reported scores were better in patients treated with an active lozenge.<sup>78</sup> Symonds and colleagues similarly tested a PTA pastille.<sup>79</sup> There was no difference between the experimental and control arms for the study's primary end point, the incidence of thick pseudomembrane formation, but there were differences in several of the measured secondary end points, including a lower incidence of worse reported grade of mucositis, dysphagia, and weight loss in patients treated with the drug. Wijers and colleagues also tested a PTA paste in a randomized, placebo-controlled, double-blind study and did not find that PTA reduced the incidence of mucositis.<sup>80</sup> El-Sayed and colleagues randomized patients to either a lozenge of bacitracin, clotrimazole, and gentamicin or placebo and found no differences in the severity of mucositis in patients receiving conventionally fractionated radiation between the two groups.<sup>81</sup>

A trial investigating iseganan hydrochloride, a broad-spectrum antimicrobial rinse, randomized patients in a phase III multi-institutional trial to active drug, placebo rinse, or best standard of care. There was no benefit to the active drug compared with placebo, but, interestingly, patients using either active drug or placebo rinses fared better with respect to both objective and subjective measures compared with patients receiving standard care only.<sup>82</sup>

#### Anesthetics

The management of radiation-induced mucositis primarily involves managing pain. Mucositis that is not severe can be managed with topical agents, although their efficacy has not been proven.<sup>26,28</sup> Baking soda rinses with or without salt are advocated, although they, too, have not been proven to alleviate mucositis.<sup>1,26</sup> However, they are important in maintaining good oral hygiene.<sup>1</sup>

Lidocaine gel (2%) is occasionally useful, particularly for anterior oral sores. Diluting lidocaine in "magic mouthwashes" is a common practice. These mouthwashes combine an aluminum hydroxide antacid, diphenhydramine (Benadryl), and lidocaine. Although prophylactic antifungal agents are not needed, some practices include nystatin in the mouthwash. It should be emphasized that there are no significant evidence-based studies to support the use of these mouthwashes. Investigating magic mouthwash for chemotherapy-induced mucositis, Dodd and colleagues found that these mouthwashes were no more effective than salt and soda rinses.<sup>83</sup>

Other topical agents include aloe vera and Gelclair, both with soothing properties. Gelclair is a bioadherent gel that adheres to mucosal surfaces and protects overstimulated nerve endings by

forming a protective barrier.<sup>28</sup> Neither aloe vera nor Gelclair has been shown in randomized phase III trials to benefit patients with radiation-induced mucositis.

Ultimately, mucositis is managed with analgesics. Early mucositis can be managed with acetaminophen or nonsteroidal anti-inflammatory agents, but as the severity of mucositis worsens, narcotics are often required.<sup>1,28,84</sup> Most pain regimens begin with codeine-based products. When patients breakthrough treatment progress to morphine-based products, primarily hydro-morphone, morphine sulfate, or other narcotic products, such as methadone. Recently, fentanyl transdermal patches are effective for patients as they are long-acting and avoid contact with oral mucous membranes.

## Xerostomia

### Definition

Xerostomia is defined as a dryness of the mouth owing to salivary gland secretion dysfunction that can be caused by multiple conditions, for example, autoimmune disorders, medications, and oncologic treatments. Virtually all patients undergoing radiation therapy for head and neck cancers suffer from xerostomia, which causes oral discomfort and pain, increased dental caries and oral infection, and difficulty in speaking and swallowing. This significantly impairs quality of life and can compromise nutritional intake and continuity of cancer therapy.

### Incidence and Risks

Salivary secretion may be decreased by a number of disease processes and other factors. Xerostomia has been estimated to affect 22 to 26% of the general population<sup>85</sup> but may occur more commonly in the elderly<sup>86</sup> and patients with advanced cancer (29–77%).<sup>85</sup> Radiation damage to the major glands results in either a transient or a permanent decrease in salivary flow. In a study of patients followed up to 25 years after radiation therapy, Liu and colleagues found that, compared with a nonirradiated group, patients who received bilateral ionizing radiation therapy involving the major salivary gland tissue exhibited, over time, mean decreases of 81% in stimulated and 78% in unstimulated salivary flow.<sup>87</sup> Patients who received unilateral radiation therapy involving only one parotid gland and one submandibular gland experienced mean decreases of 60% in stimulated and 51% in unstimulated salivary flow.<sup>87</sup> Patients who underwent cervical with supraclavicular radiation therapy (ie, mantle field treatment) experienced mean decreases of 43% in stimulated and 32% in unstimulated salivary flow.<sup>87</sup> Even low-dose total-body irradiation (as used in allogeneic bone marrow transplantation) may induce varying degrees of salivary hypofunction.<sup>87–89</sup>

### Etiology and Pathophysiology

The most common cause of salivary gland dysfunction is drug treatment. Several medications can produce xerostomia, including chemotherapy agents (eg busulfan, procarbazine) and supportive care agents (eg analgesics, antidepressants, antiemetics).<sup>90</sup> Drug-induced salivary dysfunction is generally reversible, that is, discontinuation of the drug leads to resolution of the problem. Other medications associated with xerostomia include antihypertensives,<sup>91</sup> pain medications,<sup>91</sup> overactive-bladder agents,<sup>92</sup> and psychiatric agents.<sup>92–94</sup> Xerostomia has also been reported in association with some immunotherapies,<sup>95</sup> particularly involving the oral cavity or salivary glands.<sup>96</sup>

Salivary gland dysfunction is a predictable side effect of radiation therapy to the head and neck region.<sup>97</sup> It also occurs in patients who receive total-body irradiation as part of the conditioning regimen for a bone marrow transplant.<sup>89</sup> Radiation-induced xerostomia is generally irreversible. The severity of radiation-induced xerostomia is influenced by both the radiation therapy regimen (field, dose) and pretreatment salivary gland function (Figure 2).<sup>97</sup> In therapy for head and neck cancer, the appropriate daily and total radiation doses are based on tumor size and individual clinical situations.<sup>97</sup> Clinically, xerostomia has been reported with as little as two or three doses of 2 Gy, although many changes occurring with less than 60 Gy are reversible.<sup>97</sup> However, doses greater than 30 Gy can cause permanent xerostomia.<sup>97,98</sup>

Damage to the salivary glands results in reduced salivary flow, changes in the electrolyte and immunoglobulin composition of saliva, a reduction in salivary pH, and repopulation of the mouth by cariogenic microflora.<sup>99</sup> When the major salivary glands are included in the radiation field, salivary function often decreases by 50 to 60% in the first week, with basal salivary flow reaching a measurable minimum 2 to 3 weeks

**FIGURE 2** The patient received radiation therapy to the head and neck region involving the major salivary glands, resulting in post-treatment xerostomia. Note the fissuring of the dorsal tongue.

after 23 Gy of fractionated radiation therapy.<sup>100,101</sup> The extent of glandular change is generally directly related to the dose of radiation to the salivary glands, with the most severe and irreversible forms of salivary dysfunction resulting from damage to or loss of salivary acinar cells.<sup>102</sup>

Some workers have attributed the pathogenicity of radiation therapy administered to salivary glands to the atrophic effects of this treatment on the secretory cells of the glands.<sup>103</sup> Serous cells, found predominantly in the parotid glands, are extremely radiosensitive and undergo apoptosis when exposed to low doses of radiation.<sup>104</sup> Others have attributed salivary gland dysfunction to the direct effects of radiation on the vascular and connective tissues of the glands.<sup>103,105</sup> This may account for the effects on the submandibular glands, which have a high proportion of mucinous cells and are essential for resting saliva.

### Clinical Features

Individuals with xerostomia can exhibit innumerable problems, including oral discomfort; taste disturbance; difficulty in chewing, swallowing, and speaking; dental caries; and other oral infections. Salivary gland dysfunction may intensify or prolong the process of oral mucositis.<sup>106</sup> These problems reflect the major functional roles of saliva: protection, early digestion, and lubrication.

Radiation-induced xerostomia can be an acute complication that improves with time but is often a permanent condition that seriously impairs the patient's well-being. Xerostomia predisposes patients to an altered oral microflora with increased virulent bacteria and fungal activity.<sup>16</sup> When not monitored and controlled, xerostomia may lead to accumulation of plaque and other debris on teeth and periodontal tissues.<sup>106,107</sup> Cariogenic plaque buildup on teeth may lead to tooth decay, gingivitis, and periodontitis. According to Berger and Kilroy,<sup>108</sup> elevated plaque matrix resulting from xerostomia may pose the greatest risk of ORN. Ill-fitting removable prostheses in patients with xerostomia, causing tissue irritation, can compound mucositis and result in fenestration of supporting mucosa and post-treatment ORN.<sup>1</sup>

### Management

Current management strategies include stringent dental and oral hygiene, parotid gland-sparing radiation techniques to prevent or minimize xerostomia, and pharmacotherapies, such as salivary substitutes and sialogogues.<sup>89</sup> Future strategies may include salivary gland transfer, newer sialogogues, and gene therapy. To minimize the severity of xerostomia and oral complications, it is important to begin aggressive oral care before radiation therapy. Evaluation by a dental team

experienced in oral oncology is essential to determine oral health status, perform necessary dental and oral interventions, and allow for healing from any invasive procedures required. Particulars that may require attention include mucosal lesions, dental caries and endodontic disease, periodontal disease, ill-fitting dentures, orthodontic appliances, temporomandibular dysfunction, and salivary abnormalities. A stringent oral hygiene program is critical and should be continued before, during, and after therapy.<sup>1,17,107</sup>

Amifostine is a cytoprotective agent used in the prevention of xerostomia in patients treated with radiation therapy for head and neck cancer.<sup>108</sup> This recommendation was based on the results of a phase III multi-institutional study reported by Brizel and colleagues.<sup>48</sup> Although randomized, the study was not blinded. The incidence of grade  $\leq 2$  chronic xerostomia was reduced from 57% in the control arm to 34% in patients receiving amifostine. There were no differences in survival or disease control, suggesting that amifostine protected salivary function without protecting the cancer. The recommended dose of amifostine is 200 mg/m<sup>2</sup>/d given as a slow intravenous push over 3 minutes, 15 to 30 minutes before each fraction of radiation therapy. Patients require close monitoring for side effects, including hypotension and nausea, and some patients may require antiemetics.<sup>109</sup> Investigations using a subcutaneous administration of amifostine are ongoing as this form of administration may be more practical and lower the toxicity of the drug.

The risk of complications of radiation therapy depends largely on the dose and the field. Devices and techniques such as interstitial implants, shrinking-field approaches, customized immobilization molds, and customized lead-alloy blocks are used to achieve safe and permanent control of larger lesions, shielding of peripheral tissues (ie, radiation stents), accurate and reproducible delivery, and protection of normal structures.<sup>110–112</sup>

An emerging parotid gland-sparing technique, three-dimensional intensity-modulated radiation therapy (IMRT), involves the manipulation of beam intensity across each treatment field, providing a dose distribution that conforms more accurately to the three-dimensional configuration of the target volume than conventional three-dimensional conformal radiation therapy.<sup>89</sup> This technique delivers a higher dose to the tumor target without increasing the dose to normal tissues, delivers a higher dose per fraction, and offers an improved physical and biologic therapeutic ratio.<sup>98</sup> IMRT can potentially deliver a lower dose of radiation to the parotid glands compared with conventional beam arrangements and thus offers the greatest potential for patients with mucosal primary tumors who require bilateral neck irradiation.<sup>100,101</sup>

Eisbruch and colleagues assessed long-term xerostomia in 84 patients with head and neck cancer who had undergone comprehensive bilateral neck radiation therapy using conformal and multisegmental IMRT to spare major salivary glands.<sup>97</sup> Xerostomia was assessed with a validated xerostomia-specific questionnaire. These researchers observed that, with these parotid gland-sparing techniques, xerostomia improved over time, with rising salivary production from the spared major salivary glands. In addition, the oral cavity mean radiation dose was found to be significantly correlated with xerostomia scores, indicating that it may be beneficial to spare the noninvolved oral cavity to further reduce xerostomia.

Chao and colleagues conducted a prospective clinical study to determine whether parotid gland-sparing techniques result in objective and subjective improvement in xerostomia.<sup>100</sup> Twenty-seven patients underwent inverse-planning IMRT and 14 received forward-planning three-dimensional radiation therapy, with attempts to spare the superficial lobe of the parotid glands. Dose-volume histograms were computed for each gland. Stimulated salivary flow 6 months after treatment was reduced exponentially, for each gland independently, at a rate of approximately 4% per Gy of mean parotid dose. Patients' answers to quality of life questions about eating and speaking function were also significantly correlated with salivary flow. In another study, Chao and colleagues concluded that the dosimetric advantage of IMRT conferred a significant reduction in late salivary toxicity, with no adverse impact on tumor control or disease-free survival.<sup>101</sup>

Although further study is needed, these and other emerging data indicate that IMRT and other new parotid gland-sparing techniques hold promise for the treatment of head and neck cancer, potentially offering reduced severity of xerostomia without compromised tumor control for appropriately selected patients.

Although the radiation ports used in treating head and neck cancer generally deliver 60 to 65 Gy to the major salivary glands, the submental region is regularly shielded, receiving only scatter radiation of 5% of the total dose.<sup>17,97</sup> Several animal studies have demonstrated the feasibility of microvascular autotransplantation of submandibular and parotid gland tissue.<sup>113–115</sup> In a recent human study, Seikaly and colleagues transferred the submandibular gland to the submental space in patients undergoing surgery and radiation therapy for head and neck cancer.<sup>116</sup> The glands survived transfer and continued to function after radiation therapy with appropriate shielding.

Emerging research and medical technology are providing specificity and sensitivity methods

to determine the roles of human salivary components. Gene transfer may be potentially useful for treating inherited single-gene deficiency disorders and malignancies refractory to other therapies, as well as for repairing radiated salivary glands.<sup>116,117</sup> There are no published reports examining a prophylactic gene transfer approach to reducing or eliminating radiation damage of the salivary glands.<sup>116</sup> Translational studies involving plasmid-mediated gene transfer for reducing radiation-induced damage have been conducted, and the results of *in vivo* animal studies in lung and esophageal tissue are quite promising.<sup>118,119</sup> Research in nonviral gene-mediated therapeutics for restoring radiation-induced salivary gland dysfunction may prove beneficial.<sup>120</sup>

Current therapies for the pharmacologic management of radiation-induced xerostomia include the use of prescription fluoride agents to maintain optimal oral hygiene, antimicrobials to prevent dental caries and oral infection, saliva substitutes to relieve dryness, and sialogogic agents to stimulate saliva production from remaining intact salivary gland tissues.<sup>122,89</sup> Saliva substitutes containing hydroxyethyl-, hydroxypropyl-, or carboxymethylcellulose may be beneficial as palliative agents to relieve the discomfort of xerostomia by temporarily wetting the oral mucosa.<sup>89</sup> New saliva substitutes (moisturizing gels) with enzymatic and protein components (ie, glucose oxidase and lactoperoxidase), which present prospective antibacterial effectiveness and increased oral moisture, are under study.

For patients with residual salivary gland function, cholinergic agonists may produce symptomatic improvement.<sup>1,89</sup> Pilocarpine is currently the only sialogogic agent approved by the FDA for radiation-induced xerostomia. Pilocarpine functions primarily as a muscarinic-cholinergic agonist with mild  $\beta$ -adrenergic activity, which can increase secretion of exocrine glands, such as salivary and sweat glands, and the tone of smooth muscle in the gastrointestinal and urinary tracts. Studies have shown oral pilocarpine to have efficacy in patients with Sjögren's syndrome, radiation-induced xerostomia, and opioid-induced xerostomia, as well as increasing salivary flow and restoring salivary composition in those with graft-versus-host disease owing to allogeneic bone marrow transplantation.<sup>102,121–127</sup> LeVeque and colleagues conducted a randomized, placebo-controlled, dose-escalation study, and Johnson and colleagues a three-arm, randomized, placebo-controlled trial (placebo, pilocarpine 5 mg three times daily, and pilocarpine 10 mg three times daily).<sup>122,128</sup> In both studies, significantly more pilocarpine-treated patients than placebo recipients reported improvement in xerostomia. In addition, LeVeque and colleagues found that treatment with pilocarpine led to a significant decrease in the use of oral comfort

agents, such as artificial saliva, hard candies, and water.<sup>122</sup>

Other cholinergic agents with sialogogic properties, such as cevimeline hydrochloride, may prove beneficial for cancer patients with xerostomia. Cevimeline is a newer muscarinic agonist that has been found to be safe and effective in treating xerostomia associated with Sjögren's syndrome and received FDA approval for that use.<sup>89,129,130</sup> It is currently under study for use in patients with head and neck cancer who have radiation-induced xerostomia. The most common drug-related side effects are excessive sweating, nausea, rhinitis, and diarrhea.<sup>131</sup>

## Osteoradionecrosis

### Definition

ORN has been defined as “radiological evidence of bone necrosis within the radiation field, where tumour recurrence has been excluded.”<sup>132</sup> ORN is death of the bony tissues of the maxillae and mandible secondary to radiation therapy (Figure 3). ORN can be a debilitating condition that can occur either soon after a course of radiation therapy or months to years following treatment. It can be self-limiting, and in its most severe form, ORN is characterized by severe pain, trismus, fistula and cicatrix formation, pathologic fracture, and loss of soft and osseous tissues.<sup>1</sup>

ORN is not infection of compromised bone, as was previously believed. It is now understood to be a progressive avascular necrosis by the tissue effects of either external beam radiation therapy or brachytherapy. These tissue effects include hypocellularity, hypovascularity, and hypoxia and create a new composite tissue referred to as “three-H tissue.”<sup>133</sup> ORN can occur spontaneously, but most commonly trauma to this three-H tissue creates further pathophysiologic changes that result in ORN.

**FIGURE 3** A patient who received induction chemotherapy followed by external beam radiation therapy with mandibular osteoradionecrosis. The patient will undergo hyperbaric oxygen therapy followed by surgical intervention.

### Incidence and Risks

ORN is rare in patients who receive less than 60 Gy of radiation therapy. However, the frequency of ORN is uncertain because there is no standard mechanism for reporting the disease. The RTOG requests its members to report radiation toxicity, including ORN; however, universally, the condition is probably underreported. On average, ORN may occur within the first few years after radiation treatment and is not captured in most head and neck cancer longitudinal multicenter studies. Additionally, this late sequela of radiation is often reported as a crude incidence rather than an actuarial incidence, making the incidence fewer in frequency than it is in reality.

The mandible is much more susceptible to ORN than the maxilla. Patients with teeth are at greater risk of developing ORN than edentulous patients.<sup>134</sup> ORN may occur at any time following radiation therapy but commonly occurs within 3 years of the radiation therapy.<sup>135</sup> Cases have been reported describing ORN developing over 35 years after radiation therapy.<sup>136</sup>

### Etiology and Pathophysiology

The underlying mechanisms of ORN relate to the “three-H principle” of irradiated tissue, that is, hypocellularity, hypovascularity, and hypoxia. In such tissue, the ability to replace normal cellular and collagen loss is severely compromised, with resultant necrosis occurring in relation to the rate of normal or induced cellular death and collagen lysis.<sup>137</sup> The risk of ORN following trauma or oral surgical procedures can be significant.

ORN can be either spontaneous (39% of cases) or the result of an insult (61% of cases).<sup>133,137</sup> Spontaneous ORN occurs when, in the process of otherwise normal turnover of bone, the degradative function exceeds new bone production. ORN develops following injury when the reparative capacity of bone within an irradiated field is insufficient to overcome an insult. Bone injury can occur through direct trauma (eg, tooth extraction [up to 84%], related tumor ablative surgery or biopsy [12%], frictional irritation [1%]) or exposure of the oral cavity to the environment secondary to overlying soft tissue necrosis.<sup>133</sup> The cumulative progressive endarteritis caused by radiation therapy results in insufficient blood supply and tissue oxygen delivery, with resultant poor wound-healing capacity.<sup>137,138</sup>

### Clinical Features

The clinical features are influenced by the stage of ORN. Patients with early-stage necrosis may be relatively asymptomatic. In contrast, patients with advanced-stage ORN are often very symptomatic (eg, pain, discharge). The diagnosis of ORN is based on a combination of clinical and radiologic features.<sup>135</sup>

Store and Boysen proposed the following staging classification of ORN<sup>132</sup>:

- Stage 0: exposed bone; no radiologic signs
- Stage 1: mucosa intact; radiologic signs present
- Stage 2: exposed bone; radiologic signs present
- Stage 3: exposed bone; radiologic signs present; orocutaneous fistula; localized infection

In working up a patient with ORN, conventional laboratory studies and diagnostic imaging are ordered to rule out recurrence and second primary malignancy with a biopsy as indicated. Information pertaining to the volume of tissue irradiated can be obtained in radiation oncology treatment summaries to determine the method of treatment, dosimetry, and energy used.<sup>1,22</sup> Diagnostic imaging can include studies of plain radiographs of the mandible and maxillae, such as a panoramic radiograph, to determine gross areas of local decalcification or sclerosis. Plain radiographs can show decreased bone density and detect fractures. Magnetic resonance imaging (MRI) depicts ORN with reduced bone marrow signal intensity on T<sub>1</sub>-weighted images and increased signal intensity on T<sub>2</sub>-weighted images.<sup>139</sup> Absence of a marrow signal on MRI can be used to identify significant radiation injury in the mandible. Computed tomographic (CT) scans are excellent in identifying sites of significant bone injury and diagnosing ORN.<sup>139</sup> Alteration in trabeculation, cortical thinning, and sclerosis are common findings in sites of injury. Single-photon emission tomography may have a role in the future as more experience is gained with this modality.<sup>139,140</sup>

### Management

The most important aspect of ORN-related treatment is prevention. ORN may be avoided if patients receive appropriate dental care prior to radiation therapy, maintain high standards of oral hygiene during and after radiation therapy, and avoid dental extractions and other types of oral surgery after radiation therapy. Strategies for preventing ORN include appropriate dental prophylaxis prior to, during, and following a course of treatment with radiation to the head and neck. Should ORN develop despite these measures, management will depend on the individual clinical status.

In most cases, the management of ORN is conservative and involves some or all of the following modalities: removal of loose bone fragments, gentle sequestration, irrigation, topical antiseptics, systemic antibiotics, and hyperbaric oxygen (HBO).<sup>135</sup> Other modalities that have been reported to be effective include pentoxifylline and vitamin E, ultrasound therapy, and electromagnetic stimulation.<sup>135</sup>

In advanced cases (symptomatic), surgical intervention is required and involves either radical sequestration or hemimandibulectomy with reconstruction.<sup>140,141</sup> If oral surgical intervention is required after radiation therapy, then pre- and postoperative HBO therapy may increase the potential for healing and minimize the risk of ORN.<sup>142</sup> HBO therapy increases wound-healing capacity by stimulating osteogenesis and angiogenesis. It should be noted that many dental procedures can be safely done after radiation therapy, including routine restorative procedures, endodontic procedures, and prosthetic procedures.

Currently used HBO protocols by stage of disease are as follows:

- Stage I.** Perform 30 HBO treatments (one treatment per day, Monday–Friday) to 2.4 atmospheres for 90 minutes breathing 100% oxygen. The patient is closely monitored to evaluate decreased bone exposure, granulation tissue covering exposed bone, resorption of nonviable bone, and absence of inflammation and infection. For patients who respond favorably, continue treatment to a total of 40 or more treatments. For patients who are not responsive, advance to stage II.<sup>133,143–147</sup>
- Stage II.** Perform transoral sequestrectomy, attempting primary wound closure followed by continued HBO therapy to a total of 40 treatments. If wound dehiscence occurs, advance patients to stage III. Patients who present with orocutaneous fistula, pathologic fracture, or resorption to the inferior border of the mandible advance to stage III immediately after the initial 30 treatments.<sup>146,147</sup>
- Stage III.** Perform transcutaneous mandibular resection, wound closure, and mandibular fixation, that is, maxillomandibular fixation or reconstruction plating, followed by an additional 10 to 20 postoperative HBO treatments.<sup>146,147</sup>
- Stage IIIR.** Perform mandibular reconstruction 10 weeks after successful resolution of mandibular ORN. Marx advocates the use of autogenous cancellous bone within a freeze-dried allogeneic bone carrier and/or packed with plasma rich protein. Complete 10 to 20 additional postoperative HBO treatments.<sup>146,147</sup>

In addition to a staged therapy with HBO treatment, as described by Marx, microvascular free-tissue transfer reconstruction affords the clinician and patient another opportunity to

correct ORN.<sup>1,147–150</sup> Excellent outcomes of immediate reconstruction of the mandible and maxilla following resection of ORN using free-tissue transfer techniques have been reported in the literature.<sup>148–150</sup>

Radiation can permanently destroy cellular elements of bone and thus limit the potential for wound maintenance and the ability to heal after infection or trauma (eg, dental extraction, alveoloplasty).<sup>151,152</sup> Further, the risk of complications following trauma or oral surgical procedures in an irradiated field can be highly significant, depending on a predetermined threshold of irradiation, and can result in ORN.<sup>152–154</sup> For these reasons, elective oral surgical procedures, such as extractions or soft tissue surgery, are contraindicated within an irradiated field owing to hypovascularity, hypocellularity, and hypoxia.<sup>1</sup> However, nonsurgical dental procedures that can be safely performed include routine restorative procedures, oral prophylaxis, radiography, and endodontic and prosthodontic procedures.<sup>1,22</sup>

Following initial recovery from radiation effects, nonsurgical periodontal therapy, usually with prophylactic antibiotic coverage, is appropriate for treatment of the periodontium within the radiation field. It is important to detect and treat dental caries or traumatic dental injury that could lead to pathosis. However, ORN can occur spontaneously if wound healing is compromised.<sup>155–157</sup> If postradiation extractions are necessary, HBO therapy, along with a specific oral care regimen, is indicated to augment wound healing. In such cases, tissues should be managed gently, and antibiotic coverage is required. Local anesthetics containing epinephrine should be avoided, when possible, to prevent further vascular constriction.<sup>1,3</sup> Workers have reported successful placement of endosseous implants in irradiated fields with a pretreatment regimen of HBO.<sup>158,159</sup> In contrast, ORN has been initiated by such an elective surgical intervention.<sup>1,133,155,159</sup>

## Oral Infections

### Definition

Oral infections are a common acute complication of chemotherapy and radiation therapy. The oral cavity is a complex environment composed of a myriad of commensal bacteria, fungi, and viruses that populate the oral mucosa, connective tissue, salivary glands, taste buds, bones, and teeth. Multiple factors predispose individuals to infections such as treatment-induced neutropenia, hypogammaglobulinemia, T-cell dysfunction, and mucosal damage.<sup>37</sup>

### Incidence and Risks

Most of the patients treated for head and neck cancer and almost half of the patients receiving chemotherapy for non-head and neck cancer

develop acute oral complications, that is, mucositis and/or infections (Figure 4).<sup>160,161</sup>

### Etiology and Pathophysiology

The etiology of infections includes damage to the oral mucosa and systemic immunosuppression.<sup>162</sup> Oral infections usually occur in association with the hematologic nadir, although they may occur at other times in the chemotherapy cycle. For example, oral herpes simplex virus (HSV) infections can be seen early in the chemotherapy cycle. The treatment-induced mucosal barrier injury is a risk factor for severe infectious complications. The intact mucosa is the first defense against systemic infections. Compromise of the mucosal barrier can contribute to local invasion by colonizing microorganisms and eventual systemic infection.<sup>37</sup> Mucosal injury can lead to gram-positive infections, anaerobic infections, neutropenic enterocolitis, *Candida* infections, acute graft-versus-host disease, and malnutrition.<sup>37</sup> The risk of infection is directly related to the depth and length of neutropenia or lowered white blood cell count. More than 60% of patients with neutropenia will become infected. If the absolute neutrophil count is  $<100/\text{mm}^3$ , approximately 20% of febrile patients will have a documented bacteremia.<sup>163–165</sup> Most infections are due to bacteria, although fatal infections are usually due to fungal organisms.<sup>163</sup>

### Clinical Features

Patients with cancer who undergo treatment with chemotherapy, radiation, or surgery are at significant risk of infection. This risk is related to compromised host defenses and sequelae of treatment owing to the absence of neutrophils, infection barrier disruption, and shifts in microbial flora. The mortality attributed to infections has decreased over the years because of the development of  $\beta$ -lactam and fluoroquinolone antibiotics, the increased use of prophylactic

**FIGURE 4** A patient with acute myelogenous leukemia undergoing therapy with a fungal infection at the edentulous premaxilla. The patient wears a maxillary complete denture.

antifungals and antivirals, and the use of colony-stimulating factors in selected patients.<sup>163</sup> The interaction of infection and mucosal barrier injury is well displayed in the third phase of a mucosal barrier injury of the gastrointestinal tract, as described by Blijlevens and colleagues, when necrosis and ulcerations occur with the translocation of resident microflora and their products (ie, endotoxin) into the bloodstream.<sup>166</sup> Damaged mucosa leads to significant morbidity and potential infection. Oropharyngeal candidiasis is a common infection in patients undergoing oncologic treatment. Oral mucosal colonization (up to 93%) and infection (ranging from 17 to 29%) with *Candida* are particularly common in patients receiving radiation therapy for head and neck cancer.<sup>167</sup> Although all patients with cancer who are undergoing chemotherapy are at risk of oral complications, some patients are at a greater risk than others, depending primarily on the type of malignancy and the aggressiveness of the cancer treatment. Patients with hematologic malignancies (eg, leukemia and lymphoma) have a greater risk than patients with solid tumors (eg, breast cancer, lung cancer, and sarcomas) because the protective elements that maintain bodily homeostasis are part of the malignant process of hematologic malignancies.<sup>168,169</sup>

Viral reactivation may lead to severe oral or disseminated infections during periods of myeloimmunosuppression. In particular, HSV infections are often associated with severe, painful, and prolonged ulcerations atypical of those found in immunocompetent hosts.<sup>12,170-174</sup> Suspected HSV lesions should be treated with antiviral agents such as acyclovir administered orally or intravenously and managed as described above for irradiated patients. The diagnosis should be established using viral cultures, direct immunofluorescence or other rapid diagnostic tests, and the lesions.<sup>12,170-173,175,176</sup>

Bacterial infections following chemotherapy can cause localized mucosal lesions, sialoadenitis, periodontal abscesses, pericoronitis, or acute necrotizing ulcerative gingivitis.<sup>22,177</sup> Because systemic infection is a serious complication in neutropenic patients, constant vigilance must be maintained to prevent or manage oral infections of any type.<sup>1,21,22,175</sup> Because antileukemic therapy is designed to achieve myelosuppression, this risk may be higher among patients with leukemia than among those with solid tumors.<sup>175,178</sup> Oral infections should be treated with selected antibiotic combinations (broad-spectrum antibiotics), including an agent effective against anaerobic gram-negative bacilli, such as *Pseudomonas*, *Klebsiella*, or enterobacteria, which are often found in the oral cavity of immunocompromised individuals.<sup>21,22,177,179</sup> Oral microbial culture testing should be used to ensure antibiotic sensitivity and resistance selection and to assist in identification of the causative organisms.<sup>180</sup>

Vascular endothelial damage can occur following stem cell transplantation or external beam radiation therapy with release of higher levels of proinflammatory cytokines and radiation-induced fibrosis of the vascular lining.<sup>37</sup> This cascading event can exacerbate multiple manifestations in the head and neck area, that is, graft-versus-host disease and ORN. A variety of different infections may occur in the oral cavity at separate or combined times, such as candidiasis, anaerobic infection, herpes simplex viral shedding, and caries. As previously described, the etiology of these infections includes damage to the oral mucosa and salivary gland dysfunction.<sup>162</sup> The chronic nature of these infections reflects the ongoing nature of hypovascularity and the salivary gland dysfunction.

Oral infections can cause morbidity per se, can aggravate oral mucositis, and can lead to systemic infections. The clinical features may be relatively specific or relatively nonspecific (ie, oral mucositis). Moreover, the clinical features may be typical or atypical, particularly in immunosuppressed patients. Thus, health care professionals should have a low threshold for screening for the presence of such oral infections.

#### Management

The management of upper aerodigestive tract infections relies on the identification of the patients at significant risk of life-threatening infections, initiation of appropriate clinical and diagnostic tests, and timely initiation of antimicrobial therapy, that is, broad-spectrum antibiotics.<sup>37</sup> In response to more effective drug therapy, the types of infections have changed as resistant and opportunistic organisms emerge.<sup>163</sup> Strategies to minimize and prevent infection in patients with mild to moderate short-term neutropenia are generally successful. Prophylactic treatment of infection with oral antibiotics in neutropenic patients is now being widely used. However, complete prevention or elimination of infection has not been accomplished in high-risk patients, such as those undergoing stem cell transplantation or intensive chemotherapy.<sup>163</sup> Therefore, to minimize the risks of oral infection, it is important to develop simple and practical guidelines for maintaining periodontal health and for diagnosing, preventing, and treating periodontal infections during therapy.<sup>1,22</sup> Cancer patients should make regular dental visits for overall dental and periodontal assessment. Patients receiving chemotherapy can undergo a dental cleaning provided that they meet the following hematologic conditions: first, an absolute neutrophil count of approximately 1,000/mm<sup>3</sup> (white blood cell count times the percentage of neutrophils equals the absolute neutrophil count), a level at which the risk of developing an infection is minimal, and second, a platelet count > 50,000/mm<sup>3</sup> with a

normal coagulation profile.<sup>180</sup> The administration of prophylactic antibiotics is essential owing to the induced bacteremia, immunocompromised status, and potential for hypofunctioning white blood cells introduced by chemotherapy.

Patients with an uninfected dentition and good periodontal health do not pose a diagnostic treatment challenge, nor do patients with advanced periodontal disease that mandates immediate surgical intervention. However, patients with increased loss of attachment with furcation involvement or periodontal pocket formation with furcation involvement pose a treatment dilemma.<sup>22</sup> Patients in whom the soft tissue parallels the bone loss and in whom pocket depth is normal can be treated with regular periodontal care and maintenance. Extraction should be considered only for patients with pathologic mobility of dentition or with a fulminant periapical abscess.<sup>1,22</sup> Patients with moderate to advanced periodontal disease present a greater challenge and would, under usual circumstances, receive instructions for infection prophylaxis and dental hygiene, as well as surgical correction. However, the feasibility of such comprehensive therapy during chemotherapy can be limited by several factors, including performance status, type of malignant disease, cycling of chemotherapy, and hematologic competence. The clinician should strive to provide a thorough scaling and to encourage maintenance through exceptional plaque control (ie, brushing, flossing, and use of chlorhexidine gluconate).<sup>22,168,169</sup> To reduce the risk of septic foci, extractions should be considered for patients with any exacerbated acute periodontal infection. This oral surgical correction should be performed at the appropriate time in the treatment cycle (at the beginning of the cycle or during the recovery phase with hematologic or chemistry stability) or when the patient's cancer is in complete remission. If chemotherapy is on hold, periodontal surgery could be considered provided that the hematologic status is appropriate. The dentist must discuss with the treating medical oncologist the patient's oral status, treatment plan, and contraindications to surgical intervention, as well as the appropriate timing of oral treatment intervention.<sup>29,57,134</sup>

Toothbrushing and flossing should be the standard of dental care for patients who routinely brush and floss. However, as in the general population, many patients with cancer either do not floss or floss infrequently. Thus, clinicians may either instruct patients to floss or may stress brushing techniques only. In most cases, patient factors and limited time parameters do not permit the patient to become proficient in flossing techniques. However, if the clinician identifies an area where food continually lodges, the patient should be encouraged to floss the area to reduce the risk of gingival inflammation.<sup>21,22</sup> Patients who floss

on a regular basis are instructed to modify the flossing technique in certain clinical situations. First, patients are instructed to floss gently when the lining of the oral cavity starts to become sensitive to thermal changes or food substances, indicating mucosal thinning owing to the suppressive effects of chemotherapy on the normally proliferative epithelium.<sup>38–40</sup> Second, patients are instructed to floss only to the gingiva when the platelet count falls below 50,000/mm<sup>3</sup>. This technique removes most of the debris from this area.<sup>22</sup>

Oral lavage therapy, including toothbrushing, is imperative for plaque control. The patient should be instructed to brush after every meal. In certain clinical situations, such as increased mucosal sensitivity to food or thermal changes, increased sensitivity to toothbrush bristles, irritation of the gingival tissues by the toothbrush, or profound thrombocytopenia (<20,000/mm<sup>3</sup>), patients should change from a soft to an ultra-soft-bristled or sensitive-bristled toothbrush.<sup>1,21,22</sup> In controlling plaque accumulation, it is important to minimize the risk of gingival inflammation, the oral bacterial load, and the potential for infection.<sup>22</sup> Along with routine brushing and flossing, rinsing with chlorhexidine gluconate should be initiated when patients begin chemotherapy. Such rinsing is an adjunct to ideal oral-periodontal care and can also be used when indications arise, such as oral mucosal changes secondary to chemotherapy and subsequent increased soft tissue sensitivity.<sup>22,181–185</sup> Patients undergoing chemotherapy should be encouraged to rinse with a dilute saline and sodium bicarbonate solution (5%) to reduce adherent mucoid debris on oral soft tissues, lubricate oral mucosal and oropharyngeal tissues, and elevate the pH of oral fluids.<sup>21,22</sup> Patients encountering nausea and anorexia should be encouraged to rinse with a sodium bicarbonate and salt water solution several times throughout the day to reduce oral acidity and minimize the mucosal insult.<sup>1,22</sup>

## Caries

### Definition

Dental caries is defined as a soft decayed area in a tooth. Progressive decay can lead to the death of a tooth.

### Incidence and Risks

Tooth decay is one of the most common of all disorders, second only to the common cold. It usually occurs in children and young adults but can affect any person. It is the most important cause of tooth loss in humans. Dental caries is a common sequela of radiation and is often exacerbated by xerostomia.<sup>1,22</sup> Irradiation of major salivary glands leads to qualitative and quantitative changes in salivary secretions. This results in an

increase in plaque and mucoid debris accumulation and a reduction in the salivary pH antimicrobial proteins and the buffering capacity of saliva.<sup>186</sup> This creates a cariogenic oral environment, particularly in patients ingesting a diet high in carbohydrates or sucrose.

### Etiology and Pathophysiology

Dental caries is an infectious and multifactorial disease. Caries-forming bacteria (ie, *Streptococcus mutans*, *Lactobacillus*, *Actinomyces*) are commonly present in the oral cavity.<sup>1</sup> Dental caries occur when bacterial by-products, that is, acids, cavitate the hard surfaces of teeth. Without intervention, the bacteria will penetrate the cavitated enamel surface and underlying dentin and encroach onto the pulp tissue. The bacteria convert all foods, especially sugar and starch, into acids. Cariogenic bacteria and by-products are found in dental plaque, a sticky organic matrix of bacteria, food debris, dead mucosal cells, and salivary components, adhering to the tooth surface. Bacteria colonize on tooth surfaces and produce polysaccharides that enhance adherence of the plaque to the enamel. A demineralization process occurs, and the underlying tooth surfaces lose calcium, phosphate, and carbonate. Cycles of demineralization and remineralization continue throughout the lifetime of the tooth.<sup>187</sup> Plaque that is not removed from the teeth mineralizes into calculus. Plaque and calculus irritate the gingival tissues, resulting in gingivitis and, ultimately, periodontitis. Plaque begins to accumulate on teeth within 20 minutes after eating, which is the time when most bacterial activity occurs. If this plaque is not removed thoroughly and routinely, tooth decay will not only begin but flourish.

### Clinical Features

Initially, cavities are usually painless until they proliferate inside the tooth and destroy the pulp tissue (Figure 5). If left untreated, a periapical infection can develop, requiring endodontic therapy. In the early years of the twentieth century, basic dental research led to significant advances in the understanding of the histopathology of caries in enamel and dentin, microbial risk factors, the physiology and pathology of saliva, and the understanding of fluoride mechanisms. As a result, the development of new preventive interventions and restorative materials made a significant impact on the restoration of caries and the retention of dentition. Additionally, a second major development in caries prevention was scientific validation of the efficacy and effectiveness of sealants and fluoride therapy.

### Management

Treatment strategies must be directed to each component of the caries process. Optimal oral

**FIGURE 5** A patient on chronic use of analgesia therapy with severe xerostomia and rampant caries.

hygiene must be maintained on a routine basis. Xerostomia should be managed whenever possible by sialogogue therapy or salivary substitutes. Owing to the harmful effect of postradiation caries, patients who have undergone radiation should be treated with a prophylactic regimen, specifically flossing, brushing, and fluoride therapy. Caries resistance can be enhanced with the use of antimicrobial topical fluorides. *Streptococcus mutans*, when exposed to low concentrations of fluoride, produces less acid.<sup>187–190</sup> The combination of oral hygiene, frequent dental follow-up examinations, and appropriate prophylactic treatment procedures is essential to caries prevention, as is fluoride treatment consisting of a daily application of 0.4% stannous fluoride or 1.1% sodium fluoride and applied to the dentition using a brush-on technique or gel-filled trays (ie, fluoride carriers).<sup>1,23,186</sup> The efficacy of topical medication is enhanced with the use of customized carriers that extend the contact time of active drug with tooth structure that leads to increased uptake into the enamel matrices. Fluoride is more readily taken up by demineralized enamel than by sound enamel. Compared with sodium fluoride, stannous fluoride is slightly more acidic, but its uptake into the enamel matrices is four times greater.<sup>1,23</sup> In adults with xerostomia, fluoride leaches out of the enamel within 24 hours; thus, the fluoride regimen must be performed daily for optimal protection. The most efficient method of fluoride application is to use a custom-made polypropylene polypropylene fluoride carrier that completely covers, and extends slightly beyond, the tooth surface.<sup>23</sup> Patients fill the carriers with fluoride gel and place them onto the dentition daily for 10 minutes.<sup>1,23</sup> Patients who receive low doses of radiation and are expected to have a slight degree of xerostomia can use a toothbrush to apply the fluoride gel.<sup>191</sup> Sensitivity and pain are common side effects of fluoride and may necessitate a change in the fluoride concentration or the method of application. A daily fluoride program can decrease postradiation dental hypersensitivity,

remineralize cavitated enamel matrices, and, more importantly, inhibit caries-forming organisms.<sup>1,23</sup>

## Conclusions

The oral cavity should be thoroughly evaluated in all patients diagnosed with cancer, as well as in patients undergoing any immunosuppressive therapy. Preventing and treating the oral complications of cancer are important responsibilities of the oral health care provider, and anticipating primary and secondary mucosal insults and recognizing oral complications promptly in this setting can decrease the incidence of such complications or ameliorate their morbid side effects. By fostering communication and compliance among members of the multidisciplinary team, the dental specialist can ensure quality preventive, therapeutic, and maintenance care to patients with cancer.

# Upper Airway Problems

Rex C. Yung, MD, FCCP

The respiratory tract is often involved in cancer, either by primary malignancies or cancers metastatic to the respiratory tract. Bronchogenic carcinoma is the leading cause of cancer mortality, accounting for 30% of cancer-related deaths in both males and females in the United States.<sup>1</sup> Other upper aerodigestive tract malignancies, that is, head and neck and esophageal cancers, are also tobacco related and frequently cause complications in the upper airways. Disease progression, deteriorating patient functional status, and/or the effects of therapies contribute to the overall high morbidity and mortality owing to cancer complications of the respiratory tract.

This chapter focuses on upper airway problems encountered in the care of cancer patients. It reviews the anatomy of the region of interest, that is, the larynx, hypopharynx, and trachea, functional defects of which will lead to the principal problems of upper airway obstruction, vocal cord paralysis (VCP), and aspiration, manifested clinically as respiratory distress and gas-exchange derangements. A myriad of other signs and symptoms can be caused by direct tumor involvement of the upper airway and its adjacent soft tissue and vascular structures or as a result of iatrogenic complications from antineoplastic therapy and adjunctive interventions.

## Anatomy of the Upper Airway

The region of the airways under consideration in this chapter is confined to the larynx, hypopharynx, and the central nonconducting airways, including the trachea and main carinal branching into the right and left mainstem bronchi.<sup>2</sup> Malformations and cancer-associated pathologies of the orofacial region and airway segments distal to the zero (trachea) and first-generation (right and left mainstem bronchi) branching can also lead to breathing and gas-exchange abnormalities, but these are addressed in preceding and following chapters.

The larynx is the organ of voice production and consists of the soft tissue structures interposed between the pharynx and the upper trachea. Dysfunction of the vocal cords, cartilage, and muscular and membranous structures of this region may lead to voice dysfunction, airflow obstruction, and increased risk of aspiration.

The pharynx is the upper expanded portion of the digestive tube, with the mouth and nasal cavities above and in front and connected to the esophagus below. The hypopharynx is the longest and most inferior of the three segments of the pharynx and is somewhat funnel shaped, defined superiorly by the level of the epiglottis and anteriorly by the lateral aspects of the thyroid cartilage and narrowing toward the level of the cricopharyngeal muscles. Although it is structurally made up of voluntary smooth muscles arranged in outer circular and inner longitudinal layers, the hypopharynx has a far more complex function than merely serving as a passage for solids and liquids on its way to the digestive tract. The orderly coordination of action with the tongue in propelling a bolus of food, timely relaxation of the cricopharyngeus and subsequent peristaltic action of esophageal musculature, and other dynamic interactions with laryngeal structures allow feeding, swallowing, and avoidance of aspiration. Hypopharyngeal pathology and dysfunction may therefore lead gas-exchange abnormalities and nutritional deficits.

The inferior aspect of the upper airway consists of the trachea, which consists of 16 to 20 hyaline cartilage rings connected by a membranous annular ligament. It extends from the subglottis to the carina, which is superimposed to the level of the fifth to sixth thoracic vertebrae posteriorly and just about inferior to the angle of Louis of the sternum anteriorly. Except for the cricoid cartilage ring, the remaining tracheal cartilage “rings” are C shapes, open in their posterior aspect. This paraesophageal aspect formed by a fibrous and smooth muscular membranous wall allows for deglutition without resistance from a series of firm cartilage. Unfortunately, this functional-anatomic adaptation leaves the posterior portion of the trachea especially vulnerable to direct endotracheal invasion or extrinsic compressive effects by posterior and inferior mediastinal pathology. In addition to airway compromise by upper airway obstruction, fistulae developing in the central tracheobronchial tree from direct tumor invasion or iatrogenic causes from cancer therapies can lead to tracheobronchial-esophageal-pleural fistulae. These pathologic connections clinically manifest themselves as coughing,

aspiration, pneumothorax, and pneumomediastinum. These lead to subsequent mediastinitis and pneumonitis, which can lead to respiratory embarrassment and sepsis. The complex anatomic connections of the trachea and mainstem bronchi to a number of mediastinal, vascular, and bronchial structures, plus the tenuous tracheal blood supply, also limit surgical interventions in relieving obstructions or in repairing an injured trachea. Because of the close anatomic relationship of the thoracic esophagus to the left mainstem bronchus, certain pathology affecting the left and right mainstem bronchi is considered as a continuum of the trachea in this chapter.

## Clinical Manifestations of Upper Airway Problems

Clinical manifestations of the upper airway problems associated with cancers are listed in Table 1. Specific signs, symptoms, and physical findings are discussed further in the respective sections on the specified conditions of upper airway obstruction, vocal cord dysfunction, and aspiration.

## Upper Airway Problems

### Tumor Invasion of the Upper Airways

Cancers affecting the upper airways consist of the following: primary cancers of the upper aerodigestive tract (ie, pharyngeal, laryngeal, and tracheal cancers); cancers that invade this space by direct extension, primarily thyroid, esophageal, bronchogenic carcinomas, mediastinal tumors, including lymphoproliferative disorders; and cancers of almost all origins that may metastasize to the upper airways.

Primary cancers of the upper aerodigestive tract share much that is common in etiology, and they can all present with similar upper airway symptoms. As shown in Table 2, taken together, they still constitute only a minority of all new cases of incident cancers but may have a disproportionately high morbidity and mortality, even acknowledging the overweighing in mortality given to lung cancers by including all bronchogenic cancers.

There are, however, important differences in their cancer biology that lead to different

**Table 1** Clinical Signs and Symptoms of Upper Airway Problems

Common Symptoms	
Cough	
Dysphonia: hoarseness, voice change	
Throat, neck, and chest pain	
Dysphagia, including a chronic foreign body sensation	
Dyspnea: from central airway obstruction, parenchymal pneumonia	
Bleeding: oropharyngeal, hematemesis, or hemoptysis	
Fever: from infections (pharyngitis, laryngitis, tracheitis, bronchitis, pneumonitis, mediastinitis, abscess formation) or tumor necrosis	
Retained airway secretions, difficulty clearing secretions	
Uncommon Symptoms	
Referred otalgia, especially ipsilateral ear pain	
Massive exsanguination from vascular erosion and rupture	
Possible findings on physical examination	
Hoarseness	
Fluctuance of the soft tissue of the neck, other signs of inflammation	
External draining sinus tract or skin breakdown	
Crackles and other findings suggesting consolidation owing to pneumonia	
Fever, clinical signs of sepsis	
Stridor and/or wheezing, especially inspiratory and when supine	
Tracheal deviation: compression by extrinsic mass or deviation toward volume loss	
Superior vena cava syndrome: facial plethora and edema, superficial varicosities	
Hamann's crunch and subcutaneous crepitus as a result of pneumomediastinum	
Clubbing and other paraneoplastic syndromes	
Weight loss and generalized cachexia	

**Table 2**

	<i>Estimated New Cancer Cases</i>	<i>Cancer Deaths 2006</i>
All sites	1,399,790	564,830
Pharynx (all oral cavity and pharyngeal)	8,950 (30,990)	2,110 (7,430)
Larynx	9,510	3,740
Lung	174,470	162,460
Esophagus	14,550	13,770
Total of four sites (% of all cancers)	207,480 (14.8)	182,080 (32.2)

Adapted from Jemal A et al.<sup>1</sup>

prognosis and management goals. Tobacco is a major risk factor for the development of all upper aerodigestive tract malignancies, including tumors of the lung, esophagus, larynx, and hypopharynx.<sup>3</sup> Laryngeal cancer in particular is more likely in heavy smokers; however, unlike hypopharyngeal cancer, it tends to be detected earlier because of clinically obvious and chronic voice changes, as well as the higher diagnostic sensitivity of a direct endoscopic examination. Hypopharyngeal cancer is also due to tobacco use but is also associated with heavy alcohol intake.<sup>4</sup> Patients present with a chronic sore throat, gradual but persistent dysphagia that may be dismissed and adapted to by alterations in diet, and, less commonly, an ipsilateral referred otalgia (ear pain). A foreign body sensation may be felt, but hemoptysis and voice changes are late sequelae of direct tumor extension into the larynx. Diagnosis would most often require detailed esophagoscopy under sedation. Because of the vascular and lymphatic

drainage of hypopharyngeal tumors, at the time of diagnosis, many or most of these cancers already have regional or distant spread of disease. Radiologic assessment by computed tomography (CT), magnetic resonance imaging (MRI), and chest radiography to detect synchronous lung primary cancers is needed. Prognostically, laryngeal cancers generally fare better than hypopharyngeal cancers, again because of the latter's late diagnosis and early dissemination, as explained. However, in time, laryngeal tumors can also extend to the hypopharynx and vice versa, and both can extend down into the trachea. Hence, for a discussion of additional etiologic risk factors, these upper airway cancers are considered together.

In addition to tobacco products and alcohol, a number of chemical carcinogens have been linked to laryngeal, hypopharyngeal, and bronchogenic carcinomas. These include arsenic, asbestos, chromates, nickel compounds, cobalt

and certain heavy metals, chloromethyl ethers, polycyclic aromatic hydrocarbons, certain mineral oils, and aniline dye compounds.<sup>5</sup> Occupational or environmental radon exposure and previous radiotherapy also increase the risk of the development of upper aerodigestive (UAD) cancers.

Environmental risk factors are admixed with genetic predispositions to greatly increase the risk of the development of UAD cancers. One example is in Fanconi's anemia, a rare autosomal recessive disorder with a high degree of genomic instability in which affected individuals are predisposed to cancers, especially hematologic and squamous cell cancers.<sup>6</sup> Hence, Fanconi's anemia patients in the international registry have been noted to have a 500 times standard incidence ratio for the development of head and neck cancers and a high degree of recurrence approaching 50%, which may be made worse when the patient is given therapeutic external beam radiation.<sup>7</sup> Whether individuals have transmitted germline mutations or acquired losses of tumor suppressor genes, the accumulation of genetic and epigenetic abnormalities leads to the development of precursor lesions and eventually invasive carcinomas, which may be single or multiple primary tumors over time.<sup>8-11</sup>

One nongenetic syndrome complex associated with hypopharyngeal carcinoma is the Plummer-Vinson or Paterson-Brown Kelly syndrome of progressive dysphagia, esophageal and hypopharyngeal webs, vitamin B and iron deficiency anemia, and weight loss identified and characterized between 1914 and 1922.<sup>12-14</sup> The pathophysiologic basis of this association is thought to be due to a chronic inflammation response. It is hoped that improved recognition and management with vitamin B and iron supplementation plus dilation should make this condition an interesting historical vignette.

Acquired immune deficiency syndrome (AIDS)-related malignancies (AIDS-defining cancers) include Kaposi's sarcoma (KS), non-Hodgkin's lymphoma (NHL), and human papillomavirus (HPV)-associated cervical and anal cancers. KS in particular and NHL will involve the aerodigestive tract. In the first decade and a half of AIDS, KS has been listed as the leading cause of AIDS-related malignancy, and pulmonary KS, almost always involving the central airways, has been noted in between a fifth to a third of AIDS-related KS.<sup>15</sup> In fact, pulmonary KS may be the solo or initial site of KS presentation, with between 10 and 20% of patients presenting with pulmonary KS absent cutaneous and oral mucocutaneous lesions.<sup>15,16</sup> Although pulmonary KS lesions can become profuse in the lung parenchyma and lead to significant gas exchange impairment, endobronchial KS lesions may also present in various upper airway locations and

lead to significant central airway obstruction or to life-threatening bleeding, especially on biopsy.<sup>17,18</sup> Although KS found in the airways in the AIDS era was most recently associated with human immunodeficiency virus (HIV) infection, it is important to consider KS in other patients in immunocompromised states, such as on transplant-related immunosuppression,<sup>19,20</sup> and episodic spontaneous cases that may present with acute airway obstruction.<sup>21,22</sup> AIDS-related lymphoma may also involve the mediastinum with extrinsic compression or intrinsic involvement of the trachea and mainstem bronchi. In the past decade, perhaps as a result of changes in personal practices limiting exposure to herpes simplex virus 8, the putative causative agent for KS, and/or because of highly active antiretroviral therapy (HAART) reconstituting the immune system, there has been a decline in the number of KS cases.<sup>23,24</sup> Conversely, perhaps because of HAART resulting in longer overall survival, there has been a noted rise in tobacco-related malignancies, including primary bronchogenic and head and neck carcinomas,<sup>25,26</sup> and their consequential upper airway involvement and complications as well.

Another infection-related tumor is squamous papilloma in the larynx and tracheo-bronchial tree caused by HPV passed by maternal-neonatal transmission during childbirth. Unlike HIV-associated papillomavirus-associated cancers of the female genital and anal tract, this is primarily a benign tumor of childhood that often regresses in adulthood. However, recurrent papillomatosis may be prolific in its polypoid growth, leading to upper airway obstruction and dysphonia. Although uncommon, between 1.6 and 5% of papillomatosis have been reported to undergo malignant transformation into squamous cell and verrucous carcinoma, even in the absence of tobacco products, ionizing radiation, or other carcinogenic exposures.<sup>27</sup> This malignant transformation is most common with HPV type 11 and, as with other cancers, seems especially prone to develop in association with *TP53* and other tumor suppressor gene mutations.<sup>28–30</sup>

Primary tracheal cancers are relatively rare compared with secondary cancers. In the adult patient, most primary cancers are malignant and few are benign (Table 3).<sup>31,32</sup> Although certain primary tracheal tumors, such as adenoid cystic carcinomas, mucoepidermoid carcinomas, and central carcinoid tumors, are clearly tracheal in origin, the most common primary tracheal cancer of the squamous cell type often raises the question as to whether it may be of a metastatic origin from the nearby head and neck, esophageal, or lung origin when these cancers are also present since it is known that metachronous lesions are more common when there is one primary UAD cancer

**Table 3** Classifications of Laryngeal and Tracheal Tumors

Lymphomas

present, and patients who have had any previous UAD malignancy are at a much increased risk of developing second primary malignancies of the UAD tract.<sup>33–35</sup> Overall, however, most cancers involving the trachea are metastatic in origin, with most by direct extension from tumors arising in the adjacent structures of the thyroid, head and neck, and esophageal sources. Direct tracheal invasion occurs in up to 6.5% of thyroid cancers, and subsequent upper airway obstruction is a leading cause of death.<sup>36</sup> Tracheal involvement by extrinsic compression or by direct extension is a frequent complication of esophageal carcinomas. In this instance, fistulae formation presents as much of a problem as does airway obstruction.

Aside from direct extension from tumors of the UAD tract, cancers of almost any origin may metastasize to the larynx, hypopharynx, and trachea (see Table 3). These are, however, relatively rare, and as documented by Nicolai and colleagues, only 143 cases of cancers metastatic to the larynx were reported by 1996, these being primarily melanoma, renal cell carcinoma, and sporadic cases from the colon and lung.<sup>37</sup> Similarly, sporadic cases of renal cell carcinomas, sarcomas, chondrosarcomas and other mesenchymal cell tumors, and breast, colon, uroepithelial, male genital, and gynecologic tumors have all been reported to have metastasized to the central conducting airways of the trachea and mainstem bronchi.<sup>38</sup> Although melanomas detected in the upper airways are most often metastatic in origin, primary tracheobronchial melanomas have also

been diagnosed presumptively when a cutaneous primary source cannot be ascertained.

Prognostically, cancers arriving by distant metastases to the upper airways are rarely, if ever, curable. In fact, only direct thyroid cancer invasion and squamous cell metastases from a lung primary tumor could be considered for curative resection if the metastatic involvement is limited and the patient is a functionally fit candidate. Palliative measures to mechanically reduce or to cytoreduce the tumor bulk and to maintain airway patency are mentioned in the following section.

### Vocal Cord Paralysis

VCP is predominantly unilateral in pattern, in which case, symptoms can range from minimal to notable dysphonia, especially progressive hoarseness, and, given the central role of the vocal cords in protecting the airway inlet during swallowing, aspiration symptoms resulting in cough, dyspnea, and pneumonia. At the same time, failure of normal apposition of the cords limits effective coughing and airway clearance. The degree of vocal cord dysfunction ranges from mild paresis with weakened but residual function to complete immobility. The position of the paralyzed cord may be fully lateralized to full medialization. The left vocal cord is much more commonly involved than the right because of the longer path of the recurrent laryngeal nerve looping below the aortic arch and is hence easily entrapped by lung cancers originating in the aortopulmonary window or metastasizing to nodal stations L2, L4, or L5 or by large mediastinal cancers. Bilateral VCP, when present, leads to more severe symptoms, including upper airway obstruction, when both cords are fixed in a medialized position.

The two leading causes of VCP are neoplasia and postsurgical injuries, accounting for between 70 and 80% of adult cases.<sup>39,40</sup> In the cancer patient, iatrogenic causes also include head and neck radiotherapy,<sup>41</sup> but surgical resection of thyroid, head and neck, and mediastinal cancers remains the primary cause. Because of the very different concerns regarding VCP causing airway obstruction and VCP leading to aspiration, the specifics of diagnostic evaluation and therapy of these entities are addressed separately in the respective sections.

### Upper Airway Obstruction

Obstruction of the upper airways as a result of cancers of the UAD tract (head and neck, esophagus, and lungs), thyroid, mediastinal structures, and metastatic diseases may present subacutely with progressive symptoms, such as increasing dyspnea, cough, dysphonia, dysphagia, and mild bleeding, or acutely, with life-threatening asphyxiation and massive hemorrhage. The levels of the obstruction may occur anywhere from the soft supraglottic tissues of the hypopharynx to direct

involvement of the larynx or the subglottic trachea. The larynx and the trachea together form a semirigid tubular structure in which injuries may irreversibly damage the cartilaginous-membranous network, leading to scarring and fixed stenosis, malacia, or both.

The most common cause of upper airway obstruction in the cancer patient would be direct tumor growth and invasion or extrinsic compression of the tracheobronchial tree by the tumors listed in Table 3. Additional causes are as listed in Table 4, including conditions that may be complications of cancer progression, iatrogenic from cancer therapy, or entirely unrelated.

Critical airway obstruction as a result of vocal cord dysfunction owing to cancer is unusual in that both vocal cords will have to be affected and both vocal cords will have to be paralyzed in a paramedian position to cause critical airflow limitation. In large retrospective series, bilateral (VCP in the adult patient is more commonly secondary to trauma, either owing to external forces or as a result of surgery, especially thyroid resection.<sup>42,43</sup> In the cancer patient, this most commonly results from surgically induced recurrent laryngeal nerve injuries<sup>42,43</sup> or radiation- and other treatment-induced nerve injuries.<sup>44</sup> Rare

cancer-related causes of bilateral VCP included paraneoplastic syndromes, such as bulbar amyotrophic lateral sclerosis secondary to small cell carcinoma.<sup>45</sup> Bilateral VCP may occur in the setting of prolonged endotracheal intubations, especially in patients with conditions of compromised vasculature, including diabetes, stroke, and ischemic heart disease. These individuals have increased risk of developing acute laryngeal injuries from intubations; therefore, cancer patients with these comorbidities who are intubated without immediate prospects of weaning may be candidates for early tracheostomies.<sup>46</sup> Symptomatic or occult gastroesophageal reflux disease is also a predisposing cause of glottic and subglottic stenosis, as well as Barrett's esophagus and esophageal carcinoma.<sup>47</sup> Hence, in cancer patients, especially ones with UAD tract malignancies leading to impaired swallowing function, esophageal cancer patients with resections, and gastric pull-ups or colonic interpositions, reflux as a cause should be considered and evaluated as indicated and preventive measures taken.<sup>48</sup>

Obstruction of the subglottic trachea in the cancer patient may present as a fixed airway narrowing or variable airway collapse. Fixed obstructions are due to extrinsic tracheal

obstruction by upper mediastinal and neck structures, direct tracheal invasion by tumors, or a combination of both processes. Fixed tracheal obstruction may also result from cancer therapies, including external beam radiation, scarring from surgical resection and especially at the anastomotic site, and again as a result of prolonged endotracheal tube intubations. Airway narrowing in the trachea varying with the respiratory cycle, especially during exhalation and cough maneuver, is due to tracheomalacia, and in the cancer patient, this may be the result of cancer invasion and destruction of cartilaginous rings, treatment such as thyroidectomy, or a limited tracheal resection or again as a result of tracheal cartilage destruction after prolonged endotracheal intubation or tracheostomy tubes, both of which may cause pressure necrosis of the supportive cartilage.

Hemorrhage may cause upper airway obstruction by direct obstruction of the airway passage or from extrinsic blockage by an enlarging hematoma. Blood clots blocking the trachea and mainstem bronchi leading to potentially life-threatening obstruction have been reported in both pediatric and adult oncology patients.<sup>49,50</sup> In addition to critical narrowing of the airways lumen, the aspirated blood volume, if sufficiently large, may lead to sufficient alveolar filling to impair oxygenation. The source of the blood may originate from anywhere along the oropharynx, larynx, and trachea to oozing or being coughed up from the lung parenchyma itself owing to friable cancer masses or from diffuse alveolar hemorrhage. Retropharyngeal, sublingual, and neck hemorrhages may be spontaneous from a cancer<sup>51</sup> or a malignancy-associated marrow dysfunction<sup>52</sup> and severe enough to cause airway obstruction, or it may be the result of biopsies,<sup>53</sup> postoperative hemorrhage,<sup>54</sup> or anticoagulation therapy.<sup>55-57</sup> Patients with head and neck cancer or lung cancer compounded by severe chronic obstructive pulmonary disease (COPD) may have tracheostomy tubes. Subsequent tracheoinnominate artery fistulae are a rare but potentially devastating cause of bleeding into the airway.<sup>58</sup> Radiation- and chemotherapy-induced mucositis may be severe, leading to diffuse bleeding and oral and esophageal mucosal sloughing. Pain and administered narcotic analgesics and sedatives may further inhibit good airway clearance and cloud the sensorium, and patients may develop frank airway obstruction.<sup>59</sup>

Among the iatrogenic causes of upper airway obstruction, the role of the central lines placed in the jugular or subclavian vessels deserves mention as a large number of cancer patients have long-term indwelling central venous catheters placed for infusion of chemotherapy and nutrition, or they may have temporary lines for hemodynamic monitoring of the administration of fluids, blood products, and medications. Cancer

Foreign bodies, including food, teeth, and dental appliances that are dislodged or aspirated
Malpositioned artificial airways (endotracheal tubes, tracheostomies, airway stents)
Obstruction of endogenous or artificial airways by secretions, mucus, and/or blood
Airway edema owing to anaphylaxis, angioedema, trauma
Extrinsic compression by hematoma, fluid extravasation
Infections including epiglottitis, pharyngeal and retropharyngeal abscesses
Chemical and heat inhalational airway burn injuries
Congenital anomalies: bronchial and mediastinal cysts in a paratracheal position, piriform sinus cyst, hemangiomas, laryngeal and tracheal webs, tracheolaryngomalacia, vascular anomalies, etc.
Obstructive sleep apnea-related upper airway obstruction
Psychogenic, eg, psychogenic asthma and paradoxical vocal cord dysfunction

patients may have thrombocytopenia and coagulopathy that increase the risk of hemorrhage and impair normal hemostasis. Landmarks used for central venous cannulation may be effaced in the patient with anasarca or the veins collapsed in the dehydrated and debilitated patient. In any case, intravenous fluid extravasation from a malpositioned line,<sup>60</sup> neck hematoma leading to upper airway obstruction,<sup>61</sup> and inadvertent arterial cannulation, with subsequent subcutaneous hemorrhage even leading to death from airway obstruction,<sup>62</sup> have all been reported. Cancer patients may also be hypercoagulable, and even surgically placed tunneled catheters may malfunction when placed into a thrombosed superior vena cava (SVC) and cause a backflow with subsequent upper airway obstruction.<sup>63</sup>

There are many other causes of fixed and variable upper airway obstruction, not specifically related to a malignant condition or antineoplastic therapies, that may predate or develop coincidentally with the cancer diagnosis and subsequent treatment. These are listed in Table 4 as part of the differential diagnosis of upper airway obstruction but are not specifically addressed further in this discussion.

### Diagnosis and Evaluation of Upper Airway Obstruction

Patient presentation includes dyspnea, cough, and a variable degree of adventitious breath sounds.<sup>64</sup> Audible stridor and subjective wheezing would occur only with significant compromise of the upper airway lumen, narrowed down to a 4 to 5 mm caliber. The pattern of stridor and wheezing may depend on whether the critical airway narrowing is fixed or variable, as in malacia or edema and hematoma in a location above or below the thoracic inlet.<sup>65</sup> Patients may have difficulty clearing secretions, especially if they also have VCP with incomplete adduction, cancer treatment-related mucositis, neuromuscular weakness, impaired mentation, or any other condition leading to an impaired ability to cough or protect the airways. Exertional dyspnea may also be due to systemic effects of concomitant anemia, advanced COPD, and cardiovascular disease.

Voice change may be due to direct tumor invasion of the larynx and vocal cords or entrapment of one or both of the recurrent laryngeal nerves. The left vocal cord is more likely to be paretic because of the longer path length of the recurrent laryngeal nerve. A patient with known paralysis of one vocal cord and dysphonia who then develops increasing dyspnea while regaining voice quality may be developing fixed bilateral VCP and worsening airway obstruction.

A physical examination should include observation of cutaneous findings of vascular

obstruction leading to SVC syndrome; this would include facial and possibly upper extremity edema, plethora, and prominent skin surface collaterals. Tenderness and swelling, with fluctuance and warmth, may suggest the site of an abscess, hematoma, or fluid extravasation. The trachea should be observed and palpated. Deviation of the trachea may be due to a space-occupying process such as a large parenchymal lung mass or pleural effusion pushing the trachea contralateral, lung volume loss from postoperative changes, or ipsilateral atelectasis. Auscultation and percussion of the chest may detect concomitant pneumonitis and the consolidation and presence of pleural effusion.

For patients who are sufficiently stable as outpatients or who may leave the monitored setting, pulmonary function studies with maximal effort flow-volume loops may clarify whether they have fixed or variable upper airway obstruction and the level of the narrowing by the pattern of flow limitation.<sup>65,66</sup> Baseline lung function studies will also provide a basis for evaluating an objective response to any palliative measures.

Imaging studies of the upper airways are indispensable in the current diagnosis and management of cancer-related upper airway and thoracic problems. Because of the complex anatomy of the UAD tract, planar radiographs of the thorax and neck seldom provide sufficient information about the specific pathology. On the other hand, in the initial evaluation of an unstable patient with upper airway problems who may not tolerate being in a recumbent position, a chest radiograph and posteroanterior and lateral neck films can be easily and rapidly obtained in a monitored setting to provide a global overview of the affected area. The chest radiograph with a properly aligned patient in full inspiratory breath-hold should offer a rapid assessment of gross central airway patency and the presence of any lung masses, infiltrates, pleural effusions, or pneumothoraces that may affect the intrathoracic trachea. Figure 1 illustrates the lateral leftward displacement of the midtrachea by a large right lung tumor. The tracheal air column is narrowed but remains grossly patent. Contrast studies provide additional information by outlining specific structures. Figure 2 illustrates a pharyngeal swallow study of the same patient who complains of dysphagia in addition to dyspnea, hoarseness, cough, and increasing problems with clearing secretions. There is no evidence of a fistula formation, complete esophageal obstruction, or proximal aspiration, but there is impingement and compression of the esophagus. CT has improved significantly such that with multislice detector CT scans, acquisition time is shortened to a single breath-hold and the data can be easily and rapidly manipulated at a workstation to provide three-dimensional imaging information.<sup>67,68</sup>

**FIGURE 1** Planar anteroposterior upright chest radiograph showing tracheal deviation and narrowing at the level of the thoracic inlet to aortic arch by a large right upper lobe small cell lung cancer.

**FIGURE 2** A pharyngeal study demonstrates no aspiration but definite esophageal narrowing and is complementary to the planar chest radiograph (see Figure 1).

Unless contraindicated by insufficient renal function or known sensitivity to the intravenous contrast dye, a contrast-enhanced CT scan provides much additional useful information. Given that most, if not all, of the patients in question present with increasing dyspnea and cancers generally

increase the risk of thromboembolism, a significant pulmonary embolism may be ruled out at the same time. Contrast enhancement in the chest CT can help distinguish a tumor mass from distal compressive atelectasis. Tumor involvement of the vasculature by direct invasion or extrinsic compression can be assessed and therapeutic decisions regarding the need for vascular stenting or radiotherapy for SVC syndrome taken. Contrast localization of the larger vessels is also important in the planning for surgical or endoscopic interventions to avoid vascular complications. Figure 3 shows the contrast-enhanced CT scan of the same patient in Figures 1 and 2, with greater details of the extent of tumor invasion, including chest wall involvement and developing SVC compression. Another advantage of CT is the ability to view the acquired data in different windows and planar projections. Figure 4 demonstrates even more critical airway narrowing in a patient with concomitant emphysema and radiation fibrosis, all of which contribute to the symptom of dyspnea. MRI and magnetic resonance angiography may more accurately depict vascular anomalies and neural structures, but the length of image acquisition, and with the exception of open magnetic resonance units, may complicate the monitoring of patients with severe upper airway symptoms. These and diagnostic and interventional angiographic studies to detect a significant bleeding source and to direct embolization management of severe bleeding may need to be carried out after elective intubation.

Even with the advent of advanced three-dimensional reconstructions of airways and generation of virtual bronchoscopy “fly-through,”<sup>68,69</sup> direct endoscopic imaging, preferably with anesthetic assistance and emergency surgical standby for tracheostomy, will provide the most direct assessment of the pharyngeal and laryngeal spaces and of the tracheobronchial tree. A variety of rigid and flexible fiberoptic laryngoscopic and bronchoscopic instruments are available.<sup>70</sup> The choice of instrument depends on the purpose of the examination. Initially, a small-caliber instrument with or without a working channel provides visual

**FIGURE 3** Contrast-enhanced computed tomographic scan showing superior vena cava compression, chest-wall involvement, and tracheal compression by tumor.

**FIGURE 4** A computed tomographic scan demonstrates the extent of critical airways narrowing at the upper trachea caused by concentric tumor encroachment in a patient with progressive non-small cell lung cancer. Note the severe emphysema (*left*) and postradiation scarring (*right*), which is best appreciated in the lung-window setting.

examination and allows passage of a narrowed upper airway segment to assess the integrity of more distal airways.<sup>71</sup> Such small instruments are less likely to induce trauma and further airway edema. Conversely, larger instruments, including rigid bronchoscopes and suspension laryngoscopes with better imaging and suctioning capabilities and the ability to pass accessory instruments, may be needed on follow-up examination to clear secretions, débride obstructing lesions, and deploy stents to maintain the airway patency (Figure 5).<sup>70</sup> These instruments can also be used to secure an airway, whether by passing an endotracheal tube through the rigid instruments or over a flexible endoscope. Hence, endoscopy often encompasses both a diagnostic and a therapeutic component.

In the case of bilateral VCP, provided that the degree of airway obstruction is not critical, a thorough otolaryngology evaluation is performed, including electromyography if direct tumor invasion and involvement of bilateral recurrent laryngeal nerves are not obvious, because in these cases, conservative reconstructive surgery should be

**FIGURE 5** Rigid bronchoscopy image of an obstructing central airway non-small cell cancer about to be mechanically débrided.

offered rather than destructive procedures, which will leave the patient permanently hoarse, or bypass tracheostomy, with all of its attendant side effects.<sup>72</sup>

## Management of Upper Airway Obstruction

The first priority in the management of upper airway obstruction is to preserve the patient's ability to ventilate and to oxygenate. In acute situations, this may require the need for an emergency airway placement, most often by endotracheal intubation but occasionally necessitating emergency tracheostomy or temporizing cricothyroidectomy. Specialized approaches may include the use of jet ventilation to maintain adequate gas exchange when an airway cannot be secured,<sup>73</sup> but the special techniques and technical considerations of surgery are beyond the scope of this discussion. Patients may present with acute airway obstruction anywhere from home to while being monitored in an intensive care unit. In a patient with known cancer, especially one that may involve the upper airways or has progressive symptoms suggestive of upper airway compromise, it is hoped that they will have been assessed and given warning signs for urgent follow-up evaluations to obviate the need for emergency interventions in the field.

For subacute cases of increasing respiratory and gas-exchange compromise, urgent assessment and intervention are still critical, but time and palliative measures may be available to defer immediate invasive airway interventions while the cause for the deterioration is determined. As always, treating the primary cause for the airway compromise is preferable and necessary for a good outcome.

In the hospital setting, especially in institutions in which a number of difficult airways cases are encountered on a regular basis, ideally, there should have been assembled a “difficult airways team” encompassing individuals from disciplines with interest and training in this area. This would include specialists from anesthesia, otolaryngology, pulmonary and critical care, thoracic and foregut surgery, gastroenterology, radiology, and support from respiratory care services. For the general internist or primary care physician triaging the overall care of a cancer patient, the presence of an established team will expedite the evaluation and management of the obstructed airway. Nevertheless, short of an acute deterioration necessitating immediate intubation, some standard orders can be implemented while an urgent assessment proceeds.

Any patients with the potential for a catastrophic airway closure should be placed in a monitored setting, either in the emergency department, a critical care unit, or at least on a

monitored unit in which cardiac telemetry, circulatory vital signs, and blood oxygen saturations by pulse oximetry are continuously assessed. Unless there is concomitant circulatory arrest, the patient should be encouraged to sit in an upright position and supplemental oxygen as needed provided with adequate humidification since inspissations of tenacious secretions may further compromise a narrowed air passage. Bronchodilators of the  $\beta$ -agonist class and including racemic epinephrine may be given by nebulization, again via a small-volume nebulizer rather than with a metered-dose inhaler (MDI) or by dry powder inhalation (DPI) without humidification.  $\beta$ -Agonists have the advantage of providing airways with smooth muscle relaxation and may assist in mucociliary clearance and in patients with concomitant alveolar edema may assist in alveolar fluid clearance.  $\beta$ -Agonist agents may, however, exacerbate tachyarrhythmias in distressed patients with preexisting cardiac disease who may not tolerate additional adrenergic stimuli. Additional inhalational therapies with quaternary antimuscarinic agents (ipratropium bromide) have proven to have additional benefit in an asthmatic population in the emergency department but may not be extrapolatable to patients with cancer-associated airway narrowing. Corticosteroids are often used to reduce airway edema; however, there would be questionable benefit of giving inhaled steroids, either by standard MDI or DPI preparations in patients with acute airway narrowing. Starting systemic steroids of a stress dosage range between 100 mg of hydrocortisone or 125 mg methylprednisolone (Solu-Medrol) (roughly five times the potency

**FIGURE 6** Cine-esophagram in an oblique plan showing the leakage of contrast material via an tracheoesophageal fistula into bilateral bronchi.

range) can be given with small risk of severe complications, even in patients with known or suspected glucose intolerance, active infections, or tissue breakdown, such as a mediastinitis or fistulae, as the steroids may be rapidly tapered with the definitive management of airway compromise. Broad-spectrum antibiotic therapy, often empiric, may be started in the cancer patient with upper airway obstruction as these patients are susceptible to infections, may have concomitant neutropenia and impaired mucosal barriers, and are very likely to have follow-up surgical interventions and antineoplastic therapies. The choice of agent should include coverage for oropharyngeal anaerobes and directed therapy against any known pathogen already recovered from the patient.

Although patients with upper airway obstruction and the associated discomforts of dyspnea and other symptoms are understandably anxious, sedative and hypnotic agents should be withheld lest they suppress the respiratory drive and interfere with effective communication. The at-risk patient should be kept fasting and given nothing by mouth to lessen the risk of reflux aspiration during acute intubation and resuscitation if that becomes necessary. As many cancer patients with UAD malignancies have impaired swallowing and are at increased risk of stress gastritis, should they require eventual intubation and mechanical ventilation, empiric therapy with proton pump inhibitors is warranted.<sup>47</sup> Hydration is given intravenously, and these patients should, in fact, always have reliable intravenous access as they may need volume resuscitation and pressor support in the immediate aftermath of intubation and positive pressure ventilation that may precipitously reduce cardiac preload in a malnourished cancer patient who has probably been poorly feeding when he or she has upper airway compromise.

**FIGURE 7** Computed tomographic scan of a patient with an esophageal primary cancer with previous tumor erosion and fistula formation into the left mainstem, status stent placement, who now presents with a new fistula connecting into the right lower lung and subsequent abscess formation.

**FIGURE 8** Flexible videobronchoscopic image of the tracheal opening of a tracheoesophageal fistula with leakage of methylene Blue dye that had been sipped and swallowed.

The work of breathing may be reduced by several other modes of noninvasive ventilatory assistance. This generally brings to mind noninvasive positive pressure ventilation (NIPPV) in the form of continuous positive airway pressure, bilevel positive airway pressure devices, or a ventilator with pressure support ventilation provided with a tight face mask or nasal mask. However, although there is now ample evidence to support the use of NIPPV in providing temporizing support and thus avoiding the iatrogenic complications of invasive airway ventilation in patients with acute exacerbations of COPD,<sup>74</sup> cardiogenic pulmonary edema,<sup>75</sup> and even with active hematologic malignancies presenting with neutropenia and respiratory insufficiency,<sup>76</sup> in a more recent retrospective analysis of NIPPV, there are insufficient data on this mode of therapy for upper airway obstruction.<sup>77</sup> In fact, in the patient with pure upper airway narrowing without parenchymal lung disease owing to cardiogenic or noncardiogenic edema, COPD exacerbations, or infections, caution must be exercised as the positive pressure may distend the esophagus and abdomen, predisposing the patient to reflux and/or aspirate while the tight mask used will impair communication and the ability to safely vomit. There have been reports of iatrogenic barotraumas leading to pneumomediastinum, especially when anatomic defects, such as esophageotracheal fistulae, may be present.

Another approach at reducing the work of breathing is to reduce airflow turbulence that occurs at the point or length of critical airway stenosis. Helium-oxygen (heliox) gas mixtures at a premixed or blended ratio of 80:20 (percentage ratios of helium to oxygen, with helium replacing nitrogen) or 70:30 are usually available in the respiratory department of most hospitals. Heliox use has a long history of safety in use dating back to 1935<sup>78</sup> in a wide range of patients with airway

**FIGURE 9** Three-dimensional image reconstruction showing the relationship between the tracheal and esophageal stents placed to manage a tracheo-esophageal fistula secondary to esophageal primary cancer.

narrowing, from pediatric patients with acute inflammatory epiglottitis to the elderly with multiple comorbidities who have developed upper airway stenosis<sup>79</sup> and specifically in patients with malignancy-associated upper airway obstruction.<sup>64</sup> The limitations of heliox include the limited amount of oxygen that can be mixed in as any percentage of greater than 40% oxygen, or the converse of less than 60% helium, will negate the beneficial effects of reduced airflow turbulence and reduced work of breathing. The choice of whether to select heliox or a higher percentage of oxygen therefore depends largely on the need for supplemental oxygen.<sup>80</sup> Therefore, for patients with a critical airway narrowing but also with another cause of poor gas exchange, and for patients with neurologic, metabolic, or infectious causes of altered sensorium, endotracheal intubation or elective or emergent tracheostomy may be required for controlled airway management and gas exchange.

When possible, surgical resection of a malignant upper airway obstruction for cure is optimal<sup>31,32</sup>; however, in most instances, palliative treatment measures are more likely. These would include external beam radiotherapy, cytotoxic chemotherapy, and, for the maintenance of airway patency, a variety of interventional endoscopic procedures,<sup>70,81</sup> which are covered in detail in Chapter 44.

## Summary

Problems in the upper airways of a cancer patient may present with myriad symptoms and clinical findings. The primary goals, as in the ABCs of life support, are to maintain airway patency and to ensure respiration and adequate gas exchange. Noninvasive supportive maneuvers are preferred; however, given the potential lability of potentially debilitated and unstable patients, careful moni-

toring may be required and preparations made for emergency critical care interventions as the need arises. Upper airway pathology only rarely directly causes circulatory collapse, and iatrogenic causes, such as positive pressure ventilation without adequate volume resuscitation, barotraumas, iatrogenic pneumothoraces, or vascular injuries, should be avoidable. Because the same symptoms may be caused by a variety of pathologies at different levels of the airways and adjacent structures, evaluation should be initially directed by the history. Various imaging modalities often provide the initial and confirmatory diagnostic information, and it is important to retrieve any baseline imaging studies for comparison to determine whether observed findings were actually preexisting and to ascertain the rapidity of any deterioration. Direct physical and endoscopic examination of the oropharynx and laryngo-tracheal and esophageal tracts should be performed as indicated. Ideally, an experienced, interested, and cooperative team of specialists, including the otolaryngologist, thoracic and foregut surgeon, pulmonologist, gastroenterologist, anesthesiologist, and diagnostic and interventional radiologist, should be available to lend support to the primary care physician and medical and radiation oncologists. Many patients with cancer-related upper airway problems have curable disease or malignancies that may be put into a period of remission and control. Certain complications, such as paralyzed vocal cords or post-treatment airway stenosis, may not be reversible but can often be remedied. For other, less fortunate patients with progressive and advanced disease, upper airway dysfunction and/or progressive respiratory compromise may herald the inevitable demise. Although supportive and comfort care is always provided, additional palliative procedures may be available, asphyxiation should certainly be avoidable, except in the most challenging cases, and advanced directives should be addressed to avoid further aggressive, often invasive, and, ultimately, futile interventions.

# Pneumonia in Cancer Patients

Christoph Schmidt-Hieber, MD

Daniel N. Ginn, MPH

John N. Greene, MD

With the increasing number of cancer patients receiving immunomodulating therapy, a growing number of pulmonary infectious complications are developing. These patients are also more likely to develop more severe infections and present in an atypical pattern. Early recognition and timely administration of antimicrobial agents are dependent on the awareness of the clinician of the disease presentation and appropriate imaging and diagnostic testing. Based on the infectious etiology, this chapter reviews common causes of pneumonia in cancer patients.

Bacterial pneumonia is a potentially life-threatening complication in a wide variety of cancer diagnoses and treatments. Many etiologic agents are associated with infections leading to pneumonia, and among the implicated bacteria, five primary organisms and groups are noted: *Streptococcus pneumoniae*, *Legionella* species, gram-negative bacilli, *Staphylococcus aureus*, and *Nocardia* species. Generally, the cancer patients most at risk of bacterial pneumonia are those with chemotherapy-induced neutropenia and patients receiving hematopoietic stem cell transplantation (HSCT). One study reported that during their disease course, approximately 80% of leukemia patients will develop pneumonia and that it is most commonly bacterial in origin.<sup>1</sup>

Bacterial pneumonias generally present atypically as severe sepsis with systemic signs and symptoms in cancer patients with neutropenia.<sup>2,3</sup> Airspace consolidation in the lungs is most commonly caused by bacterial pneumonia. Attributable mortality owing to bacteremic pneumonia in neutropenic patients has been reported at 55%, with 53% for gram-positive cocci and 54.2% for gram-negative bacilli.<sup>2</sup> Pneumonia is the most common cause of acute respiratory failure in cancer patients, which is the most common cause of intensive care unit admission.<sup>3</sup> Mortality rates are generally the highest for patients with ventilator-associated pneumonia and late-stage disease or prolonged neutropenia.<sup>4</sup> Treatment of bacterial pneumonias is typically the same for cancer patients as it is in the general population.<sup>5</sup>

As a consequence of the life-threatening nature of bacterial pneumonia in cancer patients, rapid diagnosis and prompt administration of appropriate antibiotic therapy are essential. The underlying malignancy of a patient can have a significant impact on the etiology of infection, leading to pneumonia, and the patient's immune status is almost always a contributing factor. Keen observation of the immune status of the patient and the antimicrobial resistance patterns in the area are necessary to choose the appropriate treatment for the cancer patient with pneumonia.

## *S. pneumoniae*

*S. pneumoniae* is an encapsulated gram-positive bacterium and is one of the most common causes of pneumonia in both cancer patients and immunocompetent noncompromised patients.<sup>5</sup> It is typically a community-acquired pathogen and is of increasing concern to the neutropenic patient and as a late infection in HSCT patients with chronic graft-versus-host disease (GVHD).<sup>5,6</sup> Patients with decreased humoral immunity are predisposed to *S. pneumoniae* infection, particularly those with multiple myeloma, chronic lymphocytic leukemia, and Hodgkin's disease who have undergone splenectomy.<sup>5,6-8</sup> The development of neutropenia owing to myeloablative chemotherapy increases the possibility of *S. pneumoniae* infection and the likelihood that previously asymptomatic colonization may become symptomatic.<sup>8</sup> As a cause of 5% of bacteremias in one study, *S. pneumoniae* infection resulted in pneumonia in 71% of those patients.<sup>6</sup> Elsewhere, *S. pneumoniae* has been responsible for 30% of bacteremic pneumonias, including 20% of early-onset pneumonias in neurosurgical patients.<sup>2,9</sup> *S. pneumoniae* has also been implicated as a causative agent of postobstructive pneumonia and aspiration pneumonia, a common complication following laryngectomy.<sup>10,11</sup>

Lung cancer patients are obviously at heightened risk of infection leading to pneumonia. There is an increased risk of respiratory

failure and mortality from community-acquired pneumonia (CAP) owing to *S. pneumoniae* in patients with underlying chronic obstructive pulmonary disease (COPD) and malignancy.<sup>10</sup> On a chest radiograph, *S. pneumoniae* infection generally presents as a focal infiltrate that develops in less than 24 hours during the course of pneumonia.<sup>6,12</sup>

Treatment options for community-acquired *S. pneumoniae* pneumonia should be approached syndromically, and efforts to identify the pathogen should be aggressive.<sup>13</sup> Initial treatment for early neutropenic patients with focal infiltrates is the prompt start of empiric broad-spectrum antibiotic therapy.<sup>6</sup> Drug resistance is a paramount concern with *S. pneumoniae*. Approximately 44 to 50% of strains exhibit greatly diminished susceptibility to penicillin, and approximately 16% are fully resistant.<sup>2,6,8</sup> Decreased sensitivity to some  $\beta$ -lactam antibiotics has been reported, with ceftazidime showing poor activity. The recent administration of a  $\beta$ -lactam antibiotic is a risk factor for the appearance of penicillin-resistant strains in adults.<sup>2,8,10</sup> Reported data have also demonstrated in penicillin-resistant *S. pneumoniae* isolates that there is an increase in resistance to erythromycin and cephalosporins, such as ceftriaxone and cefotaxime.<sup>8</sup> Resistance to  $\beta$ -lactam antibiotics has been correlated to increased resistance to macrolides and to trimethoprim-sulfamethoxazole (TMP-SMX). The recommended empiric treatment for *S. pneumoniae* infection is a macrolide, doxycycline, ceftriaxone, or a respiratory fluoroquinolone.<sup>10</sup> Recent studies have also shown all strains to have been susceptible to imipenem and vancomycin.<sup>2</sup> Nevertheless, the likelihood of new resistance remains a cause of concern.

In addition to antibiotics, corticosteroids have been useful in the treatment of severe community-acquired pneumonia<sup>14</sup> and severe viral respiratory infections, such as coronavirus (severe acute respiratory syndrome) and parainfluenza virus (croup in children). A multicenter placebo-controlled study of patients admitted to the intensive care unit with severe CAP demonstrated remarkable results in favor of the use of

hydrocortisone. There was a significant improvement in alveolar-arterial oxygen gradient and chest radiograph score, a significant reduction in multiorgan dysfunction syndrome score, C-reactive protein levels, septic shock, length of hospital stay, and mortality in the hydrocortisone treatment arm compared with the placebo arm. Hydrocortisone was infused intravenously as a 200 mg bolus followed by a rate of 10 mg/h for 7 days.

### Legionella Species

Of the *Legionella* species that are a threat to the health of cancer patients, *Legionella pneumophila* is responsible for 90% of infections, with serotype 1 responsible for 70% alone.<sup>15</sup> *Legionella* causes an atypical pneumonia (legionnaires' disease) and opportunistically affects patients with malignancies, HSCT patients, and those who are immunosuppressed and/or neutropenic owing to corticosteroid use or chemotherapy; cigarette smoking is also a major risk factor.<sup>7,10,15</sup> A prolonged course of steroid use will put a patient at a 10-fold increased risk of infection.<sup>6</sup> One epidemiologic study has shown that *Legionella* pneumonia is nine times more likely in the immunocompromised host than in the normal population.<sup>16</sup> Unlike *S. pneumoniae*, the primary host defense against *Legionella* is cell-mediated immunity, predisposing both lymphoid leukemia and hairy cell leukemia patients to infection because of their decreased cell-mediated immunity.<sup>15</sup> *Legionella* outbreaks are typically community acquired and are related to some environmental contamination when found nosocomially.<sup>17</sup>

Diagnosis of *Legionella* pneumonia requires a positive urinary antigen, direct fluorescent antibody, or a positive sputum or bronchoalveolar lavage (BAL) culture on charcoal yeast extract.<sup>6,15</sup> Infection is difficult to distinguish based on routine laboratory screenings and chest radiography, but isolation is always indicative of disease.<sup>6,12,15</sup> On a chest radiograph, bilateral or asymmetric infiltrates may be diffuse, cavitory, or nodular and multilobar consolidation is frequently present.<sup>1,5,6,15</sup> Pleural effusion may also be seen on a radiograph.<sup>17</sup> *Legionella* pneumonia follows a subacute progression of symptoms with refractory or late infiltrates that lasts for up to a week or more.<sup>6,12,17</sup> Symptoms include high fever, malaise, myalgia, confusion, multiple rigors, anorexia, and headache.<sup>15</sup> As legionellosis progresses, a slightly productive cough, pleuritic chest pain, hyponatremia, elevated transaminases, gastrointestinal symptoms such as watery diarrhea, and bradycardia may be experienced.<sup>13,15</sup> Left untreated, the pneumonia can progress to stupor, shock, and multiorgan failure and can be fatal. Poor prognostic indicators include acute renal

failure, shock, or the need for mechanical ventilation.<sup>18</sup> Although rare, the recurrence of infection is possible in the immunocompromised patient.<sup>15</sup>

In the immunocompromised cancer patient, extrathoracic *Legionella* infection may develop, such as arthritis and encephalitis.<sup>19</sup> Also in those with a compromised immune status, mixed infections are found more commonly than in the immunocompetent. Pathogens found along with *Legionella* include *S. pneumoniae*, *Streptococcus pyogenes*, *Enterococcus faecium*, *Enterobacter*, *Prevotella*, *Listeria*, *Nocardia*, and cytomegalovirus (CMV).<sup>18</sup>

As with other bacterial causes of pneumonia, it is important to begin treatment as soon as possible for *Legionella* pneumonia as it can run a fulminant course in cancer patients. The treatment of any severe CAP should include empiric treatment for *Legionella* as incorrect therapy leads to reported mortality rates approaching 80%. Currently, the best recommended treatment of legionellosis includes new macrolides and fluoroquinolones with or without rifampin. Azithromycin, doxycycline, ofloxacin, ciprofloxacin, and levofloxacin are all preferred to erythromycin.<sup>15</sup>

### Gram-Negative Bacteria

There are a number of gram-negative bacteria with the potential to cause pneumonia in the cancer patient. *Pseudomonas aeruginosa*, *Haemophilus influenzae*, *Neisseria meningitidis*, *Klebsiella pneumoniae*, and *Stenotrophomonas maltophilia* are all relevant to the scope of this discussion; however, *P. aeruginosa* and *S. maltophilia* are the most significant. Although there has been an etiologic shift in recent years to gram-positive bacteria as the source of infections in neutropenic patients, 30 to 40% of these infections are due to gram-negative bacteria.<sup>20</sup>

*P. aeruginosa* is one of the leading causes of bacterial pneumonia in cancer patients.<sup>6,16,20</sup> At the advent of methicillin use, *P. aeruginosa* posed a major threat to persistently neutropenic cancer patients, with a fatality rate of 90%. The  $\beta$ -lactam antibiotics were the first to curb this agent, and the fatality rate has dropped precipitously. One report noted that *P. aeruginosa* and *S. pneumoniae* account for 42 and 30%, respectively, of total pneumonia-causing bacterial infections and that *P. aeruginosa* is responsible for 68% of the gram-negative pneumonias.<sup>20</sup> *P. aeruginosa* infections are primarily nosocomial, and patients with solid tumors and those with acute leukemia are the most affected.<sup>5,20</sup> Also, it is the most frequently isolated bacteria in ventilator-associated pneumonia and is an indicator of poor prognosis.<sup>11,17,21</sup> Patients receiving HSCTs may have coinfection with *P. aeruginosa* and *Aspergillus* species.<sup>16</sup> In neutropenic patients, *P. aeruginosa* may exhibit

acute infiltrates with a nodular pattern and cavitation on a chest radiograph.<sup>5,6</sup>

Untreated *Pseudomonas* infections can be rapidly fatal in neutropenic patients. Ever-increasing resistance to available antimicrobial drugs highlights the importance of proper treatment selection. Antipseudomonal penicillins and cephalosporins have declined in efficacy with the emergence of resistance. Multiple studies have measured the resistance of *P. aeruginosa* to meropenem at 6 to 11%; piperacillin, ticarcillin, imipenem, and ceftazidime at 5 to 17%; and cefepime at 17%.<sup>20</sup> Ciprofloxacin resistance has been reported over a range of 21 to 75%, suggesting that corresponding rates are institution specific.<sup>20</sup> After prolonged neutropenia and use of broad-spectrum antibiotics, superinfection with *P. aeruginosa* is possible.<sup>7</sup> Combination therapy recommended for severe *P. aeruginosa* infections includes cefepime, piperacillin-tazobactam, or a carbapenem combined with an aminoglycoside or a fluoroquinolone with antipseudomonal activity. Because of better lung penetration, an antipseudomonal quinolone is preferred over aminoglycosides when used in combination with a  $\beta$ -lactam antibiotic.

*S. maltophilia* (formerly *Xanthomonas maltophilia*) is an important nosocomial cause of pneumonia in cancer patients. Those infected with *S. maltophilia* tend to have serious underlying conditions, such as lung cancer, acute leukemia, and chronic myelogenous leukemia, resulting in a reported pneumonia mortality rate of 50%.<sup>22</sup> Long-term neutropenia, extended hospitalization (more than 1 week), and the presence of central venous catheters are also risk factors for *S. maltophilia* colonization.<sup>22,23</sup> A reported 42.6% of patients with upper respiratory tract (URT) colonization with *S. maltophilia* developed pneumonia, but for sites other than lung colonization, 14.7% developed pneumonia. The clinical picture of *S. maltophilia* pneumonia is not particularly distinct from other causes of bacterial pneumonia. *S. maltophilia*-induced pneumonia may cause nonspecific alveolar infiltrates and focal areas of necrosis and hemorrhage. In one series, radiographic findings included bilateral infiltration in 50% and pleural effusion in 20%. However, none had cavitation.<sup>22</sup>

The primary challenge presented by *S. maltophilia* is the selection of appropriate therapy as it is especially prone to developing resistance. The agent is universally resistant to imipenem and has shown complete resistance to ceftazidime, tobramycin, and amikacin.<sup>22,24</sup> Previous treatment with imipenem is an important risk factor because its ineffectiveness against *S. maltophilia* makes superinfection possible. Other antimicrobials considered to be risk factors include ampicillin, gentamicin, vancomycin, metronidazole, piperacillin, cefotaxime, and ceftazidime.<sup>22,23</sup> Currently

effective drugs against *S. maltophilia* strains include ceftazidime, ticarcillin-clavulanate, TMP-SMX, the newer fluoroquinolones and tigecycline of the fluoroquinolones, Moxifloxacin has the highest activity in vitro against *S. maltophilia* (80% susceptibility).<sup>22,23</sup>

### **S. aureus**

*S. aureus* is also a common cause of life-threatening pneumonia. Infections generally arise in late neutropenia and originate most often from central venous catheters.<sup>9,25,26</sup> In patients receiving HSCTs, matched unrelated and mismatched allogeneic recipients are at risk of more frequent and more severe infection than sibling recipients.<sup>27</sup> Neurosurgical patients may experience early-onset pneumonia and, if there is tracheal colonization, ventilator-associated pneumonia owing to *S. aureus*.<sup>21</sup> Aspiration pneumonia with lung abscess is also a risk of infection.<sup>10,11</sup> The radiographic presentation of *S. aureus* pneumonia includes early focal infiltrates, with cavitory and nodular lesions progressing in less than 24 hours. Abscesses can occur in areas of consolidation where necrosis has developed.<sup>1,5,6,12</sup> A newly discovered virulence factor that produces tissue necrosis has been found in some strains of methicillin-resistant *Staphylococcus aureus* (MRSA), called Panton-Valentine leukocidin (PVL). Severe CAP caused by MRSA carrying the PVL gene has been described in healthy adults.<sup>28</sup> In several patients, concomitant influenza A infection contributed to the severity of the illness. Cancer patients could likewise be susceptible to this infection, and MRSA-carrying PVL genes should be considered if severe CAP is diagnosed.

This bacterium maintains a genetic plasticity that allows it to continually develop resistance to new antibiotics. MRSA has become a ubiquitous etiology of infection, and resistance to vancomycin, although scarce, is being reported as well.<sup>29</sup> Where resistance has not developed, MRSA frequently demonstrates 100% susceptibility to vancomycin.<sup>25</sup> MRSA susceptibility has been retained by minocycline, TMP-SMX, and a newer agent, linezolid, which has been an effective treatment for nosocomial and ventilator-associated MRSA pneumonia. Recent studies demonstrated the superiority of linezolid over vancomycin for nosocomial MRSA pneumonia and MRSA ventilator-associated pneumonia, with better clinical and microbial response rates and a higher survival rate.<sup>30,31</sup> Another new therapeutic, daptomycin, has shown effectiveness against MRSA but is specifically contraindicated for pneumonia treatment.<sup>2</sup>

### **Nocardia**

*Nocardia* species are aerobic actinomycetes found universally in soil. *Nocardia* infections

are most often due to *Nocardia asteroides* and are pulmonary in nature, affecting patients with lymphomas and lymphocytic leukemias, especially in the terminal stages of disease.<sup>5,32</sup> A review of 1,050 cases of nocardiosis from the 1970s found that 17% of patients had a solid or hematologic malignancy.<sup>33</sup> Prolonged use of corticosteroids (more than 1 month) is a significant risk factor for the development of nocardial infections. Interestingly, neutropenia is not a risk factor for nocardiosis.<sup>32</sup>

Allogeneic HSCT is another risk factor for nocardial infections. One study found that nocardiosis was diagnosed a median of 210 days after transplantation, with an 84% survival rate from the infection.<sup>34</sup> Interestingly, 40% (10 of 25 patients) were receiving oral TMP-SMZ twice-weekly prophylaxis for *Pneumocystis carinii* pneumonia (PCP).

Pulmonary infection presents with fever, night sweats, and cough, but the severity varies with the degree of immunosuppression.<sup>17</sup> Pneumonia caused by *Nocardia* progresses subacutely or chronically with a multifocal pattern, consisting of consolidation and cavitory or nodular lesions that are detectable on a computed tomographic (CT) scan before they can be seen on a chest radiograph.<sup>5,6,12</sup> However, one study indicates that 75% of non-acquired immune deficiency syndrome (AIDS) immunosuppressed patients with pulmonary nocardiosis will exhibit singular nodularity, with only 21% having cavitation.<sup>1</sup> Isolation and identification of *Nocardia* species are diagnostic, and gram staining distinctively shows beaded gram-positive, filamentous rods.<sup>13,16</sup> Distinguishing *Nocardia* from *Actinomyces*, which has a similar Gram stain pattern, requires a modified Kinyoun stain. *Nocardia* is acid-fast positive, whereas *Actinomyces* is acid fast negative.

*Nocardia* has a propensity to spread to the central nervous system, presenting as a brain abscess, which is frequently asymptomatic. Up to 44% of patients with disseminated nocardiosis will have brain involvement.<sup>33,35</sup> Therefore, all patients with pulmonary nocardiosis should have a CT scan of the brain to rule out central nervous system involvement.

Antibiotics with bactericidal activity are replacing the mainstay of therapy, TMP-SMX, which is bacteriostatic. Treatment for *Nocardia* infections is a combination of a third-generation cephalosporin, such as cefotaxime, or carbapenem and amikacin intravenously followed by oral minocycline or TMP-SMX. Because of the tendency for relapse of *Nocardia* infection, treatment should continue for a prolonged period of time (6–12 months).<sup>32</sup>

### **Cytomegalovirus**

CMV is a member of the Herpesviridae family. More than 50% of adults in the United States and

Europe have antibodies against CMV. CMV is a well-known cause of severe infections in HSCT patients, especially following allogeneic HSCT between the first and the third month after transplantation.<sup>36,37</sup> Important risk factors in these patients for developing CMV disease include seropositivity for CMV antibodies of either or both the donor and the recipient, age older than 20 years, GVHD, and failure of reconstitution after HSCT.<sup>38</sup> Prior to the introduction of specific antiviral therapy with ganciclovir and intravenous immunoglobulin (IVIG), CMV pneumonia occurred in 17% of allogeneic SCT patients and had an associated mortality rate of 85%.<sup>37</sup> Since the introduction of preemptive therapy, the overall rate of CMV pneumonia has decreased (6% in one study),<sup>39</sup> but the proportion of patients with late CMV disease (>100 days after transplantation) has increased,<sup>39,40</sup> and the mortality rate remains high (up to 76%) once pneumonia has developed.<sup>39</sup> Occasionally, *P. carinii* will be found together with CMV in severe pneumonia.

The acute syndrome preceding CMV pneumonia typically consists of flu- or mononucleosis-like symptoms, such as fever and myalgia. Thrombocytopenia, leukopenia, atypical lymphocytosis, and liver function abnormalities may be observed during this time. Once CMV pneumonia has developed, patients present with tachypnea, a nonproductive cough, dyspnea, and unilateral or bilateral rales.<sup>36,41</sup>

On a chest radiograph, pulmonary parenchymal infiltrates will be visible in most patients. The pattern of infiltrates can be consolidation, interstitial, ground-glass, or a combination of all three, and is most often located at the bases of the lungs. More rarely, a nodular pattern or pneumothorax has been described.<sup>42</sup> A CT scan of the lung will most commonly reveal ground-glass opacification, areas of consolidation, and small bilateral nodules.<sup>43</sup>

CMV pneumonia is defined by the presence of symptoms of pulmonary disease combined with the detection of CMV in BAL fluid or lung tissue samples.<sup>44</sup> The preferred diagnostic approaches are deoxyribonucleic acid (DNA) or pp65 antigen detection methods and viral culture. Recently, several real-time polymerase chain reaction (PCR) assays that increase sensitivity and decrease processing time have been described.<sup>45–47</sup>

General prevention strategies in allogeneic SCT patients include matching of seronegative recipients and donors and use of seronegative or leukocyte-reduced blood products. Other than that, two different strategies using antiviral drugs have been studied in recent years: either preemptive or prophylactic treatment. In preemptive therapy, antiviral treatment is started as soon as CMV infection is diagnosed by DNA detection methods or antigenemia assays. By contrast,

prophylactic treatment is typically started at engraftment and continued at least during the first 3 months after transplantation. Although several studies have shown prophylactic treatment to decrease early CMV disease, the mortality rate was not changed because of other intercurrent infections and a higher incidence of late CMV disease. Because preemptive treatment seems to reduce mortality, especially when a short-term antigenemia- or DNA-based strategy is used, it has become the strategy favored by most authors for the general situation.<sup>38,40,48</sup> However, prophylactic treatment remains warranted when the risk of severe GVHD is unusually high and when corticosteroids are used for the treatment of GVHD. Usually, no preemptive or prophylactic treatment is required when both donor and recipient are seronegative for CMV. The same holds true for autologous SCT recipients without risk factors.<sup>38,40</sup> Preemptive treatment should be started as soon as CMV is detected in blood by either an antigenemia assay, PCR, or, more rarely, viral culture. Ganciclovir should be used at a dosage of 5 mg/kg twice daily for 1 to 2 weeks, followed by 5 mg/kg daily for 100 days or until no CMV DNA or antigen can be detected on several occasions. Foscarnet at a dosage of 60 mg/kg twice daily can be used instead of ganciclovir when marrow toxicity or ganciclovir resistance is observed.<sup>38,40,48</sup> Prophylactic treatment consists of ganciclovir at a dosage of 5 mg/kg once daily, started at engraftment and continued for 100 days.

Once CMV pneumonia has developed, ganciclovir should be used at a dosage of 5 mg/kg twice a day for 1 or 2 weeks and then at a dosage of 5 mg/kg daily for 3 to 4 weeks. IVIG (500 mg/kg) or CMV immunoglobulin (150 mg/kg) is added every other day for the first 2 weeks and then weekly. Longer treatment may be required in cases of severe immunosuppression. Foscarnet at a dosage of 90 mg/kg twice daily can be used as an alternative to ganciclovir in cases of marrow toxicity or ganciclovir resistance.<sup>40</sup> Other antiviral drugs that have some activity against CMV include valganciclovir and cidofovir. Valganciclovir is an effective oral formulation for treatment of CMV infection with good systemic absorption. Cidofovir is nephrotoxic and is rarely used for the treatment of CMV infection in the setting of HSCT.

## Influenza Virus

Influenza virus is one of the most common causes of severe respiratory disease in the world. Most epidemics are caused by influenza A, subtype H3N2, resulting in about 140,000 hospitalizations per year in the United States.<sup>49</sup> Influenza has a typical seasonal distribution, with most cases occurring between November and April.<sup>49,50</sup> Among the cancer population, patients with

leukemia and/or undergoing HSCT have an increased risk of developing severe disease from influenza infection. In these patients, the risk of developing influenzal pneumonia has been reported to be between 28 and 80%, with an associated mortality rate of 17 to 33%.<sup>51–55</sup> However, the incidence is relatively low (about 1%), probably owing to prevention measures such as vaccination of both patients and staff. The risk factors for influenza infection include HSCT during the influenza season, female sex, and advanced disease, and the risk factors for progression to pneumonia are lymphocytopenia and steroid use.<sup>54</sup> During the winter of 1993–1994 in Houston, one-third (15 of 45) of adults with leukemia who were hospitalized in a local cancer center with an acute respiratory illness were infected with influenza.<sup>56</sup> Twelve (80%) of the patients infected with influenza virus had pneumonia, and of these, four (33%) died. They expired owing to progressive respiratory failure at a mean of 24 days (range 8–31 days). Patients who died tended to have received chemotherapy more recently and to be more myelosuppressed.

Typical symptoms of respiratory tract infection and pneumonia owing to influenza include fever, productive or nonproductive cough, wheezing, and nasal congestion. More rarely, a sore throat, shortness of breath, myalgia, and chest pain have occurred.<sup>52,57</sup> On a chest radiograph, bilateral or unilateral consolidation and nodular opacities will be seen. A CT scan of the lung will show ground-glass opacities, consolidation, centrilobular nodules, and branching linear opacities.<sup>58</sup>

In the previously mentioned study, the most common presenting symptom in leukemia patients infected with influenza was fever (87%), followed in frequency by cough (73%) and wheezing (67%). Sore throat and nasal congestion were noted, 33% (5 of 15) and 53% (8 of 15) of the time, respectively. Myalgia occurred in only 4 (27%) patients. Five patients had radiographically documented sinusitis (one of whom had concurrent *Aspergillus* sinusitis). Pneumonia was diagnosed at a mean of 8 days (range 0–24 days) after the onset of symptoms in 80% (12 of 15) of the patients. Bilateral infiltrates were noted in 10 patients and unilateral infiltrates in 2. Three (25%) patients with pneumonia were concurrently infected with *Aspergillus* species, respiratory syncytial virus (RSV), and RSV combined with *Candida* species, respectively.

A high frequency of infection occurred in another influenza epidemic recorded in the same city and institution during the winter of 1991–1992.<sup>59,60</sup> Twenty-eight (29%) adult HSCT recipients and 37 (11%) adults with leukemia hospitalized with an acute respiratory illness were infected with influenza virus. The complication

rate in those patients was quite high. Seventy-five percent (6 of 8) of the HSCT recipients and 75% (3 of 4) of the leukemia patients with influenza developed pneumonia with a high mortality rate, 17% and 33%, respectively.

Pneumonia complicating influenza is frequently bacterial or mixed bacterial and viral in origin.<sup>56</sup> Cancer patients, especially those with neutropenia, with prolonged corticosteroid therapy, or following HSCT may be particularly vulnerable to coinfection with *Aspergillus* species.

Influenza can be diagnosed by culture or, more rapidly, by antigen assays, neuraminidase activity assays, or reverse transcriptase polymerase chain reaction (RT-PCR). Culturing influenza virus, although time-consuming, may provide important information about the virus subtype and drug resistance<sup>61</sup>; however, RT-PCR has been shown to have a higher sensitivity than viral culture and is therefore now considered the reference standard by some authors.<sup>62</sup> Adequate specimens can be obtained by nasopharyngeal wash, throat swab, or BAL. Using BAL specimens has been reported to increase the diagnostic yield.<sup>63</sup>

## Prevention

Although the immune response to immunization with inactive influenza virus vaccine in cancer patients is less than in the general public, its use is highly recommended in this population by the Centers for Disease Control and Prevention.<sup>49,64,65</sup> In addition, chemoprophylaxis is highly recommended in immunosuppressed patients with cancer if they are exposed to the influenza virus. The drug that appears to be the most popular and useful for chemoprophylaxis and treatment for influenza in all populations is the new neuraminidase inhibitor oseltamivir. Its low toxicity, high efficiency, and oral formulation make it favored over the inhaled neuraminidase zanamivir (Relenza). Older drugs that also may be useful for prophylaxis and treatment include amantadine or rimantadine. Of the older drugs, the latter is preferred because of less toxicity. For HSCT patients, vaccination should be begun before transplantation and resumed more than 6 months after transplantation. Chemoprophylaxis with either M2 inhibitors or neuraminidase inhibitors (oseltamivir or zanamivir) should also be considered in times of nosocomial or community outbreaks of influenza.<sup>55,61,66</sup>

## Treatment

Both M2 inhibitors and neuraminidase inhibitors are known to be effective in preventing and treating influenza infection in immunocompetent patients. In immunosuppressed HSCT patients, early therapy with oseltamivir or zanamivir has

been shown to decrease progression to pneumonia and mortality from influenza infection.<sup>54,67</sup> Since resistance against M2 inhibitors in immunocompromised patients has been reported,<sup>68</sup> it has been suggested that neuraminidase inhibitors should be used either alone or in combination with M2 inhibitors.<sup>54</sup> However, no large-scale clinical studies are available that would justify a general recommendation.

Finally, inhaled ribavirin, used mostly for RSV infections, has also been successfully used in patients with influenza pneumonia. Dosage recommendations are 100 mg twice daily for both rimantadine and amantadine, 10 mg twice daily for zanamivir, and 75 mg twice daily for oseltamivir.<sup>49</sup>

## Respiratory Syncytial Virus

RSV, a single-stranded RNA virus of the Paramyxoviridae family, is the most common cause of lower respiratory tract (LRT) disease, such as bronchiolitis and pneumonitis, in infants between 6 weeks and 6 months of age.<sup>69</sup> Among immunocompetent adults, RSV infection usually produces symptoms of the common cold. However, severe respiratory disease is seen in immunocompromised cancer patients with leukemia and those receiving HSCT.<sup>70</sup> RSV infection usually occurs during the winter months, but illness during the summer can occur.<sup>71</sup> RSV can colonize the URT without causing symptoms. However, URT colonization and/or infection frequently lead to LRT infection in HSCT recipients and patients receiving myeloablative chemotherapy. Transmission seems to occur mainly by direct contact with large particulate droplets and/or fomites, with a high risk of nosocomial spread.<sup>72</sup> The mortality rate of RSV pneumonia in immunocompromised patients, especially HSCT recipients, has been reported to approach 100% but can be largely reduced by prompt and adequate therapy.<sup>73–75</sup>

RSV pneumonia in immunocompromised adults typically starts with symptoms of URT infection, such as cough, rhinitis, or sinusitis. Progression to LRT infection is more likely to occur in patients with renal failure, elevated serum lactate dehydrogenase (LDH), or mucositis and recipients of allogeneic HSCT (especially during the immediate post-transplant period) and/or myelosuppressive chemotherapy.<sup>71</sup> RSV has a propensity to cause tracheobronchitis, with resultant necrosis, edema, and increased mucous secretion, resulting in obstruction. Wheezing is a characteristic finding on physical examination. A chest radiograph will show bilateral infiltration in 40%. High-resolution computed tomography (HRCT) of the chest will demonstrate ground-glass infiltrates. RSV can be detected by antigen testing (enzyme-linked immunosorbent assay or immunofluorescence) or viral culture. However,

PCR is the most sensitive method for detecting RSV.<sup>76</sup> Although samples can be obtained by nasal wash or throat swab, sensitivity greatly improves when a BAL or an endotracheal aspiration is performed.<sup>77</sup>

In immunocompromised HSCT patients, a combination therapy with aerosolized ribavirin and IVIG has been shown to be effective in RSV URT illnesses and RSV pneumonia.<sup>75,78,79</sup> However, no controlled clinical trials of this regimen have been performed to date, and there is no general consensus on which patients to treat and when to start therapy. Ghosh and colleagues suggested treating patients according to individual risk factors, such as the level of immunosuppression, the age of the patient, the clinical course of the respiratory illness, and the presence of underlying lung disease.<sup>78</sup> A monoclonal antibody against RSV, palivizumab, is 50 to 100 times more active than RSV-specific IVIG and has been approved for prophylactic use in infants at risk of severe RSV infection. Monthly prophylaxis with intramuscular palivizumab has shown a 55% reduction in RSV infection-related hospitalization in premature infants and infants with chronic lung disease (bronchopulmonary dysplasia).<sup>80</sup> It has been reported to be effective in adults following HSCT for prophylaxis and treatment of severe RSV infection as well.<sup>80,81</sup> A short course of therapy with corticosteroids, as shown in several studies of children with RSV tracheobronchitis and croup, may be of benefit.<sup>71,80</sup> The use of aerosolized ribavirin is quickly falling out of favor because of difficulties with administration and a lack of efficacy. Because RSV is transmitted nosocomially at a high frequency, infection control measures, such as contact isolation, gowns, and gloves, are crucial in preventing nosocomial RSV pneumonia outbreaks.<sup>72</sup>

## Human Metapneumovirus

Human metapneumovirus (hMPV) was first isolated in 2001 from infants with clinical syndromes closely resembling those caused by RSV infection, including bronchiolitis, croup, asthma exacerbation, and pneumonia.<sup>82</sup> As a member of the Paramyxoviridae family, it belongs to the same subfamily (Pneumovirinae) as RSV. The only other member of its genus (*Metapneumovirus*) identified so far is avian pneumovirus type C, which is known to cause rhinotracheitis in turkeys. Further studies have shown hMPV to be a frequent cause of respiratory tract illness, not only in otherwise healthy infants and children<sup>83</sup> but also in elderly and immunocompromised patients.<sup>84–86</sup> Most cases of hMPV infection have been reported during the winter and early spring months, suggesting a seasonality that is similar to that of RSV infection.<sup>87</sup> Furthermore, some data indicate that hMPV infection might aggravate

respiratory tract disease caused by RSV<sup>88</sup>; however, this finding could not be confirmed in another study.<sup>89</sup> Patients with malignancy are included in a large series of patients with hMPV respiratory infections.<sup>86</sup> However, two patients with cancer and hMPV infection are reported in the literature with significant detail, in a case report fashion.<sup>90,91</sup> Both patients died from severe pneumonia with respiratory failure. One patient was a 17-month-old female with acute lymphoblastic leukemia (ALL),<sup>90</sup> and the other patient was a 33-year-old female also with ALL.<sup>91</sup>

The most common symptoms caused by hMPV include fever, cough, dyspnea, tachypnea, and wheezing. Despite clinical features that are very similar to RSV infection, it has been suggested that hMPV respiratory illness tends to be less severe, with less hypoxemia and dyspnea.<sup>83,86,87</sup> A chest radiograph may show atelectasis, hyperinflation, and infiltrates. HRCT of the chest usually reveals bilateral ground-glass infiltrates. With rapid antigen detection tests being unavailable to date, RT-PCR is currently the method of choice for detecting acute hMPV infection. Adequate primers were recently described by Côté and colleagues.<sup>92</sup> Although samples obtained by nasopharyngeal aspirate have been used in most studies, sensitivity might be increased by BAL as it has been described in the diagnosis of RSV pneumonia.<sup>93</sup>

At the time of writing, no treatment for hMPV infection has been evaluated in any large-scale study. However, a combination of ribavirin and IVIG, as used for RSV infection, has been shown to have some in vitro activity against hMPV and might therefore be considered for severe hMPV respiratory illness in immunocompromised patients.<sup>94</sup>

## Rhinovirus

The majority of common cold syndromes are caused by human rhinoviruses (HRVs) and coronaviruses. These are generally considered to replicate principally in the URT. However, severe respiratory infection requiring hospitalization can occur in the elderly and immunosuppressed population. Patients with COPD are particularly at risk of serious infection.<sup>95</sup> In one study, the most common pathogen found as a cause of exacerbation of COPD was the picornaviruses, 75% of which were due to rhinoviruses.<sup>96</sup>

Most patients with common colds present with a self-limited syndrome characterized by nasal obstruction, coryza, sneezing, sore throat, and cough. Fever is uncommon in immunocompetent adults. However, infants, hospitalized elderly patients, and HSCT recipients can develop LRT disease, including viral pneumonia.<sup>97</sup>

One series of myelosuppressed HSCT patients with HRV pneumonia diagnosed by viral culture resulted in a fatal outcome in 32% (7 of 22).<sup>98</sup> All

of the patients presented with infection within the first 10 days after transplantation, suggesting nosocomial acquisition.<sup>96</sup> The mean time between the onset of acute respiratory symptoms and respiratory failure was 12 days (range 3–21 days). The duration of viral shedding was 8 days (range 1–18 days). In another study, HSCT recipients with acute pulmonary infiltrates were found to have HRV in 8% (6 of 77 patients) of the cases.<sup>99</sup> All of them were detected by RT-PCR of BAL. Most of the patients presented with HRV infection after the first 100 days after transplantation, which is consistent with a community acquisition of infection. All of the patients had copathogens (three with *Aspergillus* species, three with parainfluenza virus, two with RSV, and one with CMV, *P. aeruginosa*, *S. aureus*, and *S. pneumoniae*). Death occurred in five of six patients, with a mean time of 54 days between illness onset and death. The most sensitive available technique for diagnosing HRV presence is RT-PCR because cell culture is relatively insensitive.<sup>99</sup>

There is no known treatment for severe rhinovirus infection that is readily available. However, a promising agent, pleconaril (a viral capsid function inhibitor), shortens the course of illness but induces the P-450 hepatic enzyme, which could result in drug-to-drug interactions.<sup>95</sup>

## Aspergillus

The genus *Aspergillus* consists of more than 600 species, with *A. fumigatus*, *A. flavus*, *A. terreus*, and *A. nidulans* being the most common causes of infection in humans. Because *Aspergillus* species are ubiquitous, infections can occur in the community and in the hospital setting, especially during periods of renovation or construction in the latter case. The respiratory tract is the primary portal of entry, and the pulmonary alveolar macrophage is the first line of defense against infection. Neutrophils and circulating peripheral blood monocytes are the secondary line of defense. Chemotherapy, radiation therapy, and corticosteroids significantly alter these primary and secondary lines of defense to allow for *Aspergillus* infection. The most common risk group that develops invasive pulmonary aspergillosis (IPA) is composed of those with prolonged neutropenia (greater than 7 days) or GVHD and those receiving corticosteroids or another immunosuppressive therapy.

The mortality rates of IPA are 60% or higher in patients with a hematologic malignancy and 80% or higher in patients following allogeneic SCT. The longer the duration of neutropenia, the greater the mortality rate in patients with IPA. A bimodal pattern of IPA has been noted in patients following allogeneic SCT at 16 and 96 days after transplantation, which corresponds to the periods of neutropenia and GVHD, respectively.<sup>100</sup>

The most common clinical finding in patients with IPA includes fever, pleuritic pain, cough (usually nonproductive), and hemoptysis. Decreased breath sounds owing to pulmonary consolidation or a pleural friction rub, which can be evanescent, may be noted on the examination. *Aspergillus* species have a strong predilection to invade blood vessels, resulting in vascular thrombosis, infarction, and tissue necrosis. This, in turn, results in the characteristic radiographic findings, which include bronchopneumonia, lobar consolidation, multiple nodular lesions resembling septic emboli, cavitary lesions, the halo sign, and the air crescent sign. The earliest lesions are best seen by HRCT scans, which can detect infection a week earlier than plain chest radiographs. Peripheral nodular lesions greater than 2 cm are suggestive of *Aspergillus pneumoniae* in high-risk patients. A halo of ground-glass infiltrates can frequently be seen surrounding the dense core of the nodular lesions. In some cases, an air crescent can be visualized within the nodular infiltrates and represents separation of the necrotic center from the hemorrhagic outer rim. After several weeks, cavitation frequently develops from lung necrosis. Although the radiographic findings mentioned above are highly suggestive of IPA in the high-risk patient, definitive diagnosis requires visualization of the pathogen by fungal stains and culture of sputum, BAL, or biopsy of affected tissue. *Aspergillus* species in tissue form angular, dichotomously branching septate hyphae, which are indistinguishable from *Fusarium*, *Scedosporium*, and other pathogenic molds. Culture of *Aspergillus* in the high-risk patient with characteristic radiographic findings is diagnostic of IPA. Serologic testing (galactomannan)<sup>101</sup> and antigen-based testing by PCR are not universally accepted but can be useful for early detection of IPA and for following the response to treatment. Reducing morbidity and mortality from IPA require prophylactic therapy, early detection, effective therapy after diagnosis, and resolution of immunosuppression.

Voriconazole has become the drug of choice for IPA after an improved response, a higher survival rate, and less toxicity were noted when compared with amphotericin B.<sup>102</sup> Combination therapy is considered more effective than monotherapy. Voriconazole combined with caspofungin resulted in a better response rate and a higher survival rate than voriconazole alone in the treatment of IPA.<sup>103</sup> Other drugs that are effective alone or in combination include itraconazole, caspofungin, and lipid formulations of amphotericin B, which are less nephrotoxic than amphotericin B. A newly approved antifungal, posaconazole, also has excelled activity against *Aspergillus* as well as other molds, including zygomycosis. Granulocyte colony-stimulating factor, granulocyte-macrophage

colony-stimulating factor, or granulocyte transfusions may be used to improve the response to antifungal therapy with IPA.

The duration of therapy ranges from 6 weeks to 6 months depending on resolution of pulmonary lesions by serial CT and the recovery of host immunity. Because the risk of relapse of IPA is over 50% with future episodes of neutropenia, appropriate antifungal therapy is begun with onset.

## Fusarium

The *Fusarium* genus belongs to the fungi imperfecti and derives its name from its fusiform spores. It is a ubiquitous fungus and a common soil saprophyte and plant pathogen. In the hospital setting, this mold and other dematiaceous fungi have been shown to be present in water or water-related surfaces and potted plants, which serve as a potential reservoir for infection.<sup>104</sup> In some areas, the rainy season is associated with a two- to sixfold greater incidence of *Fusarium* infections in cancer patients than the drier months.<sup>105</sup> Localized and systemic diseases have been described in the literature in both non-neutropenic and neutropenic hosts. Improved antibiotic treatment, use of prophylactic antibiotics, intensification of antileukemic treatment resulting in profound and prolonged myelosuppression, and HSCT contribute to the emergence of *Fusarium* species as a significant cause of severe, often fatal disease.<sup>104</sup> Almost half of the reported cases of disseminated fusariosis occur in patients with acute leukemia, and prolonged neutropenia is the predominant risk factor.<sup>105</sup> Corticosteroid use has not been identified as a major risk factor for fusariosis and is, therefore, far less frequent than aspergillosis in patients with GVHD receiving corticosteroids.<sup>106</sup> Portals of entry for this fungus include the respiratory tract (nasal passages, sinuses, and lung) and skin, especially between the toes and in the periungual area.

Pulmonary fusariosis resembles aspergillosis with nodular, cavitary, or nonspecific pulmonary infiltrates. The typical course is described as fever, nodular lung lesions or sinusitis, periungual or toe cellulitis, disseminated nodular skin lesions, myalgias, and fungemia. The eventual outcome is resolution with myeloid recovery or death secondary to disseminated infection. Boutati and Anaissie recently reviewed the cases of 43 patients with invasive and/or disseminated fusariosis, all of whom were immunocompromised and most of whom were neutropenic at diagnosis (84%) or undergoing steroid therapy.<sup>107</sup> Skin lesions were present in up to 70% of patients in a review by Richardson and colleagues and in 79% (34 of 43) in the review by Boutati and Anaissie.<sup>107,108</sup> Interestingly, all 18 patients in the latter review who had blood cultures positive for *Fusarium* species had skin lesions. Skin lesions present as multiple

painful erythematous subcutaneous nodules approximately 2 to 3 cm in diameter. Occasionally, the lesions form a black necrotic eschar and may ulcerate. Clinical and histopathologic findings of septate branching hyphae, with a propensity for vascular invasion and thrombus formation, are very similar to those for other mold infections. A unique feature of *Fusarium* species, in contrast to other molds, such as *Aspergillus*, is the high rate of positive blood cultures, up to 50% in some reports, and the frequent finding of skin lesions.<sup>104</sup> The frequent finding of fungemia is thought to be due to the propensity for intravascular sporulation of *Fusarium*, which is not a characteristic of *Aspergillus*.

Outcome generally relates to recovery of bone marrow and the overall condition of the host. Susceptibility to antifungal therapy seems to be a significant factor, with *Fusarium* shown to be consistently resistant to 5-fluorocytosine and variably sensitive to amphotericin B and amphotericin B lipid formulations posaconazole, ketoconazole and miconazole.<sup>104</sup> Voriconazole alone or combined with amphotericin B lipid formulations remains the drug of choice. Recurrent infection has been described, generally among patients with repeated episodes of neutropenia.<sup>107</sup> Therefore, prompt reinstatement of antifungal therapy and a search for evidence of recurrence during subsequent neutropenic episodes are essential.<sup>104</sup> HSCT recipients may develop infection before or after engraftment, even when they have adequate neutrophil counts. Overall, the prognosis remains poor with disseminated disease, and early diagnosis and aggressive combination antifungal therapy and surgery or débridement, coupled with leukocyte transfusions or growth factors, remain the best approach.<sup>104</sup>

### Scedosporium

Infections owing to *Scedosporium* are primarily caused by *S. apiospermum* and *S. prolificans* (inflatum). *Scedosporium apiospermum* is the asexual form of *Pseudallescheria boydii*, better known as the most common cause of Madura foot in the United States. This phaeohyphomycete, found commonly in soil, standing water, and sewage, has been known to cause locally invasive infections and systemic fungemia in the immunocompromised patient.<sup>110</sup> Locally invasive infections are usually caused by traumatic or penetrating injuries that introduce the fungus into deep tissues, as in Madura foot or mycetoma.<sup>109</sup> Other deep tissue infections have been described, including osteomyelitis, endocarditis, sinusitis, parotitis, pneumonia, and brain abscess.<sup>109</sup> Although *S. apiospermum* infections have been described in immunocompetent patients, disseminated infection is far more common in the immunocompromised host, with prolonged neutropenia or chronic GVHD, or in those

receiving corticosteroids or amphotericin B.<sup>110</sup> *Scedosporium* is inherently resistant to amphotericin B.

In one review of the literature, 25 disseminated *Scedosporium* species infections in cancer patients were reported, with a mortality rate of 96%.<sup>110</sup> The time from the onset of symptoms of disseminated infection until death ranged from 1 to 29 days (average 12 days). All patients had a hematologic malignancy in various stages of therapy; 15 patients were receiving amphotericin B therapy when their cultures were positive for *Scedosporium* species.

The triad of fever, nodular skin lesions, and myalgia, once considered to be pathognomonic of disseminated candidiasis (especially *Candida tropicalis*), is common in patients with disseminated *Scedosporium* and *Fusarium*.<sup>105</sup> In addition, positive blood cultures are common with disseminated *Scedosporium* and *Fusarium* but are rare when *Aspergillus* disseminates.<sup>105</sup>

Invasive *Scedosporium* pulmonary disease resembles aspergillosis, with fever, cough, pleuritic pain, and hemoptysis being the most common.<sup>111</sup> In one study, the most common clinical features among the 25 patients with disseminated infection included fever (92%), pulmonary symptoms (48%), central nervous system findings (44%), rash (28%), and arthralgias or myalgias (16%).<sup>110</sup> Findings on chest radiography or CT of the lungs are similar to those of invasive pulmonary aspergillosis with nodular consolidation that may develop cavitation. Multiple brain infarcts can be seen by CT or magnetic resonance imaging of the brain when dissemination to the central nervous system develops. Culture of the organism from involved sites by sputum, BAL, or biopsy sampling is required for diagnosis. The acute angle branching and septation of hyphae seen on histopathology for *Scedosporium* cannot be distinguished from *Aspergillus* and other molds.

*Scedosporium* is resistant to amphotericin B. Lipid formulations of amphotericin B have been successfully used for *Scedosporium* infections in case reports.<sup>105</sup> However, voriconazole is the drug of choice for *Scedosporium* infections, possibly combined with a lipid formulation of amphotericin B. Posaconazole also has based invitro activity against *Scedosporium*. Ultimate recovery from all mold infections is dependent on resolution of neutropenia.

### Zygomycosis

Zygomycosis is an opportunistic infection caused by organisms belonging to the class Zygomycetes. The organisms most commonly implicated in clinical disease belong to the genera *Mucor*, *Rhizopus*, *Absidia*, and *Cunninghamella*, with *Rhizopus* being the most common. These

organisms are widely disseminated in the environment, and most of the infections are due to the inhalation of spores.

Zygomycosis is an uncommon acute and often fatal opportunistic fungal infection that is classically seen with poorly controlled diabetes mellitus with acidosis, acute leukemia, or other immunosuppressive conditions. Neutrophils and monocytes or macrophages are the essential host defense factors against the Zygomycetes. Patients with acute leukemia are at high risk of developing zygomycosis as a result of prolonged neutropenia. A relatively new association of zygomycosis occurring in patients with iron and aluminum excess who receive deferoxamine therapy has been reported with increasing frequency.<sup>111</sup> Although most commonly noted in patients receiving hemodialysis, zygomycosis develops in patients with various iron overload states such as thalassemia, sideroblastic anemia, and myelodysplasia in which deferoxamine may be used.

The clinical manifestations of zygomycosis consist of rhinocerebral, pulmonary, gastrointestinal, cutaneous, and disseminated infection. The rhinocerebral form is the most common presentation. Rhinocerebral zygomycosis is found most commonly in uncontrolled diabetics with ketoacidosis and then in patients with prolonged neutropenia. It is associated with the development of sinusitis with involvement of the orbit leading to proptosis and ophthalmoplegia. Pulmonary zygomycosis more often occurs in patients with leukemia or lymphoma with prolonged neutropenia.<sup>112</sup> Symptoms of pleuritic chest pain, fever, cough, and hemoptysis with radiographic findings of consolidation and cavity formation are indistinguishable from those of pulmonary aspergillosis.<sup>112</sup>

Hematogenous dissemination can result in brain, spleen, kidney, heart, liver, and omentum metastatic infection. Pulmonary zygomycosis has a predilection to spread to the brain. Cerebral forms of zygomycosis are more like to de?? in patients with a hematologic malignancy and associated neutropenia. Regardless of the anatomic site of the lesion, invasion of blood vessels results in downstream tissue necrosis, and a black necrotic eschar develops if the skin is involved. The diagnosis of zygomycosis is best made by biopsy of involved tissues with histopathology and fungal culture. Microscopy will reveal broad, irregularly shaped, ??? nonseptate hyphae with right-angled branching. The fungi are often seen invading through tissue planes and blood vessels. Thrombosis and resultant infarction of the surrounding tissue ensue. The diagnosis of pulmonary zygomycosis is rarely made antemortem as the yield from sputum fungal smears, culture, and BAL is low.<sup>112</sup>

Without early aggressive therapy, zygomycosis is almost always fatal. Therapy consists of early surgical débridement, administration of amphotericin B or lipid formulations of amphotericin B,

and correction of the underlying disease process. Lipid formulations of amphotericin B allow for administration of amphotericin B at higher doses with less nephrotoxicity.<sup>113</sup> Posaconazole with in-vitro activity against zygomycetes, can be used alone or in combination with lipid formulations of amphotericin B. If surgical débridement or the correction of the underlying conditions is not possible, then the response from medical treatment alone is poor. A better therapeutic response is obtained in patients with diabetic ketoacidosis and zygomycosis than in patients with underlying leukemia and lymphoma because ketoacidosis can be quickly corrected and the sinus, rather than the lung, is usually affected. Therapy with high-dose lipid formulations of amphotericin B, combined with aggressive surgery and immune reconstitution, offers the best chance for survival of cancer patients with zygomycosis.<sup>113</sup> If consolidation chemotherapy is needed in patients with a history of zygomycosis, prophylaxis with amphotericin B or its lipid formulations or posaconazole can prevent a relapse of infection.<sup>114</sup>

### **P. Carinii Pneumonia**

*P. carinii* is a unicellular eukaryote thought to be a protozoon for more than 80 years. Its taxonomy had remained unclear until 1988, when Edman and colleagues demonstrated it to be a fungus by analyzing its ribosomal ribonucleic acid.<sup>115</sup> *P. carinii* was named after Antonio Carini, who discovered the organism in rats in 1912. A new name for the cause of *Pneumocystis* infection in humans was recently selected: *P. jiroveci*, after Otto Jirovec, who demonstrated the organism in premature newborns who died of interstitial plasma cell pneumonia in 1951.<sup>116</sup> We use *P. carinii* in place of *P. jiroveci* in this chapter owing to its familiarity and extensive use in the literature. Most children have acquired antibodies against *P. carinii* by the age of 4 years.<sup>117</sup> Primary infection is usually asymptomatic, and the latency of the organism seems to occur in some cases.<sup>118</sup> However, several studies now suggest that PCP is due to reinfection rather than to reactivation of latent infection.<sup>119</sup> It has been known as a complication in both human immunodeficiency virus (HIV)-positive and HIV-negative immunocompromised patients with T-lymphocyte disorders for a long time.<sup>120,121</sup> In the AIDS population, PCP may develop in more than 75% of persons in the absence of chemoprophylaxis.<sup>122</sup> Because of standard prophylaxis for PCP with TMP-SMX in HIV-infected patients with a CD4 lymphocyte count below 200 cells/mL, PCP has been much less common in this population in recent years. However, in cancer patients, PCP may be increasing because of more intensive and prolonged suppression of cellular immunity with corticosteroids and

monoclonal antibodies. In addition, mortality owing to PCP is higher in cancer patients compared with AIDS patients, partly because of late recognition of the infection.

Several large studies of PCP in HIV-negative patients published recently found that lymphocytic leukemias and lymphomas predominated.<sup>123–126</sup> A few patients had multiple myeloma, acute and chronic myelogenous leukemia, and solid tumors. The primary risk factors were cytotoxic chemotherapy, prolonged corticosteroid therapy, and SCT. Admission to the intensive care unit was required for 45 and 56% of patients in two of the studies, respectively.<sup>124,126</sup> In the same two studies, 30 and 41% required mechanical ventilation, and the mortality rate was 33 and 38%, respectively.<sup>124,126</sup> Poor prognostic indicators were prolonged corticosteroid therapy, a high respiration rate, a high heart rate, an elevated C-reactive protein level, an elevated serum LDH level, and mechanical ventilation.

Antecedent corticosteroid use is cited in 80 to 94% of cases of non-HIV PCP.<sup>126–130</sup> Paradoxically, corticosteroid treatment predisposes patients to PCP and also improves the outcome once PCP occurs. The use of corticosteroid therapy to treat PCP in immunosuppressed patients without HIV was only recently proved to be as effective as in HIV-positive patients.<sup>131</sup> As illustrated in many published series, the high incidence of corticosteroid use as adjuvant therapy may account for the decreased mortality in recent years.<sup>127–129,132</sup>

PCP historically has been noted in children with ALL who are receiving corticosteroids and intensive chemotherapy.<sup>133</sup> It is now relatively uncommon in this age group because of the routine use of TMP-SMX prophylaxis. In adults with ALL, PCP generally occurs during consolidation or early maintenance therapy.<sup>134</sup> However, earlier presentations may occur with more intensive chemotherapy. Because of the association of PCP with the tapering of corticosteroids, many ALL treatment protocols institute intermittent TMP-SMX prophylaxis following induction chemotherapy.<sup>135</sup>

Of all of the solid organ tumors, brain cancer metastasis—both primary and secondary—is associated with the highest incidence of risk of PCP. The incidence ranges from 1.7 to 6%.<sup>136,137</sup> The predisposition to PCP stems from long-term use of corticosteroids to reduce cerebral edema in patients with brain tumors.<sup>130,136,137</sup> Two-thirds of cases of PCP become symptomatic during corticosteroid taper. A dose reduction in long-term corticosteroid therapy may unmask an ongoing pulmonary inflammation from PCP that initially developed while the patient was receiving immunosuppressive therapy.

Patients with brain tumors who are receiving corticosteroid treatment for more than 5 weeks are at risk of PCP, especially when the dose is

tapered. Among patients with brain tumors, those with primary central nervous system lymphoma are at the highest risk of PCP, with a mortality of nearly 50%.<sup>138,139</sup> The major risk factors are corticosteroid, high-dose methotrexate, and radiation therapy, all of which reduce CD4 cell counts.

HIV patients with PCP classically present with a gradual onset of fever, nonproductive cough, and dyspnea over a few weeks. However, PCP causes a somewhat different manifestation in HIV-negative immunocompromised patients, in whom symptoms develop more rapidly (few days) and appear to be more fulminant and severe than in AIDS patients.<sup>140</sup> Patients with cancer infected with PCP are hospitalized earlier and present with a more acute disease. The respiration rate is higher (39 breaths per minute vs 22 breaths per minute) and the arterial oxygen partial pressure value (52 mm Hg vs 69 mm Hg) is lower in cancer patients than in patients with HIV infection.<sup>130,140</sup> On physical examination, auscultation of the lungs is often normal, although it may sometimes reveal wheezing, rales, or rhonchi.

Laboratory findings that are helpful in diagnosing PCP include arterial blood gases and serum LDH. Arterial blood gases reflect the severity of pulmonary involvement and typically show hypoxia and an increase in the alveolar-arterial oxygen gradient.<sup>141</sup> LDH is elevated in most cases of PCP, as it is in other diseases causing lung parenchymal damage. Therefore, its increase is nonspecific, but a normal LDH will help rule out PCP with a high negative predictive value.<sup>142</sup>

Classic findings on a chest radiograph show diffuse interstitial infiltration, and, rarely, cystic or cavitory lesions and pneumothorax can be seen.<sup>141</sup> Because the chest radiograph may be normal, HRCT is indicated when the clinical suspicion of PCP is high. The usual finding on an HRCT scan is bilateral ground-glass alveolar infiltration with interstitial pneumonia.<sup>142</sup>

Final diagnosis of PCP can be made only by identification of the organism. Since *P. carinii* cannot be cultured, sputum samples or BAL fluid will have to be obtained for histochemical staining and subsequent microscopic examination. Appropriate staining techniques include the Gomori methenamine silver stain, modified Wright-Giemsa stain, and, more recently, immunofluorescent stain, which increases sensitivity and specificity.<sup>143</sup>

Since the 1970s, multiple clinical trials have clearly shown that TMP-SMX decreases the incidence and mortality of PCP. Currently, TMP-SMX remains the drug of choice for treatment and prevention and is recommended by the Infectious Diseases Society of America for all patients at risk of PCP. Standard treatment starts with intravenous administration at a dose of 15 to 20 mg/kg trimethoprim per day and can be switched to the oral form of the drug when

improvement occurs. The duration of treatment is 3 weeks, followed by prophylaxis for 6 months. On rare occasions, mutations in *P. carinii* associated with TMP-SMX failure have been reported, indicating that resistance may be emerging. However, the major limitation of TMP-SMX therapy is side effects. Allergic reactions, primarily rash and myelosuppression, are the most common toxicities that require drug discontinuation.

Alternatives to TMP-SMX include aerosolized pentamidine or dapsone for prophylaxis; intravenous pentamidine, trimetrexate, or combination clindamycin-primaquine for treatment; and the newer agent, atovaquone, which is useful for both treatment and prophylaxis.

In cancer patients, if TMP-SMX prophylaxis is not tolerated, the second drug of choice is atovaquone. One study found that PCP prophylaxis with atovaquone was better tolerated and associated with less toxicity than TMP-SMX following autologous HSCT. In other studies, prophylaxis with dapsone and inhaled pentamidine following HSCT was associated with higher rates of PCP when compared with TMP-SMX.

Adjunctive corticosteroid therapy has been shown to improve survival and decrease the occurrence of respiratory failure in severe cases of PCP both in patients with AIDS<sup>144</sup> and in non-HIV patients.<sup>145</sup> Corticosteroids should be added if the arterial oxygen tension is below 70 mm Hg while on room air.

### ***Mycobacterium tuberculosis***

Tuberculosis (TB) is a dramatic problem worldwide, with 2 billion people (one-third of the world's population) infected with *Mycobacterium tuberculosis*. In cancer patients, especially following HSCT, a high incidence of TB might be expected owing to the resultant cellular immunodeficiency from cancer therapy. However, in spite of the worldwide high prevalence, TB has not been described in cancer patients to the extent expected. Nonetheless, the incidence of TB in cancer patients after HSCT has been estimated to be 10 to 40 times higher than in the general population.<sup>146</sup> A similarly high estimated incidence of TB has been found in solid organ transplant patients, in whom TB has been much better studied than in HSCT patients, with more than 270 cases reported.<sup>146</sup> Countries with a high prevalence of TB would be most likely to see significant numbers of cancer patients with active disease. Most of the literature on TB in cancer patients is in the HSCT population.

In Taiwan, where pulmonary TB is endemic, 8 of 350 SCT recipients were found to have pulmonary TB over a 6-year period.<sup>147</sup> The relative risk of having pulmonary TB after HSCT was 13.1-fold higher than in the general population. There was a trend toward an increased risk of

having pulmonary TB in allogeneic HSCT patients compared with autologous HSCT patients. All eight patients with pulmonary TB received allogeneic HSCT, and most (seven of eight patients) developed the infection during treatment for GVHD. CT of the chest was normal in one patient, with the rest showing either interstitial (two patients) or alveolar infiltrates (five patients) at the onset of pulmonary TB. The four fatal cases had an obviously shorter duration between HSCT and the onset of infection.

Another study found four patients with *Mycobacterium tuberculosis* infection identified from 641 adult patients who received a HSCT over a 12-year period (prevalence 0.6%).<sup>148</sup> The pretransplantation diagnosis was acute myelogenous leukemia in two patients and chronic myelomonocytic leukemia in the other two. The sites of infection were the lung (two patients), spine (one patient), and central nervous system (one patient). The onset of infection ranged from 120 days to 20 months post-HSCT. Two patients had coexisting CMV infection. One patient had graft failure. The two patients who received anti-TB therapy recovered from the infection.

Of five HSCT series with a total of more than 5,000 patients, only 10 cases of *M. tuberculosis* infection were described, with an overall incidence of 0.19%.<sup>149</sup> The median age of the 10 patients who developed TB was 29 years (range 17–40 years). The median time for onset of symptoms was 150 days (range 23–550 days), with the patients mainly presenting with fever and cough, with infiltrates on a chest radiograph. A respiratory tract specimen, mostly sputum, yielded positive smears for acid-fast bacilli in three patients and positive *M. tuberculosis* culture in eight patients, whereas lung tissue histology was the first diagnostic test in two patients. Treatment with standard anti-TB drugs for a longer duration was highly effective, with no excessive side effects. The risk factors identified for development of TB included allogeneic HSCT, total-body irradiation, and chronic GVHD.<sup>150</sup>

The Infectious Diseases Working Party of the European Blood and Marrow Transplant Group conducted a survey to obtain information about the frequency, presentation, and treatment of mycobacterial infection (MBI) in HSCT recipients.<sup>150</sup> Among 29 centers, MBI was diagnosed in 0.79% of 1,513 allogeneic and 0.23% of 3,012 autologous HSCT recipients during 1994–1998 a median of 160 days after transplantation. The mean interval between first symptoms and diagnosis was 29 days and was still longer for patients with atypical MBI or recipients of corticosteroid therapy. The prevalence of MBI was highest among those who received matched unrelated or mismatched HSTC's from related donors. Of 31 patients, 20 had TB, 8 had atypical MBI, and 3 had diagnoses based on histologic findings only.

Five patients (16%) died, all of whom had received an allogeneic HSCT.

A national survey of TB after HSCT was undertaken to study the incidence, clinical presentation, and outcome.<sup>146</sup> Twenty confirmed cases were found among 8,013 patients (8 in 5,147 autologous and 12 in 2,866 allogeneic HSCT's). The estimated incidence in cases/10 patients/year was 101 (56.5–145) for the whole group, 71.1 (21.8–120) in autologous transplant patients, and 135.6 (58.9–212) in allogeneic transplant patients. Compared with the general population, TB was more frequent after allogeneic (relative risk 2.95) but not after autologous HSCT. TB after HSCT is a late infection (median 324 days post-transplantation), predominantly affects the lungs (80% of the cases), and appears to respond well to treatment but has a high mortality rate (25%) in allogeneic recipients. It can also complicate the post-transplantation management as anti-TB drugs frequently decrease the serum levels of cyclosporine, causing an aggravation of GVHD.<sup>146</sup> GVHD, corticosteroid treatment, and total-body irradiation appear to be associated with TB in allogeneic recipients.<sup>146</sup>

In summary, pulmonary TB is uncommon in cancer patients. Countries and areas with endemic TB will, by nature of frequent exposure, encounter more cancer patients with active disease. As in AIDS patients, those with cancer and profound immunosuppression will have a greater likelihood of developing active infection (the lifetime risk in AIDS patients is 50%) when exposed to TB. In addition, extrapulmonary disease would be expected to be more common in immunosuppressed cancer patients as in AIDS patients (more than 50% of cases). Treatment of TB is the same in the cancer patient as in the noncancer patient, but the potential for drug interactions will be more common. Other than allogeneic HSCT recipients, prognosis with effective therapy is the same in cancer and noncancer patients.

### **Nontuberculous Mycobacteria**

Nontuberculous mycobacteria (NTM) are ubiquitous in the environment and have been recovered from fresh and salt water (including hot water pipes), soil, animals, and milk and food products. Colonization of body surfaces and secretions can occur naturally and without causing disease. As the incidence of TB has declined in the United States and other developed countries, NTM are now the most common isolates detected from clinical specimens. Prior to the AIDS epidemic, most cases of NTM produced an indolent, cavitary pulmonary infection in nonimmunosuppressed patients, mostly male, with COPD or previous TB.<sup>151</sup>

In HIV-infected patients, NTM, mostly *Mycobacterium avium* complex (MAC), usually

causes disseminated infection. Pulmonary findings are not as common as fever of unknown origin, with diffuse lymphadenopathy in AIDS patients. Prophylaxis for NTM is a standard recommendation for HIV-infected patients with a CD4 lymphocyte count less than 100 cells/mL.

In cancer patients, NTM can cause catheter-related infections, bacteremia, skin and soft tissue infections, pneumonia, and disseminated infections. Patients with leukemia, lymphoma, or HSCT and those requiring prolonged corticosteroid therapy are at highest risk of NTM infection.

As with TB in cancer patients, NTM infections are more commonly reported in HSCT recipients, who tend to be more profoundly immunosuppressed and thus more likely to develop active disease. An increase in NTM infections in HSCT patients has been observed and may reflect increased numbers of transplants, intensification of immunosuppressive regimens, prolonged survival of transplant recipients, and/or improved diagnostic techniques.<sup>152</sup> The difficulty of diagnosis and the impact associated with infections owing to NTM in HSCT necessitates that, to ensure prompt diagnosis and early initiation of therapy, a high level of suspicion for NTM disease should be maintained.<sup>152</sup> The most common manifestations of NTM infection in HSCT recipients include cutaneous and pleuropulmonary disease and catheter-related infections.<sup>152</sup>

*Mycobacterium kansasii* is the most virulent of the NTM and usually presents as lung disease that is nearly identical to TB. The major predisposing factor to lung infection is COPD, which is present in over two-thirds of cases. Lung cancer, lymphocytic leukemia, and lymphoma are the most common associated malignancies. The clinical presentation is similar to pulmonary TB, with fever, weight loss, cough, and hemoptysis.<sup>151</sup> Cavitation occurs in 85 to 95% of cases, being bilateral in 20%. In some cases, the cavities tend to have thinner walls and less surrounding parenchymal infiltration than in TB.<sup>153</sup> Treatment is similar to that for *M. tuberculosis*, with rifampin, isoniazid, pyrazinamide, and ethambutol (except without pyrazinamide because of inherent resistance).<sup>151</sup> The duration of treatment, 18 months, is the same for noncancer patients. Radiologic improvement, symptom resolution, and sputum conversion to negative are expected during therapy.

### ***Mycobacterium avium* complex**

Pulmonary symptoms owing to MAC may be present for months or years before the diagnosis is made. The median interval from onset of symptoms to the correct diagnosis was reported to range from 25 weeks to 10 months.<sup>154</sup> Early cases may be asymptomatic and discovered only by routine screening chest radiographs. Most

patients experience chronic cough, usually productive of purulent sputum but usually without hemoptysis. Constitutional symptoms, including fever, night sweats, weight loss, malaise, lethargy, and fatigue, are not common unless patients have extensive lung disease. Symptoms usually improve with successful therapy.

Patients with underlying lung disease and MAC infection often have cavities apparent on the chest radiograph.<sup>154</sup> It has been suggested that MAC-related cavities tend to be thinner, with less surrounding parenchymal opacification and more contiguous but less distal bronchogenic spread of opacification than in TB.<sup>154</sup> In middle-aged and older women without underlying lung disease, MAC primarily involves the lingula and right middle lobe associated with bronchiectasis and subcentimeter peripheral nodules.<sup>154</sup> This entity is known as Lady Windermere syndrome, after the play with the same name.<sup>155</sup> Often reticular changes, a single nodule, or multiple small nodules are present. Pleural effusions are not common in MAC lung infections.

HRCT is more sensitive than chest radiography for detecting the abnormalities associated with MAC lung disease.<sup>156</sup> The presence of bronchiectasis and multiple small nodules is predictive of MAC lung disease, especially when they are adjacent to each other.<sup>156</sup> In a study, one-quarter of patients with typical changes of fibronodular bronchiectasis produced sputum that grew MAC on culture.<sup>156</sup> Other reported abnormalities include atelectasis, consolidation, “tree in bud,” and ground-glass opacities.<sup>156</sup> Serial CT in MAC lung disease has shown that bronchiectasis tends to become more severe and nodules spread to other segments over time.<sup>156</sup> The development of consolidation and ground-glass opacities is preceded by the appearance of nodules. Some small nodules will disappear with successful treatment.<sup>156</sup>

The reported rates of treatment success have ranged from 20 to 90% in individual studies, but if patients who were unable or unwilling to complete treatment, those requiring surgery, those who died, and those with relapse during an adequate follow-up period are included, the cure rate is approximately 40%.<sup>156</sup> Serious toxicity limited the number of medications, dose, and duration of therapy in these regimens.<sup>156</sup> Some have suggested that adjusting therapy to sensitivity testing results improves outcome in MAC lung disease, but others have not been able to show a benefit.<sup>156</sup>

The newer macrolides, clarithromycin and azithromycin, are concentrated in alveolar macrophages and have good activity against MAC, an intracellular organism.<sup>156</sup> Clarithromycin and azithromycin, administered alone or in combination with other medications, are effective for pneumonia owing to MAC in cancer patients.

Emergence of resistance to the macrolide may be prevented by the addition of ethambutol, rifabutin, or streptomycin. Newer fluoroquinolones (such as moxifloxacin and levofloxacin) and linezolid may also be useful for treatment of MAC and other mycobacteria, such as *Mycobacterium tuberculosis* and rapidly growing mycobacteria (RGM). The recognition that these patients have a failure of the interferon- $\gamma$  pathways has led to some preliminary studies of cytokine therapy in MAC lung disease, and preliminary results suggest that interferon- $\gamma$  may have a role in the treatment of MAC.<sup>156</sup>

### **Rapidly Growing Mycobacteria**

RGM will grow on solid media in less than 7 days, unlike other NTM and TB, which grow slowly. *M. fortuitum*, *M. chelonae*, and *M. abscessus* are the most common RGM-causing infections in cancer patients. Other risk factors include underlying lung disease (such as emphysema), achalasia and rheumatologic conditions, HSCT, and cancers that require immunosuppressive therapy. *M. chelonae* primarily causes cutaneous disease, whereas *M. fortuitum* and *M. abscessus* primarily cause lung infection. One report reviewed the epidemiology and clinical manifestations of 154 patients with RGM pulmonary disease and found that 82% was due to *M. abscessus*.<sup>157</sup>

Most patients with pneumonia owing to RGM are white, female nonsmokers who are at least 60 years of age.<sup>158</sup> Forty percent have an underlying medical condition, such as previously treated pulmonary MAC, cystic fibrosis, lipoid pneumonia, achalasia, or lung transplantation.<sup>159</sup> The symptoms, signs, and radiographic findings are indistinguishable from those of MAC pneumonia. Treatment of RGM is very similar to that of MAC infection and is reviewed above and in Daley and Griffith.<sup>158</sup> If limited disease is found, surgical resection of the involved lung may be curative. Patients with pulmonary or disseminated NTM infections can be safely transplanted by receiving effective antimicrobial therapy before, during, and after HSCT.<sup>152</sup>

### ***Mycobacterium bovis***

Bacille Calmette-Guérin (BCG) is a live attenuated strain of *Mycobacterium bovis* and when administered intravesicularly is an effective treatment for patients with superficial transitional cell carcinoma of the bladder. By inducing granulomatous inflammation, the host immune system destroys the cancer in the mucosa and submucosa of the bladder.

Although infection owing to dissemination of *M. bovis* outside the bladder is rare, it can be quite debilitating. One report of adverse effects of BCG therapy reported in a study of more than 1,200 patients included a 2.9% incidence of high

fever ( $>39^{\circ}\text{C}$ ), 1.0% major hematuria, 0.9% granulomatous prostatitis, 0.7% granulomatous pneumonitis or hepatitis, 0.5% arthritis or arthralgia, 0.4% epididymo-orchitis, 0.4% life-threatening BCG sepsis, 0.3% urethral obstruction, 0.2% bladder contracture, 0.1% renal abscess, and 0.1% cytopenia.<sup>159</sup>

The mechanism of complications in patients after disseminated BCG infections is that the hematogenous spread of mycobacteria to sites such as the liver, bone, or lung induces direct organ damage, and a hypersensitivity response to *M. bovis* occurs at the same time. For this reason, the recommended treatment for patients with severe *M. bovis* infections in the acute setting is a combination of antimycobacterial therapy and corticosteroids.<sup>160</sup> Symptoms of BCG dissemination with pneumonitis include shortness of breath, nonproductive cough, fever, sweats, weight loss, and malaise.<sup>160</sup> Radiographic findings are best seen with HRCT scans of the chest with a miliary pattern of 2 to 5 mm nodules seen in the lower lobes of the lung.<sup>160</sup> Diagnosis requires open lung biopsy since BAL or biopsy is usually unsuccessful. However, the readily apparent clinical diagnosis and usual response to appropriate therapy preclude the need for a surgical diagnosis. PCR for *M. bovis* of a blood sample may be positive during active dissemination of BCG from the bladder. Treatment of disseminated BCG or pneumonia includes isoniazid and rifampin for 3 to 6 months. Corticosteroids are considered when severe symptoms or a poor response to antimicrobial therapy occurs.

# Noninfectious Pulmonary Problems in the Patient with Cancer

Shirin Shafazand, MD

Jeffrey Rubins, MD

Gene L. Colice, MD

In 2006, about 1,900,000 people in the United States will be diagnosed with cancer.<sup>1</sup> In the United States, the lifetime probability of developing cancer at any site is now one in two (about 50%) for a man and one in three (about 33%) for a woman. Although overall cancer survival rates have improved over the last three decades, death rates in cancer are still substantial. In 2004, slightly more than 560,000 deaths in the United States were caused by cancer. These statistics vividly demonstrate the importance of cancer as a public health concern but actually represent just a portion of the problem. Cancer also causes substantial morbidity. Pulmonary complications are especially common, including those relating to pulmonary spread of the cancer, initiated by systemic procoagulant effects of cancer, and owing to toxicity from the chemotherapy and radiotherapy regimens used to treat the primary cancer. This chapter reviews these major noninfectious pulmonary complications of cancer.

## Pleural Effusions in Cancer Patients

In evaluating the cancer patient with a pleural effusion, clinicians should be concerned about pleural metastases. An estimated 50% of all cancer patients develop a malignant pleural effusion at some point during the course of their illness, and approximately 15% of cancer patients die with malignant effusions.<sup>2</sup> Malignant effusions are most common in lung and breast cancer (50–75% of malignant effusions), lymphoma (both Hodgkin's and non-Hodgkin's), mesothelioma, and colon and ovarian cancer.<sup>2,3</sup> Malignant effusions indicate a very poor prognosis, with 30-day mortality rates of 30 to 50% and a median survival of 4 months.<sup>2</sup> Because of the poor prognosis in many cancer patients with pleural effusions, clinicians should make decisions regarding the aggressiveness of the diagnostic and therapeutic procedures based on maximizing the patient's quality of life.

Nonmalignant pleural effusions must also be considered in the cancer patient. Depressed immune defenses predispose these patients to pneumonia, which may be complicated by parapneumonic effusions. Increased levels of tissue factor or activation of the coagulation cascade predispose cancer patients to pulmonary embolism (PE), which can produce pleural effusion. Bronchial obstruction by cancer can produce postobstructive pneumonia or atelectasis, which, in turn, can cause effusions. Mediastinal nodes can obstruct the thoracic duct, producing an exudative effusion or a chylothorax.<sup>2</sup> Pleural effusions may complicate cancer treatments. Chest radiation for lung cancer, mesothelioma, lymphoma, or breast cancer can cause a direct radiation pleuritis, resulting in pleural effusion.<sup>4</sup> Effusions usually appear within 6 months of radiation therapy, although they occasionally pose a diagnostic puzzle when occurring years later. Mediastinal radiation can cause mediastinal fibrosis, which can lead to effusions by obstructing pleural lymphatic drainage. Chemotherapy can produce pleuritis and pleural effusions, most commonly with the use of methotrexate, procarbazine, cyclophosphamide, or bleomycin.<sup>2</sup>

## Diagnosis

The etiology of a pleural effusion in cancer patients can often be suspected based on the patient's clinical presentation and history of previous treatments. A definitive diagnosis, however, usually requires diagnostic thoracentesis. Thoracentesis should be considered in any cancer patient with an unexplained pleural effusion. Relative contraindications to thoracentesis include a bleeding diathesis, anticoagulation, mechanical ventilation, and cellulitis at the puncture site. If pleural fluid is not obtained readily or in patients with smaller effusions, ultrasonography is useful in identifying an appropriate puncture site.

The initial diagnostic studies to order on pleural fluid in cancer patients can be

remembered as the “5 C's.” The first “C” is a reminder to “see” the gross appearance of the fluid and order additional studies accordingly. A bloody pleural fluid suggests malignancy, PE, or parapneumonic causes, although bloody fluid can also be seen in asbestos effusions and in post-pericardiotomy syndrome. A purulent effusion is diagnostic of an empyema requiring drainage. A milky effusion indicates either a chylous or pseudo-chylous effusion, which can be distinguished by testing pleural cholesterol and triglyceride levels.

The second “C” is for chemistries to distinguish transudates from exudates (Table 1). Although transudative effusions may be

**Table 1 Causes of Pleural Effusions in Cancer Patients**

Transudates
Congestive heart failure

Pulmonary embolism (<35%)
Urinothorax
Exudates
Metastatic disease
Parapneumonic
Pulmonary embolism
Radiation
Chylothorax
Pancreatitis
Esophageal perforation
Tuberculosis pleuritis obstruction
Post-cardiac injury syndrome
Drug induced
Viral pleuritis

interpreted to indicate that no further evaluation is needed, pleural effusions from PE and malignancy rarely present as transudates. In contrast, exudative effusions indicate inflammatory or malignant diseases that require further diagnostic studies. The criteria identified by Light and colleagues in 1972 have high sensitivity for distinguishing transudates from exudates but require simultaneous measurement of pleural and serum protein and lactate dehydrogenase (LDH).<sup>5</sup> Newer criteria have a sensitivity and a specificity similar to those of Light and colleagues and require only pleural fluid measurements of protein, LDH, and cholesterol.<sup>6</sup> A low pleural fluid glucose and pH in a patient with a parapneumonic effusion indicate the need for drainage. A low pleural fluid glucose and pH suggest a very poor prognosis in patients with malignant effusions.<sup>4,7</sup>

The third “C,” cell count differential, may indicate possible etiologies for exudative effusions. Pleural fluid with greater than 50% neutrophils indicates an acute process, such as parapneumonic effusions and those owing to PE or pancreatitis, but tends to exclude malignancy and tuberculosis. A differential with greater than 50% lymphocytes suggests malignancy or tuberculosis.<sup>8</sup> Pleural fluid eosinophilia, defined as greater than 10% eosinophils, is often caused by blood or air in the pleural space but may be seen with malignant effusions or those caused by drug reactions (such as dantrolene, bromocriptine, or nitrofurantoin). Increased numbers of mesothelial cells tend to exclude the diagnosis of tuberculosis,<sup>8</sup> whereas markedly increased numbers of mesothelial cells in bloody or eosinophilic effusions in the absence of trauma suggest PE.<sup>9</sup>

The fourth “C,” pleural fluid cultures for bacterial, fungal, and tuberculous pathogens, should be performed routinely in cancer patients with exudative effusions. When tuberculosis is suspected, pleural fluid adenosine deaminase levels >40 U/L strongly suggest tuberculous pleuritis.<sup>8</sup> The fifth “C,” cytology, should also be obtained routinely because of the high prevalence of malignant effusions in these patients. The yield of cytology varies from 62 to 90%, depending on the extent of disease and the propensity of the pleural malignancy to shed tumor cells into the pleural fluid.<sup>2</sup> Mesothelioma, squamous cell carcinoma, lymphoma, and sarcoma involving the pleura may be missed in more than 50% of cases by pleural fluid cytology.<sup>8</sup>

In an appreciable proportion of patients, the etiology of an exudative effusion will remain undiagnosed after a single thoracentesis. Repeat thoracentesis will increase the diagnostic yield.<sup>10</sup> Pleural fluid LDH on serial thoracenteses may guide the aggressiveness of the evaluation. A rising LDH suggests an active inflammatory process that should be pursued further, whereas a decreasing LDH supports a less aggressive

approach.<sup>8</sup> If more aggressive diagnostic steps are warranted, closed-needle pleural biopsy can increase the diagnostic yield for malignancy by 7 to 12%.<sup>2</sup> However, video-assisted thoracoscopy (VATS) has emerged as the procedure of choice for undiagnosed pleural effusions because it allows visualization of the pleural space and directed biopsies.<sup>10</sup> VATS has diagnostic yields up to 95% compared with 62% for cytology and 44% for closed-needle biopsy.<sup>11</sup> After VATS, fewer than 10% of exudative effusions remain undiagnosed compared with >20% after cytology and needle biopsy.<sup>2</sup> Some patients may not tolerate the general anesthesia and single-lung ventilation required for VATS. In these patients, medical thoracoscopy, performed under conscious sedation and local anesthesia in an endoscopy suite using either rigid or semiflexible instruments, should be considered.

### Treatment

Management of pleural effusions in the cancer patient is usually directed at relieving dyspnea, which is the most common presenting symptom. Accumulation of large amounts of pleural fluid may cause dyspnea by decreasing chest wall compliance, shifting the mediastinum to the contralateral hemithorax, decreasing ventilation of the ipsilateral lung, and stimulating reflexes within the lungs and chest wall.<sup>12</sup> However, dyspnea may be unrelated to the pleural effusion, caused instead by underlying heart or lung disease, PE, pericardial effusion, or tumor infiltration of the lung parenchyma. For cancer patients with dyspnea and pleural effusions, the prime considerations are (1) whether removal of the pleural fluid relieves dyspnea, (2) the patient's general health and functional status, and (3) the patient's expected survival.<sup>13</sup> The goals in such patients should be to provide relief of dyspnea, minimize discomfort, and limit hospitalization time.

For patients with effusions owing to small cell lung cancer and for some with effusions from lymphoma and germ cell tumors, chemotherapy may effectively reduce effusions and relieve symptoms.<sup>13</sup> Most cancer patients with symptomatic pleural effusions, however, require therapeutic thoracentesis for palliation. Drainage of pleural fluid by therapeutic thoracentesis or placement of a pleural drainage catheter relieves dyspnea by increasing lung ventilation. Typically, total lung capacity increases by approximately one-third of the volume of fluid removed, and forced vital capacity increases by about one-sixth of the volume removed.<sup>14</sup> However, many cancer patients with pleural effusions do not benefit from removal of pleural fluid either because the underlying lung cannot reexpand or because the dyspnea is caused by other underlying conditions. When considering therapeutic thoracentesis, mediastinal position may predict

whether a patient is likely to benefit from this procedure. Mediastinal shift away from the pleural effusion indicates a positive pleural pressure and compression of the underlying lung that likely will be relieved by thoracentesis. In contrast, the absence of mediastinal shift or shift toward the pleural effusion implies lung entrapment by obstruction of the mainstem bronchus or extensive pleural involvement that will prevent re-inflation of the lung when the pleural fluid is removed.

At initial therapeutic thoracentesis, removal of even 300 cc of fluid should be sufficient to determine whether relief of dyspnea will occur. Removal of more than 1,500 cc of fluid is not advised because of the risk of causing reexpansion pulmonary edema. In patients with lung entrapment, far less fluid can be safely removed before unduly stretching the underlying lung. If large-volume thoracentesis is planned, using pleural manometry to ensure that pleural pressure does not fall below  $-20$  cm H<sub>2</sub>O is the safest approach and may allow removal of much larger volumes than otherwise recommended.<sup>15</sup> Generally, reexpansion pulmonary edema can be avoided by removing <1,500 cc of pleural fluid and stopping the thoracentesis if the patient begins to feel chest pain or shortness of breath.

After therapeutic thoracentesis, relief of dyspnea should be evaluated by objective measures, such as the ability to walk a defined distance without shortness of breath, and documented for future reference. A chest radiograph should be obtained immediately after thoracentesis to determine the extent of lung reexpansion. Hydro-pneumothorax on the postprocedure radiograph, especially when the apparent volume of airspace within the lung appears to be unchanged, signals lung entrapment. A thickened pleura on chest computed tomography (CT) supports this diagnosis and indicates that further thoracentesis will probably be of little value. If the lung has reexpanded, but the patient reports no relief of dyspnea, the clinician should consider contrast-enhanced chest CT to evaluate for lymphangitic carcinomatosis, thromboembolism, tumor embolism,<sup>2</sup> and other nonmalignant cardiopulmonary diseases that can produce dyspnea.

Patients whose symptoms improve after thoracentesis should be followed for recurrence of symptomatic effusions. Those remaining asymptomatic should simply be observed.<sup>16</sup> For cancer patients with poor performance status (Karnofsky score <70) and limited life expectancy (<3 months), recurring symptomatic pleural effusions can be managed with repeated outpatient thoracentesis, which avoids hospitalization for more invasive and potentially morbid procedures.<sup>13,16</sup> If effusions recur quickly and patients have sufficient support at home, insertion of

an indwelling tunneled catheter is a reasonable option to palliate dyspnea.<sup>16,17</sup> The only tunneled catheter approved by the US Food and Drug Administration (the Pleurx catheter, marketed by Denver Biomedical, Golden CO) is a 15.5F silicone catheter. A proximal polyester cuff causes subcutaneous fibrosis, which prevents dislodgement and lessens the risk of infection. The catheter has a valved hub that keeps the system closed, except when a specific dilator attached to a 600 mL vacuum bottle system is inserted. The catheter can be inserted as an outpatient procedure, and the effusion can be drained at home with the disposable vacuum bottles as frequently as necessary to relieve symptoms. The Pleurx catheter has been shown to be equivalent to or better than pleurodesis in relief of dyspnea and improvement in quality of life and induces spontaneous pleurodesis in up to 20 to 45% of patients over a median 29 days after placement.<sup>17–19</sup> However, approximately 20% of patients have complications related to the catheter, most commonly chest pain in the first week after catheter placement (10–14%). Catheter obstruction may necessitate replacement (2–8%). More serious complications, such as local cellulitis (6%), tumor seeding of the catheter track (1–3%), and pleural infection (1–5%), also occur.<sup>17–19</sup>

Cancer patients with better performance status (Karnofsky score of 70 or higher) whose lungs reexpand after the initial thoracentesis should be considered for pleurodesis if they have recurrence of a symptomatic effusion.<sup>2,13,20</sup> After complete drainage of the pleural effusion, sclerosing agents are instilled to produce acute pleural injury and inflammation, causing bridging pleural fibrosis that effectively “glues” the lungs to the chest wall and obliterates the potential pleural space. Systemic corticosteroids should be avoided or reduced to the lowest possible doses prior to pleurodesis to avoid suppressing sclerosant-induced inflammation and thereby causing pleurodesis failures.<sup>21</sup> Pleurodesis through a chest tube using a talc slurry appears to be as effective as that performed using talc powder insufflated (poudrage) during VATS.<sup>22–24</sup> For most patients, pleural effusions can be drained as effectively and with less pain using small-bore (10–14F) intercostal pleural catheters as opposed to large-bore (24–32F) chest tubes.<sup>16,25–27</sup> The main disadvantage to pleurodesis by a pleural catheter or chest tube is that a longer hospitalization may be required to fully drain the effusion prior to instillation of the sclerosing agent, but it avoids general anesthesia and intubation with VATS.

Talc is the most effective agent for pleurodesis and the least expensive. It has been recommended as the agent of choice by the European, American, and British thoracic societies.<sup>2,16</sup> Talc, which prevents recurrent effusions in 90 to 95% of patients, was found to be more effective than bleomycin,

tetracycline, mustine, or tube drainage alone in a systematic review of 10 studies including 308 patients.<sup>23</sup> The talc preparations used for pleurodesis are asbestos-free powders that require sterilization by dry heat, ethylene oxide, or gamma irradiation prior to use in talc slurry or are available in aerosol-propellant bottles for use in poudrage. Although more effective than other sclerosants, talc pleurodesis has a higher incidence of complications, including fever, empyema, and acute lung injury. Fever occurs in up to 65% of patients within 4 to 12 hours of talc pleurodesis and may last up to 72 hours before resolving spontaneously.<sup>2</sup> Empyema has been reported in up to 11% of patients, presumably related to difficulties in preparation of an adequately sterilized product for instillation. The most worrisome complication is acute lung injury and adult respiratory distress syndrome (ARDS), which has been estimated to occur in up to 9% of patients.<sup>2</sup> Because talc particles are known to be absorbed into lymphatic and venous drainage during sclerosis, the incidence of ARDS may be related to the particle size of talc and the dose used. Most cases of talc-induced ARDS have been reported in the United States, where 11 to 20  $\mu$  of talc is used, rather than in Europe, where “French talc,” with a 34  $\mu$  particle size, is used.<sup>28</sup> In addition, doses of talc up to 14 g were used in earlier studies when ARDS was first recognized, in contrast to the 3 to 5 g doses now recommended.

Pleurodesis is unsuccessful in 10 to 40% of patients, depending on the approach, the sclerosant, and, most importantly, whether the underlying lung reinflates fully as the effusion is drained. Treatment options for most cancer patients who fail pleurodesis include a repeat attempt at pleurodesis, serial thoracenteses to remove fluid as necessary, or placement of a Pleurx catheter and drainage at home.<sup>16</sup> The Pleurx catheter was shown to effectively palliate dyspnea in 10 of 11 patients with lung entrapment, even when pleurodesis was not achieved.<sup>29</sup> Some centers place a pleuroperitoneal shunt in such patients to drain the effusion into the abdominal space, but these devices have the same complications as the Pleurx catheter and a higher rate of catheter occlusion.

Pleurectomy is an invasive surgical option that effectively prevents recurrence of effusions by complete resection of the pleural space. However, the procedure is associated with complications of empyema, hemorrhage, and cardiorespiratory failure and carries an operative mortality of 10 to 13%.<sup>16</sup> Thus, it should rarely be used in cancer patients who have an already limited prognosis.

In summary, pleural effusions in cancer patients may herald metastatic malignancy, infection, or thromboembolism or may be related to underlying diseases. When symptomatic,

palliative therapies should be chosen based on maximizing the patient’s quality of life. Repeated serial thoracenteses, pleurodesis, or indwelling tunneled catheters are palliative options to consider, depending on prognosis and patient choices.

## Approach to Pneumothorax in Cancer Patients

Pneumothorax is classified as iatrogenic, traumatic, or spontaneous in origin (Table 2).<sup>30</sup> Cancer patients are at risk of iatrogenic pneumothoraces because they often undergo such diagnostic procedures as transthoracic needle biopsy of the lung and mediastinal lesions, percutaneous biopsy of the liver and adrenal lesions, and transbronchial biopsy or needle aspirates. Therapeutic procedures performed in cancer patients, such as insertion of central venous catheters for administration of chemotherapy or antibiotics, performing celiac plexus block to relieve abdominal pain from cancer, percutaneous insertion of needles into the chest for brachytherapy, radiofrequency ablation or direct immunotherapy, and laser bronchoscopy also can cause iatrogenic pneumothoraces. Pneumothorax can be a late complication of chemotherapy or radiation therapy.

Patients with bronchogenic cancer or cancer metastatic to the lungs rarely develop spontaneous pneumothorax. Rapid dissolution of a tumor mass during chemotherapy of small cell carcinoma<sup>31</sup> and a “check-valve” bronchial obstruction by bronchoalveolar cell carcinoma<sup>32</sup>

**Table 2** Cancer-Related Causes of Pneumothorax

Iatrogenic

Spontaneous
Associated with primary lung cancer
Associated with cancer metastatic to lungs

BCNU = carmustine; CT = computed tomography.

have been reported to produce large spontaneous pneumothoraces. Bronchogenic carcinoma may cavitate or rupture into the pleural space<sup>33,34</sup>; similar mechanisms may explain spontaneous pneumothoraces seen with osteogenic sarcoma metastatic to the lung.<sup>35,36</sup>

Almost all cancer patients with pneumothorax have acute pleuritic chest pain or shortness of breath. Pneumothorax occurring immediately after a procedure is rarely a diagnostic dilemma. However, delayed iatrogenic pneumothorax or spontaneous pneumothorax may be more difficult to detect as chest pain may be minimal and symptoms may resolve within 24 hours, even without resolution of the pneumothorax. A clinically significant pneumothorax is usually readily detected on a standard chest radiograph; chest CT is usually not necessary.

The management of iatrogenic pneumothorax occurring immediately after a diagnostic or therapeutic procedure is comparable to that recommended for treatment of primary spontaneous pneumothorax.<sup>37</sup> For clinically stable patients with small pneumothoraces (<3 cm from the apex to the cupola on a chest radiograph), observation with monitoring of clinical stability and a repeat chest radiograph in 4 to 6 hours may be sufficient in up to 60% of patients. Patients with a stable pneumothorax on a repeat radiograph can be discharged and followed with repeat chest radiographs every 1 to 2 days until the pneumothorax has resolved. Patients who cannot readily access emergency services or are considered unreliable should be admitted for observation. Supplemental oxygen can accelerate reabsorption of pleural air.<sup>38</sup>

Patients with significant symptoms, large pneumothoraces, or enlarging pneumothoraces on repeat radiographs should be treated by insertion of a small-bore (7–14F) pleural catheter. Simple aspiration of the pneumothorax through the catheter is successful in the majority of patients who are younger than 50 years of age and have less than 2.5 L of air aspirated.<sup>30</sup> If the lung remains reexpanded for 6 hours after aspiration, patients with reliable access to emergency services can be discharged and followed with repeat chest radiographs in 2 to 3 days.<sup>37</sup>

Patients who cannot be managed with simple aspiration should have the pleural catheter attached to a one-way Heimlich valve or a water-seal. The Heimlich valve allows patients to ambulate in the hospital more easily and may even allow carefully selected patients whose lungs have reexpanded to be treated as outpatients. However, Heimlich valves can become occluded by coexisting inflammatory or bloody pleural fluid and do not allow easy determination of the presence of a persistent air leak. In contrast, a water-seal permits prompt detection of a persistent air leak, indicating a bronchopleural

fistula, and allows application of suction to evacuate the pneumothorax. Pleural catheters should be attached to the water-seal if patients fail the Heimlich valve, are expected to have persistent bronchopleural fistula, or have underlying cardiopulmonary disease that decreases their ability to tolerate a recurrent pneumothorax.

A bronchopleural fistula is uncommon with iatrogenic pneumothorax but may occur in those patients who have underlying lung disease. If the bronchopleural fistula persists beyond 4 days, patients should be considered for pleurodesis by thoracoscopy if possible.<sup>37</sup> If surgery is contraindicated or patients refuse the procedure, pleurodesis via the chest tube is an alternative approach.

In contrast to the management of patients with iatrogenic pneumothorax, cancer patients with a spontaneous pneumothorax generally should be hospitalized. Those who are clinically stable and have small pneumothoraces (<3 cm from the apex to the cupola on a chest radiograph) can be observed with serial radiographs and, if the pneumothorax worsens, can be managed by placement of a small-bore pleural catheter as described above. In contrast, unstable patients or those with large pneumothoraces should have 24F to 28F chest tubes inserted and placed to water-seal. Most cancer patients with spontaneous pneumothorax should be considered for pleurodesis to prevent recurrence of pneumothorax, depending on their performance status and prognosis. Pleurodesis by medical or surgical thoracoscopy is the preferred management strategy discussed in consensus guidelines, but instillation of sclerosing agents via a chest tube may be more appropriate for cancer patients with a poorer performance or prognosis.<sup>37</sup>

In summary, cancer patients are at risk of iatrogenic pneumothorax related to diagnostic or therapeutic procedures or spontaneous pneumothorax related to bronchogenic or metastatic lung cancer. Management by observation or evacuation of the pneumothorax is determined by the patient's clinical stability and the size of the pneumothorax. Patients with persistent bronchopleural fistula and those with spontaneous pneumothorax should be considered for pleurodesis to prevent recurrent pneumothoraces.

### Cancer and Venous Thromboembolism

Since Armand Trousseau's initial report of migratory thrombophlebitis observed in patients with cancer in 1865,<sup>39</sup> numerous studies have shown an association between cancer and venous thromboembolism (VTE). The incidence of VTE in cancer patients is not clearly known and varies from 4 to 31% depending on the tumor histology, the methods used to diagnose VTE, and patient

characteristics.<sup>40</sup> Although a higher risk of VTE has traditionally been associated with pancreatic adenocarcinoma, recent information suggests that in men, the highest incidence of VTE is observed in patients with lung, prostate, and colorectal cancer and in women with breast, lung, and ovarian cancer.<sup>41</sup>

The strong association between cancer and VTE is further demonstrated by the often observed increased incidence of cancer during the first year after a thromboembolic event (2–4% absolute risk),<sup>42</sup> with the risk being highest among those with idiopathic VTE (on average five times higher than those with secondary causes for thrombosis).<sup>43–45</sup> Two large population-based Scandinavian studies confirmed the increased incidence of cancer during the first year postdiagnosis of VTE and showed a 10 to 30% increased long-term risk (up to 10 years of follow-up) of cancer compared with the general population.<sup>46,47</sup> Despite the strong association demonstrated in these studies, very little information exists on the impact of aggressive screening for cancer following the initial VTE and patient survival. Furthermore, the costs and morbidity associated with screening, coupled with a lack of sufficiently sensitive and specific diagnostic tests for many cancers associated with VTE, make recommendations for extensive screening for malignancy in patients presenting with idiopathic VTE controversial. However, it is reasonable to consider the possibility of occult malignancy in patients with primary VTE and to provide a thorough clinical evaluation, including a history and physical examination, routine laboratory tests, and chest radiography, for such patients. Additional testing should be offered in accordance with findings from the initial evaluation.<sup>48</sup>

### Pathogenesis and Risk Factors

The pathogenesis of VTE in cancer is complex, involving all elements of Virchow's triad (Table 3). Vessel wall injury may occur as a result of direct invasion by malignant cells or release of vascular permeability factors by tumor cells. Additionally, extrinsic factors, including surgical procedures and insertion of indwelling venous catheters, contribute to vessel wall injury. Disability from advanced disease and immobilization associated with surgical interventions increase the risk of venous stasis, whereas obstruction of blood flow by an intrinsic or extrinsic tumor mass further compounds the problem. Finally, cancer is a hypercoagulable state. Tumor cells express cell markers and can release soluble factors that have procoagulant activity; the two best described are tissue factor (TF) and cancer procoagulant (CP). TF activates factor VII, forming a complex that activates factors IX and X and increases thrombin formation. The overall effect of TF is production of fibrin and platelet

**Table 3 Pathogenesis of Venous Thromboembolism in Malignancy**

Vessel wall injury
Invasion by malignant cells
Release of vascular permeability factors by malignant cells
Indwelling central venous catheter
Surgical manipulation
Chemotherapy
Venous stasis
Obstruction of blood flow: intrinsic or extrinsic compression by tumor mass
Prolonged immobilization secondary to surgical intervention
Thrombocytosis
Hypercoagulability
Release of procoagulant factors, including tissue factor and cancer procoagulant
Release of inflammatory mediators: TNF and IL-1
Up-regulation of tissue factor and platelet-activating factor, leukocyte and cellular adhesion molecules
Down-regulation of thrombomodulin, endothelial cell protein C receptor
Necrosis of tumor
Reduced levels of antithrombin III, proteins C and S

IL = interleukin; TNF = tumor necrosis factor.

activation.<sup>49,50</sup> CP is a cysteine protease that directly activates factor X in the absence of factor VII and can induce platelet activation.<sup>49,50</sup> Inflammatory cytokines such as tumor necrosis factor (TNF) and interleukin-1 further enhance the procoagulant activity of tumor cells. Unfortunately, many of the cytotoxic and hormonal therapies offered to cancer patients may also increase the risk of thromboembolism by augmenting endothelial cell reactivity and platelet adhesion, directly damaging vessel walls, or decreasing levels of natural coagulation inhibitors (eg, protein C or S).<sup>51</sup> The increased risk of VTE in patients with cancer, combined with the higher probability of death,<sup>52</sup> necessitates a heightened awareness on the part of clinicians and an aggressive approach to the prophylaxis, diagnosis, and treatment of thromboembolic events.

### Prophylaxis

VTE prophylaxis is routinely recommended after major surgery owing to the increased risk of postoperative thrombosis.<sup>53</sup> Compared with patients undergoing surgery for benign disease, patients with cancer are estimated to have twice the risk of postoperative deep venous thrombosis (DVT) and more than three times the risk of fatal PE.<sup>54</sup> Internists taking care of postoperative cancer patients play an important role in ensuring that adequate prophylaxis is provided.

Prophylactic options include mechanical measures, for example, compression stockings, low-dose unfractionated heparin (UFH), and low molecular weight heparins (LMWHs). Only a few large trials have compared various anticoagulation regimens for surgical prophylaxis, and most were not designed specifically to evaluate cancer patients. In a meta-analysis, Mismetti and colleagues concluded that once-daily LMWH appears to be as safe and efficacious as multidose UFH in patients with and without malignancy.<sup>55</sup> The ENOXACAN study was the first randomized trial comparing the prophylactic use of enoxaparin, 40 mg once daily with UFH, 5,000 units three times a day, in 631 patients undergoing elective curative abdominal or pelvic surgery for cancer.<sup>56</sup> The study showed no statistically significant difference in efficacy and safety between enoxaparin and UFH in the prevention of venographically detected DVT and symptomatic VTE (14.7 vs 18.2%, respectively;  $p > .05$ ).<sup>57</sup> The ENOXACAN II investigators studied the extended use of enoxaparin prophylaxis versus placebo beyond initial hospitalization in postoperative cancer patients. They concluded that extended (3 months) use of enoxaparin led to a significant absolute risk reduction in VTE of 7%. This absolute risk reduction means that 14 postoperative cancer patients need to be treated for 21 days to prevent one case of VTE. The majority of DVTs in the ENOXACAN II study were asymptomatic and distal. Although extended prophylaxis will likely reduce clinically relevant proximal DVTs, more studies are needed to confirm the results of this trial prior to definitive recommendations for long-term prophylaxis following oncologic surgery.

Neurosurgical patients, many of whom undergo craniotomy for neoplasms, have an elevated risk of developing VTE in the immediate postoperative period, and this risk remains as high as 23% at 1 year.<sup>58,59</sup> Prophylaxis with LMWH, initiated within 24 hours of craniotomy, can reduce the risk of VTE without significantly increasing serious bleeding.<sup>60–62</sup> VTE prophylaxis has not been studied extensively in other surgical oncology settings. In general, medical prophylaxis is recommended after any surgery for cancer owing to the increased risk of thrombosis. If the risk of bleeding is considered to far outweigh the risk of VTE, then mechanical methods of prophylaxis are strongly recommended until the risk of bleeding has decreased.<sup>53</sup>

### Treatment

The management of VTE in cancer patients is challenging. In addition to the increased risk of VTE, cancer patients are more likely to have recurrent VTE (annual risk estimated to be 20.7%)<sup>63</sup> and have a three- to sixfold increased risk of hemorrhagic complications compared

with patients without cancer.<sup>63,64</sup> The prognosis of cancer patients with VTE is far worse than that of their thrombosis-free counterparts. In one study, the 1-year survival rate was 12% in patients with cancer and VTE compared with 36% in similar patients without VTE.<sup>52</sup> Finally, any therapeutic recommendation should take into account the patient's quality of life and minimize morbidity as much as possible.

Standard therapy for acute VTE is UFH or LMWH followed by long-term therapy with warfarin for secondary prophylaxis. Several randomized controlled trials and meta-analyses have shown that LMWHs are at least as effective as UFH in decreasing the recurrence of thrombosis<sup>65–67</sup> and may be associated with a lower risk of major bleeding and heparin-induced thrombocytopenia. Although these trials were not designed specifically to assess treatment options in patients with malignancy, extrapolation of the results from a large subgroup of patients with cancer in these studies suggests that LMWHs are as efficacious as UFH for the initial treatment of VTE in patients with malignancy. The convenience of use, without the need for frequent laboratory monitoring, has made LMWHs agents of choice in the inpatient and outpatient management of clinically stable patients with DVT. In many countries, outpatient LMWH is even being used for the treatment of hemodynamically stable PE.<sup>58</sup> The decrease in the length of hospital stay and possibility of outpatient treatment with LMWH will likely have a positive impact on the quality of life of patients with cancer and should be an important consideration in the choice of pharmacologic therapy.

Traditionally, long-term anticoagulation has been achieved with warfarin, started in combination with LMWH or UFH within the first 24 hours of diagnosis and continued for at least 3 months. This approach necessitates frequent laboratory monitoring to maintain an international normalized ratio (INR) of between 2.0 and 3.0.<sup>68</sup> In patients with malignancy, maintenance of therapeutic-range INR can be difficult, and more treatment failures are noted than in the general population. Two recent randomized trials support the use of LMWH instead of warfarin for long-term secondary prophylaxis of VTE. The CANTHANOX trial compared 3 months of warfarin therapy with enoxaparin, 1.5 mg/kg once daily, in patients with cancer and a diagnosis of proximal DVT, PE, or both.<sup>69</sup> There was no statistically significant difference between the two groups in terms of recurrence of symptomatic VTE or major bleeding. However, the warfarin group showed a trend toward more bleeding. In a similar study, the CLOT trial, investigators randomized cancer patients with VTE to receive either dalteparin alone for 6 months or dalteparin followed by warfarin therapy.<sup>70</sup> The 6-month

cumulative risk of VTE was significantly reduced from 17% in the warfarin group to 9% in the dalteparin group, with no difference in adverse bleeding complications. The main practical limitation of long-term LMWH use for secondary prophylaxis is the cost of the drug. Although evidence supports its use as superior to warfarin therapy and it is at least as safe, it remains to be determined whether long-term use of LMWH is cost-effective.

Given the increased incidence of recurrence of VTE in patients with cancer, it is prudent to continue secondary prophylaxis for several months following the initial diagnosis. However, the optimal duration of therapy is unknown in cancer patients. Most recommendations are extrapolated from studies in the general population, of whom patients with malignancy are a subset. In patients with idiopathic DVT, 6 months of therapy with oral anticoagulation was better than 6 weeks and 2 years was better than 3 months in preventing recurrent VTE.<sup>71,72</sup> In another study, 1-year prophylaxis was better than 3 months of anticoagulation, but the benefits were not sustained after discontinuation of prophylaxis at 1 year.<sup>73</sup> Some authors have recommended long-term low-intensity warfarin therapy (maintaining an INR of 1.5–1.9) after 3 months of conventional therapy. Two randomized controlled trials investigating this option have conflicting results.<sup>74,75</sup> It is not clear whether low-intensity anticoagulation is as effective and safer than conventional warfarin therapy, and more studies are needed before definitive recommendations can be made. Despite the increased risk of hemorrhage, in the cancer population, it is prudent to continue anticoagulation indefinitely or at least as long as the cancer is active to reduce the risk of recurrent VTE.<sup>76</sup>

### Failure of Anticoagulation

The management of cancer patients who develop recurrent VTE despite adequate warfarin therapy is difficult. Several options are currently available, none of which have been compared in clinical trials. After initial treatment with UFH or LMWH, the options are to continue anticoagulation with warfarin, targeting a higher INR (3.0–4.0) and accepting a higher risk of bleeding; switch to twice-daily, adjusted-dose UFH; use once-daily, weight-adjusted LMWH; or insert an inferior vena cava (IVC) filter. IVC filters have also been used for patients in whom anticoagulation is contraindicated. Decousus and colleagues evaluated the role of IVC filters in preventing PE and DVT recurrence. All patients were diagnosed with proximal DVT and received anticoagulation for 3 months after initial management with either LMWH or dose-adjusted UFH. At 12 days, 4.8% of patients without filters developed PE compared with 1.1% with filters ( $p = .03$ ). After 2 years, however, this initial benefit was no longer

sustained, and a statistically significant mortality benefit was not found with the use of an IVC. Ironically, the IVC filter group had a higher risk of DVT recurrence at 2 years.<sup>40,77</sup> Thus, IVC filters should be used cautiously in patients who are anticipated to have long-term survival following cancer therapy. Pharmacologic anticoagulation should be initiated whenever possible to decrease the recurrence of DVT and associated morbidity. Although the evidence is not very strong, long-term therapy with LMWHs may be the best option currently available in the management of patients who develop recurrent VTE while on adequate warfarin therapy.<sup>70</sup>

In summary, the management of patients with malignancy and VTE is challenging. Cancer patients are at increased risk of VTE, they are more likely to develop complications while on anticoagulation, the incidence of recurrence is high, and often the prognosis is worse than in similar patients who do not develop VTE. LMWHs are becoming the agent of choice for prophylaxis, treatment, and extended anticoagulation in patients with cancer. Interestingly, there is some indirect evidence that LMWHs may exert an antineoplastic effect in cancer patients.<sup>78,79</sup> More study is needed to further establish this potential benefit. Antithrombotic agents, such as direct thrombin inhibitors and inhibitors of factor Xa, are being evaluated in clinical trials. Their effectiveness in the cancer population is yet unknown, but they are promising and, it is hoped, will improve our management of patients with malignancy and VTE.

### Cancer and Hemoptysis

Hemoptysis is defined as expectoration of blood from the tracheobronchial tree or pulmonary parenchyma. It must be distinguished from bleeding from the gastrointestinal tract and upper airways. Hemoptysis ranges from blood streaking of sputum to gross blood. The term *massive hemoptysis* is reserved for bleeding that is potentially life-threatening but is arbitrarily defined by bleeding ranging from more than 100 mL to more than 600 mL over a 24-hour period. Although only 5% of hemoptysis is massive, it has been associated with a mortality rate as high as 85%.<sup>80</sup>

### Etiology

The bronchial arteries are generally the site of bleeding in patients with hemoptysis. In addition to having higher pressures than the pulmonary arteries, they perfuse the airways, and hemoptysis usually originates in airway mucosal lesions (Table 4).<sup>81</sup> Hemoptysis may be the first manifestation of lung cancer in 25 to 50%<sup>82</sup> of patients but is infrequently responsible for massive bleeding in this patient population.<sup>83</sup> In one series, cancer patients with massive hemoptysis typically

had large, centrally located tumors, usually squamous cell carcinoma. More often, hemoptysis is a late manifestation of lung cancer.<sup>83</sup> The etiology of hemoptysis may not be established in more than 40% of patients.<sup>84</sup> In many of these cases, nonmalignant causes were probably the source of hemoptysis. In the cancer patient, particular attention should be paid to the diagnosis and management of other factors that might exacerbate or cause hemoptysis, such as thrombocytopenia and coagulopathy secondary to deficiencies in vitamin K–dependent coagulation factors seen in patients with liver metastases.

Diffuse alveolar hemorrhage (DAH) originates from pulmonary vessels. Patients undergoing chemotherapy for leukemia or those who have received bone marrow transplantation are at risk of DAH and occasionally massive hemoptysis. Although the etiology of DAH is not entirely clear, it probably involves small pulmonary vessel injury secondary to a combination of drugs, thrombocytopenia, coagulopathy, infection, and

radiation. Management is supportive, with correction of thrombocytopenia and coagulopathy and prescription of high-dose corticosteroids.

## Management

The approach to management of a patient with hemoptysis should be initially directed toward ensuring that the patient's airway is patent and oxygenation is adequate. Volume resuscitation and correction of coagulopathy are important next steps. The urgency of evaluation and therapeutic interventions is determined by the briskness of bleeding and the patient's clinical stability. A history and physical examination, chest radiography, complete blood count, renal function, liver function tests, and prothrombin time and partial thromboplastin time are routinely recommended. Sputum samples should be evaluated for the presence of infection. The chest radiograph may be normal in patients with hemoptysis in almost half of the cases.<sup>85,86</sup> When a parenchymal infiltrate is visualized on the chest radiograph, it may not accurately reflect the site of bleeding because blood can be aspirated into portions of the lung distal from the source of bleeding.<sup>87</sup>

Fiberoptic bronchoscopy and chest CT are complementary diagnostic tests for identifying the bleeding site. Bronchoscopy can detect bleeding sites in the proximal airways, such as bronchitis and central endobronchial lesions. In addition to detection of parenchymal lesions, chest CT is valuable at detecting bronchiectasis, lung abscesses, and many peripheral tumors not accessible to the bronchoscope. The optimal timing for bronchoscopy is controversial.<sup>88</sup> Visualization of the airways is difficult in the setting of massive bleeding. However, the chance of identifying the bleeding site is enhanced if the lesion is actively bleeding at the time of bronchoscopy.

For patients with massive hemoptysis, diagnostic tests and rapid management often occur concurrently to decrease the elevated risk of death secondary to asphyxiation. Early consultation with pulmonary and thoracic surgery specialists is recommended. Protection of the nonbleeding lung is a priority; this will require knowledge of the site of bleeding, which may not be readily available. If the bleeding site is known, the patient should be placed in the lateral decubitus position with the bleeding site dependent to decrease spillage of blood into the unaffected lung. If oxygenation is compromised or bleeding continues at a brisk pace, then oral intubation should be performed. This can be achieved simultaneously with bronchoscopy. A single-lumen endotracheal tube placed into the mainstem bronchus of the nonbleeding lung can be used to selectively ventilate that lung. This is easier to achieve if the left lung is bleeding and the right mainstem bronchus is selectively intubated. However, there is the potential problem of blocking the right upper

lobe bronchus and further compromising oxygenation and ventilation. A double-lumen endotracheal tube may be used as an alternative. However, they are difficult to place, even by experienced personnel. Ensuring proper positioning as the patient moves is important and may require paralysis and sedation. The individual lumen size of double-lumen tubes is often too small to permit passage of a bronchoscope and is prone to obstruction by an intraluminal clot. Given these difficulties, double-lumen tubes are not recommended unless other approaches have failed.

In addition to localization of the bleeding site, flexible bronchoscopy may offer therapeutic options. Tamponade of the bleeding site may be achieved with the placement of a 4F, 100 cm Fogarty balloon catheter, alongside the bronchoscope, into the segmental or subsegmental bronchus leading to the bleeding site for 24 to 48 hours. Bleeding may slow or stop with intrabronchial administration of iced saline or topical epinephrine (diluted 1:20,000). Rigid bronchoscopy, performed under general anesthesia, will allow for more effective suctioning, direct cautery, and packing of the bleeding site. However, its range of visualization is limited, and it is often used in conjunction with flexible bronchoscopy if bleeding persists.

Arteriography is an increasingly important addition to available therapeutic options. Because hemoptysis usually originates from the bronchial arteries, bronchial angiography is the first step. Arteriography more commonly hints at the possible bleeding site by the indirect observation of tortuous vessels and hypervascularized regions rather than by direct visualization of extravasation of contrast. Bronchial artery embolization may stop hemoptysis acutely in more than 85% of cases. Unfortunately, in 10 to 20% of cases, rebleeding occurs in the ensuing 6 to 12 months.<sup>89-91</sup> Complications of bronchial artery embolization include bronchial wall necrosis and the risk of paralysis owing to inadvertent embolization of the anterior spinal artery. The anterior spinal artery arises from the bronchial circulation in 5% of the population; fortunately, the risk of paraplegia is less than 1% in experienced hands.<sup>80,91,92</sup>

Surgery is emergently indicated when life-threatening pulmonary hemorrhage persists despite adequate medical therapy. Morbidity and mortality are greater for emergent lung resection compared with elective resection in patients who have been stabilized and are no longer actively bleeding.<sup>80</sup>

In nonmassive cases of hemoptysis, nonspecific treatment with antibiotics, bed rest, and antitussives will usually be effective in decreasing the bleeding. This allows identification of the bleeding site and directed therapy. Local external

beam radiation may be effective in controlling hemoptysis in patients with bronchogenic tumors. Endobronchial brachytherapy may be useful in patients with endobronchial tumors not responsive to external radiation. In cancer patients, hemoptysis may be caused by PE.<sup>93</sup> In these cases, the risk of further hemoptysis with anticoagulation needs to be balanced against recurrent thromboembolism and its inherent complications. If the decision is made for anticoagulation, LMWHs have been associated with a lower risk of bleeding than warfarin therapy.<sup>94</sup> IVC filters should be considered in these patients.

In patients with advanced cancer, the treatment of hemoptysis should take into consideration not only the cause and severity of the bleeding but also the patient's life expectancy, quality of life, expectations, and family wishes. It is important to discuss the patient's wishes regarding life-sustaining therapies and resuscitation early in the management of disease. In patients with end-stage cancer, aggressive diagnostic and treatment modalities may not be indicated. Palliation and sedation with benzodiazepines and intravenously administered opioids to allow patient comfort, in addition to emotional support of both the patient and family, may be the best approach.

In summary, hemoptysis can be a difficult management problem. Massive hemoptysis may be life-threatening. Airway protection is the vital first step. Bronchial artery embolization may be useful in controlling bleeding acutely and allowing directed therapy to the source of bleeding. Careful attention must be paid to factors such as thrombocytopenia and coagulopathy, which may contribute to the bleeding. DAH is a less common cause of hemoptysis but may also cause respiratory failure.

## Radiation-Induced Pneumonitis

### Pathogenesis

Ionizing radiation injures cells and causes cell death in a variety of ways. Cellular injury has generally been attributed to deoxyribonucleic acid (DNA) damage.<sup>95</sup> Extensive single- and double-stranded breaks in DNA can overwhelm cellular repair mechanisms. Disruption of genomic sequences will ultimately impair vital cellular processes and cause cell death. Rapidly dividing cells are most vulnerable to this damage. DNA damage may not be noticeable in resting cells but may become apparent as these cells enter mitosis. The direct effects of radiation on the cell membrane may also induce apoptosis through the effects on cell membrane sphingomyelin.<sup>96</sup> Recent evidence suggests that radiation will cause the enzyme acid sphingomyelinase to convert sphingomyelin to ceramide. Ceramide will ultimately be transported to the mitochondria,

where it will activate apoptosis.<sup>97</sup> Initiation of apoptosis through this sequence of events may be most important in endothelial cells because these cells have high levels of acid sphingomyelinase.<sup>98</sup> Radiation may also damage cells by initiating complex inflammatory processes. Reactive oxygen species are generated by ionizing radiation. These reactive oxygen species can up-regulate expression of a variety of proinflammatory mediators, such as TNF and intracellular adhesion molecule 1,<sup>99,100</sup> and stimulate recruitment of inflammatory cells. Inflammation within the lung is characteristically found after radiation therapy. Gene expression profiling indicates that profibrotic and growth factors, such as platelet-derived growth factor and transforming growth factor, are activated shortly after the pulmonary inflammatory process begins.<sup>101</sup> These observations demonstrate that the acute inflammatory response to ionizing radiation is inextricably linked to the development of subsequent pulmonary fibrosis.

**Clinical Manifestations**

Radiation pneumonitis presents in one of two fundamentally different ways. Acute radiation pneumonitis has been defined as developing within 90 days of radiation therapy. Radiation-induced pulmonary fibrosis is defined as becoming evident 6 months after radiation therapy and may progress over years. However, a clear distinction between these two forms of radiation pneumonitis may be artificial as the pathogenesis of the disease suggests that acute inflammation is the basis for the development of fibrosis. The most widely accepted method for categorizing the severity of acute radiation pneumonitis and radiation-induced pulmonary fibrosis has been developed by the Radiation Therapy Oncology Group (RTOG) (Table 5).<sup>102</sup>

It is difficult to precisely define the incidence of the two forms of radiation pneumonitis. Following radiation therapy, radiographic and pulmonary function testing may show subtle abnormalities in a substantial number of patients, but most will not have symptoms related to these changes. These effects have been clearly documented in a prospective study of patients

receiving radiation therapy for management of lung cancer. Standard measures of lung function, the forced expiratory volume in 1 second (FEV<sub>1</sub>) and the diffusing capacity for carbon monoxide (DLCO), decreased between 10 and 15% over the 6 months following treatment.<sup>103</sup> Interestingly, the FEV<sub>1</sub> tended to improve by 12 months, but the DLCO remained decreased. The reduction in the DLCO may be the most sensitive indicator of radiation pneumonitis. It can reflect changes in the lung interstitium related to either fibrosis or inflammation. It is also sensitive to a reduction in lung perfusion related to endothelial cell injury, which has also been demonstrated following thoracic radiation.<sup>104</sup> Changes in DLCO, a physiologic test, nicely reflect the pathogenesis of radiation pneumonitis, which involves both endothelial damage and interstitial inflammation.

Symptomatic radiation pneumonitis may affect more than 30% of treated patients, but most will have transient symptoms that resolve without treatment.<sup>105-107</sup> In these patients, the usual presenting complaint is shortness of breath. Dry, nonproductive cough may also be described. Hypoxia, sometimes to a severe degree, will commonly accompany these symptoms. Probably less than 10% of patients receiving radiation therapy will develop more problematic pulmonary involvement (RTOG grades 3 and 4). Fortunately, respiratory failure is unusual.<sup>108</sup>

The diagnosis of radiation pneumonitis is usually established by the chest radiograph. Interstitial changes, typically described as reticulonodular shadows, are found corresponding to the radiation field or portal. In the classic example of the radiographic findings of radiation pneumonitis, the interstitial changes have sharp edges with a geometric shape (Figure 1). The shape does not correspond to lung anatomy, again emphasizing the relationship to the radiation portal. However, in unusual cases, radiographic changes may be found diffusely, or “out of (the radiation) field.” ARDS, reflecting diffuse lung disease, has been described in patients following localized lung radiation. In these cases, radiation may have induced a lymphocyte-mediated hypersensitivity reaction against lung antigens.<sup>109</sup>

Radiation pneumonitis occurs primarily in patients with lymphoma, lung cancer, bone marrow transplantation, esophageal cancer, and breast cancer who may receive ionizing radiation to the thorax. The risk of developing radiation pneumonitis is most clearly related to the dose of radiation received, the volume of lung irradiated, and the treatment schedule. The role of these factors is demonstrated by the following clinical observations. Upper hemibody irradiation with a dose of 8 Gy results in a high risk of life-threatening pulmonary complications, and a single-fraction dose of 10 Gy to the entire lungs is nearly always fatal.<sup>110</sup> The threshold dose for causing radiation pneumonitis seems to be 20 to 25 Gy administered in 1.8 to 2 Gy per dose fractions. This threshold dose is well below the usual curative intent dose administered to patients with lung cancer, which is between 63 and 70 Gy.<sup>111</sup> Tangential radiation of the breast after lumpectomy or the chest wall after mastectomy results in very low risk of radiation pneumonitis.<sup>112</sup> Daily treatments of 1.8 to 2 Gy seem to pose minimal risk,<sup>113</sup> whereas daily treatment sizes of greater than 2.67 Gy present greater risk. Continuous hyperfractionated accelerated radiotherapy, which involves using smaller doses of radiation therapy given two to three times per day, may also effectively reduce the risk of radiation pneumonitis.<sup>114,115</sup> Almost certainly genetic factors play a role in determining the susceptibility of patients to developing radiation pneumonitis, but future work is needed to more fully understand this interaction.

Understanding the relationship among radiation dose, lung volume irradiated, and treatment schedule was an essential step in developing more sophisticated methods to minimize the risk of radiation pneumonitis. Three-dimensional CT-based conformal treatment planning is currently used to determine the ideal radiation dose and portal. The ideal radiation dose is defined as the maximal dose that can be delivered to the tumor while simultaneously minimizing radiation delivered to surrounding normal tissue. Based on the results of chest CT, a dose-volume histogram is constructed that essentially graphs

**Table 5** Severity Categorization of Radiation Pneumonitis and Radiation Fibrosis

	<i>Grade 0</i>	<i>Grade 1</i>	<i>Grade 2</i>	<i>Grade 3</i>	<i>Grade 4</i>	<i>Grade 5</i>
Radiation pneumonitis	No adverse effects	Mild symptoms of dry cough or dyspnea	Persistent cough requiring narcotic antitussives/dyspnea with minimal effort	Severe cough refractory to narcotic antitussives or dyspnea at rest, radiographic evidence of pneumonitis, intermittent oxygen needs, or requirement for steroids	Severe respiratory insufficiency with requirement for continuous oxygen or assisted ventilation	Death
Radiation fibrosis	No adverse effects	Asymptomatic or mild symptoms: dry cough, slight radiographic changes	Moderate symptomatic fibrosis	Severe symptomatic fibrosis, dense radiographic changes	Severe respiratory insufficiency, oxygen required or assisted ventilation	Death

**FIGURE 1** A computed tomographic scan of a patient with acute radiation pneumonitis (*left*) with subsequent development of radiation-induced pulmonary fibrosis (*right*). Note the sharp line demarcating the parenchymal infiltrate from the normal-appearing lung and the geometric shape of the infiltrate, both of which are characteristic features of radiation pneumonitis.

the cumulative dose going to the lung versus the tumor. Cases that may benefit most from this approach are those tumors that are situated adjacent to radiosensitive tissue, such as the heart, esophagus, and spinal cord. Limiting this approach in lung cancer is the frequent combination of tumor and atelectasis. Distinguishing between tumor and either atelectatic lung or postobstructive pneumonia may be difficult. This approach does allow the average radiation dose to be calculated for normal lung; this can be a useful guide to the probability of radiation pneumonitis.<sup>116</sup> The risk of radiation pneumonitis increases from 10% in portions of lung receiving less than 10 Gy to 50% in portions of lung receiving, on average, over 30 Gy.<sup>117</sup>

## Management

Treatment of acute, symptomatic radiation pneumonitis is based on the use of corticosteroids. Although randomized controlled clinical trials have not demonstrated the value of this approach, nonrandomized clinical studies support the use of corticosteroids in patients with grade 2 or greater severity disease.<sup>118</sup> The dose and duration of therapy vary, with tapering adjusted by individual response. For patients with grade 3 severity, prednisone given at 1 mg/kg is the usual starting dose, which should be tapered by reductions of no more than 10 mg every 2 weeks. Recurrence of symptoms is common during the tapering process and requires dose escalation. Corticosteroids should not be used to prevent acute radiation pneumonitis. Patients with grade 3 severity radiation pneumonitis or fibrosis should be carefully evaluated for use of chronic oxygen supplementation and ventilatory assist devices.

There has been considerable interest in developing pharmacologic approaches to prevent radiation pneumonitis. Amifostine (Ethyol, Medimmune) is a drug approved for use as a radiation protector, but only for patients receiving radiation therapy for cancers of the head and

neck region. It may act as a scavenger of reactive oxygen species. The drug may be preferentially taken up by normal cells, protecting them from reactive oxygen species generated by irradiation. Small clinical trials in patients with advanced non-small cell lung cancer suggest that amifostine may prevent acute radiation pneumonitis, but further long-term trials are needed to clearly demonstrate this benefit.<sup>119,120</sup> Pentoxifylline (Trental, Aventis) was also found in a small double-blind randomized trial to protect against radiation pneumonitis.<sup>121</sup> The protective effects of pentoxifylline may occur by interference with TNF signaling. There is active interest in a variety of other classes of drugs as protective agents. Angiotensin-converting enzyme inhibitors have been shown in preclinical studies with rodents to have promise in protecting against radiation pneumonitis, but the mechanism of action is unclear.<sup>122</sup> Future studies will be directed at inhibitors of cytokines and other mediators of the inflammatory and fibrotic response.

In summary, radiation pneumonitis occurs through the effects of ionizing radiation on normal lung and endothelial cells. Factors predisposing patients to radiation pneumonitis relate to the amount of normal tissue being exposed to irradiation, the total dose, and the dosing schedule. Modern radiotherapy techniques have successfully reduced the risk of radiation pneumonitis by carefully adjusting the radiation portal according to three-dimensional visualization of the tumor obtained by CT scans. Radiation pneumonitis can usually be controlled with corticosteroids, but severe toxicity still may occur. There is promise for the development of pharmacologic approaches to prevent radiation pneumonitis.

## Chemotherapy-Related Lung Disease

### Pathogenesis and Risk Factors

The mechanism by which chemotherapeutic agents cause lung damage is not well understood.

This is in large part because so many different chemotherapeutic drugs, with multiple different modes of action, have been implicated as causes of lung injury. Finding a common mechanism among the various classes of chemotherapeutic agents implicated in causing lung damage has not been possible. Further complicating the relationship between drug and lung injury is the possibility that the drug itself may not be causing the injury; rather, the lung damage may be caused by a metabolite of the drug.

A possible common theme for chemotherapy-induced pneumonitis is that the alveolar epithelial cell seems to be the target cell for injury. One possible mechanism for chemotherapeutic agents to damage this cell is through enhanced apoptosis. Apoptosis pathways can be initiated through interaction of an anticancer drug with the cell surface molecule Fas ligand. Alternatively, chemotherapeutic agents may trigger apoptosis through interactions with cytochrome *c* in the mitochondria. A key intermediate step leading to cell death in both the Fas ligand and the mitochondrial apoptosis pathways is activation of the caspase cascade.<sup>123</sup> Toxic drug metabolites may be an alternative way for chemotherapeutic agents to damage alveolar epithelial cells. Biotransformation of drugs usually occurs through oxidation. This process can produce reactive oxygen species; accumulation of these reactive oxygen species may cause cell death through oxidative stress and lipid peroxidation. This observation may be particularly relevant to the alveolar epithelial cell because of its exposure to ambient air. Hyperoxia has been clinically implicated as being associated with an increased susceptibility to chemotherapeutic drug-induced lung toxicity. Hyperoxia will also increase the production of reactive oxygen species.<sup>123</sup> Toxic drug metabolites may also trigger an immune response.<sup>124</sup> Whatever mechanism is responsible for the initial alveolar epithelial cell injury, the inflammatory response also triggers increased production of growth factors, particularly members of the epidermal growth factor family. Activation of growth factors is probably critical for epithelial cell repair but may also be responsible for initiation of pulmonary fibrosis.<sup>123</sup>

Other important issues in the pathogenesis of chemotherapy-induced lung disease are the relationship of genetic factors with risk and the enhanced risk associated with either combined chemotherapy and radiation therapy or concomitant administration of multiple drugs that have pulmonary toxicity. The importance that genetic factors might play in the susceptibility of population groups to chemotherapy-induced pneumonitis became apparent with the introduction of gefinitib, an epidermal growth factor receptor tyrosine kinase inhibitor, into Japan. The reported incidence of interstitial lung disease following the

use of gefitinib in Japan was 1.9%, which is higher than reported rates for the rest of the world. Whether part of this increase in risk was due to unsuspected, preexisting lung disease in patients treated with gefitinib is still unclear.<sup>125</sup> Combined administration of chemotherapy and radiation therapy seems to increase the risk of lung injury.<sup>126</sup> Chemotherapy given prior to the initiation of radiation therapy (neoadjuvant chemotherapy) seems not to increase the risk of radiation pneumonitis, but concomitant administration of chemotherapy and radiation therapy is associated with a substantially higher risk of radiation pneumonitis.<sup>102</sup> Chemotherapeutic agents that seem to be associated with this increased risk include gemcitabine, bleomycin, and anthracyclines.<sup>127–129</sup> Another chemotherapeutic agent that possibly might increase the likelihood of radiation pneumonitis is paclitaxel.<sup>130</sup> There is concern that taxine-containing regimens pose a greater risk of inducing radiation pneumonitis than platinum and platinum-etoposide regimens.<sup>102</sup> The simultaneous use of multiple drugs that are associated with pulmonary toxicity may also be a significant hazard. The combination of gemcitabine and bleomycin seems to be associated with an unacceptably high rate of pulmonary toxicity.<sup>131</sup> Interestingly, amiodarone has been associated with enhancing the pulmonary toxicity of cyclophosphamide.<sup>132</sup>

### Clinical Manifestations

Chemotherapy-induced lung injury may present in multiple different ways, ranging from acute respiratory failure to the more insidious development of dyspnea and nonproductive cough. Although the symptoms and radiographic manifestations of chemotherapy pneumonitis are often nonspecific, in general, lung injury associated with the use of chemotherapeutic agents will usually fall into one of six different types.<sup>133</sup> These six different categories are differentiated definitively by histologic means, but the diagnosis may often be suspected by the combination of clinical and radiographic findings.

Diffuse alveolar damage has been associated most commonly with bleomycin.<sup>134,135</sup> Clinically, it may present with an acute to subacute course, with symptoms of dyspnea and nonproductive cough developing over weeks. Radiographic changes are most clearly seen on chest CT, which demonstrates diffuse ground-glass opacities. Histologically, it is characterized by hyaline membrane formation in alveolar spaces along with alveolar and interstitial edema. Hypersensitivity pneumonitis has been related to the use of methotrexate and cyclophosphamide.<sup>133,136</sup> In some cases, it may present in a similar way clinically to diffuse alveolar damage, with an acute to subacute onset of symptoms. However, it may also present in a more indolent fashion. Radiographic

abnormalities may consist of ground-glass opacities, especially with the more acute onset of symptoms; with chronic presentation, it is more likely that poorly defined nodular opacities will be found on a chest radiograph or CT scan. The histologic appearance of hypersensitivity pneumonitis shows granulomas, indicating an immunologically mediated disorder. Bronchoalveolar lavage will reveal high numbers of lymphocytes.

Probably the most common form of chemotherapy-induced pneumonitis, confirmed histologically, is nonspecific interstitial pneumonitis.<sup>137</sup> It has most commonly been associated with methotrexate. This form of drug-related lung injury tends to present over a longer time course. Radiographic changes are often described as patchy, but diffuse ground-glass opacities may also be seen in more severe cases. As the disease progresses, chest CT will begin to show such evidence of pulmonary fibrosis as a reticular pattern and peripheral traction bronchiectasis with honeycombing. Lung biopsy will show infiltration of interstitial spaces with fibrosis and a mononuclear inflammatory process. Bronchiolitis obliterans organizing pneumonia, formerly known as BOOP and now referred to as cryptogenic organizing pneumonia, has been described with methotrexate, cyclophosphamide, bleomycin, and busulfan.<sup>135,137</sup> The clinical symptoms usually progress in a more chronic fashion, similar to nonspecific interstitial pneumonitis. Radiographically, patchy infiltrates are seen either peripherally or peribronchially. Histologically, nonspecific inflammation and fibrosis are found in the interstitial spaces and plugs of loose connective tissue with immature fibroblasts are seen within respiratory bronchioles.

Unusual forms of chemotherapy-induced pneumonitis include eosinophilic pneumonia and pulmonary edema. Eosinophilic pneumonia has been described in association with the use of methotrexate.<sup>134,135</sup> The clinical presentation may be either acute or subacute, and respiratory failure may occur. Bilateral airspace consolidation, characteristically involving the lung periphery, is the typical radiographic appearance. The alveoli, and often the interstitium, are filled with eosinophils. Peripheral eosinophilia may not be apparent, but bronchoalveolar lavage will show a very high percentage of eosinophils. Diffuse capillary leak syndrome may cause acute pulmonary edema. Capillary leak has been associated with cytosine arabinoside and docetaxel; it has been clearly described in the all-*trans* retinoic acid syndrome.<sup>138</sup> Patients present within days of beginning all-*trans* retinoic acid with respiratory distress, pleural and pericardial effusions, and bilateral, diffuse airspace consolidation on a chest radiograph or CT scan. Lung histology is nonspecific, with alveoli filled with proteinaceous material.

### Management

Treatment is based on first establishing the diagnosis. Usually, the onset of symptomatic chemotherapy-induced lung injury and associated radiographic abnormalities and changes in pulmonary function tests coincide temporally with the use of the drug. Unfortunately, serial measurements of the DLCO do not always predict the development of drug-induced lung disease.<sup>131</sup> Disease recognition should prompt discontinuation of the offending agent, which may be sufficient to allow reversal of the disease. The standard approach to treatment of symptomatic chemotherapy pneumonitis is the use of corticosteroids. With severe forms presenting with respiratory failure, high-dose corticosteroids (methylprednisolone at a dose of 250 mg four times per day) is most often advised.<sup>133</sup> In less severe cases, as with radiation-induced pneumonitis, the use of prednisone 1 to 2 mg/kg/d is an accepted approach. Tapering is a slow process, often taking months, and may be complicated by recurrences of symptoms. Immunosuppressive agents, such as azathioprine, have been used as corticosteroid-sparing agents in patients suffering from intolerable side effects, but the value of these agents has never been demonstrated. Interest in developing pharmacologic approaches to either preventing or treating chemotherapy-induced lung disease is high.

In summary, chemotherapeutic agents can damage the lungs in a variety of ways, with the alveolar epithelial cells appearing to be most vulnerable. Chemotherapy-induced lung damage may develop acutely or insidiously. Presenting symptoms are usually dyspnea and nonproductive cough with either ground-glass opacifications or reticulonodular infiltrates found on CT. Histologic abnormalities vary widely, but fibrosis may be an ultimate end point. Early recognition and timely withdrawal of the offending agent, along with corticosteroids, are usually effective in controlling the disease.

### Conclusion

Noninfectious pulmonary problems in the patient with cancer range widely in type. This chapter has reviewed the major types that should be considered. These problems are associated with metastatic spread of the cancer (to the pleura, causing effusions and pneumothorax, or to the airways, precipitating hemoptysis), systematic procoagulant effects of the cancer (promoting the risk for VTE), and side effects of the treatments (radiotherapy and/or chemotherapy) used to treat the primary disease. Unfortunately, many of these noninfectious pulmonary problems are associated with an overall poor prognosis. Sensitivity to this issue in cancer patients suffering from noninfectious pulmonary problems should be an important aspect of the management approach.

# Cancer-Related Issues in Mechanical Ventilation

Bruce P. Krieger, MD, FCCP  
Mark Rumbak, MD, FCCP

Acute respiratory failure (ARF) is the most common diagnosis among adult cancer patients who require admission to the intensive care unit (ICU).<sup>1,2</sup> Recent reports noted that approximately 50<sup>1,3,4</sup> to 87%<sup>5</sup> of oncology patients with ARF will require mechanical ventilatory support (MVS). Advances in our understanding of ARF and MVS, especially in the spectrum of acute lung injury (ALI) and acute respiratory distress syndrome (ARDS),<sup>6</sup> have been applied to patients in the ICU and resulted in significant improvements in their survival. These encouraging techniques have been adopted for use in cancer patients with ALI/ARDS with the expectation of improved survival. The majority of diseases that precipitate ARF in cancer patients are potential causes of ARDS/ALI (Table 1). However, the precise number of cancer patients who develop ARDS is not known.<sup>2</sup> One series of 153 patients who suffered from hematologic and solid neoplasms and developed ARF documented a 30% incidence of ARDS and a 35% incidence of other causes of acute hypoxemic and ventilatory failure.<sup>3</sup> A more recent series documented a 20% incidence of ARDS among 203 cancer patients with ARF.<sup>1</sup>

Until the past decade, most clinicians and experts maintained a very pessimistic attitude toward the outcome of using MVS in oncology patients after the development of ARF. A review of the literature prior to 1999 disclosed mortality rates between 72 and 98% in this group of patients.<sup>3</sup> The mortality for patients with hematologic malignancies who required MVS exceeded 80%, whereas it was slightly lower (70%) in reports of patients with solid malignancies. The requirement for MVS in oncology patients who were admitted to an ICU significantly increased the risk of mortality in recent series ( $p < .05$ ), raising the odds ratio of dying by 3.55 to 13.7 (Table 2).<sup>3-5</sup> However, more recent studies have evoked a less nihilistic opinion because of better survival rates, especially in hematologic patients who required MVS (Table 3).<sup>3,5-7</sup> Some of the proposed reasons for

the improved outcomes include advances in critical care and invasive MVS,<sup>6</sup> targeted therapy for septic shock,<sup>5</sup> better treatments for malignancies, improved ventilatory strategies for MVS,<sup>3</sup> better support of nonpulmonary organ failures,<sup>5</sup> and noninvasive positive pressure ventilation (NIPPV).<sup>8-13</sup> This chapter explores the etiologies of ARF in oncology patients, problems with airway management in cancer patients, conventional MVS, lung-protective strategies for ventilating patients with ARDS, and how NIPPV has been used in treating cancer patients with ARF. A pragmatic algorithm is also presented that will aid interested clinicians in their approach to the adult oncology patient who requires MVS.

## Incidence of and Indications for MVS in Oncology Patients

Various studies have reported the incidence of MVS that was required in adult oncology patients who were admitted to an ICU. However, because of the general nihilistic attitude toward this aggressive modality,<sup>3</sup> the actual need for ventilatory assistance in the cancer patient who develops ARF may be far greater than the reported incidence. Kress and colleagues documented the need for MVS in 46% of 44 lung cancer patients who were admitted to a university hospital ICU.<sup>3</sup> This was similar to the 54% incidence noted by Azoulay and colleagues in a group of 120 patients

**Table 2 Effect of Mechanical Ventilatory Support on the Risk of Mortality in Oncology Patients Admitted to the Intensive Care Unit**

NIPPV = noninvasive positive pressure ventilation.

with solid tumors who presented with ARF, of whom 27% had lung cancer.<sup>4</sup> Azoulay and colleagues extended their findings in a later study to include hematologic malignancies in addition to solid tumors.<sup>1</sup> They also included patients who were prescribed noninvasive MVS. The requirement for MVS was similar to that in their earlier study (56%), with an additional 17% of patients treated with NIPPV alone.<sup>1</sup> NIPPV was used alone in 33% of 100 patients with hematologic and solid malignancies reported by Darmon and colleagues.<sup>5</sup> An additional 54% of these patients were intubated for MVS. In 80 patients with leukemia who developed ARF, 41% required MVS compared with 53% of 47 patients with lymphoma.<sup>3</sup> As noted earlier in this chapter, the need to institute MVS significantly increased the risk of mortality in all patient groups (see Table 2).

ARF is the most common diagnosis for oncology patients who were admitted into an ICU. Collating the data from three studies that involved 568 patients, the incidence of ARF was 40%.<sup>3-5</sup> The only recent study that provided detailed information concerning the etiology of ARF in cancer patients was Azoulay and colleagues' analysis of 203 cancer patients with ARF.<sup>1</sup> The majority (91%) of these patients had a hematologic malignancy, and 35% were neutropenic when admitted to the ICU. Infectious pneumonia was the cause of ARF in 58% of the patients, and multilobar radiologic involvement was present in 79% of all the subjects. Bacterial pneumonia was the most frequent infection (29.5%) and was associated with a statistically increased risk of mortality ( $p = .04$ ) by univariate analyses but not multivariable analyses. Pneumocystis pneumonia, viral pneumonia, tuberculosis, and invasive aspergillosis were also diagnosed. The odds ratio of dying by multivariable analysis for patients with aspergillosis was significantly increased (3.78;  $p < .05$ ). Twenty percent of their patients met the criteria for the diagnosis of ARDS. Noninfectious etiologies for ARF included congestive heart failure (12.3%), isolated alveolar hemorrhage (6%), toxic pneumonia (4%), pulmonary infiltration by malignant cells (8%), and no definite diagnoses despite an invasive diagnostic workup (21%). Patients with no definite diagnosis also had an increased risk of

dying ( $p < .01$  by univariate analysis), whereas those who developed congestive heart failure had a lower risk of mortality by both univariate and multivariable analyses ( $p = .01$ ). Although the authors did not comment on the incidence of ALI (which is a diagnosis that has a less impaired level of oxygenation compared with ARDS), it is likely that this was present in a significant number of their patients. Therefore, the remainder of this chapter focuses on caring for adult oncology patients with ARF who require MVS, especially in the presence of ALI and ARDS.

## Airway Management

### Upper Airway Obstruction

Upper airway obstruction is a medical emergency in any patient group and must be dealt with as soon as possible.<sup>14</sup> The causes of upper airway obstruction in cancer patients are similar to those in noncancer patients (Table 4), except the prevalence of obstruction in cancer patients is higher. Physicians with experience in these disorders, especially otolaryngologists, should be consulted early. The initial management is important, and a diagnosis should be made if at all possible.

Angioedema

Early symptoms and signs include shortness of breath, difficulty in breathing, anxiety, increased pulse rate, heart rate, blood pressure, and stridor. Later manifestations include increasing stridor, little movement of air, abnormal mentation including agitation, use of accessory muscles of respiration, and arterial desaturation. The obstruction is now severe, and reestablishing the airway is urgent and vital. The most experienced physician on the team should attempt the reestablishment of the airway as quickly as possible. Finally, if reestablishment of the airway fails, the pulse slows and the blood pressure drops as the patient's heart begins to stop. At this point, even if the patient is finally resuscitated, brain damage can occur if hypoxia is prolonged.<sup>14</sup>

If the cancer itself is the cause of the obstruction, then the airway may be maintained while the cancer is treated. Successful treatment allows the patient to be safely extubated. It is important to explain to patients or their health care surrogate that if treatment fails, withdrawal of life support becomes a possibility. In these patients, it is expected that a cancer is obstructing the airway, but infection and bleeding are also common causes of airway obstruction. A diagnosis should be made as soon as possible as the treatment of cancer, infection, or hemorrhage is different. Major bacterial infections include *Streptococcus* sp, *Staphylococcus aureus* (which often may be methicillin resistant), and *Haemophilus influenzae*. Sometimes fungal infections may occlude the airway, usually when immunity recovers. Antibiotics, antivirals, antifungals, treating the coagulopathy, and, if necessary, drainage are the definitive treatments. Massive bleeding can occlude the airway, and reestablishment of the airway is performed before attention to the primary lesion is given. Laryngeal abnormalities should be diagnosed as soon as possible, especially preextubation.<sup>15,16</sup> If the latter necessitates reintubation, a tracheostomy is performed to allow the edema and other damage to resolve itself. In these cases, decannulation is performed only after inspection of the larynx, usually 2 weeks later. Otolaryngology should be involved in every step. Most patients are intubated, but some can be treated conservatively. However, if they are not intubated immediately, they must be carefully observed in the ICU with a tracheostomy, difficult airway, or cricoidotomy tray at the bedside.

### Translaryngeal Intubation

After the patient has failed noninvasive mechanical ventilation or if it is decided to intubate directly, an endotracheal tube (ET tube) is inserted into the trachea. The ET tube can be inserted through the nose or mouth. It is sometimes easier to insert the ET tube through the nose when the patient is awake, obese, or combative. Cancer

patients are preferably intubated through the nose because they have low platelet counts. The prevalence of sinusitis and subsequent ventilator-associated pneumonia is increased in the nasally intubated patient.<sup>17,18</sup>

## Tracheostomy

The exact timing of tracheostomy is controversial. In patients in whom long-term mechanical ventilation or other reasons for long-term tracheostomy is suspected, tracheostomy is performed as early as possible. In most patients, tracheostomy is performed at some time during the ventilation of patients who fail to wean easily. Prolonged translaryngeal intubation has the disadvantages and complications of injury to the mouth, larynx, and trachea, as well as the dangers of self-extubation and malposition, paranasitis, extreme physical discomfort, and needing increased sedation.<sup>19–23</sup>

A tracheostomy provides a relatively stable, well-tolerated airway. It makes oral feedings possible, enhances communication, permits earlier ambulation, and facilitates pulmonary toilet and oral hygiene. Unfortunately, tracheostomy is associated with such complications as stomal infection, pneumothorax, subcutaneous emphysema, hemorrhage, tracheal stenosis, tracheomalacia, granulation tissue, and, rarely, death.

Most recent studies support the American College of Chest Physicians recommendations on the timing of tracheostomies.<sup>24</sup> Patients are treated for 5 days or so and assessed for extubation. If they will be extubated in the next day or so, they are left translaryngeally intubated. If they are not expected to be extubated soon, then a tracheostomy is performed.<sup>24</sup> The advantages and disadvantages of early tracheostomy are listed in Table 5, and the disadvantages of translaryngeal intubation are found in Table 6.

## Mechanical Ventilatory Support

Cancer patients are ventilated when they cannot support themselves and develop respiratory failure. In most cases, the patients are ventilated until the disease, which causes the respiratory failure, is treated.<sup>25</sup> Occasionally, the respiratory failure is due to the cancer itself and the patient is ventilated until the cancer is treated sufficiently enough to allow the patient to breathe on his or her own. Patients and their families must be warned that if radiation, chemotherapy, or surgery fails, then withdrawal of life support should be withdrawn. Cancer patients are treated similarly to noncancer patients for the most part. However, there are some differences. Cancer patients are intubated through the mouth rather than the nose. Many of these patients are immunosuppressed, and bacterial and non-bacterial pathogens are diagnosed by protected specimen brush, bronchoalveolar lavage (BAL), or mini-BAL.<sup>24</sup>

### Conventional Mechanical Ventilation

Most cancer patients are ventilated using conventional mechanical ventilation. Patients can be ventilated using pressure modes (pressure support or pressure-regulated volume control) or volume modes (volume control or synchronized intermittent mandatory ventilation [SIMV]). The most commonly used mode is volume controlled followed by SIMV and then pressure support ventilation (PSV). Pressure-regulated volume control is used when the peak pressures in the airway are high.<sup>26</sup>

#### Volume Control Ventilation or Assist Control

The volume control or assist control ventilation is the most commonly used mode. The patient can trigger a preset volume (tidal volume [ $V_t$ ]) after exerting enough of a negative pressure to overcome the preset trigger sensitivity. There is also a preset backup rate (frequency). Positive end-expiratory pressure (PEEP) can be used with this mode. This is a good mode at which to rest the patient during ventilation. The flow rate is also preset. Caution must be exercised in patients with hyperinflated lungs as they need time to exhale fully before the ventilator gives the next breath. Increasing the flow rate to greater than 80 L per minute will help ensure that there is enough time

for adequate exhalation. Assist control is the best mode at which to rest the patient.<sup>26</sup>

#### Synchronized Intermittent Mandatory Ventilation

If the patient is not breathing spontaneously, then there is no difference between assist control and SIMV. SIMV is also a popular ventilatory mode. It is used mainly with pressure support (see below). There is usually a preset backup rate. The patient can breathe on his or her own but has no extra support unless pressure support is also used. This mode is used to gradually allow the patient to breathe on his or her own as the rate is decreased. Many authors feel that this is a poor mode to ventilate or wean patients unless it is used with pressure support.<sup>26</sup>

#### Pressure Support Ventilation

PSV is a patient-initiated, pressure-regulated ventilatory mode. The ventilator senses the patient's inspiratory flow and will then give a volume up to a preset pressure. As the patient's flow rate decreases, the ventilator will cease its flow. Nonbreathing the patient does not trigger the ventilator, and the patient will become apneic as there is no backup rate. Here the patient can breathe spontaneously with pressure support. Pressure support can be used as a primary ventilation mode provided that the patient can initiate a spontaneous breath. To ventilate a patient, the  $PSV_{max}$  is used. This is giving enough pressure support to return 10 mL/kg ideal body weight from the ventilator. Pressure support can be used with SIMV, the so-called "SIPS" (SIMV with pressure support). Patients are usually ventilated using the assist control mode and weaned using the SIPS mode.<sup>26</sup> Table 7 contrasts the ventilator parameter for normal lungs, hyperinflated lungs, and lungs with ALI or ARDS.

### Ventilating the Patient with ALI or ARDS

Any patient who presents with bilateral infiltrates and a ratio of partial pressure of oxygen in arterial blood to fraction of inspired oxygen ( $PiO_2$ ) of between 300 and 200 (ALI) or less than 200 (ARDS), with no evidence of heart failure, must be ventilated using a lung-protective strategy.<sup>25</sup> Patients with ALI/ARDS will have some of their alveoli filled with fluid, whereas others are normal. If the usual tidal volume is given to these patients, then those normal alveoli will be overdistended, causing a production of cytokines and further damage to the lung. This will further perpetuate the systemic inflammatory response syndrome (SIRS). The ARDS Network published a large study using lower tidal volumes, which decreased the all-cause mortality by 9% and decreased the SIRS response. Low  $V_t$  (6 mL/kg ideal body

**Table 7** Difference between Ventilation of Common Disease States

Lung Type	V <sub>t</sub> (Ideal Body Weight; mL/kg)	pH Goal	Oxygen Saturation Goal (%)
Normal	8–10	7.36–7.45	92–100
Hyperinflated	8–10	7.36–7.45	92–95
ALI/ARDS	4–6	7.15–7.45	88–95
Neuromuscular disease	10	7.36–7.45	92–100

ALI = acute lung injury; ARDS = acute respiratory distress syndrome; V<sub>t</sub> = tidal volume.

weight) was used compared with 12 mL/kg ideal body weight. The plateau pressures should be as far below 30 cm/H<sub>2</sub>O as possible. Once the ALI/ARDS is diagnosed, then the lower V<sub>t</sub> is reached after 1 to 4 hours. If the plateau pressures are still above 30 cm/H<sub>2</sub>O, then the V<sub>t</sub> can be reduced to 4 mL/kg. Lower tidal volumes allow the arterial carbon dioxide pressure to rise to the so-called “permissive hypercarbia.” The respiratory rate may be increased to a maximum of 35 per minute. The pH is allowed to fall to 7 or more. The arterial oxygenation goal using this protocol is an arterial saturation greater than 88%. There is an arbitrary ratio of PEEP to FiO<sub>2</sub>. Prone positioning of patients with severe ARDS has fallen out of favor. Ideal body weight calculation for females is 45.5 + 2.5(height in inches –60) and for males is 50 + 2.5(height in inches –60).<sup>25</sup>

### Outcomes of Cancer Patients Undergoing Mechanical Ventilation

The expectations and management of cancer patients admitted to an ICU are difficult to predict. Many patients are young and may have undergone chemotherapy and radiation therapy. Physicians may not be receptive to either applying full measures or to cease these same measures when appropriate. Unfortunately, most studies of this patient group are retrospective with heterogeneous populations. Azoulay and colleagues reported on the 30-day mortality of 120 patients with solid malignancies.<sup>4</sup> This was 58.7%, with 92% occurring in the ICU. Not surprisingly, previous surgery, pulmonary edema, and remission were good prognostic factors. Knaus scale D or C, vasopressor use, and late failure from noninvasive ventilation were poor prognostic factors. This is better than previous studies. Lin and colleagues studied lung cancer patients with ARF requiring mechanical ventilation in a tertiary care hospital.<sup>7</sup> The overall mortality rate was 85.2%. The adverse prognostic features were FiO<sub>2</sub> greater than 0.6, more than two organ failures, and an APACHE III (Acute Physiology and Chronic Health Evaluation III) score greater than 70. Kress and colleagues documented 348 consecutive critically ill cancer patients from their ICU.<sup>3</sup> They looked at different common types of patients and found that there was no mortality difference between leukemia, lung cancer, or lymphoma. Neutropenia was not an independent risk factor

for death except when combined with mechanical ventilation (53%). Persistent ARF (eg, ARDS) and hepatic and cardiovascular failure predicted mortality (41%). In the bone marrow transplant group, the overall mortality rate was 39%. The mechanical ventilation and allogeneic bone marrow transplant groups had a higher mortality rate. Darmon and colleagues found that the mortality of patients with newly diagnosed malignancies who come to the ICU depends on the number and nature of the organ failure and not on the type of malignancy or extent of the malignancy at presentation.<sup>27</sup> Finally, patients over the age of 60 years have a poorer prognosis. However, selected older patients can have better prognoses.<sup>28</sup> Therefore, cancer patients should be encouraged to be treated as aggressively as possible.

### Noninvasive MVS

Noninvasive MVS has only recently been applied to oncology patients with ARF.<sup>1,5,6,8,9</sup> Thoracic societies from America, Britain, and Europe have published consensus guidelines concerning the indications for noninvasive MVS (NIPPV), contraindications, monitoring, establishing teams to provide NIPPV in the hospital setting, training, infection control, and equipment safety.<sup>29,30</sup> NIPPV delivers mechanically assisted breaths via a tight-fitting nasal, oronasal, or full facial mask without requiring intubation. The oronasal mask is the most commonly used interface, and newer designs and safer anxiolytic medications have helped patients tolerate wearing the device for longer periods of time.<sup>9</sup> The tight-fitting system allows high concentrations of oxygen to be delivered. In the machines that have been devoted to delivering NIPPV, the patient's spontaneous V<sub>t</sub> is augmented by an operator-set amount of pressure during inspiration. The inspiratory pressure commences when the machine senses a predetermined drop in airway pressure. When the inspiratory flow decelerates to a threshold value, the added inspiratory pressure ceases and the patient is able to exhale passively to an operator-set expiration pressure (PEEP level). Thus, the difference between the preset inspiratory and expiratory pressures is analogous to a pressure-supported breath delivered by a conventional ventilator. Many ventilator manufacturers have modified their standard machines to allow conventional volume and pressure-positive

pressure modes to be delivered via a mask interface. NIPPV has been well established as a preferred mode of MVS in patients with exacerbations of chronic obstructive pulmonary disease as a means of avoiding intubation and the associated higher complication and mortality rates.<sup>11,13,29,30</sup> In these patients, NIPPV not only improved hypoxemia and hypercarbia, it also reduced diaphragmatic energy expenditure and dyspnea.<sup>31</sup> NIPPV, especially in the form of continuous positive airway pressure, has also been accepted as a useful adjunct in treating patients with cardiogenic pulmonary edema. Although mortality rates were not significantly reduced, the time to resolution of the acute phase of respiratory failure was significantly shortened, whereas oxygenation improved more rapidly.<sup>11,13,32</sup> Intubation may also be avoided in the subgroup of hypercarbic patients owing to cardiogenic pulmonary edema.<sup>11,32</sup> However, its role in hypoxic respiratory failure is not as well established.<sup>11,13,30</sup>

Interestingly, one of the first patient populations with hypoxic respiratory failure in which NIPPV showed statistically significant efficacy was in immunocompromised patients with diffuse radiographic pulmonary infiltrates, fever, and ARF.<sup>8</sup> Greater than 50% of the 52 adult patients who were prospectively studied by Hilbert and colleagues had a hematologic malignancy complicated by neutropenia.<sup>8</sup> The 26 patients who were assigned to the NIPPV modality via a face mask and pressure-supported ventilator mode experienced lower mortality (relative risk reduction of 0.56; *p* = .03) and lower rates of intubation (*p* = .03). They also developed fewer (*p* = .03) fatal ICU complications, such as nosocomial pneumonia, severe sepsis, and sinusitis. These observations were similar to those of another study that randomized 40 immunosuppressed solid organ transplant recipients with ARF to NIPPV or conventional therapy.<sup>33</sup> The allure of these results led Hilbert and colleagues to suggest in a review that NIPPV may be the preferred mode of ventilation in immunocompromised patients with ARF because of the lower rates of fatal infectious complications and lower overall mortality.<sup>9,12</sup> However, in a later study that compared 26 patients with hematologic malignancies who received NIPPV for ARF with 52 case-controlled matched patients who underwent invasive MVS, there was no difference in in-hospital mortality rates (65% in both groups).<sup>6</sup>

An accompanying editorial to the Hilbert and colleagues' article warned that the indiscriminate use of NIPPV in oncology patients with ARF may be harmful.<sup>12</sup> This admonition was actually borne out in another group of patients (postextubation respiratory failure) in whom NIPPV was originally touted to be helpful but proven to be harmful because its use significantly delayed necessary reintubation.<sup>31</sup> The patients in Hilbert

and colleagues' study were highly selected.<sup>8</sup> They excluded patients who suffered multiorgan failures, uncorrected bleeding diathesis, poor neurologic status, or hemodynamic instability. In addition, NIPPV was applied early in the patients' treatment. This latter observation may be clinically relevant as evidenced by the results of Azoulay and colleagues' recent study.<sup>1</sup> When NIPPV was the only means of MVS that was required, the mortality rate was significantly less than that of invasive MVS. However, late NIPPV failure (> 3 days) and the need to change from NIPPV to invasive MVS both carried a statistically increased risk ( $p < .05$ ) of in-hospital death. Various conditions may preclude the successful application of NIPPV in oncology patients (see Table 7).<sup>13,30</sup> When a noninvasive MVS strategy is instituted, then either physiologic improvement (pH, oxygenation, or ventilation) or favorable changes in the physical examination (less tachypnea, improved thoracoabdominal coordination) should be realized within the first 1 to 3 hours if NIPPV is to be safely continued.<sup>13,b</sup> Continued use without signs of improvement has been shown to place the patient at risk of a worse outcome.<sup>12,13,30-34</sup>

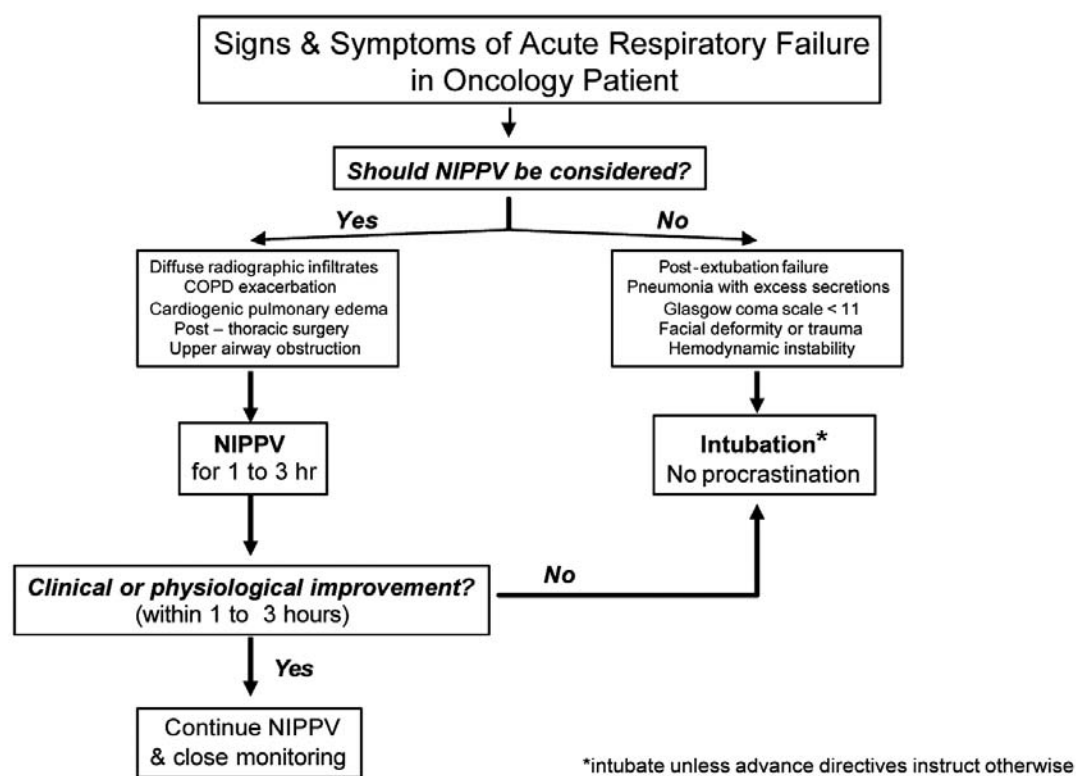

## Conclusions

As outlined in this chapter, the prognosis for adult critically ill oncology patients has significantly improved over the past decade. The more favorable outcomes also extend to patients with ARF who require MVS.<sup>1,3,5,6</sup> Although the decision to commence MVS is not always straightforward, it needs to be decided early in the course of a patient's ICU admission since delayed intubation has been associated with significantly increased mortality rates.<sup>1</sup> NIPPV offers an alternative form of MVS that may be more "acceptable" when tackling the question of whether to be "aggressive" in the care of the individual with ARF and an underlying malignancy.

**Table 8** Conditions that May Preclude the Use of Noninvasive Positive Pressure Ventilation

Hemodynamic instability
Hypotension, shock
Cardiac dysrhythmias, uncontrolled cardiac ischemia
Unfavorable patient characteristics
Inability to clear secretions
Facial abnormalities (trauma, edentulous individuals, surgery)
Upper gastrointestinal bleeding
Recent esophageal surgery
Inability to protect airway, cough, or swallow
Inability to fit or tolerate mask
Confusion or impaired consciousness
Institution's lack of experience with NIPPV

NIPPV = noninvasive positive pressure ventilation.

**FIGURE 1** Suggested approach to mechanical ventilatory support for the adult oncology patient with acute respiratory failure. COPD = chronic obstructive pulmonary disease; NIPPV = noninvasive positive pressure ventilation.

However, NIPPV is not a panacea.<sup>12,13,34</sup> Indeed, when used in the wrong clinical setting<sup>31</sup> (Table 8) or when its use is continued despite the patient showing no physiologic or clinical improvement within 1 to 3 hours,<sup>11,13,34</sup> then the patient's outcome may be negatively impacted.<sup>1,31</sup> Figure 1 outlines our approach to this vexing decision. Advances in the understanding of ARF and the application of MVS, along with better care of the airway in patients who require prolonged MVS, have contributed to attenuating the pessimism that, until recently, pervaded the clinician's thinking when treating adult oncology patients who developed ARF.

# Bronchoscopy and Lung Cancer: Diagnostic and Therapeutic Modalities

Michael J. Simoff, MD

Bronchoscopy has evolved tremendously over the past several years. It has become a more developed diagnostic tool and a more effective therapeutic one. This chapter discusses the great variety of forms that bronchoscopy has taken on in the diagnosis and management of lung cancer.

This topic is geared toward those physicians who do not practice bronchoscopy. It is important that those physicians who send patients to have bronchoscopies for diagnosis or rely on the pathologic answer for the management of their patients realize the scope of diagnostic procedures available, their advantages, and their limitations. This further understanding will enhance the capacity for management. The therapeutics section informs the physician managing cancer about interventions, which can be used in the event of an airway obstruction or the sequelae of one (eg, postobstructive pneumonia).

## History

The history of bronchoscopy is actually not that of a diagnostic tool; rather, it is a therapeutic technique. In 1897, Gustav Killian, a professor of otorhinolaryngology at the University of Freiburg, Germany, successfully removed a bone splinter from the right mainstem bronchus of a farmer using a rigid bronchoscope. His techniques and methods improved with time and expanded to different physicians and countries. In 1904, Chevalier Jackson, of Philadelphia, Pennsylvania, continued to advance the field of therapeutic bronchoscopy by improving on the equipment first developed by Professor Killian. It was not until the Ninth International Congress of Diseases of the Chest in August 1966 that Professor Dr. Shigeto Ikeda presented his new invention, the bronchofiberscope.<sup>1</sup> In the early 1970s, the fiberoptic bronchoscope went from a novelty to a routine tool in the diagnosis of diseases of the chest. It took about 70 years of use for the bronchoscope to become a diagnostic tool from its therapeutic roots. As this chapter progresses, I discuss how the future of this medically historical tool continues to evolve.

## Bronchoscope

Initially, the fiberoptic bronchoscope was just that, a bundle of about 25,000 image- and light-specific guide fibers. As recently as the early 1990s, the fiberoptic bronchoscope was still state of the art. The fibers were smaller and transmitted images and light better than their predecessors, but in many ways, they remained essentially the same scope.

The next evolution to bronchoscopy was the addition of charge-coupled device (CCD) cameras to the tips of scopes, introducing digital technology to the bronchoscopy suite. The CCD cameras permitted the development of video-bronchoscopes, which allowed bronchoscopists and their assistants to view the procedure on a television screen. As video chip technology continues to improve, the optical systems available with modern bronchoscopes also advance significantly. These new developments not only provide improved visualization, they also allow the scopes to have smaller and smaller external diameters with larger working channels through which to perform procedures, creating a more flexible and dexterous tool for working within the airways.

The modern video bronchoscope has a working length of 60 cm (Figure 1). The typical diagnostic bronchoscope (eg, Olympus P160, Olympus Inc., Tokyo, Japan) has an external diameter of 4.2 mm with a working channel of 2.0 mm. The working channel is a conduit through the length of the bronchoscope, which allows the passage of forceps, brushes, and laser fibers, to name a few. The tip of the bronchoscope can flex (bend up) 180° and retroflex (bend down) 130°. The small external diameter makes the scope more comfortable to the patient as it is routinely passed through one of the nares and more agile for the bronchoscopist to use. Larger fiberoptic bronchoscopes can be used as therapeutic and diagnostic tools. As an example, the Olympus XT160 (Olympus America Inc., Melville, NY) has an external diameter of 6.2 mm but provides a working channel of 3.2 mm. Although the additional 1.2 mm may not sound like a

significant amount of additional space, it provides a distinct advantage to the bronchoscopist performing more advanced procedures or in the event of significant bleeding in the airways. Currently, some bronchoscopes are becoming available that use hybrid technology, using fiberoptic bundles from the tip of the scope up to the handle, which is where the CCD camera chip is located to provide excellent digital images, but provide smaller external diameters and larger working channels and maintain improved flexibility.

## Diagnostic Bronchoscopy

Diagnostic bronchoscopy would be defined as those procedures and techniques that are used to make the diagnosis of disease, in the case of this chapter, specifically lung cancer. The following is a brief overview of the available techniques, their advantages, and their limitations. This review is meant to provide the nonbronchoscopist with an understanding of the everyday techniques used to diagnose lung cancer. Further discussion will then continue toward the more modern tools and advanced diagnostic techniques available commercially, as well as some that are just becoming available, to fully understand the diagnostic capabilities of bronchoscopy.

**FIGURE 1** Bronchoscope: Olympus flexible video-scope.

## Airway Examination

The object from the inception of bronchoscopy was to look into the airways. The modern flexible bronchoscope makes this much easier to do than with the still available but much less common rigid bronchoscope. Typical airway anatomy begins just distal to the cricoid within the trachea and continues branching through multiple generations to the level of the respiratory bronchioles and, finally, the alveoli. There are usually 24 to 26 generations of airways branching from the level of the trachea.<sup>2</sup> With a typical diagnostic flexible bronchoscope, the bronchoscopist can visualize down through three to five generations of airways. This limitation may seem surprising to some, but the diameter of the airways quickly gets smaller with each generation of airway and modern bronchoscopes, with diameters of 4.2 to 6.0 mm are currently limited purely by size. The use of smaller bronchoscopes, termed “thin” or “ultrathin” bronchoscopes, is currently being explored, but at this time, they would not be used in the “usual” bronchoscopic examination of the airway.

Another advantage of modern digital scopes is that as video technology continues to improve, the available CCD camera chips used to create visual images continue to improve, creating images that give detail that far surpasses previous generations of bronchoscopes. The improved optics improve the diagnostic capability of modern bronchoscopes by allowing bronchoscopists the advantage of picking up more subtle changes of the mucosa, which often mask underlying sites of early cancer growth.

What may seem obvious is that in those patients with lesions that are endoscopically visible, the diagnostic yield is greater than in those in whom the airway examination is otherwise normal. A variety of techniques can be used to sample both the visible and the, in essence, endoscopically invisible lesion. There are multiple techniques used by bronchoscopists to diagnose lung cancer. Diagnostic procedures used by the bronchoscopist obtain both cytologic and histologic samples. A significant advantage of cytology is that it often requires very little cellular material to make a diagnosis. Histologic samples, when enough tissue is acquired, can help further refine the cell type of the cancer.

## Airway Washes and Bronchoalveolar Lavage

After the airways have been examined, the bronchoscopist next begins collecting samples to make the diagnosis of cancer. The simplest of these sampling methods is merely collecting the secretions, which are always present within the airways. This random collection of secretions is both simple and of little risk to the patient but

usually is of very low yield as to making the diagnosis. The bronchoscopist may also choose to instill small amounts (10 to 40 mL) of saline into the airways before suctioning to improve the potential yield of this procedure. Reported cytologic yields of washes vary from 31.6 to 45.1%.<sup>3,4</sup>

Bronchoalveolar lavage (BAL) is another technique that uses a more directed approach to sampling of the airways for cancer cells to make the diagnosis. The tip of the flexible bronchoscope is moved into the lobe, then the segment, and eventually the subsegment that the bronchoscopist suspects as the location of the cancer. The leading edge of the bronchoscope is thus placed into a “wedge” position. This wedging seals off the bronchial tree from that point out to the level of the alveoli. Instead of just collecting the secretions that are then in this location, the bronchoscopist instills 20 to 50 mL aliquots of normal saline into this area and then suction back the instillate after allowing a short time for the liquid to move into the distal airways. Continuous suction is then used to collect the infused saline. Approximately 120 mL of collected BAL fluid is often the goal of the procedure.<sup>5</sup> Some bronchoscopists will routinely collect only 35 to 50 mL of sample for diagnosis. Typically, returns of 40 to 60% of the infused volume are achieved with this procedure. The yield can be affected by the amount of fluid instilled, the site lavaged (dependent segments having lower yields), and how well the bronchoscope was wedged.<sup>6–8</sup> BAL is only occasionally used in the evaluation of the patient for lung cancer. The few studies available report a diagnostic yield of 33 to 69%.<sup>9–11</sup>

## Cytologic Brushing

This technique uses a flexible cytology brush that is passed through the working channel of the bronchoscope and then “brushed” onto a visible lesion, blindly into an area of suspicion, or directed to a peripheral lesion under fluoroscopic guidance (Figure 2). Once the brush is placed at the location of interest, it is vigorously agitated in a back-and-forth manner. This motion assists the bristles in picking up as many cells as may be in the area, actually rubbing cells off the tumor. The brush is then removed through the working channel of the bronchoscope and is used to create slides, which are fixed with spray preservative or placed in 95% ethyl alcohol to prepare them for interpretation. Often the brush is then placed into a cytologic solution so that any remaining cells can be removed and possibly help improve the cytologic diagnosis of cancer.

As in washes, and soon to be discussed in biopsies, endobronchial tumor (visible tumor in the airway) has a higher yield when using cytologic brushing. In cases of endobronchially

**FIGURE 2** A cytology brush exiting the working channel of a bronchoscope.

visible tumor, the reported sensitivities vary from 65.9 to 84%.<sup>3,4,12,13</sup> Cytologic brushings of lesions invisible to the bronchoscopist have lower diagnostic sensitivities, from 22 to 47%.<sup>12,13</sup> Overall, cytologic techniques, including washing and brushings, add a significant amount to the diagnostic yield of bronchoscopy for lung cancer. Both of these techniques are relatively simple to perform and are low-risk procedures.

## Endobronchial Biopsy

An endobronchial biopsy is the sampling of a lesion that is endoscopically visible during the bronchoscopy. Biopsies through a bronchoscope are performed with flexible biopsy forceps, which are passed through the working channel of the bronchoscope. The forceps themselves have hinged cups with either a smooth or a serrated cutting edge. When open, the forceps have a diameter of 6 mm, allowing a reasonably sized biopsy specimen to be obtained. Once the forceps exit the distal end of the bronchoscope, there is no way to guide the forceps independent of the bronchoscope. Biopsies must therefore be performed in reasonably close approximation to the end of the bronchoscope (1–3 cm). When the biopsy forceps are passed through the working channel of a bronchoscope, they nearly occlude the working channel (normal working channel 2.0 mm, with an average forceps diameter of 1.8 mm). As the forceps are pushed out of the bronchoscope, secretions, tissue, and/or blood can be pushed out in front of the forceps, obscuring the bronchoscopists’ vision of the previously identified lesion that they want to biopsy. Owing to the size of the forceps, there is little to no room for suctioning away these secretions, making the procedure much more difficult (Figure 3).

It is not uncommon for the bronchoscopist to see a lesion in the airway that can be reached using forceps and/or a brush to sample for diagnosis. Although it may seem simple to make a diagnosis at this point, it is not always true. The reported diagnostic yield of endobronchial biopsy for bronchogenic carcinoma ranges from 73 to

**FIGURE 3** Biopsy forceps exiting the working channel of a bronchoscope.

96%.<sup>14–19</sup> Nonbronchoscopists may ask why the yield is not 100% if you can see the lesion. The answer is that although sometimes a lesion can be seen, its position in the airway makes it difficult, if not impossible, to direct biopsy forceps or a brush into the location of the lesion. Second, many rapidly growing cancers have necrotic slough and tissue on their surfaces, and the initial samples, or possibly all of the samples, may be of this material, which will not provide a histologic diagnosis. Lastly, owing to the fact that the “view” of the lesion may change as discussed above, it is recommended that three to five biopsies of an endoscopically visible lesion will give the highest sensitivity (90–100%) for this diagnostic procedure.<sup>19,20</sup> If less than four biopsies are performed, the diagnostic yield for this procedure can be reduced, thereby potentially not yielding a diagnosis.<sup>18</sup>

### Transbronchial Biopsy

The solitary pulmonary nodule or, in many cases, the large radiologically evident mass has to be biopsied for diagnosis. This requires performing biopsies on lesions that are not endoscopically visible; instead, using previously performed chest radiographs and computed tomographic (CT) scans, bronchoscopists must identify very specifically where they believe the lesion to be within the lung and, subsequently, which airways will lead to it. This procedure is known as transbronchial lung biopsy. Procedurally, it entails entering the airways with the bronchoscope, identifying the appropriate lobar, segmental, and subsegmental bronchi that will direct the biopsy forceps toward the previously identified lesion. Once the bronchoscope is in place, the tip of the bronchoscope is advanced until it can advance no further. This positioning is known as a wedge position. The advantage of the wedge positioning is that it will leave the bronchoscope in one place for the entirety of the procedure, allowing repeated introduction of biopsy forceps, a cytology brush, or other diagnostic tools the bronchoscopist chooses to use. The added benefit is that if there is

significant bleeding, it is localized and controlled within the airways distal to the tip of the bronchoscope, minimizing the risk to the patient.

Once in position, many bronchoscopists will use fluoroscopy to assist with transbronchial biopsies. Fluoroscopy can be performed in a single plane, or, to improve accuracy, several planes can be used to assist in the three-dimensional assessment of the lesion and the location of the bronchoscope in the chest. The lesion is first localized with fluoroscopy. The bronchoscope tip is then assessed for proper positioning in relation to the lesion. The forceps (or other diagnostic tool) are then watched moving toward and optimally directly into the desired lesion. Once in position, the forceps are drawn backward, opened, and moved into position (Figure 4). Many bronchoscopists like to observe the lesion being tugged by the forceps as the biopsy is taken fluoroscopically.

Many factors influence the diagnostic yield of transbronchial biopsy techniques. The first is the size of the lesion to be biopsied. As might be expected, the smaller the lesion, the lower the diagnostic yield. For those peripheral tumors less than 2 cm in size, the diagnostic yield is 28 to 30%. Tumors greater than 2 cm but less than 4 cm in diameter have a diagnostic yield of 64%, and those greater than 4 cm up to 80%.<sup>21–25</sup> The number of biopsies performed also influences the diagnostic yield of transbronchial biopsies. Diagnostic yields of 21 to 52% are reported when four or fewer biopsies were taken for a peripheral lesion (size indeterminate). This is compared with a diagnostic yield of 70 to 78% when more than four biopsies were taken during the bronchoscopic procedure.<sup>26–28</sup>

As might be expected, blind biopsies into the lung parenchyma, even when fluoroscopically guided, have risks. The two greatest risks with transbronchial biopsies are bleeding and pneumothorax. The reported risk of pneumothorax is 3 to 5%. The use of fluoroscopy reduces the risk of pneumothorax versus blind procedures.<sup>29–32</sup>

**FIGURE 4** Fluoroscopic image of a transbronchial biopsy.

Bleeding in excess of 50 mL is considered significant when induced by a bronchoscopic biopsy. There is a less than 3% risk of serious bleeding with transbronchial biopsies. When the procedure is performed by maintaining a good wedge position, the risk to the patient of a poor outcome is significantly reduced.<sup>29,31,32</sup>

### Transbronchial Needle Aspiration

Transbronchial needle aspiration (TBNA) is another technique to assist in the diagnosis of patients with lung cancer. This technique is used when the mass in question lies outside the bronchus. TBNA can be used to sample centrally located masses, lymph nodes, and peripheral tumors. TBNA can be used for cytologic or histologic samples. A number of different types of needles are available for this technique, each with specific characteristics to maximize efficiency when using them. The two most common types of needles are the 22-gauge cytology needle and the 19-gauge histology needle.

Both needles are 1.9 mm in diameter. They are passed through the working channel of the bronchoscope with the needle withdrawn into the needle sheath. Once the hub of the needle has been passed out of the end of the bronchoscope, the needle can be exposed. The cytology needle is 13 mL long. The histology needle actually has a 21-gauge needle inside its core. When projected, this 19- or 21-gauge needle is 18 mm long; once the 21-gauge needle is withdrawn, the 19-gauge needle is 15 mm long (Figure 5). The tip of the TBNA needle (any size) is then placed against the wall of the bronchus (in approximation to the node or tumor that the bronchoscopist wishes to sample) and is pushed through the wall as perpendicular to the mucosa as possible to maximize the depth of penetration of the needle. The initial concern of most newcomers to TBNA is that this procedure must have a high risk of the development of pneumothorax and bleeding. This is actually incorrect; there are only two reported cases of pneumothorax in the literature, with a

**FIGURE 5** A transbronchial needle aspiration needle exiting the working channel of a bronchoscope.

reported risk of pneumothorax of 1.4%.<sup>33,34</sup> The risk of bleeding is also very small. To illustrate this, it is best to look at invasive cardiac and hemodynamic studies performed via the airways in the 1940s and 1950s. Large-bore needles were used to penetrate the bronchial wall and then directed into the pulmonary artery, aorta, and/or the left atrium to perform various imaging and/or hemodynamic measurements.<sup>35,36</sup> With these significantly more invasive studies, there were no reported deaths or major complications of bleeding. There is actually only one reported hemomediastinum as a result of TBNA.<sup>37</sup>

TBNA is an excellent procedure for the diagnosis of lung cancer. The procedure has a degree of operator variability in the potential diagnostic yield. Reported yields in the literature vary from 38 to 73%,<sup>38–40</sup> and when a mucosal abnormality or external compression of the airway was evident, there was a reported positive aspiration yield of 88%.<sup>41</sup> As pulmonologists continue to gain experience with this procedure, the number of mediastinoscopies can be reduced for the mediastinal staging of lung cancer. In experienced hands, the bronchoscopist can clearly stage the mediastinum, minimizing further invasive procedures for our patients with lung cancer.

TBNA can also be used as part of the evaluation of a solitary pulmonary nodule. The use of the smaller, 22-gauge cytology needle for peripheral lesions is the ideal tool. After the bronchoscope is wedged, as above, the needle is passed through the working channel of the bronchoscope and extended toward the lesion. The needle is then extended and pushed into the tumor being assessed. The diagnostic yield of this procedure is up to 35%.<sup>27</sup> Other reports further define the yield as it relates to the size of the lesion. Shure and Fedullo differentiate between lesions less than and greater than 2 cm.<sup>42</sup> The yield for TBNA when tumors were less than 2 cm is 33% and 76% for those greater than 2 cm. Another study uses the cutoff of 3 rather than 2 cm and found the diagnostic yield of tumors less than 3 cm to be 27.5% and 65.5% for lesions greater than 3 cm.<sup>43</sup>

TBNA is a necessary procedure for the evaluation of patients with lung cancer. Overall, this technique is an excellent addition to the evaluation of patients with a lung mass or mediastinal lymphadenopathy, for the diagnosis of primary disease, and the staging necessary for management.

### Bronchoscopy: Putting It All Together

Individually, each of the procedures discussed above is good for the diagnosis of lung cancer. Clinically, however, most or all of these procedures are used at the discretion of the bronchoscopist performing the procedure. Aggressive bronchoscopists will almost always use several techniques to maximize the chance of making a

diagnosis at the time of the first bronchoscopy. Several studies demonstrate a much greater opportunity to diagnose lung cancer with the combination of several techniques, some with up to 80% diagnostic yields.<sup>22,24,44–46</sup> A combination of a biopsy (endobronchial or transbronchial), brushing, and washings (or BAL) should be considered the standard bronchoscopic approach in making the diagnosis of lung cancer. If there is lymphadenopathy on the CT scan of the mediastinum or hilum, TBNA should also be performed to maximize the chance of staging and diagnosing the patient with one procedure.

The procedures, which were discussed above, are routine in most medical centers. Those to be discussed below are available at only a few referral centers. These advanced diagnostic procedures are excellent additional techniques for the diagnosis and management of patients with lung cancer. As clinical experience with them continues to grow, they may become part of mainstream diagnostic bronchoscopy.

### Autofluorescence Bronchoscopy

Despite advancements in chemotherapeutic agents, radiation, and surgical techniques, the recurrence rate of lung cancer is 3.6 to 4% per year. Second primary tumors occur in 17% of patients within 3 years of treatment of their primary disease.<sup>47,48</sup> With 10 to 20% of patients having a second primary tumor or recurrence, it suggests a more complicated process than a single tumor alone. The pathologic changes of dysplasia, carcinoma in situ, and microinvasive carcinoma are very superficial. These changes develop in the intraepithelial to superficial submucosal layers of the bronchial wall. The diagnostic yield of finding these subtle visible changes with standard white light bronchoscopy is actually quite low. To improve the yield of identifying these changes requires a new diagnostic tool.

Autofluorescence uses a little known and very weak physical property of light: fluorescence. Fluorescence is always present with visible light, but it is 10,000 times dimmer than reflected light and as such is not visible to the naked eye or with standard bronchoscopy. Autofluorescence is a property of the upper submucosa, the same anatomic location of many early cancers.

Autofluorescence bronchoscopy is achieved by stimulating certain cells within the submucosa, called fluorophores. The fluorophores are stimulated by light of 390 to 460 nm (blue light), which excites them to a higher energy level. With a rapid decay from the excited state, light of predominantly 520 nm (green) and to a lesser extent 630 nm (red) is released. When the airway is visualized in autofluorescence, the airways appear green. Owing to a variety of physical characteristics of light and pathologic changes secondary to the development of a cancer, a precancerous

lesion, and microinvasive cancer, all appear red (Figure 6).

In reviewing 11 clinical studies including 1,084 patients, the sensitivity of white light bronchoscopy to autofluorescence bronchoscopy was found to be 52.4 to 84%, respectively, for the identification of early endobronchial lesions.<sup>49–58</sup> Autofluorescence is an excellent clinical tool for the detection of early lung cancer. As its popularity continues to grow, we will find more and more applications for its use. Its greatest limitation lies in the fact that only several generations of the airways can currently be examined with a bronchoscope; therefore, we can see only some of the problems that exist.

### Endobronchial Ultrasonography and Endobronchial Ultrasonography–Directed Transbronchial Biopsy

Endoluminal ultrasonography has been established as a routine diagnostic procedure in many fields of medicine owing to its diagnostic advantages over traditional radiologic evaluations.<sup>59</sup> This is especially true of gastrointestinal endoscopy. Ultrasound imaging is generated owing to the difference in resistance of various tissues to ultrasound waves (impedance). The different impedance of various soft tissues has made ultrasonography an indispensable diagnostic tool in medicine.

Two techniques exist to perform endobronchial ultrasonography (EBUS) within the airways. The first is the use of a 20 MHz transducer that uses a saline-filled balloon to eliminate an air-transducer interface, allowing delivery of the ultrasound waves to the tissue. This technique allows a 360° image of the parabranchial and paratracheal structures. Under favorable conditions, structures at a distance of up to 4 cm from the probe can be visualized.

The second technique uses a 7.5 MHz linear array transducer, which is built into the tip of a flexible bronchoscope. As the bronchoscopist is inspecting the airways, he or she can put the ultrasound probe up against the wall of the airway and visualize structures (eg, lymph nodes, tumors, blood vessels). This bronchoscope has another advantage in that a specially designed transbronchial needle can be used to sample lesions under direct ultrasound visualization. This bronchoscope is, in essence, the same as the endoscopic ultrasound gastroesophagoscopes used by gastroenterologists. By visualizing the target tissue and watching its sampling, it is hoped that greater and greater yields can be obtained with diagnostic bronchoscopy. Indications for the use of EBUS can be reviewed in Table 1.

EBUS has been used in the evaluation of patients with small radiologically invisible tumors, in which the physicians will use endobronchial therapy alone to manage the disease.<sup>60–62</sup> EBUS is

**FIGURE 6** A, White light bronchoscopic image of carcinoma in situ. B, Bronchoscopic autofluorescence of carcinoma in situ. The normal airway is seen as green; the red/brown discoloration in the center of the image is the carcinoma in situ.

**Table 1** Indications for Endobronchial Ultrasonography

Peripheral lesions

also used in the localization of peripheral tumors, which are not endoscopically visible, to improve the yield of transbronchial biopsy procedures.<sup>63,64</sup> The use of the 20 MHz system has been shown to improve identification of mediastinal lymph nodes, also improving yields of TBNA.<sup>65,66</sup> The use of directional ultrasonography has not been studied enough to demonstrate its potential addition to the technique of blind TBNA. Lastly, EBUS has been used to differentiate between tumor approximation and tumor invasion of mediastinal structures. In a prospective study, it was demonstrated that differentiation of external tumor invasion versus impression of the tracheobronchial wall by EBUS was reliable in 90% of patients compared with contrast CT (50%).<sup>67</sup> This may help influence the management of lung cancer patients who were initially thought to be unresectable, allowing them the opportunity to go to the operating room for a more definitive therapy.

Overall, EBUS is not yet a routine tool in most institutions. Its acceptance and popularity continue to grow in face of the advances being made in this tool and the corresponding bronchoscopes. The use of this technology will continue to grow with respect to managing cancer of the chest.

### Future Techniques

Despite continued advancement in diagnostic techniques and treatment protocols, lung cancer remains the number 1 cancer killer. With this in mind, we must continue to look forward in our goal of discovering, diagnosing, and treating this disease. A few of the novel diagnostic tools being clinically explored are now discussed. The first tool is electromagnetic navigation. Electromagnetic navigation is a new technology to allow improved manipulation throughout the airways to approach a peripheral lung lesion. This technology incorporates the merging of CT with three-dimensional generation imaging, an electromagnetic field formed around the patient's body, and a directional probe, which is bronchoscopically placed into the airways.

Electromagnetic navigation is currently entering more complete clinical trials. The technology is very exciting for the sampling of not only peripheral lesions but also adding the capacity of potentially using therapeutic modalities at the time of the original biopsy. There is also promise for mediastinal node sampling to be enhanced with concurrent use of this very exciting tool. There is limited clinical experience at this time with external navigation systems, but, in the future, this technology will very likely play an important part in the diagnosis and, it is hoped, management of lung cancer.<sup>68</sup>

Another area of possible future advancement in bronchoscopy is that of "optical biopsies." Optical biopsying is actually a variety of techniques that fall under this very unusual heading. An optical biopsy is actually the use of structural imaging technology, which depends predominantly on the scattering properties of light at a tissue interface. This technology includes optical coherence tomography (OCT), confocal microscopy, and light-scattering spectroscopy.

OCT is discussed here as it has entered the phase of clinical trials. This technology is in many ways analogous to ultrasonography, but instead of sound, it measures the intensity of back-reflected infrared light. As it is light, there OCT does not require direct contact with tissue or a transducing medium and can be performed through air, which is ideal for the lungs. In essence, OCT performs a high-resolution assessment of tissue microstructure. The images produced are equivalent to a low to moderate mechanical-level biopsy obtained during diagnostic procedures at the micron scale of resolution. The goal would be to "look" at a mass in the airways and diagnose it as a cancer to being therapy at the time of the original bronchoscopy, without having to wait for sample processing.<sup>69,70</sup>

Electromagnetic navigation and OCT are two of the potential tools being developed for the bronchoscopic diagnosis of lung cancer. The future would have us looking toward early, more complete diagnosis and staging, with possible nonsurgical approaches to the treatment and cure of the solitary pulmonary nodule.

### Therapeutic Bronchoscopy

#### Setting for Intervention

Most of the estimated 173,770 new cases of lung cancer diagnosed in the United States in 2004, accounting for 13% of all new cancer cases, will be in an advanced stage.<sup>71</sup> Central airways disease can be in the form of bulky endobronchial disease, endobronchial extension of cancer, or extrinsic compression of the airways by the tumor or lymphadenopathy. Shortness of breath, hemoptysis, and cough are frequent complaints of patients with lung cancer. Those patients with an endobronchial component to their disease may benefit from a bronchoscopic intervention as part of the management of their disease.

Not all endobronchial disease causes complete obstruction of the airways. Sometimes patients have partial obstruction, which often has a less severe symptom complex. As these patients enter treatment programs, the endobronchial component of their disease, in response to these treatments, can lead to more complicated concerns. External beam radiotherapy can induce endobronchial inflammation and swelling, further compromising the airways. Radiation or chemotherapy can lead to necrosis of the endobronchial component of the cancer. The inflammation and necrotic tissue can cause further airway compromise by inducing airway obstruction, lung collapse, and possible postobstructive pneumonia. Therefore, endobronchial techniques should be considered throughout the management of lung cancer patients.<sup>72,73</sup> Many studies not only demonstrate improvement in clinical symptoms and quality of life, they also suggest

increased overall survival with the use of endobronchial management techniques.<sup>74-87</sup>

Lastly, when all management options have been used, end-stage patients will often develop compromise of their airways as the cancer continues to progress.

Endobronchial management options may help relieve some of their symptoms, allowing them freedom from shortness of breath as they go home in conjunction with hospice or other palliative therapies.<sup>88-90</sup>

Most endobronchial techniques are performed on an outpatient basis. Unless a patient presents with respiratory failure, many of the procedures performed provide immediate relief of symptoms. This rapid symptomatic improvement allows patients to return home with an improved quality of life or better prepares them to continue treatment at their local programs. Although interventional procedures are not definitive therapies, they often provide partial to total relief of the strangling sensation produced by complete airway occlusion.

Interventional pulmonology is the practice of advanced techniques via a bronchoscope and thoracoscope. The direction of this chapter again concentrates on bronchoscopic techniques. Programs that include endobronchial procedures need an armamentarium of therapeutic modalities rather than a single invasive approach to manage patients with complicated lung cancer. As each patient's anatomy differs, the manner in which the patient's cancer leads to symptoms varies. Several procedures used in conjunction (ie, laser and stenting) may be necessary to provide the most efficacious management of the disease. Offering a multitude of modalities allows the best selection of approaches for the patient.<sup>88,89</sup>

The following sections discuss a variety of techniques and tools available to the interventionalist for the endobronchial management of lung cancer. In many cases, no one technique is better than the others; most often, some combination of these techniques offers the greatest benefit to the patient.

## Bronchoscopy

Since the inception of flexible fiberoptic bronchoscopy in the late 1960s in Japan and in 1970 in the United States, the flexible bronchoscope has become the most widespread tool for evaluating and diagnosing diseases of the airways and lungs.<sup>1</sup> The rigid bronchoscope, the flexible bronchoscope's predecessor, was in many regards forgotten as a tool until interventional pulmonology evolved in the 1980s. Interventional pulmonologists reevaluated this tool and found its properties advantageous to the procedures that are currently performed. A survey in 1991 by the American College of Chest Physicians reported that only

8% of responding pulmonologists used a rigid bronchoscope.<sup>91</sup>

Overall, concurrent use of the flexible bronchoscope with the rigid bronchoscope is necessary for the practice of interventional pulmonology. The rigid bronchoscope offers many advantages to the interventional pulmonologist, one of which is the superior control of the airway achieved with its use. Ventilation is performed through the scope itself rather than around the flexible bronchoscope. The larger-bore rigid bronchoscopes allow optical systems, large-caliber suction catheters, and the laser to pass through the scope simultaneously. Large rigid biopsy forceps are used through the rigid bronchoscope, which can provide more significant tissue biopsies and assist in mechanical debulking of lesions. However, the rigid bronchoscope is a more difficult tool to use that requires additional training. In addition, rigid bronchoscopy is most commonly performed in the operating room requiring general anesthesia, making the logistics of its use difficult for many. Overall, in difficult airway conditions, rigid bronchoscopy is an excellent technique for the management of endobronchial disease.

The rigid bronchoscope can be used not only as a delivery device of therapeutic tools; the scope itself can be used as a tool in the management of endobronchial disease. The distal end of the bronchoscope has a beveled end. This edge can be used to shear large sections of endobronchial tumor away from the airway wall in a technique often referred to as "applecoreing." Mathisen and Grillo described their experience with 56 patients with endobronchial obstruction from the trachea to the distal mainstem bronchi.<sup>92</sup> After an applecoreing application of the rigid bronchoscope, they reported an improvement in 90% of their patients. Only 3 of the 56 patients had more than minor bleeding with this procedure. Although this procedure is technically difficult, applecoreing combined with the use of larger biopsy forceps allows the tumor to be quickly resected from the obstructed airway.

## Ablative Techniques

This includes all of those technologies used in the debulking and/or resection of endobronchial cancer. They include laser, electrocautery, argon plasma coagulation, cryotherapy, and photodynamic therapy. Each is discussed below.

### Laser Therapy

Laser is an acronym derived from light amplification by stimulated emission of radiation. Lasers have many medical uses, including the endobronchial management of lung cancer. The most common laser used within the bronchi is the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser. The potassium-titanyl-phosphate

and diode lasers are also occasionally used. As in all lasers, the Nd:YAG laser delivers a very specific wavelength of light, 1,064 nm. This wavelength allows the laser energy to be conducted via a quartz monofilament and thus can be easily used with either the rigid or the flexible bronchoscope. Normally, the Nd:YAG laser is used at 30 to 60 watts, but it has a wide range of power outputs, up to 100 watts. Depending on the energy level used, the laser can affect tissue several millimeters to several centimeters in depth (Figure 7).

The predominant tissue effects of Nd:YAG lasers are thermal necrosis and photocoagulation. Of these, photocoagulation is the most commonly used effect. Using lower energy levels, the surface of the tumor is heated, causing shrinkage of the tumor and diminishing the blood flow to that region. By devascularizing the tumor, more rapid mechanical debulking can be performed, with improved control of bleeding.

Thermal necrosis uses higher energy levels to destroy tissue, causing the formation of eschar. The problem with this approach is that most tumors are significantly vascular, and in destroying tissue with laser energy, large blood vessels can also be destroyed. These blood vessels may then perforate with the tissue destruction, leading to significant hemorrhage and an increase rather than a decrease in morbidity and mortality with this procedure. Despite this, cautious use of the thermal necrosis technique of laser therapy can be safely and efficiently used in the airway.

Ablative therapy with a laser can be performed via flexible or rigid bronchoscopy. The majority of interventionalists use rigid bronchoscopy as the predominant tool for the performance of laser procedures when possible owing to the ease of the debulking part of the procedure. Using the flexible bronchoscope, the Nd:YAG fiber can be passed through the working channel, and thereby energy can be delivered to areas that cannot otherwise be reached with the rigid bronchoscope.<sup>74-87,92</sup>

The reported success rate of symptom palliation using laser energy in the endobronchial management of lung cancer is high. Reports of

**FIGURE 7** A laser fiber exiting the working channel of a bronchoscope.

clinical improvement rates range from 84 to 92% following laser bronchoscopy.<sup>78,81,93–95</sup> Further review of the literature identifies studies that demonstrate improved survival in patients treated with laser bronchoscopy.<sup>80,84,85,96</sup> Brutinel and colleagues compared 25 historical controls (ie, patients who would have been candidates for laser management but did not receive it secondary to the unavailability of the procedure at the time of their management) with 71 patients treated with laser bronchoscopy as part of the treatment program.<sup>80</sup> The authors reported 76 and 100% mortality rates at 4 and 7 months, respectively, in the control population. In the group treated with laser bronchoscopy, survival rates at 7 months and 1 year were 60% and 28%, respectively. Although no definitive randomized studies are available, review of historical studies would suggest improved survival in patients treated with endobronchial techniques.

#### Electrocautery

Electrocautery is another ablative technique available to the interventional pulmonologist. Similarly to laser, thermal energy is used to cauterize and/or cut through tissue. This thermal effect is secondary to the resistance of tissue to the flow of electrical current. This phenomenon leads to tissue temperatures elevating to 160°F (71°C), with cellular or tissue destruction. Electrocautery delivers electrical energy via one of several introducer devices to cut and/or destroy tumor cells. The various tools of electrocautery can be introduced through a rigid or flexible bronchoscope (the bronchoscope must be grounded to prevent the physician operator from receiving electrical energy). The tools include a blunt probe for delivering higher-level electrical energy and destroying tissue; a “hot” forceps, which can cauterize before debulking or biopsying; a snare that cauterizes as it cuts; and an electrocautery scalpel for resecting tumor. Electrocautery techniques continue to gain popularity, and its use continues to spread.<sup>97</sup>

#### Argon Plasma Coagulation

Argon plasma coagulation (APC) is another electrically based technique. Instead of using one of the varieties of contact probes available for electrocautery procedures, the APC is a form of non-contact electrocautery. Argon gas is ionized as it exits the delivery catheter. This ionized argon gas then acts as a conductor for the electrical energy being delivered. The advantages of this system are that the electrical energy can be used to “paint” the surface of the tumor, cauterizing the entire surface quickly (similar to a laser). Depending on the energy level used, the cauterizing effects of APC can penetrate 3 to 5 mm of the tumor surface. The added benefit to this tool is that the

argon, being a gas, flows as any gas and therefore can form eddies around corners. When the proper orientation of flow across an obstruction is used, this eddying allows cautery around corners to maximize the surface area being covered.<sup>98</sup>

#### Cryotherapy

Cryotherapy differs from the other ablative techniques thus far discussed in its use of cold rather than heat to destroy tissue. A probe is placed through a bronchoscope and then onto or directly into an obstructing tumor mass. The probe tip is cooled by the use of either liquid nitrogen (–196°C) or nitrous oxide (–80°C). Tissue freezing causes destruction of all cells in an area of approximately 1 cm in diameter around the probe tip. Vascular thrombosis occurs with the supercooling of tissue, minimizing bleeding during resection of the tumor.

Overall, cryotherapy is an excellent technique for tumor ablation. One of the limiting factors to the use of cryotherapy is that the tissues destroyed with the freezing take 24 to 36 hours to die and necrose. This therefore requires repeating the bronchoscopy in 36 to 48 hours to remove the necrosed tissue. In many cases, repeat treatments with cryotherapy are performed at the time of the second bronchoscopy, requiring a third debulking. Although cryotherapy is effective at tumor destruction and management, the necessity of repeated procedures makes this a more time-consuming procedure to perform, limiting its usefulness in the management of symptomatic bulky endobronchial disease.<sup>99</sup>

#### Photodynamic Therapy

Photodynamic therapy (PDT) is an important adjunctive modality to the management of endobronchial lung cancer. PDT can be used with bulky disease, but most interventionalists feel that it is of limited benefit in this role.<sup>100,101</sup> The most suitable lesions for PDT are in situ carcinomas or those limited to 4 to 5 mm of microinvasion.<sup>102</sup>

PDT requires that a photosensitizing drug be intravenously administered to the patient 48 to 72 hours prior to the procedure. Porfimer sodium (Photofrin) is the most common agent currently used for this. This photosensitizer penetrates all cells systemically. Photofrin is not cleared as quickly in cancer cells as in the other cells of the surrounding tissue 48 to 72 hours after injection and is therefore found in higher concentrations in cancer cells as opposed to the endothelium surrounding the tumor.<sup>102,103</sup> An argon dye laser is then used to provide a 630 nm wavelength of light energy to activate the intracellular porfimer sodium. The laser energy is transmitted via a flexible quartz fiber, which can be used through a flexible or rigid bronchoscope. The fiber tip can

be placed in close approximation to the tumor with a directed or cylindrically diffused laser delivery, or it can be imbedded into the tumor to provide the energy needed to start the intracellular activation of the porfimer sodium. This reaction leads to cellular destruction by a variety of mechanisms. Tissue necrosis then ensues as the cancer cells die over the next 24 to 36 hours.<sup>102–104</sup>

As the neoplastic tissue necrotizes, it must be removed by repeated bronchoscopies. Flexible bronchoscopy is commonly performed daily or every other day for up to 1 week to remove the necrotic tissue. The necrosis of bulky tumor can be dangerous to the patient if the necrotic tissue separates from the bronchial wall and occludes the airway. In some programs that use only PDT, patients remain intubated following the procedure for 1 to 2 days secondary to this concern. If necrotic tissue is removed over the first 24 to 48 hours, a second laser application to the cancer can be performed, thus improving the cancer tissue destruction. PDT is an excellent therapeutic modality for patients with early-stage cancers. It destroys neoplastic tissue effectively and is an outstanding therapeutic modality in carcinoma in situ and microinvasive cancers. PDT is a necessary tool in our armamentarium of endobronchial treatments, but the time delays and multiple steps of management make it a more cumbersome therapy for the management of late-stage endobronchial lung cancer.<sup>104</sup>

A great limitation to the use of PDT is that the drug stays not only in tumor cells for an extended period of time but also in the skin and cells of the eyes. This therefore makes patients photosensitive, not only to the argon laser but also to any source of white light, most significantly sunlight, which contains light with wavelengths of 630 nm. Patients must therefore stay out of all forms of white light for at least 6 weeks to prevent damage to their skin and/or eyes. If a patient were to have advanced disease, this limitation to the patient's life seems very cumbersome indeed. Owing to PDT's excellent management of early disease, the inconvenience may well be worth it.

#### Endobronchial Prosthesis

Endobronchial prostheses are most often referred to as stents, which can be used in several clinical situations: intrinsic, extrinsic, or mixed endobronchial obstruction. Stents work well in conjunction with other modalities, such as laser and mechanical debulking of tumors. Currently, there is no one perfect stent. The stents clinically available are composed of Silastic rubber, metal alloys, and hybrids of materials. The advantages and disadvantages of each stent type are noted in Tables 2 and 3.

**Table 2** Advantages and Disadvantages of Silastic Stents

<b>Advantages</b>
Removable and replaceable
No growth through stent
Low cost
Low likelihood of granulation tissue formation
<b>Disadvantages</b>
Potential for migration/dislodgment
Rigid bronchoscopy needed for placement
Possible secretion adherence

**Table 3** Advantages and Disadvantages of Metal Stents

<b>Advantages</b>
Easy to place
Good wall–internal diameter relationship
Powerful radial force
Excellent conformity for irregular tracheal or bronchial walls
Good epithelialization
<b>Disadvantages</b>
Permanent
Tumor regrowth (noncovered)
Possible migration of covered stents
Significant granulation tissue stimulation
Epithelialization affecting wall mechanics and secretion clearance
Radial force causing necrosis of bronchial wall, erosion, fistulae, perforation

### Silastic Stents

In 1990, Dumon reported the use of what is now referred to as the Dumon stent (Bryan Corp., Woburn, MA).<sup>105</sup> Developed in 1987, it is a Silastic stent with evenly spaced studs along its outside walls (Figure 8). These studs not only assist in maintaining placement of the stent in the airway, they also allow the clearance of secretions around the walls of the stent. Although the use of expandable wire mesh stents is increasing, the Dumon stent remains the most commonly used stent worldwide.

**FIGURE 8** A, Dumon tracheobronchial stent. B, Dumon Y stent.

When placed endobronchially, the Dumon stent is effective in maintaining the structural integrity. Its solid walls prevent tumor growth from reobstructing airways. Endobronchial tumors are often debulked, and then a stent is placed to relieve the airways obstruction. This can be performed prior to the initiation of radiotherapy and/or chemotherapy. This may afford the patient a clinical advantage owing to the improved ability to breathe. Patients may be able to tolerate more aggressive treatment programs owing to their improved ability to breathe.

Another advantage of the Dumon stent is its ease of removal. This can be significant when endobronchial procedures are used early in the management of cancer patients. After definitive therapies have been used (radiation, chemotherapy), reevaluation of the airway can be performed, and the stent can be left in place, removed (if deemed of no further clinical advantage), or replaced with a larger stent that would further improve the caliber and stability of the airway. The disadvantages of the Dumon stent are the potential for migration and the need for a rigid bronchoscope for placement. The migration issue, although often referred to, occurs less often when an experienced interventional endoscopist places the stent.<sup>105–111</sup> In regard to the need for rigid bronchoscopy, the number of interventional pulmonologists using this technique is small but continues to grow.

Other Silastic stents include the Hood stent (Hood Laboratories, Decatur, GA) and the hybrid Rüschi Y stent (Rüsch Inc, Duluth, GA). The Hood stent is similar to the Dumon stent in design and use. The Hood stent (Figure 9) is placed in the same manner as the Dumon stent.<sup>112</sup>

The Rüschi Y stent (Figure 10) is a Silastic stent with stainless steel C-rings that artificially replicate the cartilage. The posterior wall of the stent is made of a thinner Silastic plastic to make it more functional, similar to the membranous trachea itself. The three available sizes of this stent are designed to traverse the entire length of the trachea with branches into the right and left

**FIGURE 9** Hood bronchial stent.**FIGURE 10** Rüschi Y stent.

mainstem bronchi. The Rüschi Y stent requires rigid bronchoscopy and a special delivery device. This stent is difficult to place and remains uncommon in clinical practice.

### Metallic Stents

Metal stents, such as the historical Gianturco (Cook Inc, Bloomington, IN), Palmaz (Johnson & Johnson Interventional Systems, Warren, NJ), and Wallstent (Schneider Inc, Minneapolis, MN) stents, as well as the commonly used Ultraflex (Boston Scientific, Natick, MA) stent and soon to be released Alveolus stent (Alveolus Inc., Charleston, SC), have been used in the endobronchial management of lung cancer.

The advantage of metal stents is the relative ease of placement via a flexible bronchoscope with or without fluoroscopic assistance. This ease of placement allows some bronchoscopists to use these stents as their sole modality in the management of endobronchial disease. This practice, however, limits the options to patients that may otherwise be available if all interventional modalities are considered. The wire mesh design of many of the original metal stents did not prevent the tumor from growing through the stent over time. The Ultraflex and Alveolus stents are both available covered. The wrap is applied to the outside of the wire mesh to prevent tumor invasion through the stent.<sup>106,107,113–115</sup>

**FIGURE 11** A, Ultraflex uncovered stent. B, Ultraflex covered stent.

The Ultraflex stent is made of nitinol, a titanium and nickel alloy, which has little bioreactivity. This stent has an excellent inner to outer diameter and conforms well to various airway shapes, maintaining an equal pressure along the entire length of the stent. The Ultraflex stent is available in a variety of lengths and diameters. It is available in both covered and noncovered forms. The covered stent uses a polyurethane wrapping around all but the proximal and distal 1 cm of the stents. The covered version of this stent is excellent for use in the palliation of airway obstruction in lung cancer patients (Figure 11).

The Alveolus stent is also a wire mesh stent. At the time of the writing of this chapter, this stent is not commercially available, although it should be in the near future. This stent is also made of nitinol but is completely covered, preventing all tumor ingrowth. This stent's design characteristics make it very promising, but no clinical studies exist to validate its use (Figure 12).

Stents are effective tools for the endobronchial management of lung cancer. The choice of which stent to use should be made carefully, weighing the advantages and disadvantages of each so that the proper tool is used in all situations. Multiple stent types need to be available to the endoscopist to allow the proper choice for the appropriate clinical situation.

**FIGURE 12** Alveolus stent.

## Conclusion

Bronchoscopy has expanded the bounds of the innovative thinkers who created this wonderful technique. The goal of this chapter was to introduce the techniques and technologies of both diagnostic and therapeutic bronchoscopy. Both areas continue to evolve, with the goal of new innovative thinkers being the earliest conceivable detection of lung cancer, with the opportunity to treat it more aggressively and, it is hoped, more successfully.

# Direct Neurologic Complications of Cancer

Robert Cavaliere, MD  
David Schiff, MD

Neurologic complications of systemic cancer are common and widely recognized. The entire neuraxis, from the muscle to the cerebral hemispheres, is susceptible to the adverse effects of cancer and its treatments. The consequences of neurologic complications of cancer can be considerable, as the resulting pain and functional and cognitive dysfunction may result in significant degradation of quality of life. As advances in therapies for systemic cancer improve patient survival, an increasing incidence of neurologic complications can be expected. Patients may present to the medical system at any level, from the office of the primary care physician or oncologist to the emergency room. It is essential that all clinicians become familiar with common neurologic complications of cancer. The focus of this chapter is common direct neurologic complications of systemic cancer that affect the peripheral and central nervous systems. Typical presentation, diagnostics, and therapies will be reviewed. Indirect neurologic complications of cancer and its therapies are covered in other chapters in this volume.

## Plexopathy

### Brachial Plexus

The brachial plexus is an anastomotic collection of nerves formed by the nerve roots of the fifth cervical through first thoracic spinal segments. The malignant involvement of the brachial plexus occurs by two mechanisms, compression by a mass or infiltration by cancer cells. The former arises by metastases to axillary lymph nodes or direct extension of apical lung tumor, both of which lie in close proximity to the lower trunk of the brachial plexus. The most common malignancies to do so are breast and lung cancers, accounting for approximately 70% of cases of malignant plexopathy.<sup>1,2</sup> Both lesions tend preferentially to involve the lower trunk of the plexus derived primarily from C8 and T1 spinal segments. Lymphomas occasionally infiltrate the brachial plexi.<sup>3,4</sup> Pain is the most common and

significant symptom. It commonly involves the shoulder region and radiates down the medial aspect of the arm into the fourth and fifth digits of the hand. Muscle weakness and sensory loss may also be present (Table 1). A Horner's syndrome is present in approximately 50% of patients.<sup>1</sup>

### Lumbosacral Plexus

Colorectal tumors, genitourinary tumors and sarcomas are the most common cancers to impact the lumbosacral (LS) plexus.<sup>5,6</sup> Tumors invade the plexus by direct extension from the primary site in a majority of cases although metastases from extra-abdominal malignancies occurred in 27% of cases.<sup>5</sup> Similar to neoplastic brachial plexopathy, the predominant symptom among patients with neoplastic LS plexopathy is pain. Weakness and sensory abnormalities are common, the distribution dependant on the extent of plexus involvement (see Table 1).<sup>7</sup> Symptoms are typically unilateral.<sup>6</sup> Incontinence is rare, and its presence suggests epidural extension of tumor.<sup>5</sup>

### Diagnosis

Electrophysiologic evaluation, including nerve conduction studies and electromyography, may help localize the disease as well as help differentiate it from other disease processes such as radiation plexopathy.<sup>8,9</sup> CT scanning of the plexi has been employed in the work-up of patients with suspected neoplastic plexopathies, identifying abnormalities in 89% and 74% of patients with brachial and LS plexopathy respectively.<sup>6,10</sup> There are several limitations of this technique, including beam hardening artifact from surrounding bone, limited separation vascular structures from nerve bundles, and single-plane imaging.<sup>11</sup> Magnetic resonance imaging (MRI) provides much better anatomic detail and has become the imaging modality of choice. The most common finding with both CT and MRI is a mass either in or near the plexus.<sup>10,11</sup> Increased T2 signal adjacent to the brachial plexus is occasionally seen on MRI.<sup>11</sup> Often, imaging is sufficient to

**Table 1** Neurologic Deficits Associated with Injuries of the Plexus

<b>Lower Brachial Plexus</b>	
Muscle Weakness	Finger Flexion Wrist Flexion Grip and intrinsic muscles of hand
Sensory Loss	Inner border of arm Inner border of forearm Inner border of hand
Horner's Syndrome	Ipsilateral ptosis Ipsilateral miosis Anhidrosis

Muscle Weakness	Dorsiflexors and plantar flexors of ankle Inversion and eversion of foot Hip abduction Hip extension
Sensory loss	Outer leg Dorsum and sole of foot Posterior thigh
Reflex	Depressed ankle jerk

Adapted from Brazis PW.<sup>7</sup>

establish the diagnosis. Nine percent of MR scans, however, are normal, and surgical exploration is often necessary.<sup>1,2,11</sup> More recently, positron emission tomography (PET) has been employed and may help confirm metastases in patients with indeterminate MRI.<sup>12-14</sup> Experience with this modality is limited to small case series, and more research is necessary to evaluate its utility. Spine imaging may also be indicated, as coexistent epidural disease is present in approximately 50% of cases.<sup>15</sup> Restaging with systemic imaging to evaluate for active disease outside of the plexus should be considered.<sup>1</sup> Hydronephrosis should be ruled out in patients with LS plexopathy; it was detected in 44% of cases in one series.<sup>5</sup>

### Treatment

Depending on tumor type, a variety of treatment modalities have been used, including radiation, chemotherapy, and steroids. Response to treatment, however, has been poor. Pain control is improved in only 15% of patients with LS and 46% of patients with brachial lesions. Only rarely do patients improve neurologically.<sup>1,10</sup> Supportive treatment, including pain management with opioids, is essential to ensure patient comfort.

### Leptomeningeal Metastases

Once thought to be rare, infiltration of the leptomeninges by tumor is increasing in incidence, estimated to be approximately 4 to 15%, 7 to 15%, and 5 to 15% in patients with solid tumors, lymphoma, and leukemias, respectively.<sup>15</sup> The reported incidence of leptomeningeal metastases (LMM) varies depending on method of case ascertainment (Table 2).

The clinical presentation of LMM is variable and dependant on the area of the nervous system involved. Multifocality is typical (Table 3).<sup>15,16</sup> Headache and back and neck pain arise from meningeal irritation and may be non-localizing. Headaches may also be secondary to hydrocephalus resulting from obstruction of cerebrospinal fluid (CSF) flow or impaired CSF reabsorption.

Table 2 Frequency of LMM by Cancer Type

Cancer Type	Frequency of LMM (%)	Proportion if all cases LMM
Lung		10 to 26%
NSCL	1-5	
SCLC	6	
Breast	1-2	12 to 34%
Melanoma	5	17 to 25%
GI	1	4 to 14%
Unknown	1 to 7%	
Primary		

Adapted from Hitchins RN et al,<sup>33</sup> Chamberlain MC and Kormanik,<sup>42</sup> Boogerd W et al,<sup>30</sup> Fizazi K et al,<sup>40</sup> and Chamberlain MC.<sup>15</sup>

Table 3 Signs and symptoms of LMM

Symptoms	Signs
<b>Cerebral symptoms</b>	
Headache	Mental change
Mental change	Seizures
Difficulty walking	Papilledema
Nausea/Vomiting	Diabetes Insipidus
<b>Cranial Nerve</b>	
Diplopia	Ocular nerve palsies
Hearing loss	Facial weakness
Vertigo	Diminished hearing
Vision loss	Diminished facial sensation
Facial numbness	Lingual weakness
Dysphagia	Diminished gag
Hoarseness	Optic neuropathy
<b>Spinal symptoms</b>	
Lower motor neuron weakness	Reflex asymmetry
Paresthesias	Weakness
Radicular pain	Sensory loss
Back or neck pain	Positive straight leg raise
Bowel or bladder dysfunction	Decreased rectal tone
	Nuchal rigidity

Adapted from Wasserstrom WR et al.<sup>16</sup>

Nerve root involvement may cause neuropathic type pain in a radicular distribution. Limb weakness may result from involvement of the cerebral hemispheres and spinal cord (upper motor distribution) or cauda equina and nerve roots (lower motor neuron distribution). Often patients have a cauda equina syndrome including paraparesis and bowel or bladder function disturbance. Cerebral hemispheric dysfunction may result from underlying brain irritation, compression, or strokes (secondary to vascular compression or infiltration).

### Diagnosis

CSF analysis is an essential component of the evaluation of patients with suspected LMM. Nearly all patients with LMM have CSF abnormalities, the most common finding being elevated protein often with a lymphocytic pleocytosis. Occasionally, opening pressure is elevated, and glucose is low. Although suggestive of LMM in the appropriate clinical setting, these findings are not diagnostic. The identification of malignant cells within the CSF is considered the gold standard. Cytology is positive on the first analysis in approximately 54 to 91% of cases. The yield increases to approximately 76 to 100% by the third analysis.<sup>17</sup> The yield of additional lumbar punctures is small. In about 10% of cases, cytology remains negative. The variability may be accounted for by several factors, including the method by which fluid is collected and processed and case ascertainment. It is not uncommon for

fluid that has been collected at night, on weekends, or even during the workday to be refrigerated prior to processing. Such delays may decrease the yield of cytology relative to immediate processing by a cytopathologist.<sup>17</sup> Variations in CSF composition at different levels of the neuraxis in the absence of a CSF block have been demonstrated.<sup>17-21</sup> The extent of disease may partially account for the variation.<sup>15,20</sup> CSF collected from an Ommaya reservoir or ventricular shunt may be falsely negative in the presence of more caudal disease, such as in the brain stem or spinal cord.<sup>21</sup> Conversely, fluid obtained from the lumbar cistern via a lumbar puncture may be falsely negative in a patient with cerebral or brain stem disease.<sup>22</sup> CSF obtained in the vicinity of a radiographic abnormality or clinically defined lesion may have a greater yield.<sup>17,18</sup> Often, an insufficient volume of CSF is submitted for cytopathologic review. A minimum of 10 cc is recommended for cytology alone.<sup>17</sup> Flow cytology, especially in patients with hematological malignancies, may further increase the yield of CSF analysis. Other testing with potential benefit includes testing for tumor markers and immunohistochemistry.<sup>15,23</sup>

Neuroimaging is a valuable tool in the evaluation of patients with suspected LMM, particularly in those with a coagulopathy or elevated intracranial pressure prohibiting lumbar puncture. In addition, in the appropriate clinical context, typical radiographic findings may be sufficient to establish the diagnosis, even in the absence of positive cytology. Previously, cranial computerized tomography (CT) and spinal myelography were frequently utilized. MRI is now the method of choice as it is readily available, has better sensitivity and is less invasive. Leptomeningeal or subependymal linear or nodular enhancement is the most common finding. This may take the form of enhancement of the sulci within the cerebral hemispheres, or of the folia in the cerebellum. Enhancement may outline the brainstem or spinal cord. Frequently, enlargement of the cranial nerves or roots and matting of the cauda equina is evident. Hydrocephalus is often present. MRI also has the advantage of detection of coexistent parenchymal or spinal epidural disease that may require additional intervention.<sup>22,24,25</sup> MRI demonstrates leptomeningeal seeding in approximately 75% and 36 to 46% of patients with and suspected LMM, positive and negative cytology respectively.<sup>22,26</sup>

CSF flow studies are often performed in patients with LMM, especially when intrathecal (IT) chemotherapy is planned. Flow abnormalities may be detected that were otherwise not predicted based on conventional imaging and clinical evaluation.<sup>27,28</sup> Only 31% to 42% of patients with flow abnormalities had hydrocephalus.<sup>27,28</sup> On occasion, flow studies may detect asymptomatic

areas of disease.<sup>27</sup> The presence of flow abnormalities is associated with a worse prognosis and may interfere with the distribution of drugs administered intrathecally.<sup>15,27–29</sup> Once identified, areas of CSF block can be corrected with radiation in about 50% of cases, thus restoring flow and improving survival.<sup>15,27,28</sup>

## Treatment

The disseminated nature of LMM is such that the entire neuraxis must be treated. Craniospinal radiation effectively targets not only the leptomeninges, but also the parenchyma of the CNS and vertebral column. As such, coexistent disease in the structures is treated as well. Craniospinal radiation, however, is associated with significant toxicity, including severe myelosuppression, that may limit the delivery treatments to systemic disease. In addition, large areas of the gastrointestinal tract are included in the treatment field, resulting in mucosal damage and notable morbidity. As such, radiation therapy (RT) is generally reserved for the focal treatment of bulky disease, symptomatic regions, or areas of CSF block. Doing so may palliate symptoms, especially pain, or restore normal CSF flow dynamics.<sup>15,27,30–33</sup>

Systemic or IT delivery of chemotherapy is commonly used to treat LMM. A notable advantage of systemic chemotherapy is the treatment of coexistent active systemic disease. In addition, the distribution of the agents is not dependant on the normal flow of CSF. In fact, therapeutic levels of medications have been detected both proximal and distal to known CSF blocks.<sup>34</sup> Systemically delivered chemotherapy may penetrate bulky disease more effectively than agents delivered intrathecally. Intravenous administration of chemotherapy obviates the need for repeated lumbar punctures or placement of an Ommaya reservoir, the latter of which is associated with significant complications.<sup>34,35</sup> A wider array of agents is available for systemic delivery than IT delivery. The blood-brain barrier, however, limits the penetration of most chemotherapies used to treat malignancies that most commonly metastasize to the leptomeninges. The impact of this barrier is debatable, as the blood-brain barrier is known to be disturbed in this setting.

IT chemotherapy, delivered via an Ommaya reservoir or repeated lumbar punctures, is perhaps the most common treatment employed. Cytotoxic agents administered directly into the CSF bypass the blood brain barrier that excludes agents given systemically. Also, systemic toxicity is reduced without compromising effective treatment of leptomeningeal disease. Repeated lumbar punctures, however, are inconvenient and uncomfortable. Placement of an Ommaya reservoir requires a surgical procedure and is

associated with short and long-term complications, including infection, hemorrhage, catheter malfunction, and peri-catheter necrosis. Furthermore, CSF dynamics are frequently disturbed in the setting of LMM and homogenous distribution of medication cannot be ensured. Neurotoxicity may occur in areas of trapped chemotherapy.<sup>27,29</sup> Alternatively, insufficient levels of chemotherapy may be achieved at other sites.

Methotrexate (MTX), cytosine arabinoside and thiopeta are the agents available for Intrathecal (IT) administration. Traditionally, they have been given as single-dose injections 2 days per week during an induction phase. Depending on the response, the frequency of administration is tapered during a consolidation phase. The optimal duration of therapy is unknown. The short half-life and rapid clearance of these medications has raised the concern that the exposure of tumor cells to cytotoxic levels of the agents is insufficient, particularly distant from the injection site.<sup>36</sup> Alternative schedules have been developed in which IT chemotherapy is given on several consecutive days, thereby ensuring a steady drug level is maintained for an adequate period of time.<sup>15</sup> However, the frequent injections required may be difficult and inconvenient for the patient. Recently, a lipid-encapsulated version of cytosine arabinoside (DepoCyt, Enzon Pharmaceuticals, Bridgewater, NJ) was developed that effectively increases the half-life such that cytotoxic levels are maintained for 14 days.

Several retrospective and prospective trials have been performed evaluating the effectiveness of IT therapy. Most trials differed in their inclusion criteria, treatment methods and schedules, and criteria for diagnosis and response. Thus, comparisons of the results are difficult. Nonetheless, some conclusions can be drawn. Approximately 20 to 30% of patients die during early phases of treatment.<sup>30,35,37</sup> The agents all appear to have equal efficacy, although there is a trend towards better survival and longer time to disease progression with DepoCyt in the treatment of both solid and hematologic tumors.<sup>38,39</sup> Clinical response rates vary between 9 and 69%. Cytologic response rates are about 25 to 50%. Melanoma and non-small cell lung cancer are relatively more resistant, and breast cancer, small cell lung cancer, and lymphomas are more responsive. Duration of response is short, and median survival remains only 4 to 5 months with aggressive therapy. One study of MTX in breast cancer patients suggested a benefit of IT therapy on a concentration, versus time, schedule.<sup>40</sup> Most studies failed to demonstrate a benefit when multiple agents were administered simultaneously<sup>33,41</sup> although Kim and colleagues, in a small retrospective study, noted improved survival and response rate among those treat with MTX, cytosine arabinoside, and hydrocortisone, compared to MTX alone.<sup>31</sup> Patients with normal CSF flow dynamics have better

responses.<sup>28,42</sup> Toxicity is similar among the agents and includes headache and nausea. Arachnoiditis is common and can be minimized with the administration of dexamethasone several days prior to and after IT treatment.<sup>15</sup> As the agents are cleared into systemic circulation, systemic toxicity may occur. IT MTX is occasionally associated with mucositis and myelosuppression. Folinic acid is generally given in conjunction with MTX to minimize this complication.

Systemic chemotherapy, particularly MTX, is occasionally given to treat LMM. MTX penetrates the CNS poorly when given at standard doses. When given at high doses, however, cytotoxic concentrations are obtained within the CSF. In addition, clearance from the CSF is slower relative to IT administration of MTX.<sup>34</sup> Significant hematologic and gastrointestinal toxicity can be prevented with folinic acid rescue. Few studies have been published reviewing the effectiveness of this intervention in the treatment of LMM, although the data available are encouraging.<sup>34</sup>

Although systemic chemotherapy is generally thought to penetrate the CNS poorly, patients with LMM treated with a variety of chemotherapeutic regimens specifically directed at the underlying systemic malignancy have a better response than those who do not receive systemic treatment.<sup>30,40,43</sup> Bokstein and colleagues compared patients treated prospectively in two separate trials differing only in the use of IT chemotherapy.<sup>35</sup> Exclusion of IT chemotherapy did not change the overall response to treatment, the median survival or the proportion of long-term survivors. The rates of early and delayed IT treatment-related complications were decreased significantly.

Survival of patients with LMM is poor. Untreated, patients succumb to their illness within 1 to 2 months. Even with aggressive management, survival is typically less than 6 months. Patients with hematological malignancies are more responsive than those with solid malignancies.<sup>44</sup> Patients with better prognostic features, including little neurologic disability, limited systemic or parenchymal CNS disease, and higher performance status may benefit more from treatment.

## Epidural Spinal Cord Compression (ESCC)

ESCC is a common problem among patients with systemic cancer. A recent population-based study reported an incidence of 2.5% of patients preceding death. The cancers with the greatest propensity to cause this problem are multiple myeloma and prostate carcinomas. However, reflecting the higher incidence within the population, breast, prostate, and lung cancer account for most cases, approximately 20% each.<sup>45,46</sup>

ESCC results most commonly from the growth of metastases present within the vertebral body into the spinal canal. Alternatively, the resulting bony destruction results in compression fractures. Less commonly, lesions in the paraspinous region grow into the spinal canal through the neural foramina. Any segment of the spinal column can be involved, although thoracic and lumbar segments are most often involved. Multiple lesions are common, occurring in one-third of patients.<sup>47,48</sup>

Pain is the most common symptom, affecting almost all patients with this condition. It is usually the first symptom and may precede decline in neurologic status by weeks to months. Pain is progressive and severe and occasionally positional, with exacerbation in the supine position. It is often localized to the symptomatic vertebral segment. A coexistent radiculopathy is often associated with neuropathic discomfort in the limbs. As the disease progresses, focal deficits develop, including lower extremity weakness and, ultimately, loss of ambulation. As a result, there is significant decline in performance status and quality of life. As neurologic status at presentation is strongly predictive of functional outcome, it is imperative that a high index of suspicion is present such that the appropriate diagnostic and therapeutic interventions can be instituted in a timely manner.

## Diagnosis

The cornerstone of diagnosis is the radiographic detection of a lesion within the spinal canal. The imaging modality of choice is MRI. MRI is a non-invasive means of imaging the entire spinal axis thereby detecting not only the clinically suspected lesion but also other lesions less clinically apparent.<sup>49</sup> It provides superior anatomic detail of the spinal cord and surrounding structures, such as leptomeninges, vertebral body, and bone marrow. Alternative or coexistent non-malignant pathology that may be present can be seen.<sup>49</sup> Certain patients, including those with metallic objects such as artificial heart valves, cannot receive MRIs. A high-quality MR image necessitates that the patient remain still during the study to prevent movement artifact. The pain associated with ESCC, often exacerbated by recumbency, may limit the ability of the patient to tolerate the exam. This is particularly true given the duration of an MRI study, which is typically longer than myelography. Otherwise, few other contraindications exist, and the procedure is generally well tolerated.

Alternatively, CT myelography, which, prior to MRI, was the imaging modality of choice, may be performed. It requires the injection of a dye directly into the epidural space via a lumbar puncture. The dye is then allowed to diffuse caudal and rostral to the injection site, after which

a CT is performed. The dye forms a "cast" of the epidural space that may be deformed by a lesion, malignant or non-malignant, extending into it. Myelography, however, is invasive and, in the presence of a complete block, requires a second cervical injection to visualize the rostral extent of the lesion. Although CT allows visualization of anatomic structures, it is less sensitive and more limited than MRI.<sup>50</sup>

## Treatment

ESCC is a true neurologic emergency. Without treatment, it follows a relentless course resulting in significant pain and progressive neurologic deterioration culminating in death. A delay in therapy may result in rapid, irreversible loss of function. Treatment is palliative as most patients succumb to their underlying systemic disease. Median reported survival remains approximately 6 months, although certain patients may survive longer. Prognostic factors have been elucidated and scales established to assist the clinician in identifying appropriate patients for more aggressive surgery.<sup>51,52</sup> Prognostic factors include underlying tumor histology, medical and neurologic status at presentation, extent of systemic disease, and number of vertebral metastases.

Although corticosteroids have long been used to treat patients with ESCC, it was not until recently that their benefit was demonstrated in a prospective, randomized clinical trial.<sup>53</sup> In this study, successful treatment, defined as retained ability to walk in pretreatment ambulatory patients and recovery of ambulation of non-ambulatory patients, was demonstrated in 81% of those who received dexamethasone compared to 63% of those who did not. At 1 year, a significantly greater percentage of treated patients remained ambulatory. The high-dose regimen tested in this study, however, is associated with significant toxicity.<sup>54,55</sup> Subsequently, a second study randomized patients to either a 100 mg or 10 mg bolus of dexamethasone followed by 16 mg daily. No difference was found in pain control, ambulation, or continence.<sup>56</sup> The optimal dose of steroids in ESCC remains unknown. High-dose regimens are typically reserved for patients with notable neurologic deficits or those progressing rapidly, while less symptomatic patients are treated more conservatively.<sup>46</sup> Occasionally, steroids can be avoided entirely.<sup>57</sup>

RT is routinely used in the treatment of patients with ESCC. Besides effectively controlling pain, it preserves ambulation in 90% of ambulatory patients. In addition, 30 to 40% of paraparetic and 10% of paraplegic patients regain ambulation. Several regimens have been evaluated, although none have been found to be superior.<sup>58</sup> Generally, the treatment field includes one uninvolved spinal segment above and below the lesion.

Response to treatment may be dependant on the degree of radio-responsiveness of the underlying tumor. Breast carcinoma, lymphoma, multiple myeloma, and small cell lung cancer are among the tumors responsive to RT. Conversely, melanoma, sarcoma, and renal cancer are considered relatively resistant. A smaller proportion of patients are ambulatory at completion of RT in the latter group, and responses are less durable.<sup>59-61</sup> The effectiveness of radiation therapy may be diminished in patients with structural disease such as vertebral body collapse and compression by bony fragments.<sup>62,63</sup> Such patients are often treated with surgery to stabilize the spine and relieve the compression.

Radiation is generally well tolerated. The presence of hematological precursors sensitive to radiation within the spinal canal increases the risk of bone marrow suppression if sufficient spinal segments are included within the treatment field. Other innocent bystanders include the mucosal lining of the gastrointestinal tract, made up of rapidly dividing cells that, when extensively irradiated, may result in mucositis and diarrhea. In addition, patients are at risk of radiation-induced myelopathy especially those treated with large fractions. This complication is rare, however, even in those retreated with RT for a loco-regional recurrence.<sup>64-66</sup>

Though surgery is frequently employed in the treatment of ESCC, its role is controversial. Laminectomy had long been the procedure of choice. Laminectomy, however, provides only limited exposure to the anterior elements of the spine that are most frequently involved by metastases. In addition, removal of posterior support elements in the setting of vertebral body disease further destabilizes the spine. This results in potential instability and increases the risk of future complications. Not surprisingly, early studies did not demonstrate benefit when laminectomy was performed in conjunction with radiation therapy.<sup>67,68</sup> With the advent of modern instrumentation, surgeons can implant a variety of devices that provide necessary support. Studies of posterior approach surgeries, including laminectomy, that incorporate instrumentation have demonstrated improved results with 60 to 70% of non-ambulatory patients regaining ambulation.<sup>69,70</sup> Other surgical approaches have been attempted as well.<sup>51,71-77</sup> These frequently include an anterior approach through body cavities, which provides a direct route to the vertebral body for decompression and stabilization. Among the advantages relative to the posterior approach, the anterior approach permits minimal removal of uninvolved bone and reconstruction of the often diseased and unstable, weight-bearing, anterior column. With modern imaging, surgeons can now determine the extent of disease within the spine as well as the structures involved.

Hence, the type of surgery employed may now be tailored to the individual case. Modern reports of such techniques have been encouraging, with 60 to 82% of patients having improvement in their neurologic status.<sup>71–73,76,77</sup> Only recently, however, has modern surgery has been compared to RT. Patchell and colleagues reported a randomized control trial of surgery and postoperative RT versus RT alone for patients with a single level of compression.<sup>78</sup> Fifty-six percent of patients in the surgery-plus-radiation group regained the ability to walk, versus 19% of those who received radiation alone. Those who received surgery were ambulatory for 126 days, versus 35 days who were only treated with radiation. Narcotic use was significantly lower in those who were operated on. The authors concluded that surgery plus radiation was more effective than radiation alone.

Surgery, like every invasive procedure, is associated with complications. Most modern surgical series report about a 30% complication rate.<sup>71,73,77,79</sup> Many of the complications are medical, including pneumonia, gastrointestinal bleeding, and pulmonary embolus. About 12 to 20% of patients sustain wound dehiscence or infection or failure of instrumentation.<sup>70,76–78</sup> Frequently, such complications require a second surgery. Nonetheless, surgical mortality remains low, with most series reporting a 30-day mortality of less than 7%.<sup>71,72,75–77,79</sup> Preoperative RT increases the risk of wound and instrumentation failure.<sup>72,76,78,79</sup> Patients with poor performance status may also be at higher risk of complication.<sup>72,79</sup>

## Cerebral Metastases

Cerebral metastases represent the most common complication of systemic cancer. Although any malignancy can metastasize to the brain, the most common to do so are melanoma and lung cancer. However, given the relatively higher incidence within the population, non-small cell and breast cancer account for the majority of cases (Table 4).<sup>80,81</sup> Hematological malignancies only rarely metastasize to brain parenchyma.

**Table 4** Proportion of Cerebral Metastases by Primary Cancer Type

Cancer Type	Proportion of cases (%)
Lung	40 to 64
Non-small cell	24 to 49
Small Cell	15
Breast	14 to 17
Unknown Primary	5 to 8
Melanoma	4 to 11
Gastrointestinal	3 to 6
Genitourinary	2 to 6

Adapted from Zimm S et al.<sup>80</sup> and Nussbaum ES et al.<sup>81</sup>

Any region of brain can be involved by metastases. The most common locations are the cerebral and cerebellar hemispheres. Usually lesions are located at the gray white junction. In the CT era, approximately 50% of patients with metastatic disease had solitary lesions.<sup>81</sup> This undoubtedly is an overestimate as MRI is more sensitive in detecting lesions. In a recent study, 31% of patients with solitary lesions on contrasted head CT had multiple lesions on MRI.<sup>82</sup> Typical symptoms include headache and focal neurologic deficits, the latter dependant on the region of brain involved by the lesion. Patients can also present with seizures, altered mental status, cognitive decline, and behavioral changes. Occasionally, metastases are asymptomatic and detected only on staging imaging. Symptoms may be acute or subacute in onset. Most commonly, cerebral metastases develop over the course of one's illness. Occasionally, cerebral metastases, most commonly from a lung primary, may represent the first symptom of a systemic malignancy.

MRI is the preferred diagnostic imaging modality. Typically, lesions enhance following the administration of gadolinium, either in a ring or homogenous pattern. Usually, surrounding T2 signal abnormality is present, occasionally resulting in significant mass effect and shift. Metastases in the cerebellum may result in compression of the fourth ventricle and secondary hydrocephalus. CT scanning is also used in the evaluation of patients with suspected metastases, although it is less sensitive than MRI. MRI provides better anatomic detail for surgical planning, is less susceptible to bony artifact, is able to visualize smaller lesions, and provides superior visualization of the posterior fossa.<sup>82–84</sup>

Once detected, systemic staging is indicated to establish the extent of disease. Usually, a CT of the chest, abdomen, and pelvis is performed. Occasionally, PET scanning is employed in patients with cerebral metastases of unknown primary. In one study, PET scanning identified the primary tumor in 24% of patients.<sup>85</sup> However, survival was not altered by the discovery of the primary tumors. More research is necessary to define the role of this imaging modality.

Prognostication is important in the treatment planning of patients with cerebral metastases. Several factors have been identified to correlate with outcome, including extent of systemic disease, patient age and performance status, and underlying tumor histology. Recursive partitioning analysis has stratified patients based on prognostic factors into three classes (Table 5).<sup>86</sup>

## Treatment

Corticosteroids, usually dexamethasone, may provide rapid although transient, palliation by reducing the surrounding edema.<sup>87</sup> The optimal

**Table 5** Recursive Partitioning Analysis (RPA) of Prognostic Factors in Patients with Cerebral Metastases

RPA Class	Prognostic Factors	Median Survival
Class I	KPS <sup>1</sup> > 70; Age < 65; Primary tumor controlled; No additional metastases	7.1 months
Class II	KPS > 70; Age > 65; Primary uncontrolled; Additional metastases	4.2 months
Class III	KPS < 70	2.3 months

KPS = Karnofsky Performance Status. Adapted from Gaspar L et al.<sup>86</sup>

dose is unknown, although lower doses have been shown to be as effective as higher doses.<sup>88</sup> Furthermore, lower doses are associated with fewer side effects. In the event of impending herniation, larger doses may be required. Once patients are symptomatically improved, steroids should be tapered to the lowest effective dose.

Patients with seizures require an antiepileptic medication. Phenytoin is most often used because it is effective and can be rapidly loaded. Phenytoin, however, is highly protein-bound and interacts with the cytochrome P-450 system thereby predisposing to drug interactions. The use of antiseizure medications in patients who have not had a seizure is controversial. Several studies have failed to demonstrate a statistically significant reduction in patients who subsequently develop seizures.<sup>89,90</sup> Thus, patients may unnecessarily be exposed to possible side effects and complications of these medications. As such the prophylactic use of antiseizure medications is not recommended.<sup>91</sup>

More definitive treatment directed at the metastases involves surgery, radiation and sometimes chemotherapy. Which interventions are employed depends on a number of factors, including status of systemic disease, patient performance status, previous treatments, and number and location of metastases.

## Radiation Therapy

Radiation therapy has been the mainstay of therapy for patients with metastatic deposits within the CNS. Traditionally, treatment has been delivered to the whole brain. Several treatment schedules and doses have been assessed although none has been found to be superior to the others.<sup>92–94</sup> A commonly utilized treatment plan is 30 gray divided in 10 fractions delivered over 2 weeks. Early studies reported that approximately 40 to 50% of patients had improvement in their

neurologic status and that 60 to 90% of specific symptoms improve.<sup>92,94</sup> However, more recent studies failed to show such a significant clinical benefit. In a prospective study of 85 symptomatic patients with metastases from solid tumors, 19% improved and 55% died or progressed 1 month following radiation therapy. Furthermore, there was a statistically significant decline in performance status with a trend toward worse quality of life.<sup>87</sup> Assessment of the response to whole brain radiation therapy (WBRT) is difficult to separate from the effects of dexamethasone given concomitantly.

## Surgery

Until recently, the disseminated nature of metastatic malignancies has limited surgery to palliative interventions directed at symptomatic lesions. Early retrospective studies have demonstrated a benefit of resection of solitary metastases, although interpretation was limited by selection bias. Two prospective, randomized trials performed in the CT era, however, demonstrated a survival advantage when resection of a solitary metastasis was performed in conjunction with radiation compared to radiation alone.<sup>95,96</sup> Patients who underwent resection remained independent for a significantly longer period of time and had better local control of the metastatic disease. Patients with active extracranial disease, however, did not benefit from surgery, and overall survival approximated that of those treated with radiation alone in this group.<sup>96</sup> Age was a significant, independent prognostic factor in both studies. A third prospective randomized trial failed to demonstrate an advantage to resection of a solitary metastases, although ten of 43 patients randomized to radiation alone underwent resection. In addition, a greater proportion of patients had active systemic disease.<sup>97</sup> Nonetheless, the weight of the evidence supports resection of solitary cerebral metastases in patients with controlled systemic disease.

The use of surgery in patients with multiple metastases is less clear. Patients with a dominant lesion causing significant mass effect or symptoms are frequently resected. One retrospective study assessed the impact of resection of up to three lesions on survival.<sup>98</sup> Survival of patients who underwent gross total resection of all lesions closely approximated that of patients with solitary lesions. This intervention has yet to be tested in a prospective fashion, and surgery in patients with multiple metastases should be reserved for select cases.

The role of WBRT following the resection of a solitary metastasis remains a matter of debate. The only prospective study published to date found that postoperative WBRT reduced the rate of failure both in the vicinity of, and distant to,

the resected lesion. In addition, patients were less likely to die of neurologic causes. However, there was no difference in overall survival or the time in which patients remained functionally independent.<sup>99</sup> Yet the potential toxicity of WBRT may outweigh the benefit. One study reported an 11% incidence of dementia in one-year survivors with metastatic disease treated with WBRT.<sup>100</sup> Patients reported in this study, however, were treated with unconventional treatment regimens that included high-dose fractions. Furthermore, several patients were treated with methotrexate, a medication with higher CNS toxicity, especially when given in conjunction with radiation therapy. On further analysis, none of the patients treated with conventional treatment schemes developed cognitive disturbances. In addition, it is difficult to separate the effects of treatment from the underlying tumor. Most patients with metastatic disease may not survive long enough to suffer from this delayed complication, although the acute and subacute toxicities of radiation therapy and the inconvenience of daily treatment sessions remain problematic. Alternatively, careful radiographic surveillance for patients who choose to defer radiation therapy may detect recurrences early, prior to development of symptoms and associated performance decline, such that they can then be treated with additional focal therapies or WBRT. This is particularly true since MRI, which is more sensitive than CT and capable of detecting smaller lesions, has become readily available.

## Stereotactic Radiosurgery

Stereotactic radiosurgery (SRS, Elekta, Stockholm, Sweden), as delivered by Gamma Knife or a modified linear accelerator, is an emerging technology that accurately delivers high doses of radiation to a target in a single treatment session. As a treatment modality, it has several advantages over both conventional surgery and radiation therapy. Neurosurgeons are often limited by the anatomic constraints of the central nervous system. As such, even patients with solitary lesions may not be candidates for resection. Surgical resection entails a craniotomy that is associated with significant mortality and morbidity and requires a several-day hospitalization. SRS, although not risk-free, is less invasive and, in many facilities, done as an outpatient procedure. Patients with a surgically inaccessible solitary lesion or multiple metastases can be treated in a single session. Unfortunately, SRS does not provide tissue for pathological examination. As many as 11% of cancer patients with a solitary cerebral lesion suspected to be a metastases based on preoperative imaging are found to have an alternative pathological diagnosis.<sup>95</sup> Also, larger lesions, which may be amenable to surgery, are less responsive to SRS, and their treatment is associated with greater toxicity.<sup>101</sup>

Relative to WBRT, SRS has several distinct advantages. The precision with which radiation is delivered with SRS, as well as the steep dose gradient, spares the normal surrounding brain tissue thereby minimizing CNS toxicity. In addition, even radioresistant tumors are sensitive to the high doses of radiation delivered by SRS.<sup>102–104</sup> Fractionation of conventional WBRT requires daily visits to a treatment facility, which may be difficult and inconvenient for both the patients and their caregivers. Recurrent lesions can be retreated without significant toxicity. However, SRS is a focal treatment strategy similar to surgery and does not treat micrometastases not visualized on head CT or MRI. The addition of WBRT to surgical resection reduces failure distant from surgical site to 14% from 37%.<sup>99</sup> The cost of SRS at present is significantly greater than that of WBRT.

## Solitary Metastases

Several studies have demonstrated the effectiveness of SRS in the treatment of solitary metastases.<sup>103,105–107</sup> When employed with WBRT, local control rates of 80 to 85% at 1 year and median survival of 56 weeks are similar to that reported in trials of surgical resection followed by WBRT<sup>95,99</sup> and exceed control rates of patients treated either with surgery<sup>99</sup> or WBRT alone.<sup>95,103</sup> Randomized, prospective trials comparing surgery to SRS have not been performed, and retrospective reports have yielded conflicting results. Binda and colleagues demonstrated superior survival among patients treated with conventional surgery<sup>108</sup> whereas others reported similar survival between the two groups.<sup>109,110</sup> Local control appears better with surgery, and patients die less often from neurologic causes.<sup>108,109</sup> Short-term toxicity is minimized with SRS relative to surgery<sup>103,109</sup> although one study found the contrary.<sup>108</sup> Long-term morbidity, however, may be greater in patients treated with SRS.<sup>109</sup>

## Multiple Metastases

SRS can be used to treat patients with multiple metastatic deposits, a distinct advantage over conventional surgery. Two prospective, randomized trials of WBRT with or without SRS that included patients with multiple lesions demonstrated significantly improved local control and time to brain failure in patients treated with SRS.<sup>105,111</sup> Although there was no difference in overall survival, patients treated with SRS required lower steroid doses and had a better performance status.<sup>105</sup> Alternatively, retrospective studies of patients with multiple metastases demonstrated similar local control when patients were treated with SRS with or without WBRT. As expected, failure at sites distant from the originally treated lesions was greater in patients treated with SRS alone.<sup>112,113</sup> As such, SRS appears to be an effective

intervention in patients with multiple cerebral metastases.

The role of upfront WBRT in patients treated with SRS is a matter of debate. Several retrospective reviews have been undertaken to address this question, although no prospective, randomized studies have been reported to date.<sup>106,112,114</sup> The addition of WBRT does not appear to improve survival relative to SRS alone. Intracranial control, however, is better with upfront WBRT, although a greater proportion of patients initially treated with SRS alone received salvage therapy at recurrence.<sup>112,114</sup> This difference may account for the similar survival between the two groups. The results of an interim analysis of a prospective randomized trial support the findings of the previously reported retrospective series. Although survival and preservation of Karnofsky Performance Score (KPS) was equivalent between the two groups, in- and out-of-field failure was more common when treated with SRS alone.<sup>115</sup>

## Chemotherapy

The role of chemotherapy in the treatment of cerebral metastases is the least well studied of all treatment modalities. Like WBRT, chemotherapy would treat the whole brain. Although it is now recognized that chemotherapy is associated with cognitive impairment, presumably it is less toxic than WBRT, thereby serving as an effective alternative. The intact blood-brain barrier (BBB) excludes many chemotherapeutics used to treat systemic disease. In the presence of metastatic lesions, however, the BBB is leaky as indicated by the presence of enhancement on imaging. BBB disruption with mannitol and intra-arterial chemotherapy have been attempted to bypass this barrier, although their role has yet to be definitively established. Occasionally, chemotherapy is given at high doses, such that the concentration gradient across the BBB is sufficient for agents to cross it. The most common agent to be delivered in this manner is methotrexate with folinic acid rescue. More recent, intracavitary chemotherapy in the form of Gliadel wafers has been employed. Novel agents, such as temozolomide, which are capable of penetrating the blood-brain barrier, are also promising.<sup>116–118</sup>

Chemotherapy has most extensively been evaluated in the treatment of small cell lung cancer, a tumor with known chemosensitivity. Most often, it has been used in the setting of recurrence following RT.<sup>119,120</sup> One randomized trial of teniposide versus teniposide with WBRT found patients treated with both modalities to have a higher response rate and longer progression-free survival. Overall survival was identical.<sup>121</sup> Small series have reported the utility of chemotherapy in the treatment of breast cancer, non-small cell lung cancer, and melanoma.<sup>122–127</sup> Thus far, data are limited, and the role of chemotherapy has yet to be defined.

## Conclusion

The neurologic complications of cancer are not uncommon. As therapies for systemic disease improve, one can expect an increased incidence of these conditions. Clinicians must be familiar with these conditions so that therapeutic interventions that palliate and cure patients can be instituted.

# Neurologic Toxicity of Radiotherapy

Kimberly Keene, MD

James Larner, MD

Radiation therapy is one of the cornerstones of cancer therapy and is often used in combination with surgery and chemotherapy as a multimodality approach to improve tumor control. While high doses of radiation can sterilize cancer cells, normal tissue tolerance to radiation limits the total dose that can safely be administered. The pathophysiology of radiation injury is not fully understood but likely represents a constellation of responses from vascular, stromal and epithelial cells. Experimental and clinical data have been used to establish the clinical limits of prescribed dose. Normal tissue toxicity is directly related to the total dose, the dose per fraction, the number of fractions, and the volume of tissue irradiated as well as the time interval between fractions. As the total dose, volume treated or dose per fraction increases, the likelihood of normal tissue damage increases. Conversely, as the interval between delivered fractions decreases, toxicity will increase. The  $TD_{5/5}$  and  $TD_{5/50}$ , (the tolerance dose at 5 years where 5% and 50% of the population would express injury, respectively); are used to set dose limitations. Most dose response curves for normal tissue toxicity are sigmoidal in shape. As a result, a small increase in prescribed dose can lead to a large (exponential) increase in normal tissue toxicity. Patient factors, such as age and comorbid illnesses, including diabetes and hypertension, predispose patients to normal tissue toxicity. The addition of chemotherapy to radiation treatment lowers the threshold for radiation-induced damage to normal cells. There is also a genetic basis for the heterogeneity of normal tissue toxicity. For example, individuals with diseases such as Fanconi's anemia and ataxia telangiectasia are hypersensitive to radiation. There is little doubt that other unidentified genes also play a significant role in determining which patients manifest normal tissue toxicity at a given dose/volume level.

New techniques, such as three-dimensional-conformal, intensity-modulated, and stereotactic radiation therapy are designed to spare normal tissues while treating the tumor to higher doses, thereby improving local control and cure. Intensity-modulated radiation therapy uses multiple blocking patterns to vary the radiation beam

intensity to conform to the target and avoid normal structures, while stereotactic radiation uses many focused slender beams of radiation that intersect within the target to deliver the prescribed dose of therapy. These exciting technological improvements allow radiation to be sculpted in elegant ways. The use of dose volume histograms allows physicians to graphically visualize the total dose received to various volumes of different tissue and provide quantitative data for planning therapy. Modifications to the plan are then made to provide maximum dose to the target tissues while sparing normal tissues. Radiosensitizers and radioprotectors are also under exploration to improve therapeutic ratios by increasing the cancer cell's susceptibility to radiation while protecting normal tissues.

## CNS Toxicity of the Brain

The critical target of radiation, which is responsible for cell death, is thought to be deoxyribonucleic acid (DNA). Irradiation of cells causes single- and double-strand DNA breaks that, if not repaired, result in cell death. Radiation also results in induction of various genes and altered protein expression, which serve to enhance repair or facilitate apoptosis. Multiple cell types, including subependymal cells, oligodendroglial cells and endothelial cells undergo apoptosis following radiation; this forms the basis of many acute effects. After injury, the progenitor cells must repopulate before differentiating into functional cells. While DNA damage occurs instantaneously after exposure, the latency to expression of injury, or of a tumor response, varies with the number and cycling time of surviving clonogens. However, the latency time to injury is not an indicator of the severity of the injury, and there is little correlation between acute and late radiation damage to normal tissue. For example, lymphocyte progenitor cells have a rapid division and turnover rate so the expression of injury is observed within days after irradiation. On the other hand, organs and tissues with a slow proliferation rate, like the kidney, heart, and brain, may take a year or more before damage is clinically apparent.<sup>1</sup>

Normal tissues are made up of many different stem cells, each with their own inherent cell kinetics, leading to different latency periods for expression of injury. Clinical toxicity of the brain has been separated temporally into acute, subacute, and late effects based on the time period to the clinical manifestation of the injury. Acute effects of radiation have been described in a few instances at autopsy, while most pathologic and radiographic changes reported are for late effects. Toxicities are related to treatment techniques, which include partial brain, whole brain and stereotactic radiosurgery.

## Acute Effects

The mechanistic basis of acute effects of radiation is unclear although radiation-induced cerebral edema appears to be a major cause. Edema results in increased intracranial pressure, headaches, nausea, fatigue, or an intensification of presenting tumor signs and symptoms. The correlation of imaging studies with the severity of acute effects of radiation (increased edema) is weak. Nonetheless, acute toxicities almost always resolve with corticosteroid administration, supporting edema as the etiology. Compromise of the blood-brain barrier is one hypothesis for the pathogenesis of radiation-induced cerebral edema. Animal studies suggest the blood-brain barrier disruption is caused by radiation-induced apoptosis of endothelial cells.<sup>2,3</sup> Other common, even universal, acute toxicities of whole or partial brain radiation include alopecia, blockage of the eustachian tubes, fatigue, and skin erythema. Serous otitis media frequently resolves spontaneously with time; however, histamine blockers or even a myringotomy may be required. Skin erythema is treated with supportive care, including water-based lotions and aloe.

## Partial Brain Toxicity

Both low- and high-grade astrocytomas are frequently treated with portals that not only include the tumor itself but also a margin of 1 to 2 cm (in order to cover microscopic tumor infiltrating into normal brain) to a dose of 54 to 60 gray (Gy) (1.8 to 2.0 Gy per fraction) combined

with chemotherapy and/or surgery. Partial brain irradiation is generally well tolerated, with most patients experiencing no severe toxicity; however, mild toxicities occur, including skin erythema (34%), otitis (5%), vomiting (8%), lethargy (7%) and headache (25%).<sup>4,5</sup> The North Central Cancer Treatment Group (NCCTG) and Radiation Therapy Oncology Group (RTOG) prospectively compared two different doses of postoperative radiation therapy, 50.4 Gy versus 64.8 Gy for the treatment of low-grade gliomas. Interestingly, there was no difference in acute toxicities between the treatment arms. However, late toxicity, as discussed subsequently, was significantly higher for the patients receiving the higher dose.<sup>6</sup>

### Whole Brain Toxicity

Whole brain radiotherapy (WBRT) using two lateral opposed fields is commonly used as a palliative regimen for patients with brain metastases to alleviate symptoms such as headaches. Since the life expectancy of these patients is short, WBRT is given in larger fractions over a shorter time period than treatment schedules employed for primary central nervous system (CNS) tumors. A standard WBRT schedule is 30 Gy in 10 fractions (ie, each fraction is 300 cGy). In contrast to partial brain irradiation, all patients treated with WBRT experience complete alopecia and skin erythema. Typically, the alopecia resolves over a period of several months, although pretreatment hair density is seldom recovered. Since both eustachian tubes are included in WBRT fields, eustachian tube dysfunction is also common.

When the dose per fraction of WBRT is escalated, severe acute complications can occur. For example, half of the patients treated with a whole brain radiation dose of 15 Gy given in 2 fractions over 3 days experienced symptoms ranging from severe headaches to pyrexia and cerebral herniation.<sup>3,6,7</sup> A single dose of 10 Gy to the whole brain has been reported to cause severe toxicity including death.<sup>8</sup>

Stereotactic radiosurgery uses multiple non-coplanar small beams that intersect within the target to produce highly conformal dose distributions while reducing the dose to normal tissues. Stereotactic radiosurgery can either be given as primary treatment or as a boost in addition to fractionated therapy. Single fraction stereotactic radiosurgery was studied in patients previously treated with external beam radiotherapy for either solitary brain tumors or metastasis. The incidence of severe acute toxicities was related not only to the prescribed dose but also tumor size. Patients with a tumor diameter of 31 to 40 mm had severe acute toxicities in up to 17% of cases at a dose of 18 Gy, while those with smaller tumor diameters, less than 20 mm, had no severe acute toxicities at 24 Gy.<sup>5,8,9</sup> The RTOG randomized 333 patients with 1–3 brain metastases between WBRT alone

or combination with stereotactic radiosurgery. In the group treated with WBRT and stereotactic radiosurgery, most toxicities were mild (43%) or moderate (18%) with only one severe toxicity. Patients receiving WBRT alone had similar toxicities although no severe toxicities were noted.<sup>10</sup> Stereotactic radiosurgery can be used safely in combination with WBRT provided appropriate doses are used.

### Subacute Toxicity

Subacute toxicity presents a few weeks to a few months after completion of radiation therapy. Symptoms include fatigue, decreased concentration, and exacerbation of presenting signs and symptoms of the tumor itself. Subacute effects of radiation are indistinguishable from tumor progression on imaging studies; however, the radiation effects resolve on subsequent scans.<sup>11</sup>

Somnolence syndrome is most frequently reported in the pediatric population and represents a constellation of one or more effects, such as fatigue, anorexia, headache, nausea and vomiting, irritability, fever, dysphagia, dysarthria, and ataxia. Up to 60% of children treated with WBRT for acute lymphoblastic leukemia have experienced this syndrome. The syndrome is typically self-limited, lasting anywhere from 2 days to 8 weeks. However, there have been reports of fatality from subacute radiation toxicity. Findings at autopsy revealed gliosis, necrosis, and diminished numbers of oligodendroglial cells. Neurons and axons are preserved.<sup>12</sup> The etiology of somnolence syndrome is thought to be related to either demyelination or vascular damage. Interestingly, the likelihood of patients experiencing somnolence syndrome does not appear to be dose-related.<sup>13</sup> Prophylactic steroids appear to decrease the likelihood of somnolence syndrome. Thirty-two acute lymphoblastic leukemia pediatric patients treated with WBRT (18 Gy in 9 fractions) were randomized between two prophylactic doses of dexamethasone. Patients receiving 2 mg and 4 mg of dexamethasone during radiation therapy had 64% and 17.6% incidences of somnolence syndrome, respectively.<sup>14</sup>

### Late Toxicity

Late radiation toxicity manifests several months to years after the completion of treatment. The probability of severe complications increases with dose and the volume of brain irradiated. The TD<sub>5/5</sub> of normal brain is 50 Gy if two-thirds of the brain is irradiated, and 60 Gy if one-third of the brain is irradiated.<sup>15</sup> Complications also increase if radiation is given concurrently with chemotherapy.<sup>15,16</sup> The principal late effects include radiation necrosis, white matter injury, brain atrophy, and vascular injury.

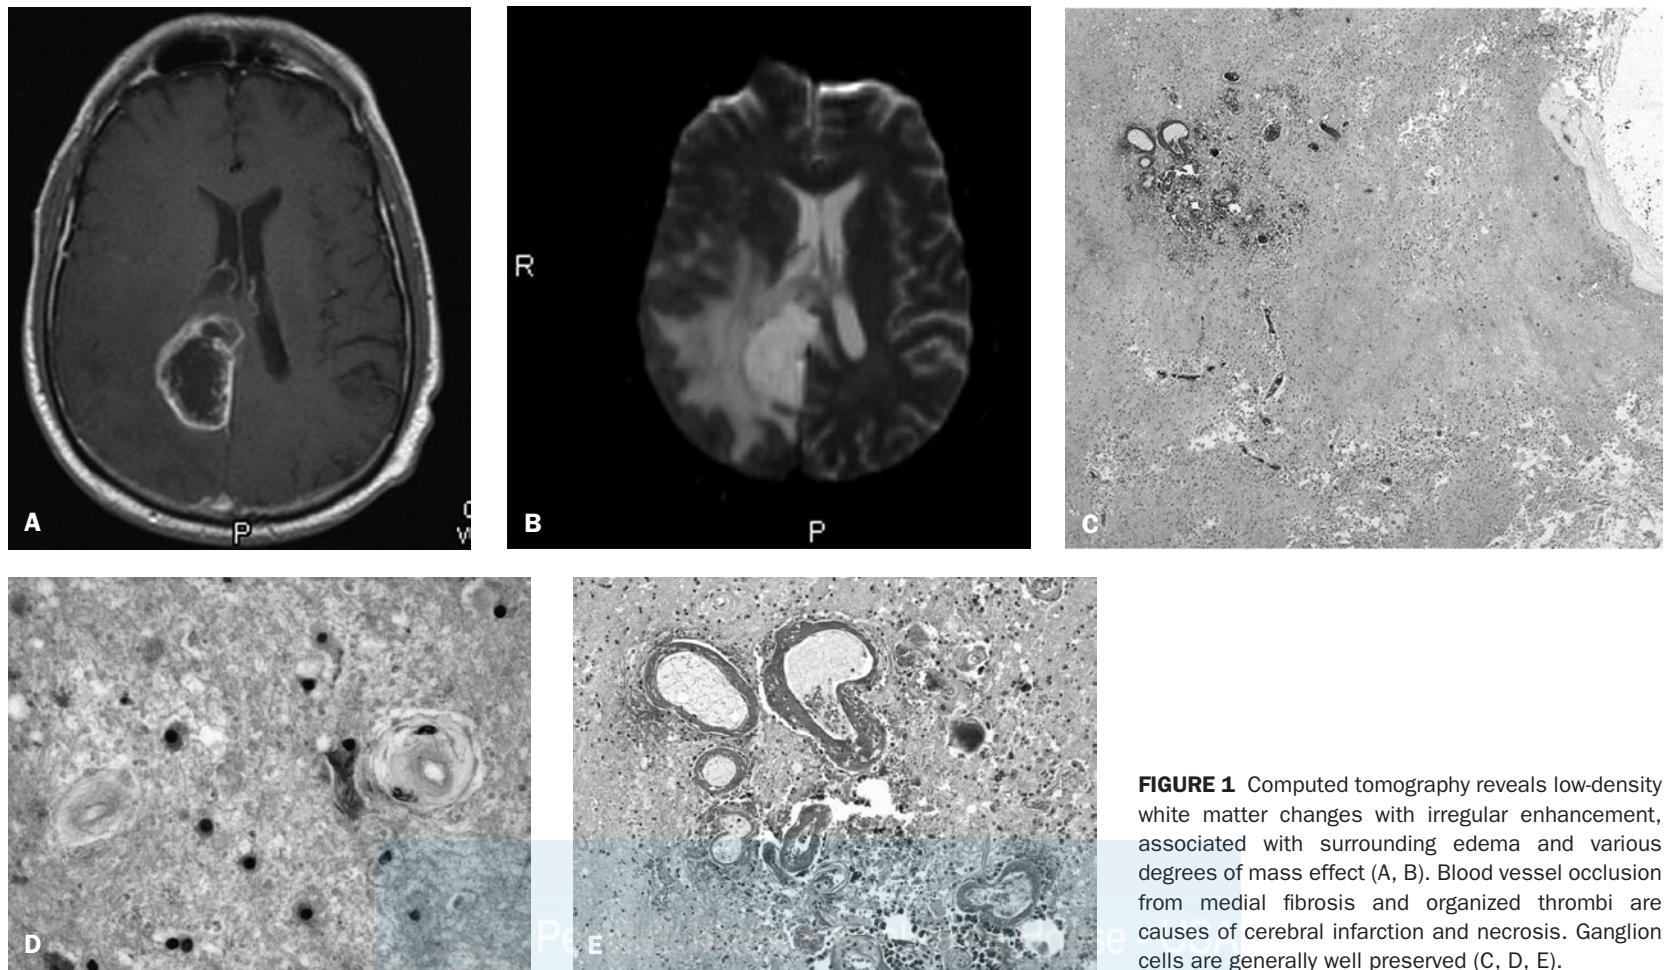

Most cases of severe radiation necrosis occur when small volumes of brain are taken to high

doses, either with stereotactic or partial brain techniques. Focal radiation necrosis is usually confined to the volume receiving high doses of radiation. Computed tomography reveals low-density white matter changes with irregular enhancement, associated with surrounding edema and various degrees of mass effect. These changes are difficult to differentiate from tumor progression or from tumor-associated necrosis (Figure 1A, 1B).<sup>17</sup> MRI demonstrates increased gadolinium uptake with necrosis with increased perilesional signal abnormality on T2 and FLAIR sequences. The abnormal signal intensity is usually periventricular but it can extend out to the cortex.<sup>18</sup> Positron emission tomography (PET) and single photon emission computed tomography (SPECT) can sometimes distinguish between metastatic brain tumor and glioma recurrences versus radiation necrosis.<sup>19–21</sup>

Pathologically, radiation necrosis may be described as yellow-brown with a waxy appearance on gross examination. Coagulation and fibrinoid necrosis with edema and dystrophic calcium deposits are seen histologically. Plaques of demyelination in the white matter and ischemic infarction are often noted. Radiation-induced infarcts demonstrate irregular reactive astrocytes, glitter cell accumulation, gliosis and vascular granulations. Blood vessel occlusion from medial fibrosis and organized thrombi are causes of cerebral infarction and necrosis. Ganglion cells are generally well preserved. (Figures 1C to 1E).<sup>22</sup>

Clinically, radiation necrosis causes symptoms related to mass effect and increased intracranial pressure, such as headache, ataxia, and nausea. Seizures and focal deficits, such as hemiparesis, hemisensory loss, and aphasia, are also seen. Treatment includes the use of high doses of corticosteroids, and surgery may be necessary to evacuate the necrotic mass. Surgical decompression can shorten the time the patient requires steroids and therefore lessens the side effects associated with long-term corticosteroid use.<sup>23</sup> Radiation necrosis is most commonly seen following stereotactic radiosurgery or when partial brain doses are above 60 Gy. Shaw and colleagues noted an incidence of radionecrosis of 5% and 11% at 6 and 24 months, respectively, in patients treated with radiosurgery following previous external beam radiation.<sup>24</sup> Of the 16 patients with radionecrosis, 15 required operation. In low-grade glioma patients randomized to 50.4 Gy versus 64.8 Gy external beam radiation, the two-year actuarial incidence of severe radiation necrosis was 2.5% and 5%, respectively.<sup>25</sup>

White matter injury is the most common late radiation injury and typically extends beyond the high-dose volume of irradiation. Magnetic resonance imaging (MRI) studies have found that 50% of patients show a significant alteration in

**FIGURE 1** Computed tomography reveals low-density white matter changes with irregular enhancement, associated with surrounding edema and various degrees of mass effect (A, B). Blood vessel occlusion from medial fibrosis and organized thrombi are causes of cerebral infarction and necrosis. Ganglion cells are generally well preserved (C, D, E).

white matter signaling. High-grade lesions are associated with radiation to large volumes and higher doses, and, therefore, have a greater likelihood of white matter injury. The frequency of white matter changes is very high. In one series, 100% of 33 patients treated with conventional radiation to a median dose of 54 Gy in 1.8 Gy fractions for primary brain tumors expressed white matter changes on MRI 6 to 25 years after treatment. Patients with confluent white matter changes reported significant physical, cognitive and social impairment. The addition of chemotherapy increased the severity of white matter injury. However, not all severe white matter changes are clinically expressed.<sup>26,27</sup> Pathology reveals white matter pallor and reactive astrogliosis. Clinically, symptoms range from mild fatigue and personality changes, to dementia. Intellectual impairment and learning disabilities are most commonly seen in children.<sup>28</sup>

Leukoencephalopathy is a syndrome characterized by white matter changes associated with the symptoms of lassitude, dysarthria, cognitive dysfunction, and seizures. More severe CNS damage manifests as ataxia, confusion, memory loss, dementia, and death. This syndrome usually appears within 4 years after completion of radiation therapy. It was first described in children with acute lymphatic leukemia (ALL) who were

treated after radiation with intrathecal methotrexate. The syndrome is now also recognized in adults. Imaging reveals white matter injury initially near the ventricles with progression to the entire cerebral white matter. MRI demonstrates an increase in T2 signal throughout the white matter. Calcifications may be scattered or confluent.<sup>29</sup> The clinical course is slowly progressive; however, stabilization has been described.<sup>30</sup>

One of the most widely recognized long-term complication of CNS radiation is a deterioration of cognitive function; however, other therapies, including medication, chemotherapy, surgery, and comorbid illnesses, as well as the tumor itself, contribute to the decline of intellectual ability. Isolating and quantifying the role of radiation therapy in cognitive decline has been extremely difficult.

Many retrospective studies examining the impact of radiation on cognitive dysfunction were methodologically flawed in that no pretreatment baseline cognitive testing was performed. Typically these studies compared neurocognitive function in long-term survivors of brain tumors treated with radiation therapy or surgery alone. Cognitive impairment has been reported in patients receiving high-dose radiation therapy for low- and high-grade gliomas, and from lower-dose radiation therapy such as prophylactic

cranial irradiation for lung cancer, as well as radiation for the pediatric malignancies.<sup>31,32</sup> In a study of surgically treated, low-grade glioma patients, 28 patients who received radiation and 23 treated with surgery alone were alive and eligible for neuropsychological testing. The group receiving postoperative radiation therapy demonstrated significantly decreased neuropsychological performance compared with the cohort treated with surgery alone. However, 19 of the 28 patients treated with radiation therapy received whole brain radiation to a dose of 40 Gy followed by a boost of 20 to 28 Gy. This study strongly suggests that whole brain radiation therapy to a dose of 40 Gy followed by a boost leads to significant neurocognitive impairment.<sup>33</sup> However, in current practice, whole brain irradiation to a dose of 40 Gy is rarely used, and patients are now treated with focal irradiation. Another study compared the neurocognitive outcomes of patients with low-grade glioma, about half of whom were treated with radiation therapy (90% with focal radiation) and half with surgery only, to patients with low-grade non-Hodgkin's lymphoma/chronic lymphocytic leukemia patients and healthy controls. Low-grade glioma patients had a decreased ability in all neurocognitive domains compared to low-grade hematologic patients or healthy controls. The authors concluded that

the tumor itself, and not the radiation therapy, was felt to have the most deleterious effects on neurocognitive outcome, although radiotherapy resulted in some long-term memory deterioration.<sup>28,29,34</sup>

Komaki and colleagues prospectively evaluated the cognitive function of patients receiving prophylactic cranial irradiation (PCI) (total dose of 25 Gy in 10 fractions over 2 weeks). Prior to PCI administration, 29 out of the 30 patients had preexisting cognitive dysfunction. Almost all the cognitive dysfunction was due to disease, as opposed to other factors, such as substance abuse or previous history of neurologic disease. Neuropsychological testing 6 to 20 months later showed no significant differences from the pretreatment state.<sup>35</sup> Thus, WBRT at a dose of 25 Gy as opposed to 40 Gy with a boost does not appear to cause any significant decline in cognition. Neurocognitive function was also determined in patients with non-small cell lung carcinoma treated with PCI (30 Gy in 15 fractions over 3 weeks). Impairments of attention and visual memory in both those treated with PCI and in the control group were noted, but there were no significant differences in neurocognitive functioning between the two treatment groups. However, MRI imaging revealed white matter abnormalities of higher grades in those receiving PCI.<sup>36</sup> Although it is extremely difficult to dissect the role of radiation therapy in the production of neurocognitive deterioration, the bulk of the evidence suggests that the whole brain can tolerate between 25 and 30 Gy without significant impairment. However, when the whole brain receives an excess of 30 Gy, the risk of neurocognitive dysfunction increases dramatically. The principal reason for neurologic deterioration in most cases is the tumor itself. When fraction sizes exceed 2 Gy, the risk of radiation-induced neurocognitive deterioration increases.

In addition to dose and fraction size, age is also a predictive factor for neurocognitive dysfunction. Pediatric cases are often treated with lower-dose irradiation in comparison to adults in the hope of reducing long-term sequelae, including cognitive effects. Ris and colleagues reported the intellectual outcome in 43 pediatric patients treated with craniospinal radiation therapy with adjuvant chemotherapy for medulloblastoma. Diminished functioning from baseline was found in verbal IQ, nonverbal IQ and full-scale IQ. Young children were more negatively affected, and patients with higher baseline functioning suffered sharper declines than those with lower baseline scores.<sup>37</sup>

Other causes of neurocognitive decline, including paraneoplastic disorders, endocrine dysfunction, nutritional deficits, medication, depression, and cancer, per se, should be addressed. Improved radiation techniques and

the use of smaller treatment fields suggest the role of RT in contributing to neurocognitive decline is small. Although there is no treatment for radiation-induced cognitive dysfunction, the concerns of late neurocognitive dysfunction are not a strong reason for omitting RT for the treatment plan in cases in where there is evidence that radiation therapy has been beneficial.<sup>38</sup>

Cerebrovascular effects of radiation therapy occur frequently after treatment to the parasellar region. Pathologic changes after radiation therapy are similar to severe atherosclerosis. Moyamoya disease results from occlusion of the internal carotid artery typically affecting the anterior and middle cerebral branches of the circle of Willis. The disease presents with multiple and diffuse ischemic or hemorrhagic vascular insults causing dementia or death, which can occur years after irradiation. Patient factors such as underlying comorbid disease (including neurofibromatosis), surgery, and tumor encasement of vessels also impact the development of vasculopathy.<sup>39,40</sup> Angiograms show a characteristic “puff of smoke” or blush at the base of the brain from the collateral blood vessel formation.<sup>41</sup>

## Spinal Cord

Radiation myelopathy is a dreaded but rare complication following radiation treatment for either primary spinal cord malignancy, spinal cord metastasis, or after definitive treatment for a thoracic, head and neck, or upper abdominal malignancy. Myelopathy may involve the white or grey matter and typically results in a chronic progressive course.<sup>42</sup> Clinically, spinal cord myelopathy occurs in a subacute (early delayed) or late fashion with either sensory or motor symptoms. Fractionated radiation therapy has a TD<sub>5/5</sub> for spinal myelopathy of 57 to 60 Gy and a TD<sub>5/50</sub> of 68 to 73 Gy.<sup>43</sup> The spinal cord is rarely treated beyond a conservative dose of 50 Gy to limit the frequency of spinal cord injury. Neurotoxic chemotherapy agents such as methotrexate, cisplatin, cytarabine, taxanes, and vinblastine may reduce the tolerance of the spinal cord to radiation. Intrathecal chemotherapy during radiation therapy is contraindicated because of the overlapping spinal cord toxicity.<sup>44</sup>

### Early Spinal Cord Toxicity

Subacute myelopathy is marked by sensory changes, including paresthesias. The latency period for subacute myelopathy is 1 to 6 months and symptoms gradually improve without specific treatment over 2 to 9 months. Lhermitte’s sign is described as an electrical shock with flexion of the neck. It is thought that the flexion of the neck elongates the spinal cord, and this tension results in the clinical symptoms. Only with a long latency period does the appearance of

Lhermitte’s sign foretell of permanent spinal cord injury.<sup>12</sup> From a cohort of 1,112 patients with malignancies of the upper respiratory system treated with radiation therapy, 40 patients (3.6%) developed Lhermitte’s sign with a mean time of development of 3 months and duration of 6 months. No patient progressed to transverse myelitis. An increased risk for the development of Lhermitte’s sign in patients receiving more than 2 Gy per fraction (one fraction per day) or a total of more than 50 Gy to the spinal cord has been noted.<sup>45</sup> Pathologically, early radiation injury to the spinal cord results in focal areas of demyelination, fibrinoid necrosis of blood vessels, and edema.<sup>22</sup> Positron emission tomography may demonstrate increased activity. MRI, although sensitive enough to diagnose demyelination associated with multiple sclerosis, does not show any pathologic change in patients with transient or chronic Lhermitte’s sign. Recovery from spinal injury has been associated with an increase in PET signaling.<sup>42,46</sup>

### Late Spinal Cord Toxicity

Late radiation injury to the spinal cord generally occurs months to years after treatment. The median latency period is 20 months with 75% of cases occurring within 30 months of treatment. The latency period is dose-dependent, with shorter periods for patients receiving higher doses. Children have shorter latency periods than adults. Patients undergoing repeat radiation therapy to the same segment of spinal cord are at particularly high risk of damage and have a mean latency period of only 5 months.<sup>12</sup>

Signs and symptoms of myelitis may be insidious or acute onset, with functional deficits ranging from paresthesias to severe sensory and motor changes, urine and bowel incontinence, and paresis. Brown-Séquard syndrome, which consists of motor weakness and pyramidal tract signs on one side with a decrease in temperature and pain sensations on the contralateral side, can precede a complete myelopathy. On the other hand, some patients present with both extremities equally affected. Radiation-induced cord changes are generally irreversible, and many die from secondary complications.<sup>12</sup>

Delayed late radiation myelopathy is a result of demyelination and axonal loss of the sensory and motor tracts. Pathology reveals white matter, tumor-like masses of cord necrosis with spongiform degeneration and vascular lesions leading to telangiectasia, fibrinoid necrosis, edema, focal hemorrhage, and hemorrhagic necrosis. Neurons are usually spared. Calcifications may be present in older lesions, and, with time, the cord may contract. The etiology of radiation injury is multifactorial. Vascular damage with resultant infarction, parenchymal radiation injury (including damage to oligodendrocytes and astrocytes),

as well as damage to the spinal cord–blood barrier all contribute to the pathogenesis of spinal cord myelitis.<sup>22</sup>

Radiographic imaging of eight patients, treated to an accidental mean dose of 136 Gy and who developed late spinal myelopathy, revealed a high-intensity signal on T2-weighted MRI images as well as gadolinium enhancement on T1-weighted MRI images.<sup>46</sup> However, some patients with myelopathy have no abnormality on MRI.<sup>47</sup> Myelography is often normal, but there may be expansion or attenuation at the level of irradiation. Cerebral spinal fluid evaluation may reveal a mildly elevated protein, but most often is normal without the presence of abnormal cells.<sup>12</sup> Myelin basic protein levels are increased.<sup>48</sup>

In order to qualify for a diagnosis of radiation myelopathy, several criteria must be met: (1) history of prior radiation treatment at or above the level of deficit; (2) the radiation dose must be high enough to cause the deficit; (3) the latency period must be appropriate; (4) other potential etiologies, such as tumor metastasis and cord compression, or a paraneoplastic syndrome, must be excluded.<sup>12</sup>

There is no effective treatment for radiation-induced myelopathy. Prevention, therefore, is critical. Steroids have been used to slow progression and anticoagulation in those with radionecrosis, in order to reverse radiation-induced small-vessel endothelial injury, and have led to clinical improvement in some patients.<sup>49</sup> If neurologic decline is due to hemorrhage into the spinal cord, the patient may recover slowly and future avoidance of nonsteroidal anti-inflammatory drugs and anticoagulants is prudent.<sup>3</sup>

## Cranial Nerves

Cranial neuropathies from radiation therapy are rare since tolerance of the cranial nerves is higher than that of the brain or spinal cord. Injury to cranial nerves is typically expressed 1 to 20 years post-radiation, and recurrent malignancy must be ruled out. Myokymic discharges can be seen on EMG due to hyper-excitability of demyelinated axons.<sup>50,51</sup> Most reported cases have been associated with stereotactic as opposed to external beam radiotherapy. The most common tumor site treated with external beam in which cranial nerve damage has been observed is carcinoma of the nasopharynx, where a 1 to 5% incidence of cranial nerve palsy has been noted.<sup>52</sup> The etiology of cranial neuropathy is thought to be due to either fibrotic encasement, vasculitis, or direct radiation damage.<sup>53</sup>

Radiation-induced olfactory nerve dysfunction is difficult to diagnose because of its close ties to the function of taste, which is often altered during and after radiation therapy. Patients sometimes report a pungent smell which may be

due to stimulation of the olfactory receptors by the free radicals and ozone formed in the nasal mucosa during therapy.<sup>54</sup> Patients also report a transient decreased ability to smell when radiation fields include the olfactory nerves.<sup>55,56</sup>

Radiation can affect visual function through multiple mechanisms, including production of dry eye syndrome, cataract formation, glaucoma, retinopathy, or by directly damaging the optic nerve.<sup>57</sup> Damage to the lacrimal gland from doses of 40 to 50 Gy, which are commonly used in treatment of head and neck carcinomas, may result in a dry eye leading to corneal opacification, ulceration, and, ultimately, in loss of vision. Dry eye syndrome has a latency period of 6 to 10 months.<sup>12</sup> Occasionally, enucleation is necessary to alleviate the pain produced by dry eye syndrome. Cataract formation can occur with doses of fractionated radiation as low as 5 Gy and has a latency period of up to 3 years.<sup>58</sup> Retinopathy is seen after 45 to 50 Gy and is expressed 1.5 to 3 years after high-dose radiation therapy. The clinical characteristics are strikingly similar to diabetic retinopathy, with occlusion of small vessels, neovascularization, hemorrhage, retinal ischemia, cotton wool spots, and retinal arterial narrowing.<sup>59</sup> Secondary angle closure glaucoma may result from neovascularization.<sup>12</sup> During radiation therapy some patients complain of seeing visual lights, which is completely benign. Optic neuropathy is thought to be caused by microangiopathy, which may lead to complete visual loss. In order to make a diagnosis of optic neuropathy, the following criteria must be met: (1) irreversible visual loss with visual field defects; (2) absence of visual pathway compression due to recurrence or progression of tumor, radiation-induced neoplasm, arachnoidal adhesions around the chiasm, radiation retinopathy or any other obvious cause; (3) absence of optic disc edema; and (4) optic nerve atrophy must coincide temporally with the onset of visual loss.<sup>60–62</sup> Radiation-induced optic neuropathy is characterized by bilateral or monocular painless blindness and diplopia. MRI reveals enhancement of the optic nerve, and, pathologically, the nerve show demyelination and gliosis.<sup>3,58</sup>

There is no specific treatment for optic neuropathy, although steroids, anti-coagulants and hyperbaric oxygen have been tried.<sup>63</sup> Prevention of radiation damage by decreasing dose to the eye whenever possible can reduce the likelihood of visual loss. However, for tumors such as pituitary adenomas, optic gliomas, and ocular lymphomas, complete shielding of the involved optic structures may not be possible.

Oculomotor, abducens, or trochlear nerve palsies usually present with a prior history of radiation to the sella turcica or parasellar region, and patients complain of intermittent diplopia or blurred vision. Neuromyotonia, characterized by

spontaneous spasm of eye muscles secondary to spontaneous discharges of the ocular nerves has been described.<sup>64</sup> Demyelination is thought to be the etiology of radiation neuropathy, and there is no treatment; however, in the case of neuromyotonia, membrane-stabilizing agents such as carbamazepine have been used with success.<sup>65</sup>

Trigeminal nerve palsy occurs in 15 to 29% of patients treated with radiosurgery for acoustic neuroma, with a median onset of 5 months.<sup>66</sup> Symptoms include facial nerve pain progressing to numbness, which differentiates this syndrome from trigeminal neuralgia. Atrophy of the muscles of mastication may occur. Tumor recurrence involving the trigeminal nerve must be ruled out. Full or partial spontaneous improvement is seen in approximately one-half of patients.<sup>67</sup>

Facial nerve palsy is rarely seen with external beam but it does occur following radiosurgical procedures for acoustic neuroma cases, where incidences vary from 17 to 67%.<sup>68</sup> Facial nerve palsy has a median onset of 6 months, and approximately one-half of patients have spontaneous partial or full recovery.<sup>69</sup>

Taste is also a function of the seventh cranial nerve, through the chorda tympani nerve, and is frequently affected during the treatment of head and neck carcinomas with external beam radiation. Cancer patients often have some alteration in taste before the initiation of treatment, due either to general malnutrition or vitamin deficiency. Patients begin to notice a loss of taste after two weeks of radiation therapy and one-half to two-thirds of patients have partial to complete taste loss 2 months after completion of radiation therapy. At 12 to 24 months, most have partial recovery. Xerostomia and mucositis can contribute to perceived loss of taste. The perception of sweet had the fastest recovery, with sour having the slowest rate of recovery. After 12 to 24 months, bitter and salt were still the qualities most impaired. The TD<sub>5/50</sub> for loss of taste is in the 50 to 60 Gy range.<sup>70,71</sup>

Radiation-induced acute hearing loss from external beam treatments is usually from a serous effusion which resolves spontaneously. Late acoustic nerve palsy is difficult to diagnose because it can also be due to normal aging, trauma to the eustachian tube, or tympanic membrane perforation.<sup>72</sup> Kwong and colleagues reported on sensorineural hearing loss in 132 patients treated for nasopharyngeal carcinoma with irradiation and cisplatin. Twenty-two percent had evidence of hearing loss, with higher frequencies affected the most; however, it is unclear how much was due to the cisplatin.<sup>73</sup> Late acoustic nerve damage has been reported in 33 patients treated for supratentorial brain tumors. Seventy-seven percent of patients treated for vestibular schwannomas with radiosurgery have hearing preservation. Significantly reduced sensorineural hearing loss

was found for all frequencies tested in both air (28 of 33 patients) and bone conduction (15 of 33 patients). Patients treated to less than 54 Gy did not have severe hearing loss. Vestibular function was also reduced in three patients, with two patients having symptoms of balance disturbances.<sup>74</sup>

The remaining cranial nerves (glossopharyngeal, vagus, spinal accessory, and hypoglossal) all course through the neck and are all potentially susceptible to encasement by radiation fibrosis after treatment for head and neck cancer, which can lead to dysfunction.<sup>75</sup> Radiosurgery of acoustic neuromas or vestibular schwannomas can result in damage to the nerves depending on the volume of the lesion and the dose prescribed. Patients with dysfunction of the ninth and tenth cranial nerves complain of dysphagia, dysphonia and, in severe cases, dyspnea due to abnormal glottic closure. Xerostomia can also contribute to dysphagia, and a trial of pilocarpine may prove beneficial.<sup>76</sup> Although xerostomia affects the perception of poor swallowing, it does not alter the physiologic aspects of bolus transport.<sup>77</sup> Axonal degeneration from microvascular damage and direct Schwann cell injury have also been implicated in the damage of nervous tissue from radiation therapy.<sup>78</sup> Treatment includes supportive care and palliative procedures such as gastrostomy tubes for dysphagia, and a laryngoplasty or tracheostomy to relieve hoarseness of voice or dyspnea, and reduce the risk of aspiration.

## Peripheral Nerves

When peripheral nerves are damaged by radiation, symptoms include pain, paresthesias, and, rarely, weakness. Of all peripheral nerves the brachial and lumbosacral plexi are the most frequently damaged. The etiology is largely speculative; however, demyelination of axon fibers, fibrosis, and nerve ischemia from radiation-induced vasculature damage have been hypothesized.

Brachial plexopathy is seen in 1.8 to 5% of patients treated for breast, lung, lymphoma, and other tumors involving the upper extremity. Latency periods range from 1 month to 18 years.<sup>79</sup> Radiation doses higher than 50 Gy, the use of chemotherapy, and extensive axillary node dissection are predisposing factors.<sup>80</sup> Before attributing the damage to radiation, other causes must be ruled out, such as tumor recurrence, vasculopathy with subclavian occlusion, or surgical structural damage. EMG studies show abnormal motor and sensory nerve conduction with myokymic discharges, which are helpful in distinguishing radiation-induced plexopathy from paraneoplastic causes.<sup>81</sup> Clinically, radiation neuropathies present as paresthesias but may progress to weakness and sensory loss to full paresis. Although pain may be a prominent

feature; the severity is usually less in radiation plexopathy compared with neoplastic plexopathy. MRI may reveal either increased or decreased T2 signal with a decreased T1 signal.<sup>82</sup> If radiation-induced fibrosis is the basis of nerve damage, enhancement with gadolinium is seen. Therapeutic options for radiation-induced plexopathies are limited. No treatment exists that will restore full function. Surgery with neurolysis, grafting of the latissimus dorsi or omentoplasty may be of some benefit. Hyperbaric oxygen, which has been successful in the treatment of osteoradionecrosis and hemorrhagic cystitis, is not useful.<sup>83</sup>

Lumbosacral plexopathy presents with lower extremity weakness and sensory loss, which may remain stable for years or progress to paralysis. Often, foot drop is the first presenting symptom. EMG reveals myokymic discharges, suggesting radiation damage instead of tumor recurrence. The etiology of lumbosacral plexopathy is thought to be similar to brachial plexopathy. Like brachial plexopathy, the latency period for lumbosacral plexopathy is long.<sup>84,85</sup> Lumbosacral plexopathy is most commonly seen in patients treated for endometrial, bladder, and other pelvic tumors, including rectal carcinoma.<sup>86,87</sup> As with brachial plexopathy, it is essential to exclude tumor recurrence before attributing the damage to radiation. Post-radiation therapy lumbosacral polyradiculopathy can also demonstrate nodular and leptomeningeal enhancement of the cauda equina and conus medullaris on MRI.<sup>88</sup>

Clinically, lumbosacral plexopathy is commonly bilateral, and the pain is milder in comparison to tumor-associated plexopathy. Incontinence is not typically a feature of radiation-induced plexopathy.<sup>89</sup> No effective treatment exists; however, supportive care with pain management and occupational/physical therapy are helpful to improve quality of life.<sup>90</sup>

## Second Malignancies

One of the most serious late complications of radiation therapy is the induction of a secondary malignancy. Radiation-induced tumors include benign and malignant processes including meningiomas, schwannomas, sarcomas, and gliomas. Typically radiation-induced lesions are high-grade and have an aggressive natural history.<sup>91</sup>

Criteria to support a diagnosis of a radiation-induced tumor include: (1) the tumor must have a different histology than the original tumor; (2) the tumor must develop within/adjacent to the radiation field; (3) a minimum period of several years must have elapsed since the radiation was received; and (4) the patient must not suffer from underlying genetic disease that favors the development of tumors, such as von Recklinghausen's disease or Li-Fraumeni syndrome. Confirmation of the presumed diagnosis must always be made

by biopsy.<sup>92</sup> Fortunately, radiation-induced CNS neoplasms are rare, with 34 cases of sarcomas and 312 cases of meningiomas reported as of 1995. The overall relative risk of developing a second neoplasm is 1 to 3% with a latency of 15 to 30 years.<sup>93,94</sup> Factors that may increase the risk of a secondary malignancy include the use of chemotherapy, young age, and genetic predisposition. Secondary tumors may arise from both low- and high-dose radiation therapy.<sup>3,77,95,96</sup> Radiation-induced tumors of the peripheral nervous system have also been described.<sup>76,79,97-100</sup>

## Endocrine Dysfunction

Loss of endocrine function is common when radiation therapy is delivered to the base of skull, pharynx, or directly to the hypothalamus-pituitary axis. In general, the hypothalamus is more sensitive than the anterior pituitary. Posterior pituitary dysfunction has not been reported.<sup>101</sup> The time to develop an endocrine abnormality can vary from a few months to 10 or more years following radiation therapy.<sup>102</sup>

The different hypothalamic-pituitary axes respond to irradiation with varying degrees of sensitivity. The growth hormone axis is the most sensitive, while the prolactin axis is the least sensitive. Growth hormone deficiency after irradiation has been reported after doses as low as 12 to 24 Gy. Abnormalities of growth can be subtle and may only manifest at puberty. In children, a high index of suspicion is prudent, and it is advisable to test for growth hormone (GH) deficiency every 6 months after therapy. To diagnose GH deficiency in children treated with spinal irradiation, it is necessary to measure growth velocity of long bones such as the femur, which is outside of the radiation field. When a decrease in growth rate is noted, growth hormone deficiency cannot be assumed. Further testing is necessary to rule out competing diagnoses, such as thyroid disease and malnutrition, before more definitive growth hormone testing is pursued.<sup>103,81</sup> Recombinant human growth hormone can restore the normal velocity of growth in children; however, catch-up growth may not occur.<sup>104</sup> Adults do not often have clinical symptoms from growth hormone deficiency, although a decrease in lean muscle mass can be seen.<sup>105</sup> Growth hormone replacement in adults after radiation therapy, therefore, remains controversial.<sup>106,107</sup>

After doses of 50 Gy to the hypothalamic-pituitary axis, 29 to 35% will have gonadotropin deficiency. Gonadotropin dysfunction may lead to precocious puberty in children.<sup>24,108,109</sup> Adults may experience infertility, abnormal menses, and decreased libido. The diagnosis of gonadotropin deficiency is based on elevated serum LH and FSH levels. A gonadotropin releasing hormone test may also be of use. Females with complete

gonadotropin deficiency require estrogen and progesterin replacement, while those with a partial deficiency need periodic progesterin administration to induce menses. Males require androgen replacement.

TSH deficiency leading to hypothyroidism presents with lethargy, weight gain, cold sensitivity and other signs of decreased thyroxin. Children may also demonstrate a decreased growth rate. Data are limited as to a threshold dose. Pediatric series report an incidence of 3 to 6% after doses of 40 to 50 Gy to the hypothalamic-pituitary axis. In adults, the incidence is 60 to 65% after doses of 50 to 57 Gy.<sup>110,111</sup> Treatment consists of thyroxin replacement and monitoring of therapy with serum TSH, T4, and T3 levels.

Symptoms of adrenocorticotrophic hormone (ACTH) deficiency include lethargy, fasting hypoglycemia and dilutional hyponatremia. Incidences range from 19 to 35% after a dose of more than 50 Gy to the HPA axis and latency time varies from 5 to 15 years.<sup>112,113</sup> Random cortisol levels below 18 µg/dL suggest the diagnosis and further testing can be pursued with an insulin hypoglycemic challenge and metyrapone. Treatment consists of replacement with hydrocortisone.<sup>114</sup>

Prolactin is controlled by the hypothalamic neurotransmitter dopamine. When the hypothalamus is damaged, the inhibitory effects of dopamine on prolactin are released and hyperprolactinemia results. Prolactin functions to initiate lactation and regulate cyclic ovulation in the female.<sup>115</sup> Hyperprolactinemia is seen after doses of 50 Gy to the HPA axis, with an incidence of 50%, and results in menstrual irregularity, galactorrhea, and infertility in the female. Treatment consists of dopamine agonists such as bromocriptine, which will reduce prolactin levels.<sup>116</sup>

# Neurologic Complications of Chemotherapy

Denise M. Damek, MD

Despite differing mechanisms of action and modes of administration, the final common pathway of chemotherapeutic agents is the reduction or cessation of abnormal cancer cell proliferation. Consequently, normal body tissues with rapid cell turnover are the most susceptible to chemotherapy-related toxicity. Neurotoxicity is not commonly seen for several reasons. First of all, in the adult central nervous system, active cell turnover is limited to neuroglial cells, macrophages, and endothelial cells. In addition, the central nervous system is protected by a blood-brain barrier which effectively excludes many large molecules and hydrophilic compounds. The peripheral nervous system is similarly protected by a blood-nerve barrier. The blood-brain barrier can be circumvented by directly administering chemotherapy into the cerebrospinal fluid or brain, providing a drug in large doses systemically or intra-arterially, or utilizing agents to disrupt the blood-brain barrier. Prior or concurrent brain irradiation, or the presence of structural lesions within the brain, may increase drug penetration into the central nervous system. As such, neurotoxicity is variable and depends not only on the drug itself, but also upon the dose provided, the route of administration, and concomitant or prior therapies. In some instances, neurotoxicity is dose-limiting.

Not all neurotoxicity is the result of direct chemotherapy action on the nervous system. Chemotherapy-mediated alteration of electrolytes, fluid balance, the coagulation system, the immune system, and body organ function may cause or exacerbate central and peripheral nervous system dysfunction.

This chapter addresses the neurologic complications of some of the most commonly used chemotherapy agents (Table 1). Central and peripheral nervous system toxicity is discussed (Table 2). Neurologic complications related to radiation are addressed in another chapter in this volume (see Chapter 42, "Neurologic Toxicity of Radiotherapy").

## Chemotherapy-Induced Toxicities of the Peripheral Nervous System

### Peripheral Neuropathy

Peripheral neuropathies result from altered function and structure of peripheral nerves. Depending on the underlying cause, there may be selective involvement of motor, sensory, or autonomic nerve fibers; or more diffuse involvement of all fibers. Toxins such as chemotherapy cause peripheral neuropathy through axonal degeneration, primary neuronal degeneration, or segmental demyelination.

Axonal degeneration is the most common cause of peripheral neuropathy. Here, a toxin acts at multiple sites along nerve axons, ultimately causing degeneration of the nerve axon and myelin sheath beginning at the most distal part of the nerve and progressing proximally towards the nerve cell body. Descriptively, these neuropathies are often referred to as dying-back neuropathies or length-dependent peripheral neuropathies. The clinical presentation is a symmetrical, distal to proximal graded loss of sensory and motor function. The sensory loss occurs in a stocking-glove distribution. By the time the sensory abnormality reaches the level of the knees, symptoms are often recognized in the hands. If large sensory nerve fiber involvement predominates, symptoms include loss of proprioception and gait ataxia. Small fiber involvement leads to paresthesias, and loss of pin and temperature sensation. Distal muscle weakness and atrophy occur when motor nerves are affected. Likewise, loss of ankle jerks occurs first, followed by other reflexes (depending on the degree of proximal spread). Axonal regeneration can occur, albeit slowly. Recovery may be significantly delayed and is often incomplete.

In primary neuronal degeneration, a toxin damages or destroys the dorsal root ganglion neurons, which are the sensory nerve cell bodies. Degeneration of the entire peripheral and central axonal processes follows. Clinically, there is prominent loss of ability to localize the extremities in space (proprioception), diffuse areflexia, and ataxia. Neuronal regeneration does not occur.

As such, symptom recovery is contingent upon the degree of damage to the dorsal root ganglion cells. Recovery is poor, but incomplete reversal of some symptoms may occur over a long interval.

With segmental demyelination, toxins injure and break down either the myelin sheath or the Schwann cells along the entire length of nerve fibers with relative sparing of the underlying axons. This most commonly occurs in the setting of immune-mediated inflammatory processes, but occasionally can be mediated by toxins. The functional correlate of demyelination is nerve signal conduction block, resulting in motor weakness and mild sensory loss. Sensory modalities relayed via small-diameter myelinated fibers or unmyelinated fibers, such as temperature and light touch, are generally spared. Remyelination of nerve fibers and clinical recovery can occur within days to weeks.

Many neuropathies present towards the end of therapy or after completion of chemotherapy, limiting the clinician's ability to impact symptomatology with drug cessation. For this reason, the early detection of neuropathy prior to the development of symptoms is paramount. Unfortunately, the use of electrophysiologic testing, in particular nerve conduction studies, to identify high risk patients, or for the early detection of peripheral neuropathy, has for the large part been disappointing. However, a decrease in sensory nerve action potentials (SNAPs) may be used to monitor the severity of a neuropathy objectively in some cases.<sup>1</sup>

### Platinum Compounds

The main neurologic complication of cisplatin is a cumulative dose-dependent sensory neuropathy. Cisplatin almost exclusively affects the large myelinated sensory nerves, both clinically and by objective measurement of nerve conduction studies.<sup>2</sup> Subclinical signs of cisplatin neuropathy, primarily absent ankle jerks and decreased vibratory function, are seen at cumulative doses > 200 mg/m<sup>2</sup>. Some patients perceive sensory symptoms after cumulative doses

Table 1 Chemotherapeutic Agents Causing Neurotoxicity

<i>Chemotherapeutic Agent and Drug Class</i>	<i>Mechanism of Action</i>	<i>Mode of Administration</i>	<i>Use</i>
<b>Alkylating Agents</b>			
<b>Platinum-based</b>			
Cis-platinum	Inhibits DNA synthesis by the formation of DNA cross-links	IV, IA	Head and neck, breast, testicular, and ovarian CA, sarcomas, bladder, gastric, lung esophageal, cervical, and prostate CA, myeloma, melanoma, small cell lung cancer, osteosarcoma, Hodgkin's and non-Hodgkin's lymphoma, neuroblastoma
Carboplatin	Covalently binds to DNA bases and disrupts DNA function	IV, IA	Ovarian cancer. Lung, head and neck, endometrial, esophageal, bladder, breast, cervical, CNS tumors, germ cell tumors, osteogenic sarcoma, and high-dose therapy with stem cell/bone marrow support
Oxaliplatin	Binds to DNA, RNA, or proteins	IV	Advanced colorectal carcinoma. Head and neck cancer, non-Hodgkin's lymphoma, ovarian cancer
<b>Nitrosoureas</b>			
Carmustine (BCNU)	Interferes with DNA function by alkylation and formation of DNA cross-links	IV, implantable wafer	CNS tumors, multiple myeloma, Hodgkin's and non-Hodgkin's lymphoma, melanoma, lung and colon carcinoma
Lomustine (CCNU)	Inhibits DNA and RNA synthesis via carbamylation of DNA polymerase, alkylation of DNA, and alteration of RNA proteins	PO	CNS tumors, Hodgkin's and non-Hodgkin's lymphoma, melanoma, renal carcinoma, lung and colon carcinoma
<b>Mustards</b>			
Ifosfamide (with mesna)	Inhibits DNA synthesis by the formation of DNA cross-links	IV	Lung cancer, Hodgkin's and non-Hodgkin's lymphoma, breast CA, acute and chronic lymphocytic leukemias, ovarian CA, sarcomas, pancreatic and gastric carcinomas
Cyclophosphamide	Inhibits DNA synthesis by the formation of DNA cross-links	IV	Hodgkin's and non-Hodgkin's lymphoma, Burkitt's lymphoma, leukemia (CLL, CML, AML, ALL), mycoses fungoides, multiple myeloma, neuroblastoma, retinoblastoma, sarcomas, breast, testicular, endometrial, ovarian, and lung CA. Conditioning regimens for bone marrow transplant
Melphalan	Inhibits DNA and RNA synthesis by the formation of carbonium ions and DNA cross-links	PO, IV	Palliative treatment of multiple myeloma, nonresectable epithelial ovarian carcinoma, neuroblastoma, rhabdomyosarcoma, breast CA
<b>Other</b>			
Thiotepa	Inhibits DNA, RNA, and protein synthesis by the cross-linking of DNA	IV, IT, intravesicular	Superficial bladder tumors, breast and ovarian adenocarcinoma, lymphoma, sarcoma, CNS leptomeningeal disease and metastases
Procarbazine	Mechanism of action is unclear; methylates nucleic acids, inhibits DNA, RNA, and protein synthesis, may damage DNA directly and suppress mitoses	PO	Hodgkin's and non-Hodgkin's lymphoma, CNS tumors, melanoma, lung cancer, multiple myeloma
<b>Plant Alkaloids</b>			
<b>Vincas</b>			
Vincristine	Disrupts the formation of the mitotic spindle by binding to tubulin and inhibiting microtubule formation	IV	Leukemia, Hodgkin's and non-Hodgkin's lymphoma, Wilms' tumor, neuroblastoma, rhabdomyosarcoma
<b>Podophyllins</b>			
Etoposide (VP-16)	Delays transit of cells through the S phase and arrests cells in the late S or early G2 phase. Inhibits topoisomerase II and appears to cause DNA strand breaks.	IV	Lymphoma, lung, testicular, bladder, and prostate CA, hepatoma, rhabdomyosarcoma, uterine CA, neuroblastoma, mycosis fungoides, Kaposi's sarcoma, histiocytosis, gestational trophoblastic disease, Ewing's sarcoma, Wilms' tumor, and CNS tumors
<b>Others</b>			
Paclitaxel	Promotes microtubule assembly and distorts mitotic spindles	IV	Breast, lung (small cell and non-small cell), and ovarian cancers
Docetaxel	Inhibits DNA, RNA, and protein synthesis by stabilization of microtubules	IV	Breast and non-small cell lung cancer

Table 1 Continued

<i>Chemotherapeutic Agent and Drug Class</i>	<i>Mechanism of Action</i>	<i>Mode of Administration</i>	<i>Use</i>
<b>Antimetabolites</b>			
<b>Antifolates</b>			
Methotrexate	Folate antimetabolite. Inhibits DNA synthesis by inhibiting purine and thymidylc acid synthesis	IV, IT	Trophoblastic neoplasms, leukemias, breast, head and neck, and lung carcinoma, osteosarcoma, soft-tissue sarcomas, GI tract, esophageal, and testicular CA, lymphomas
<b>Cytidine Analogs</b>			
Cytarabine	Inhibits DNA synthesis by incorporating into DNA and inhibiting DNA polymerase	IV, IT	Leukemias, lymphomas
<b>Fluorinated Pyrimidines</b>			
Fluorouracil	Pyrimidine antimetabolite. Interferes with DNA synthesis by blocking the methylation of deoxyuridylic acid	IV, topical	Breast, colon, head and neck, pancreas, rectum, and stomach CA. Used topically to treat skin cancer.
<b>Purine Analogs</b>			
Fludarabine	Inhibits DNA synthesis by inhibition of DNA polymerase and ribonucleotide reductase	IV	Chronic lymphocytic leukemia, non-Hodgkin's lymphoma
<b>Others</b>			
Hydroxyurea	Mechanism is unclear. Thought to inhibit DNA synthesis by inhibition of ribonucleoside diphosphate reductase	PO	CML, acute leukemia, radiosensitizing agent in the treatment of CNS tumors, head and neck tumors, uterine, cervix, and non-small cell lung cancer
Gemcitabine	Pyrimidine antimetabolite. Inhibits DNA synthesis by inhibition of DNA polymerase and ribonucleotide reductase	IV	Adenocarcinoma of the pancreas, non-small cell lung cancer
<b>Antineoplastic Antibiotics</b>			
<b>Anthracyclines</b>			
Doxorubicin	Inhibition of DNA and RNA synthesis by intercalation between DNA base pairs	IV	Leukemias, lymphomas, multiple myeloma, sarcoma, mesotheliomas, germ cell tumors of the ovary and testes, neuroblastoma, head and neck, thyroid, lung, breast, stomach, pancreas, liver, ovary, bladder, prostate, and uterine CA
<b>Antineoplastic Enzymes</b>			
L-Asparaginase	Inhibits protein synthesis through the depletion of asparagine	IV, IM, subcutaneous	Acute lymphocytic leukemia, lymphoma
<b>Antineoplastic Biologics</b>			
<b>Cytokines</b>			
Interleukin-2	Promotes differentiation, and proliferation, and recruitment of T and B cells, natural killer cells, and thymocytes; stimulates lymphokine-activated killer cells and tumor-infiltrating lymphocytes	IV, Subcutaneous	Renal cell CA, melanoma, multiple myeloma, colorectal CA, non-Hodgkin's lymphoma
Interferon	Stimulates the immune system against tumor cells; direct and indirect cytotoxic activity; increases the expression of tumor-associated antigens	Subcutaneous	Chronic myelogenous leukemia, hairy cell leukemia, Kaposi's sarcoma, malignant melanoma, follicular non-Hodgkin's lymphoma
<b>Anti-angiogenesis Agents</b>			
Thalidomide	Inhibits tumor necrosis factor-alpha; inhibits fibroblast growth factor and vascular endothelial growth factor-induced angiogenesis	PO	Multiple myeloma, Waldenström's macroglobulinemia, CNS tumors, Kaposi's sarcoma
Suramin	Inhibits a number of growth factors and enzymes essential to cell proliferation. May also have anti-angiogenic activity	IV	Chemosensitizing agent for various solid tumors; investigational use in prostate cancer and many other cancer types
ALL = acute lymphoblastic leukemia; AML = acute myelogenous leukemia; CA = cancer; CLL = chronic lymphocytic leukemia; CML = chronic myelogenous; CNS = central nervous system; DNA = deoxyribonucleic acid; GI = gastrointestinal; IA = intra-arterially; IM = intramuscularly; IV = intravenously; PO = oral.			

> 300 mg/m<sup>2</sup>,<sup>3,4</sup> but almost all patients have evidence of neuropathy at cumulative doses greater than 500 to 600 mg/m<sup>2</sup>.<sup>5</sup> Symptom onset is often delayed and may not manifest until after completion of therapy.<sup>6</sup> In fact, symptoms can worsen in the weeks to months following discontinuance of

the drug.<sup>7</sup> The first symptoms are paresthesias and numbness of the feet, progressing to involve the lower and upper extremities. Loss of proprioception results in gait ataxia. Muscle cramps are frequently reported during symptom progression and gradually resolve after symptom

stabilization.<sup>7</sup> Lhermitte's sign is occasionally present. Autonomic symptoms, while reported, rarely occur.<sup>3,8,9</sup> Somatosensory-evoked responses (SSER) may facilitate early detection of cisplatin neuropathy by showing a slight impairment of nerve conduction prior to the presence of

abnormal signs or symptoms.<sup>10</sup>; however, clinical applicability has yet to be demonstrated. SSER may be more accurate than conventional electrophysiologic studies in evaluating the progression of cisplatin neuropathy.

Cisplatin preferentially accumulates in the dorsal root ganglia, dorsal roots, and peripheral nerve, and appears to remain there indefinitely in an acutely neurotoxic state.<sup>10,11</sup> Platinum levels in the dorsal root ganglia correlate with cumulative cisplatin doses and possibly symptom severity.<sup>10</sup> However, the mechanism of cisplatin-induced neuropathy remains unknown. Prior exposure to platinum compounds is generally thought to be a major risk factor for the development of peripheral neuropathy. However, no substantial neurotoxicity was reported with re-treatment of cisplatin in one study.<sup>12</sup> Components of the neuropathy, including muscle cramps and Lhermitte's sign, are self-limited symptoms. The remaining neuropathic features, in particular the sensory deficits, are often permanent. However, a small percentage of patients show slow gradual symptom improvement.

The role of neuroprotective agents in preventing or ameliorating cisplatin-induced neurotoxicity is unclear. One randomized, double-blind, placebo-controlled trial of Org-2766, a synthetic corticotropin(4-9) analogue, in patients treated with cisplatin for ovarian cancer found that treated patients showed stable vibratory perception thresholds and less prominent neurologic deficits compared to untreated patients.<sup>13</sup> However, this result was not duplicated in a later study.<sup>14</sup> Less impairment of sensory nerve conduction abnormalities was seen in gastric cancer patients given glutathione with cisplatin chemotherapy.<sup>15</sup> Amifostine, a thiol prodrug, has shown mixed results in three clinical trials.<sup>16-18</sup> Despite some initial promising results, to date, none of these therapies has shown unequivocal benefit.

At standard doses, carboplatin causes paresthesias in approximately 5% of patients. However, high-dose carboplatin can cause a sensory neuropathy similar to that produced by cisplatin.

Oxaliplatin-induced peripheral neuropathy is indistinguishable from that produced by cisplatin. Peripheral neuropathy develops following long-term drug administration, presumptively corresponding to the cumulative dose provided. Oxaliplatin-induced neuropathy symptomatically may respond to temporary cessation of the drug. Forty percent of patients have complete symptom resolution 6 to 8 months following cessation of therapy.<sup>19</sup> Anecdotal evidence suggests some symptomatic benefit with carbamazepine and amifostine.<sup>20,21</sup>

#### Thalidomide

Peripheral neuropathy usually occurs following prolonged administration of thalidomide. Up to 70% of patients treated for more than 6 months

have signs and symptoms of peripheral neuropathy.<sup>22</sup> Peripheral neuropathy can be dose-limiting. Clinical trials utilizing a variety of daily doses report a frequency of mild neuropathic symptoms of 13 to 41%, and severe neuropathic symptoms of 5 to 20%.<sup>23</sup> The incidence of peripheral neuropathy is higher in elderly patients, patients with preexisting neuropathy, and those treated with additional neurotoxic chemotherapy. The risk is greater when the cumulative dose exceeds 50 g.<sup>24</sup> Genetically determined alterations in drug metabolism (ie, "slow acetylators") may be more susceptible to toxicity due to slower drug excretion.<sup>22</sup>

Clinical symptoms initially relate to small fiber sensory nerve involvement, with paresthesias and numbness of the toes and fingers that extends proximally. Later, large fiber involvement is seen with abnormal vibratory perception, deep pressure sensation, and poor position sense. Eventually ataxia, progressive gait disturbance, and postural tremor are seen. If the neuropathy is severe, pyramidal tract damage, proximal muscle weakness, and muscular atrophy develop. Magnetic resonance imaging (MRI) of the spinal cord of patients with neuropathy show signal abnormalities in the posterior columns, consistent with degeneration of the posterior columns.<sup>25</sup> Symptom improvement typically occurs within 3 weeks of discontinuance of the drug; however, the extent of recovery is variable.<sup>22</sup> Discontinuance of the drug at the onset of neuropathic symptoms increases the probability of recovery. Likewise, better recovery is generally seen in younger patients and those treated with lower cumulative doses of thalidomide.<sup>26</sup>

#### Vincristine

Vincristine causes significantly more neurotoxicity than the other vinca alkaloids. Peripheral neuropathy is rarely seen with vindesine sulfate and vinblastine treatment; however, it may complicate vinorelbine therapy in 20 to 25% of patients. Approximately 50% of individuals treated with a typical dose of vincristine (2 mg/dose limit) develop paresthesias of the fingers and toes. If single doses in excess of 2 mg are provided, the incidence of symptomatic neuropathy is approximately 90%.<sup>27</sup> In fact, a mixed sensorimotor polyneuropathy is dose-limiting for vincristine.

Muscle cramps affecting the arms and legs may be the first manifestation of neuropathy and may be the last symptom to resolve. Typical progression of signs and symptoms includes the early development of paresthesias in fingers and toes, loss of ankle reflexes, and then symmetrical length-dependent distal sensory and motor deficits. Impairment of fine motor skills often precedes clinically detectable weakness of the hands and feet. Vibratory sensation is generally spared. As symptoms progress, gait ataxia may

occur. Autonomic neuropathy is common, occurring in as many as one-third of patients.<sup>28</sup> Bowel motility dysfunction, manifesting as colicky abdominal pain and constipation, paralytic ileus, or megacolon, may precede the development of sensory or motor symptoms.<sup>27</sup> Orthostatic hypotension, urinary retention from an atonic bladder, impotence, and disturbed heart rate occur infrequently. Cranial nerve involvement occurs in approximately 10% of cases. Laryngeal nerve paresis is the most commonly described. Patients present with hoarseness generally after several courses of vincristine. Symptom resolution occurs 4 to 6 weeks following discontinuance of the drug.<sup>29</sup> In addition, diplopia, facial nerve palsy, ophthalmoplegia,<sup>30</sup> and sensorineural hearing loss<sup>31</sup> have been reported.

Risk factors for developing vincristine neurotoxicity include single doses greater than 2 mg, frequent vincristine administration, poor nutritional state, advanced age, liver dysfunction, and concurrent neurotoxic drugs.<sup>32</sup> Individuals with preexisting abnormalities of peripheral nerve, such as the demyelinating type of Charcot-Marie-Tooth disease (hereditary motor and sensory neuropathy type I) can develop a severe, often irreversible and sometimes fatal neuropathy.<sup>30,33</sup>

There is no clearly effective treatment for vincristine-induced neuropathy other than discontinuance of the drug. Overall, the long-term prognosis for recovery is good. If vincristine is discontinued, when paresthesias first appear, symptoms promptly resolve. Mild symptoms generally resolve within a couple of months after drug cessation.<sup>27</sup> However, when prominent, motor weakness may take months to regress, and sensory symptoms may linger for years.<sup>34</sup>

#### Paclitaxel

The occurrence and severity of peripheral neuropathy with the taxanes is single-dose and cumulative-dose-related.<sup>35-37</sup> Paclitaxel-induced neuropathy is the best characterized. Symptoms manifest following cumulative doses of 100 to 200 mg/m<sup>2</sup>.<sup>36</sup> At a single paclitaxel dose of 135 mg/m<sup>2</sup>, approximately 2% of patients develop paresthesias of the hands and feet,<sup>38</sup> but following a dose of 250 mg/m<sup>2</sup>, approximately 60% of patients develop neuropathic symptoms.<sup>28</sup> Neuropathy is the dose-limiting toxicity when paclitaxel doses > 250 mg/m<sup>2</sup> are administered in combination with granulocyte colony-stimulating factor.<sup>39,40</sup>

Paclitaxel and docetaxel produce a predominantly sensory neuropathy. The pathophysiologic mechanism of paclitaxel-induced neuropathy is thought to be related to microtubule aggregation in neurons, axons, and Schwann cells, which leads to demyelination and abnormal axoplasmic transport.<sup>35</sup> Unlike the sensory neuropathy elicited by cisplatin, all sensory modalities are affected. Within 48 hours of treatment,

patients develop paresthesias, numbness, and pain in the feet and hands. Pruritus can be a prominent feature. The rapid onset of symptoms and early presence of hand symptoms suggests preferential involvement of dorsal root ganglia and/or myelin sheath.<sup>41</sup> Fine motor skills are often compromised, but weakness is not generally seen. However, some patients may develop disabling proximal muscle weakness mimicking myopathy.<sup>42</sup> Arthralgia and myalgias, especially in the legs, can often be seen 2 to 7 days after the drug is given.<sup>43</sup> Rare autonomic neuropathy has been reported.<sup>44</sup> In addition, Lhermitte's sign can develop following docetaxel administration.<sup>37</sup> Symptoms are usually reversible after discontinuation of the drug, and may even resolve despite continued therapy.<sup>28</sup> However, there are reports of permanent neuropathy.<sup>45</sup> Predisposing factors include high-dose cycles, high cumulative doses, diabetes mellitus, and preexisting neuropathy.<sup>28</sup>

#### Suramin

Suramin produces a predominantly motor peripheral neuropathy in up to 40% of patients whose blood levels of the drug exceed 350 µg/ml.<sup>28</sup> Patients commonly describe paresthesias of the face and limbs followed by rapid onset of proximal muscle weakness that can progress to quadriplegia with bulbar and respiratory muscle weakness. The presentation is similar to acute inflammatory demyelinating polyneuropathy (AIDP) or Guillain-Barré syndrome. The underlying pathogenic mechanism is thought to be conduction block in peripheral nerves due to demyelination. Symptoms resolve after the drug is discontinued. Unlike the other neuropathies, this neuropathy can be prevented through careful monitoring of suramin blood levels.

#### Bortezomib

The clinical spectrum of bortezomib-induced peripheral neuropathy is not yet fully defined. Bortezomib causes a painful peripheral neuropathy in approximately 40% of patients.<sup>46</sup> This symptom may be dose-limiting, and, currently, dose adjustments are recommended for disabling neuropathic symptoms, which occur in approximately 15% of patients.<sup>46</sup> Nerve conduction studies in a small number of patients were consistent with axonal degeneration.<sup>46</sup> Symptom improvement is seen following discontinuance of the drug, but the time course of recovery or extent of recovery remain largely unknown.

#### Other Chemotherapeutic Agents

Various other chemotherapy drugs can produce peripheral neuropathy. A reversible peripheral neuropathy characterized by distal paresthesias, decreased deep tendon reflexes, and myalgias is fairly common during procarbazine therapy. High-dose cytarabine, particularly when given

in combination with other potentially neurotoxic drugs, rarely causes an axonal and/or demyelinating peripheral neuropathy.<sup>28</sup> Fludarabine can cause a mild peripheral neuropathy generally presenting with paresthesias or weakness. In addition, high-dose etoposide rarely causes a reversible axonal sensory neuropathy.<sup>47</sup> Furthermore, peripheral neuropathies rarely occur as a complication of treatment with high-dose ifosfamide, fluorouracil, and gemcitabine hydrochloride.

#### Muscle Weakness/Arthralgia

Muscle weakness and arthralgia most commonly occurs in the setting of sensorimotor neuropathy, such as that seen with vincristine and paclitaxel. However, a chemotherapeutic-agent-induced primary muscle disorder has been implicated in some cases. A toxic myopathy was implicated in one patient following paclitaxel administration on the basis of clinical signs and symptoms, electrophysiologic studies, and muscle biopsy findings of accumulation of acid phosphatase in lysosomes.<sup>26</sup> Dose dependent weakness and fatigue can occur 1 to 2 months from the onset of thalidomide therapy.<sup>22</sup> Furthermore, steroid-induced myopathy is a common and well-recognized complication of long-term steroid provision. Muscle aching and pseudoarthritis are frequent manifestations of steroid withdrawal.

#### Peripheral Nerve Hyperexcitability

Acutely, oxaliplatin can produce a unique syndrome that resembles neuromyotonia. Sensory manifestations are the most prominent, and generally develop within hours or days of therapy. Patients report fairly dramatic paresthesias and dysesthesias of the hands, feet, and perioral region. Pharyngo-laryngo-dysesthesias cause a subjective sense of difficulty in breathing. Cold exposure may trigger or exacerbate these symptoms. Motor nerves or muscle may also be affected, presenting as jaw tightness and pain, eye pain, ptosis, leg cramps, visual field abnormalities, and voice changes. Symptoms usually resolve spontaneously over hours to days. However, repeated drug administration may produce more severe and more prolonged symptoms.<sup>21</sup> Electrophysiologic examination findings are identical to those seen in neuromyotonia, which is produced by excessive nerve excitability of peripheral nerve axons.<sup>21</sup> Oxaliplatin may produce a transient channelopathy, acting as a direct toxin against either voltage-gated potassium or sodium channels in axons.<sup>21</sup>

### Chemotherapy-Induced Toxicities of the Central Nervous System

#### Toxic and Metabolic Encephalopathy

Toxic and metabolic encephalopathies are a group of neurologic disorders characterized by altered

mental status attributable to the presence of an exogenous or endogenous drug or toxin, or non-brain organ failure. Chemotherapeutic agents or their metabolites may act as direct toxins. Alternatively, they may cause electrolyte or fluid imbalance, renal or liver dysfunction, or other metabolic derangements. Symptoms do not distinguish causative agents in acute encephalopathy. The hallmark of acute encephalopathy is confusion, disorientation, and altered behavior. Symptoms range from simply appearing depressed and withdrawn to an agitated delirium and florid hallucinations. Seizures may represent the only manifestation of acute encephalopathy or may accompany other symptoms. Motor system abnormalities may include increased tone, tremor, multifocal myoclonus, muscle cramps, asterixis, and weakness. Widespread neurologic dysfunction can be seen.

#### Ifosfamide

The reported incidence of high-dose ifosfamide- and mesna-induced encephalopathy ranges widely from 8 to 14% to greater than 50%.<sup>48-50</sup> A transient confusional state is most commonly seen, but in some patient groups more severe symptoms of confusion, visual hallucinations, cerebellar dysfunction, seizures, cranial nerve palsies, extrapyramidal signs, and, occasionally, coma occur. Symptoms manifest hours to several days post drug administration. Diffuse slow wave activity is frequently seen on electroencephalography (EEG) following treatment, even in asymptomatic patients.<sup>49,51</sup> EEG findings are consistent with a diffuse encephalopathy of toxic or metabolic origin. Symptoms typically resolve spontaneously after several days.<sup>52</sup> However, irreversible deficits and death have been reported.<sup>52-54</sup> Successful rechallenge with ifosfamide has been reported.<sup>51</sup> Accumulation of a metabolite of ifosfamide, Chloroacetaldehyde, has been implicated as the responsible toxic agent. Risk factors for encephalopathy include short infusion times (24-hour),<sup>51</sup> renal dysfunction,<sup>49</sup> low serum albumin,<sup>49,48</sup> presence of pelvic tumor,<sup>49</sup> underlying brain disease,<sup>55</sup> phenobarbital use,<sup>56</sup> and previous ifosfamide-induced encephalopathy.

#### Other Chemotherapeutic Agents

An acute encephalopathy can complicate the treatment course of many other chemotherapeutic agents. The resultant symptoms are indistinguishable from those of a metabolic encephalopathy. Paclitaxel can cause a severe acute encephalopathy at doses in excess of 600 mg/m<sup>2</sup> with stem cell support.<sup>57</sup> Likewise, high-dose therapy with methotrexate, lomustine, and etoposide can produce an acute encephalopathy. In addition, encephalopathy can occur following standard dose treatment with cisplatin, vincristine, asparaginase, procarbazine, 5-fluorouracil, cytarabine, interleukin-2 (IL-2), and tamoxifen.

## Toxic Leukoencephalopathy

Neuroimaging and neuropathology have identified cerebral white matter as a target of chemotherapy-Induced toxicity. Toxins may affect any component of the white matter, including myelin, nerve axons, oligodendrocytes, astrocytes, and blood vessels; however, myelin often bears the brunt of the damage.<sup>58</sup> This acute or delayed structural change in cerebral white matter is called leukoencephalopathy. White matter injury has been associated with a number of chemotherapeutic agents including methotrexate, carmustine, cisplatin, cytarabine, fluorouracil, levamisole, fludarabine, thiotepa, interleukin-2, and interferon- $\alpha$ .<sup>58</sup> Both the route of administration and the dose administered influence the development of leukoencephalopathy. Less than 10% of patients treated with intravenous methotrexate develop leukoencephalopathy; however, this complication is seen in up to 40% of patients receiving intrathecal methotrexate.<sup>59,60</sup> Likewise, cytarabine and thiotepa may produce a leukoencephalopathy when administered intrathecally. On the other hand, cisplatin and carmustine can cause leukoencephalopathy when injected intra-arterially. Conventional doses of fludarabine, cytarabine, and 5-fluorouracil are rarely associated with cerebral white matter changes on MRI. However, high-dose therapy with these same agents may produce profound white matter changes.<sup>58</sup>

A wide and diverse range of signs and symptoms have been reported.<sup>61</sup> The most prominent clinical manifestation is the presence of neurobehavioral changes, which can range from a mild chronic confusional state with inattention, memory loss, and emotional dysfunction, to a devastating white matter dementia syndrome, abulia, stupor, and coma. Focal neurologic deficits such as hemiparesis, visual loss, and sensory deficits are frequently described. Notably absent are signs of cortical gray matter involvement, such as aphasia and seizures.

The diagnosis of toxic leukoencephalopathy requires clinical symptoms of white matter dysfunction and correlative neuroradiographic white matter abnormalities. Magnetic resonance imaging offers better resolution of white matter than other neuroimaging methods and is the imaging method of choice. Characteristic T2-weighted imaging findings are diffuse, increased signal intensity within the white matter, often extending from the ventricles to the cortical medullary junction. A scalloped lateral margin results from the sparing of the subcortical arcuate fibers and overlying cortex. In patients with intraventricular catheters, radiographic findings are fairly localized to white matter adjacent to the catheter path.<sup>62</sup> In patients with more widespread toxin exposure, the extent of radiographic involvement is variable. In some cases, white matter changes

can be seen on MRI in asymptomatic patients. The clinical significance of this is uncertain, but it may be a harbinger for the development of symptomatic leukoencephalopathy if additional treatment is provided.

The spectrum of neuropathologic findings in toxic leukoencephalopathy ranges from patchy intramyelinic edema with preservation of myelin, to widespread edema and demyelination with preservation of axons, and to destruction of oligodendrocytes, axonal loss, and necrosis.<sup>63</sup> However, the most common findings are gliosis, macrophage infiltration, and demyelination. The distribution of lesions and corresponding symptomatology is variable, ranging from isolated optic nerve involvement to multifocal white matter lesions, to confluent symmetrical subcortical white matter involvement.<sup>61</sup>

Drugs delivered directly into the ventricles can flow back along the reservoir catheter path and can accumulate in the white matter.<sup>62</sup> This complication can occur with properly placed catheters or a misplaced catheter tip that is directed into the brain parenchyma. Rarely, this may occur in patients with an indwelling intraventricular catheter who receive only systemic chemotherapy. In addition, factors such as increased intracranial pressure, the presence of widespread leptomeningeal tumor, or obstruction of cerebrospinal fluid outflow may increase drug concentrations within the ventricular system. The provision of intra-arterial drug is particularly conducive to vascular injury. Even though the route of drug delivery may predispose to toxicity, it does not elucidate the mechanism of white matter injury. The pathogenesis largely remains unknown, but most certainly consists of a variety of mechanisms. Proposed mechanisms include a direct toxic effect on myelin, disruption of myelin synthesis via injury to oligodendrocytes, cerebral edema secondary to breakdown of the blood-brain barrier, or reversible axonal swelling secondary to metabolic deterioration.<sup>58,64</sup>

Many patients fully recover; however, others may experience a progressive course with devastating sequelae. The prognosis depends largely on the extent of white matter injury and whether or not that injury is reversible or irreversible. If the nerve axons remain spared, and tissue necrosis has not occurred, the prognosis for recovery is favorable. Discontinuance of the inciting toxin early on in the disease process before irreversible damage has occurred remains critical. Often, however, chemotherapeutic-induced toxic leukoencephalopathy symptoms do not manifest until after the completion of therapy. This limits the value of early detection and cessation or alteration of drug therapy. Several therapeutic interventions have been tried with variable success. These include corticosteroids, anticoagulation

therapy, and ventriculoperitoneal shunting, and leucovorin for methotrexate-induced toxicity.<sup>58</sup>

## Methotrexate-Induced Mild Leukoencephalopathy

Methotrexate (MTX) can cause acute or subacute neurotoxicity that is characterized by somnolence, confusion, and focal neurologic deficits. Focal symptoms present with a stroke-like onset and include hemiparesis, aphasia, and hemisensory loss. Even though this syndrome is more commonly associated with high-dose MTX treatment, intrathecal and low-dose methotrexate therapy can also produce transient neurologic symptoms.<sup>65</sup> Prior to the routine use of leucovorin rescue in conjunction with methotrexate therapy, reported incidences of this syndrome approached 15%.<sup>66</sup> Since then, however, the incidence is approximately 3%.<sup>67</sup>

Symptoms commonly occur within 24 hours of drug administration, but can manifest up to 2 weeks following therapy. Evaluation usually reveals normal head CT, either normal MRI or diffuse periventricular high signal on T2-weighted images, normal cerebrospinal fluid (CSF), and generalized slowing on EEG. Restricted diffusion (high-intensity signal on diffusion-weighted imaging with decreased apparent diffusion coefficient) in the periventricular deep white matter bilaterally was reported in one case.<sup>64</sup> Abnormal signal on T2-weighted MR images can be found in asymptomatic patients or patients with minimal symptoms following MTX treatment.<sup>68-71</sup> The severity of the white matter insult on MRI does not correlate with clinical symptomatology.<sup>70</sup> Most patients fully recover within 72 hours; however, a chronic leukoencephalopathy has been reported.<sup>72</sup> Even though additional cycles have been provided without symptom recurrence,<sup>67,73</sup> the syndrome may recur with drug rechallenge.

The mechanism remains unknown, but an underlying vascular etiology induced or worsened by metabolic disturbance has been proposed. Proposed mechanisms include MTX-induced altered neurotransmitter levels secondary to inhibition of tetrahydrobiopterin synthesis,<sup>66</sup> increased adenosine,<sup>74</sup> or increased homocysteine levels.<sup>65</sup>

## Methotrexate-Induced Disseminated Necrotizing Leukoencephalopathy

In some cases, rapid severe neurologic deterioration occurs following MTX treatment characterized by personality changes, confusion, somnolence, ataxia, spasticity, seizures, dementia, and even coma and death. CT and MRI demonstrate extensive white matter damage.<sup>71,75</sup> This imaging abnormality in conjunction with rapid clinical deterioration represents disseminated necrotizing leukoencephalopathy (DNL), a rare

complication of MTX. DNL is associated with both intravenous and intrathecal methotrexate and cranial irradiation. Characteristic histopathologic findings include discrete or confluent foci of demyelination, scattered areas of coagulative necrosis, astrogliosis, and, occasionally, dystrophic calcification.<sup>75</sup>

#### Chronic Methotrexate-Induced Leukoencephalopathy

Leukoencephalopathy is the most common delayed central nervous system (CNS) effect of MTX. It is associated with multiple prior doses of intra-CSF or high-dose intravenous MTX, prior or concurrent provision of whole brain irradiation, and age greater than 60 years at the time of methotrexate treatment. The most significant risk factor is the provision of cranial irradiation before or during MTX therapy. The risk for leukoencephalopathy is less than 2% in patients receiving intravenous MTX alone, compared to approximately 45% in patients receiving intrathecal and intravenous MTX and brain irradiation.<sup>76</sup> Combined chemoradiotherapy for the treatment of primary central nervous system lymphoma demonstrates an overwhelming risk of dementia in patients more than 60 years of age.<sup>77,78</sup> However, treatment approaches without the use of radiation have not reported this complication.<sup>79,80</sup> Symptoms manifest months to years following methotrexate provision and include personality or behavioral change and global cognitive impairment, often progressing to severe dementia, quadriplegia, gait apraxia, and incontinence. Coma and death can eventually occur. Brain imaging studies show diffuse white matter hyperintensities most prominent in the corona radiata, cortical atrophy, and ex-vacuo ventriculomegaly. The histopathologic spectrum seen in chemotherapy/radiation-induced leukoencephalopathy ranges from myelin pallor with foamy macrophages and gliosis to severe vasculitis and necrosis.<sup>81,82</sup> The prognosis of patients developing late neurotoxicity is poor, with a 50% risk of death at 12 months despite continued remission of cerebral lymphoma.

#### Carmustine

Carmustine (BCNU)-mediated encephalopathy has been observed months following intravenous doses greater than 1,200 mg/m<sup>2</sup>.<sup>83,84</sup> More significant, however, is the neurotoxicity associated with intra-arterial BCNU. Once quite popular, intracarotid infusion of BCNU has been largely abandoned due to unacceptable toxicity. Patients frequently reported ipsilateral eye, neck, and head pain following the procedure. Infraorbital carotid artery infusion is associated with the formation of retinal and choroidal emboli and thrombosis, producing optic neuropathy and

retinopathy.<sup>85</sup> Subclinical retinal rod and cone dysfunction was also documented in the majority of patients in one series.<sup>86</sup> More significant, however, was the fairly common development of a potentially life-threatening necrotizing leukoencephalopathy.<sup>87–89</sup> In one series, delayed cerebral necrosis occurred in 80% of patients receiving supraorbital intra-arterial carotid BCNU infusions.<sup>85</sup> Generally 1 to 6 months following intra-arterial BCNU therapy, patients presented with seizures, altered mental status, and focal neurologic deficits. Unrelenting symptom progression leading to coma and death was often seen. Imaging revealed predominantly non-enhancing white matter edema and mass effect within the vascular territory of the injected artery. Pathological examination of brain tissue in patients succumbing to the disorder revealed either miliary foci of necrosis and mineralizing axonopathy or more diffuse confluent necrotizing leukoencephalopathy changes within the white matter of the treated vascular distribution.

#### Cisplatin

Encephalopathy as a complication of cisplatin therapy is more common with intra-arterial drug administration than intravenous drug administration. Cisplatin-induced encephalopathy is often characterized by focal brain dysfunction, in particular cortical blindness, and seizures. Imaging findings resemble reversible posterior leukoencephalopathy syndrome.<sup>90</sup> Symptoms occur during, immediately after, or as long as 10 days following cisplatin infusion. Drug-induced encephalopathy must be differentiated from that precipitated by the hydration preceding cisplatin treatment, electrolyte imbalance (hypomagnesemia and hypocalcemia), nephropathy, or hyponatremia secondary to syndrome of inappropriate anti-diuretic hormone secretion (SIADH). In almost all reported cases, spontaneous symptom resolution occurs. Limited information exists on recurrence with subsequent doses, but at least one report details readministration of drug without syndrome recurrence.<sup>91</sup>

#### Cytarabine

Encephalopathy is a well-recognized complication of high-dose intravenous cytarabine (ara-C). In contrast, intrathecal cytarabine-mediated encephalopathy is uncommon.<sup>92</sup> Symptoms ranging from an altered level of consciousness to coma have been reported.<sup>93–95</sup> Focal neurologic deficits may accompany diffuse cerebral symptomatology, including visual loss, anosmia, hemiparesis, and myelopathy. Some have suggested that the appearance of focal neurologic deficits early on in the treatment course may be predictive of those at risk for severe neurotoxicity.<sup>95</sup> Persistent dementia may follow concomitant radiation therapy and high-dose cytarabine.<sup>96</sup>

#### Fludarabine

A delayed progressive encephalopathy may occur at fludarabine doses greater than 40 mg/m<sup>2</sup> per day.<sup>28</sup> Cortical blindness, dementia, coma, and death can develop. Autopsy shows a diffuse necrotizing leukoencephalopathy. Toxicity may increase when fludarabine is combined with cytarabine.

#### Multifocal Inflammatory Leukoencephalopathy Associated with 5-Fluorouracil and Levamisole

5-Fluorouracil (5-FU) given in combination with levamisole rarely produces a multifocal inflammatory leukoencephalopathy. Symptom onset generally begins 6 weeks to 5 months after initiation of therapy.<sup>97</sup> Over a period of several weeks, patients develop encephalopathy and focal neurologic deficits such as hemiparesis, ataxia, aphasia, and sensory loss. Acutely, neurologic signs and symptoms correlate with multiple contrast-enhancing periventricular white matter lesions.<sup>98–102</sup> Even though these lesions appear similar radiographically to the acute demyelinating lesions of multiple sclerosis, in the cancer population, they may be mistaken for brain metastases or infectious etiologies. In some cases, <sup>201</sup>thallium chloride single photon emission computed tomography may provide a noninvasive method of distinguishing between a malignant and nonmalignant process. In other cases, stereotactic brain biopsy may be necessary to establish a definitive diagnosis. The histopathologic findings are indistinguishable from multiple sclerosis and include areas of demyelination, perivascular lymphocytic infiltration, and relative axonal sparing.<sup>99</sup> Discontinuance of chemotherapy and the provision of corticosteroids results in gradual symptom resolution over weeks to months. Likewise, sequential imaging studies show loss of enhancement followed by a decrease in lesion size.<sup>98,99,103</sup> Continued radiographic improvement was seen for at least 18 months in one reported case.<sup>98</sup> It remains unclear whether or not the combination of 5-FU and levamisole, 5-FU alone, or levamisole alone is causative. Patients rechallenged with 5-FU alone did not experience syndrome recurrence.<sup>104,105</sup> Likewise, there are reports of patients tolerating continued levamisole therapy without 5-FU or with reduced doses of 5-FU.<sup>99</sup> One reported patient deteriorated with continued levamisole therapy.<sup>106</sup> The pathogenesis of this multifocal inflammatory demyelinating syndrome is unknown. Proposed mechanisms include an immune-mediated process, as well as a levamisole-induced cell-mediated reaction to 5-FU-induced direct myelin damage.

Encephalopathy can occur with 5-FU alone, manifesting weeks to months following initiation of 5-FU therapy and quickly resolving after

discontinuance of the drug.<sup>107</sup> In addition, there is one report of an acute onset, severe encephalopathy progressing to coma within 72 hours in a patient treated with a 5-FU-based chemotherapy regimen who was later found to have a severe dihydropyrimidine dehydrogenase (DPD) deficiency.<sup>108</sup> Brain MRI was normal. Prompt symptom resolution coincided temporally with the provision of infusional thymidine. DPD is the rate-limiting enzyme responsible for 5-FU catabolism. DPD-deficient patients are often asymptomatic and remain undiagnosed until they present with unusually severe 5-FU mediated toxicities. It is estimated that severe DPD deficiency may occur in as many as 3% of cancer patients.<sup>109,110</sup> As such, patients should be appropriately evaluated for DPD if any untoward side effects of 5-FU manifest.

#### Interferons

Most CNS toxicities are seen with Interferon- $\alpha$  (IFN- $\alpha$ ) and IFN- $\gamma$ . Neurobehavioral symptoms are the most common. Typically within the first week of therapy, patients manifest somnolence, personality changes, cognitive slowing, and headache.<sup>111</sup> Symptoms appear to be dose-related, although age may also be a predisposing factor.<sup>112,113</sup> Imaging studies are often normal, but may demonstrate periventricular white matter changes or non-specific white matter changes.<sup>111</sup> Electroencephalography demonstrates diffuse slow wave activity.<sup>114</sup> Typically symptoms resolve without any specific intervention; however, some patients demonstrate persistent or progressive neurobehavioral symptoms.<sup>115,116</sup>

#### Interleukins

High doses of IL-2 and IL-1 have been associated with a mild diffuse encephalopathy characterized by headache, depressed mood, delusions, hallucinations, and mild cognitive dysfunction. Symptoms completely resolve within several weeks of the discontinuance of therapy. More significant, however, is the rare recognition of a severe leukoencephalopathy following intraventricular or intravenous IL-2 treatment. The pathogenesis is unknown, but IL-2-stimulated release of neuroendocrine hormones and cytokines has been implicated.<sup>117</sup>

### Reversible Posterior Leukoencephalopathy Syndrome

Reversible posterior leukoencephalopathy syndrome (RPLS) is a reversible encephalopathy with distinct clinico-radiographic features. It is characterized by subacute onset of headache, cortical blindness, altered mental status, and seizures associated with symmetrical parieto-occipital region white matter edema. Hypertension inconsistently heralds symptom onset. There

is increasing recognition of RPLS as a complication of hematopoietic stem cell transplantation in both childhood and adult cancers. In addition, there are case reports of RPLS in adults during cytotoxic chemotherapy with single-agent<sup>90,118</sup> and multiple-agent chemotherapeutic regimens<sup>119–121</sup> utilizing cisplatin, cytarabine, doxorubicin, cyclophosphamide, vincristine, ifosfamide, and etoposide. RPLS has not been linked with a particular drug or mode of drug administration. This entity is also recognized with non-oncologic diagnoses such as renal failure, acute hypertension, fluid overload, eclampsia, and immunosuppressive drug therapy.<sup>122,123</sup> The primary mechanism is thought to be loss of cerebral autoregulatory vascular control with subsequent microvascular infarction, petechial hemorrhage, and fluid transudation. Control of hypertension, cerebral edema, and other inciting factors leads to complete or near complete symptom resolution within days to weeks.

### Cognitive Dysfunction

A growing body of literature supports the hypothesis that adult cancer patients experience cognitive deficits associated with cancer treatments including cranial irradiation, conventional chemotherapy, high-dose chemotherapy and hematopoietic transplantation, and biologic response modifiers. Patients often use the term “chemobrain” to describe their symptoms. The majority of published studies focus on the cognitive effects of adjuvant chemotherapy or high-dose chemotherapy with stem cell transplantation for the treatment of breast cancer. These retrospective, post-chemotherapy reports identify a subgroup of patients in which cognitive decline could be attributable to chemotherapy. The reported incidence of chemotherapy-related cognitive dysfunction in these studies ranges from 16 to 75%. Cognitive deficits may be seen during or shortly after treatment<sup>124–126</sup>, approximately 2 years following treatment<sup>127–129</sup>, and 10 years following completion of therapy.<sup>130</sup> The development of cognitive deficits has not been linked to a particular drug. Cisplatin may have a long-term effect on cognitive function.<sup>131</sup> In addition, implicated breast cancer regimens consist of numerous chemotherapeutic agents, including 5-fluorouracil, epirubicin, cyclophosphamide, thiotepa, carboplatin, methotrexate, doxorubicin, paclitaxel, and vinblastine.

In four small studies of women receiving chemotherapy for breast cancer utilizing the High Sensitivity Cognitive Screen, the incidence of moderate or severe cognitive dysfunction ranged from 16 to 50%.<sup>126–129</sup> Memory and concentration appear to be especially vulnerable to the effects of cancer therapy; however, subtle dysfunction has been reported in several cognitive domains, including verbal and

nonverbal memory, information processing speed, and visuospatial processing. Patients receiving chemotherapy consistently score lower on performance tests compared to patients treated with local therapy. However, even so, they generally score within the normal range when compared with published norms. As such, while meaningful to an individual patient, the cognitive effects of chemotherapy are relatively subtle.

Few prospective studies have been reported. No differences in Mini Mental Status Examination (MMSE) scores were seen in one heterogeneous cancer patient group comparing pretreatment and approximately 4 months into treatment.<sup>132</sup> However, the MMSE is a screening measure designed to capture fairly gross cognitive dysfunction, such as dementia, and is not sensitive to subtle cognitive abnormalities. One prospective, randomized, longitudinal trial evaluated formal neuropsychometric testing pre-chemotherapy, and at 1- and 2-year intervals following chemotherapy. Overall, the reported results were consistent with previously reported conclusions that a subgroup of patients do experience subtle, but meaningful cognitive decline following chemotherapy.

The mechanism by which chemotherapy causes subtle cognitive deficits is unknown, and may differ from one chemotherapeutic agent to another. Likewise, it is uncertain if a particular chemotherapy drug or specific combinations of drugs are causative. Cognitive deficits might be attributable to a direct toxic effect on cerebral gray and white matter, microvascular injury, or secondary injury as a consequence an immunologic-mediated inflammatory response stimulated by the chemotherapy agent(s).

### Drowsiness

Numerous chemotherapy drugs are associated with drowsiness and fatigue. However, it is often unclear whether or not these symptoms reflect inherent drug effect, or the side effects from a multitude of confounding factors. In some cases, the drug is clearly causative. Thalidomide is the prototypic example. Somnolence is the most common acute side effect of thalidomide, noted in approximately 50% of patients. This dose-dependent symptom is generally mild and may be ameliorated by timing drug administration near bedtime. Many patients develop tachyphylaxis to this side effect after 2 to 3 weeks of therapy. Rebound insomnia after cessation of thalidomide has been reported.<sup>133</sup>

### Seizures

Chemotherapy-related seizures may occur as an isolated symptom or as part of a generalized encephalopathy. They may represent a direct effect of the drug, or result from a drug-induced metabolic derangement or a chemotherapy

drug-anticonvulsant medication interaction. Seizures may accompany chemotherapy-induced aseptic meningitis. In addition, they have been reported in association with intra-arterial chemotherapy injection. Structural brain lesions and a preexisting history of seizures are risk factors. However, in this setting, the contribution of the chemotherapeutic agent(s) is often unclear. Seizures have been reported with cisplatin, vincristine,<sup>134</sup> 5-FU,<sup>135</sup> L-asparaginase,<sup>136</sup> cytarabine,<sup>28</sup> and thalidomide.<sup>22</sup>

Most often, seizures are related to metabolic abnormalities. Cisplatin is a notorious cause of metabolic derangements. Approximately 60% of patients receiving cisplatin develop hypomagnesemia and secondary hypocalcemia from impaired magnesium reabsorption in the proximal renal tubule.<sup>137</sup> Hyponatremia secondary to SIADH may occur.<sup>138</sup> In addition, seizures can also result from water intoxication/cerebral edema due to the hydration before and after cisplatin infusion.

Chemotherapeutic agents can also alter the pharmacokinetics of enzyme-inducing anticonvulsant medications. Cisplatin can decrease phenytoin levels, and doxorubicin and cisplatin can reduce carbamazepine and valproic acid levels.<sup>139</sup> Furthermore, 5-FU and high-dose tamoxifen can cause elevations in phenytoin levels and subsequent drug toxicity.<sup>139</sup>

## Cerebellar Syndromes

Acute cerebellar syndromes are caused by only a few drugs, mainly cytarabine and 5-fluorouracil. Cerebellar syndromes caused by high dose ara-C and 5-fluorouracil have in common a dose-related incidence, symptom resolution with discontinuance of the drug, and the occasional presence of a transient ocular palsy.

### Cytosine Arabinoside (Cytarabine, Ara-C)

High-dose ara-C is associated with an irreversible cerebellar syndrome as well as reversible cerebellar abnormalities. Dose-limiting cerebellar toxicity occurs at cumulative doses exceeding 48 g/m<sup>2</sup>; however, individual doses >3g/m<sup>2</sup> may be more significant than the cumulative dose. Regimens providing 3 g/m<sup>2</sup> every 12 hours for 8 to 12 doses produce an acute or subacute cerebellar syndrome in 10 to 25% of patients.<sup>93,140,141</sup> Additional risk factors include renal insufficiency,<sup>142</sup> abnormal liver function (elevated transaminase, total bilirubin, or alkaline phosphatase),<sup>93</sup> age over 50 years,<sup>93,94</sup> and underlying neurologic dysfunction. Of these, renal insufficiency seems to be the most significant.<sup>142</sup>

Several days after initiating therapy, patients may develop subtle signs of cerebellar dysfunction, including a mildly unsteady gait, nystagmus, or other oculomotor abnormalities. Extracerebellar symptoms including somnolence, confusion, and, rarely, seizures may precede or

coincide with the initial cerebellar dysfunction. If treatment is continued, progressive and potentially disabling gait ataxia, appendicular ataxia, and dysarthria may develop. Following cessation of ara-C, maximal symptom recovery occurs within two weeks. The degree of recovery is inversely proportional to the severity and extent of cerebellar symptoms seen. Patients with a full cerebellar syndrome or significant disability, generally have irreversible symptoms. Conversely, if only some features of a full cerebellar syndrome develop and symptoms are mild, complete symptom recovery is often seen. If no significant cerebellar toxicity is seen, a second course can be safely administered.<sup>93</sup> Imaging studies may initially show white matter abnormalities within the cerebellum, and later demonstrate cerebellar atrophy. Pathologically, Purkinje cell dropout, loss of neurons in the dentate nucleus, and proliferation of Bergmann cells is seen.<sup>140</sup>

### 5-Fluorouracil

5-Fluorouracil-induced neurotoxicity is rare with conventional drug dosing. However, with high-dose therapy (>15 mg/kg/week), an acute cerebellar syndrome indistinguishable from that produced by ara-C is seen in approximately 2% of patients.<sup>143</sup> The concomitant provision of allopurinol, N-phosphonoacetyl-L-aspartate (PALA), thymidine, and levamisole may enhance 5-FU neurotoxicity.<sup>28</sup> Symptoms generally manifest weeks to months following initiation of chemotherapy and are reversible with discontinuation of the drug or a reduction in the dosage. If additional 5-FU is provided, symptoms may recur.<sup>144,145</sup>

## Movement Disorders

Movement disorders are rarely reported in conjunction with chemotherapeutic agents. 5-Fluorouracil may cause focal dystonia and parkinsonian symptoms, likely due to basal ganglia dysfunction.<sup>146,147</sup> Reversible athetosis, ataxia, and parkinsonian symptoms have been reported following vincristine administration.<sup>148,149</sup> Additionally, one patient who received high doses of cytarabine developed a parkinsonian syndrome that resolved within 12 weeks of drug discontinuance.<sup>150</sup> Cytarabine is also associated with painful leg, moving toes syndrome.<sup>28</sup>

## Visual Symptoms

There is increasing recognition of eye and visual pathway toxicity from chemotherapeutic agents. Of the orbital structures, the retina seems particularly vulnerable; but chemotherapy-related toxicity can involve any component of the eye. Visual toxicity often accompanies more widespread cerebral dysfunction, manifesting as visual field deficits or cortical blindness. Intrathecal drug

administration is associated with optic neuropathy. In addition, retinopathy is a prominent complication of intracarotid drug administration. Visual complications range from transient eye irritation to irreversible blindness. When studied prospectively, subclinical abnormalities are often reported. This underscores the need for surveillance ophthalmologic examinations in patients receiving drugs with known ocular toxicity. Overall, the majority of ocular symptoms are mild, and, often, visual function is maintained following treatment.

### Cisplatin

Intravenous cisplatin rarely causes papilledema, retrobulbar neuritis, or retinal cone dysfunction.<sup>151,152</sup> In addition, the focal neurologic symptoms seen with cisplatin-induced encephalopathy may include homonymous hemianopia and cortical blindness. More commonly, visual symptoms complicate intra-arterial cisplatin infusion.

Intra-arterial infusion of cisplatin into the common carotid artery produces cranial neuropathies in approximately 6% of patients.<sup>153</sup> Any cranial nerve may be affected by itself or in combination. Ocular toxicity is in part contingent upon placement of the intra-arterial catheter. If drug is delivered proximal to the origin of the ophthalmic artery (infraophthalmic), clinically significant ipsilateral visual loss occurs in up to 60% of cases.<sup>86</sup> Ipsilateral and, sometimes, bilateral retinal infarcts and frank retinal necrosis may occur.<sup>86</sup> There is one report of a patient developing a cavernous sinus syndrome following intra-arterial cisplatin infusion.<sup>85</sup> Supraophthalmic intra-arterial carotid drug delivery spares ocular complications, but is associated with cerebral toxicity. Visual symptoms are particularly common and include cortical blindness and visual field deficits. Additional complications include headache (HA), confusion, and seizures.<sup>154</sup> Many patients will recover within a few weeks; however, some patients remain blind or have permanent visual field deficits.

### Nitrosureas

Oral lomustine (CCNU) when used in conjunction with low-dose cranial irradiation and/or possibly multi-agent chemotherapeutic regimens, may cause damage to ocular structures. Patients generally present with sudden-onset total blindness followed in a few weeks by optic atrophy. Pathology from one reported case showed severe demyelination, axonal loss, and hyalinized vessels. Ocular structure damage due to low-dose cranial irradiation is exceedingly rare, further implicating CCNU as contributing factor.<sup>68</sup>

Retinal infarcts can occur following high-dose intravenous or intracarotid carmustine (BCNU). The mechanism is likely fibrinoid

necrosis of vessels and necrotizing vasculitis.<sup>84,88,155</sup>

#### 5-Fluorouracil

5-FU can cause oculomotor abnormalities, in particular vergence disturbances, and optic neuropathy.<sup>111,156</sup> Symptoms generally precede the development of typical features of 5-FU cerebellar neurotoxicity. Patients present with diplopia attributable to poor fusional capacity as a consequence of convergence and divergence weakness. Extraocular muscle paresis may occur later in the clinical course. Discontinuance of drug facilitates complete or near complete recovery in most patients. Recurrent oculomotor abnormalities may occur if additional 5-FU is provided.<sup>156</sup> Generally, each subsequent episode increases in severity and duration. Symptoms likely represent 5-FU-mediated neurotoxicity at the level of the brainstem.<sup>156</sup> Additional ocular toxicities include a presumed toxic optic neuropathy. Fluorocitrate, a breakdown product of 5-FU metabolism and potent inhibitor of Krebs cycle, has been implicated in the pathogenesis of this syndrome.<sup>157</sup>

#### Cyclophosphamide

Blurring of vision, interfering with a patient's ability to read, can occur minutes to hours following the provision of high-dose cyclophosphamide therapy.<sup>158</sup> Recovery generally mirrors time to onset, and complete symptom resolution is seen hours to days. Continuation of cyclophosphamide therapy does not result in symptom recurrence. No abnormalities have been detected on ophthalmologic examination, but often symptoms have resolved prior to evaluation.

#### Cytarabine

Cytarabine rarely produces reversible ocular toxicity, including blurred vision, photophobia, burning eye pain, blindness, Horner syndrome, and reversible bilateral lateral rectus palsies. Optic nerve damage from intrathecally administered cytarabine, when severe, can result in blindness.

#### Vincristine

Visual loss is occasionally reported when vincristine is used in conjunction with multiple chemotherapeutic agents.<sup>159–162</sup> In addition, vincristine may cause cortical blindness.<sup>163</sup> Spontaneous recovery was seen in all of the reported cases. However, one patient developed recurrent symptoms with repeated vincristine administration.

#### Methotrexate

High-dose, intrathecal methotrexate therapy, often in conjunction with cranial irradiation

and/or multiple chemotherapeutic agents, may produce visual loss.<sup>164–166</sup> No cases have been reported with intravenous methotrexate.

#### Tamoxifen

Infrequently, tamoxifen produces ocular toxicity involving the cornea, retina, or optic nerve. Ocular symptoms are more common in patients treated with high daily doses or high cumulative tamoxifen doses, but have been reported with standard doses as well.<sup>167</sup> Symptoms may be reversible if recognized early on in the disease process.

#### High-dose Multidrug Chemotherapy

High-dose multidrug chemotherapy regimens provided with hematopoietic stem cell support, in particular in breast cancer patients, have been associated with cognitive dysfunction and ophthalmologic disorders, including retinopathy, optic neuritis, and, rarely, cortical blindness.<sup>81</sup> Patients report decreased visual acuity, visual field abnormalities, or frank visual loss. Ocular symptoms can involve one or both eyes simultaneously or sequentially.<sup>81</sup>

### Hearing Loss

#### Cisplatin

Cisplatin commonly produces dose-dependent ototoxicity due to peripheral receptor (hair cell) loss in the organ of Corti. Transient tinnitus is often the first symptom to appear, but persistent tinnitus is uncommon, affecting only about 7% of patients.<sup>168</sup> Subclinical high-frequency hearing loss (4,000 to 8,000 hertz[Hz]) is detected by audiometry in approximately 70% of patients. However, symptomatic hearing loss within frequencies important for speech discrimination (500 to 3,000 Hz) is less frequent, occurring in roughly 10% of patients.<sup>168</sup>

Prior cranial irradiation,<sup>169</sup> concurrent provision of ototoxic drugs,<sup>168,170</sup> young age, and the presence of a CNS neoplasm potentiate cisplatin-induced hearing loss. The risk of substantial hearing loss is proportional to the cumulative cisplatin dose, and is nominal at cumulative doses < 540 mg/m<sup>2</sup>.<sup>169,171</sup> Furthermore, the presence of high-frequency hearing loss is fairly predictive of the risk of hearing loss within speech frequencies. If high-frequency hearing loss is present, a patient is at substantial risk of developing symptomatic hearing loss with the provision of two to four additional courses of cisplatin if no cranial irradiation has been provided, or with the provision of one additional course of cisplatin if the patient was previously treated with cranial irradiation.<sup>169</sup> As such, routine hearing screening is recommended at doses exceeding 360 mg/m<sup>2</sup>.<sup>171</sup> Recovery of hearing loss is unlikely<sup>169,171</sup>; however,

acceptable hearing thresholds can often be achieved with hearing aids. Thus, the development of ototoxicity does not necessarily mandate discontinuance of cisplatin therapy in those patients with clear anti-tumor benefit from the drug.

Cisplatin may also cause a vestibulopathy, which may or may not be associated with hearing loss. Symptoms include vertigo and ataxia. Patients frequently complain of difficulty walking in the dark and on uneven surfaces. Patients with abnormal or asymmetric vestibular function prior to initiating chemotherapy may be particularly at risk.<sup>172</sup> Vestibulopathy seems to be cumulative-dose-dependent with the greatest risk occurring at cumulative doses > 400 mg/m<sup>2</sup>.<sup>172</sup> Prior use of aminoglycosides may exacerbate the vestibulopathy.<sup>168,172</sup>

### Aseptic Meningitis

Aseptic meningitis is a well-recognized and usually transient complication of intra-cerebrospinal fluid (intra-CSF) chemotherapy. It has also been reported following intravenous cytarabine.<sup>28</sup> This side effect occurs in 5 to 40% of patients after intra-CSF methotrexate administration, and in approximately 10% of patients following intra-CSF cytarabine administration. Symptoms are more frequent following lumbar injection compared to intrathecal injection. Symptoms of headache, nuchal rigidity, back pain, nausea or emesis, fever, and lethargy generally manifest 2 to 4 hours after intra-CSF drug administration and last 12 to 72 hours. Seizures and subacute encephalopathy are rarely seen.<sup>92,173</sup> Aseptic meningitis may follow the first, or any subsequent, intra-CSF drug injection, although, once it occurs, patients usually do not experience difficulty with continued injections. CSF evaluation reveals a lymphocytic pleocytosis and elevated protein. This syndrome differentiates itself from bacterial meningitis by time of onset relative to injection. Once symptoms occur, only supportive care is indicated. However, the concurrent provision of corticosteroids, either injected intrathecally with the chemotherapeutic agent or orally is preventative.

### Stroke and Other Vascular Complications

Cerebrovascular complications of chemotherapy may be the result of a direct toxic insult to blood vessels, or represent an indirect effect of chemotherapy on the vascular system. For instance, doxorubicin-induced cardiomyopathy and subsequent thrombus formation can lead to stroke. Stroke is most commonly seen in the setting of multidrug regimens, making it difficult to determine the primary culprit. The pathogenic mechanisms appear quite diverse, and in many cases unknown.

### Cisplatin

Cisplatin has been associated with vascular toxicity including myocardial infarction, cerebrovascular ischemic events, hypertension, and Raynaud's phenomenon. Vascular complications are most common when cisplatin is administered in combination with other agents, but they have also been reported following cisplatin monotherapy.<sup>174-178</sup> Some patients present during the course of chemotherapy. However, in others, strokes occur months following completion of therapy.<sup>178</sup> Angiograms may be normal or show focal vessel occlusion. It is unclear whether vascular toxicity results from cisplatin-induced endothelial injury, hypomagnesemia-induced vasospasm, or coagulopathy. Other agents provided concomitantly with cisplatin as part of multidrug regimens may also contribute to vascular toxicity.

### Carmustine

Intra-arterial infusion of BCNU is associated with a vasculopathy of the carotid, ophthalmic, retinal, and choroidal arteries, with arterial emboli or thrombosis, or both, in up to 80% of patients.<sup>85</sup>

### L-Asparaginase

Cerebral venous and dural sinus thrombosis, cerebral venous infarction, and/or cerebral hemorrhage occur in 1 to 2% of patients treated with L-asparaginase.<sup>179</sup> Arterial infarcts are notably absent.<sup>179,180</sup> These vascular complications are more frequent at higher drug doses; however, a clear dose-dependency has not been established. L-asparaginase hydrolyzes asparagine to aspartic acid, depleting asparagine and inhibiting protein synthesis. This leads to the depletion of plasma proteins, including those involved in coagulation (anti-thrombin III, protein C and S, fibrinogen, and factors IX and XI) and fibrinolysis (plasminogen).<sup>181</sup> Elevation of serum prothrombin time (PT), partial thrombin time (PTT), and thrombin time is routinely seen during treatment in most patients but is not thought to have clinical significance.<sup>180</sup> Hemorrhagic events generally occur early on in the course of therapy, and thrombotic events are typically seen after 5 days to several weeks of therapy.<sup>179</sup> On occasion, thrombotic complications do not manifest until treatment is completed. Presenting signs and symptoms of cerebral venous and dural sinus thrombosis include severe headaches, seizures, altered mental status, focal neurologic deficits, and papilledema. Routine imaging studies may implicate venous sinus thrombosis or demonstrate secondary complications, such as venous infarcts or cerebral hemorrhage. However, definitive diagnosis is typically established by CT venogram or MR venogram demonstrating clot in cerebral sinuses.

Treatment is controversial. In the absence of hemorrhage, most recommend heparin

anticoagulation, but others provide fresh frozen plasma to prevent clot extension.<sup>179,181</sup> Most patients, even those with cerebral hemorrhage, fully recover.<sup>179</sup> No patient has ever been reported to have a second cerebrovascular event with continued L-asparaginase therapy, either with or without prophylactic pretreatment, but many propose prophylactic pretreatment with fresh frozen plasma or heparin.

### Bleomycin

Bleomycin, especially when used as part of a cisplatin-based chemotherapy regimen, has been rarely associated with delayed cerebral and myocardial infarcts. It is unclear which drug is specifically at fault, although bleomycin is thought to be the main culprit. The specific mechanism is unknown, although hypomagnesemia may be a risk factor.<sup>28</sup>

### Other Chemotherapy Agents

Other chemotherapeutic agents have been rarely associated with cerebrovascular disorders. Cerebral infarcts are rarely reported with 5-fluorouracil.<sup>182</sup> Likewise, there is one reported case of carboplatin-induced thrombotic microangiopathy that resulted in numerous small cortical infarcts, coma, and death.<sup>28</sup> Necrosis and hemorrhagic cerebral infarcts occasionally follow intracarotid doxorubicin injection when provided in conjunction with osmotic blood-brain-barrier opening.<sup>28</sup>

## Spinal Cord Syndromes

### Lhermitte's Sign

Lhermitte's sign, characterized by paresthesias or electrical shock-like sensations in the back and extremities precipitated by neck flexion, is seen in 20 to 40% of patients receiving cisplatin. In some cases, arm abduction precipitates distal paresthesias, suggesting traction on a demyelinated brachial plexus.<sup>28</sup> Symptoms typically develop during or after several weeks of treatment.<sup>183</sup> A sensory neuropathy often precedes the development of Lhermitte's sign. Rare reports of myelopathy exist.<sup>184</sup> Proposed mechanisms include transient demyelination of the posterior columns<sup>170</sup> or toxic insult to the central processes of the dorsal root ganglion cells, which travel in the dorsal columns.<sup>181</sup> Lhermitte's phenomenon is generally not associated with chemotherapeutic agents other than cisplatin, although two patients did develop Lhermitte's sign following docetaxel administration.<sup>37</sup>

### Myelopathy

One of the most emphasized complications of intrathecal chemotherapy is myelopathy, which is reported for both methotrexate and ara-C, either alone or in combination. Even though this

complication is rare, it has the potential for severe and persistent neurologic disability and even death. In fact, the provision of intrathecal vincristine is contraindicated due to the occurrence of fatal myeloencephalopathy.<sup>185</sup>

### Methotrexate

Methotrexate-induced myelopathy is generally seen following several intrathecal treatments. Symptoms typically manifest half an hour to 48 hours following intrathecal drug, but can be delayed for 2 weeks.<sup>186</sup> Clinically, patients present with back or leg pain, followed by progressive weakness of the legs, ascending sensory loss, and sphincter dysfunction. In severe cases, progressive quadriplegia, brainstem dysfunction, and death can occur. Concurrent provision of radiation, presence of active CNS leukemia, or frequent MTX treatments appear to increase risk. Gadolinium enhancement of the anterior nerve roots of the cauda equina has been reported in three patients presenting with progressive, flaccid weakness of the lower extremities.<sup>187</sup> Elevated CSF IgG synthesis and myelin basic protein has been reported.<sup>187,188</sup> Symptoms are often transient, but variable clinical improvement is seen.<sup>189,190</sup> The pathologic changes are maximal in the outer one-third of the spinal cord, similar to the expected penetration of intrathecal drug. Vacuolar myelin loss, axonal swelling, and necrosis in the absence of inflammation is reported.<sup>191</sup> The pathogenesis is unknown, but may be an idiosyncratic drug reaction.<sup>28</sup>

### Cytarabine

Rarely, intrathecal cytarabine administration causes a transverse myelopathy identical to that seen with intrathecal methotrexate. Symptoms present acutely generally weeks to months following initiation of intrathecal cytarabine.<sup>192</sup> In two reported cases, clinical symptoms and pathologic changes extended beyond the spinal cord into the brainstem producing a locked-in syndrome in one patient<sup>193</sup> and edema, cerebrospinal fluid outflow obstruction, and a herniation syndrome in another patient.<sup>188</sup> Risk factors for the development of myelopathy include concurrent intravenous ara-C, prior or concurrent intrathecal (IT) MTX, or prior or concurrent radiation therapy to the spinal cord, and daily drug administration.<sup>92</sup> Most patients recover spontaneously, but symptoms may be irreversible and fatalities have been reported.<sup>92,192-195</sup> Histopathologically, widespread spinal cord and nerve root demyelination, white matter microvasculization, and axonal swelling are seen.<sup>192,196,197</sup>

# Paraneoplastic Neurologic Disorders

Steven Vernino, MD, PhD

The term paraneoplastic literally means “around or near cancer.” Paraneoplastic syndromes are remote medical complications of cancer that cannot be attributed to direct effects of the neoplasm or its metastases. Paraneoplastic syndromes can affect almost any organ system. In a broad sense, common problems like fatigue, opportunistic infections, and side effects of chemotherapy and radiation could be considered paraneoplastic syndromes. Other paraneoplastic disorders are related to inappropriate production of secreted compounds by the tumor, leading to hypercalcemia, hyponatremia, hyperadrenalism, or cancer-associated coagulopathy. Organs distant from the tumor can also be affected when a malignancy stimulates tissue-specific autoimmunity. The most dramatic example of cancer-related autoimmunity is the paraneoplastic neurologic disorder (PND).

Patients can spontaneously mount an effective anti-cancer immune response, particularly when malignancy cells spread early to regional lymph nodes. The immune response to cancer is certainly important, and there is great interest in developing treatments that stimulate anti-tumor immunity. In several clinicopathologic studies, tumors that are heavily infiltrated with lymphocytes have a better prognosis.<sup>1,2</sup> However, in rare cases, a vigorous anti-tumor immune response may become misdirected and cause damage in remote tissues, including the nervous system.

Paraneoplastic neurologic disorders have been recognized for over 50 years, since the first descriptions of sensory neuropathy and limbic encephalitis.<sup>3,4</sup> Recent evidence indicates that most of the recognized PNDs are a consequence of an autoimmune response to cancer. A prevailing theory is that this occurs when tumor cells inappropriately express onconeural proteins that are usually restricted to the nervous system. Tumors of neuroendocrine lineage, small-cell lung carcinoma for instance, often express neuronal nuclear, cytoplasmic or membrane proteins.<sup>5-7</sup> These neuronal antigens expressed in an abnormal environment may stimulate paraneoplastic neurologic autoimmunity through a variety of mechanisms. In addition to tumor factors, many patients with PND have a personal or family history of other autoimmune conditions. Cytotoxic T-cells are thought to be

the principal effectors,<sup>8</sup> presumably by recognizing autoantigens in the context of MHC Class I on both tumor cells and neurons. Antibodies against the same or similar antigens may be produced as well, but these autoantibodies are usually not directly pathogenic. The autoimmune attack on the nervous system, although misdirected, is characteristically highly specific for one or more cell types or regions of the nervous system. In other words, these syndromes are not associated with systemic or widespread neurologic inflammation. When reported, the neuropathologic findings in PND are often rather non-specific (Figure 1).<sup>9,10</sup>

## General Principles

PND can affect any part of the nervous system and often affects multiple levels of the nervous system simultaneously (Table 1). Some PNDs have unique clinical characteristics and should be easily recognized (eg, paraneoplastic cerebellar degeneration, sensory neuronopathy, and limbic encephalitis). However, similar or identical syndromes may also occur, in the absence of cancer, as idiopathic autoimmune disorders or due to

other causes.<sup>11,12</sup> Furthermore, the presentation of PND may be indistinguishable from common neurologic disorders (eg, peripheral neuropathy, myasthenia gravis, motor neuron disease, and myelitis). In these cases, the association with cancer may be under-recognized because of the absence of clinical suspicion.

Because PND can affect any part of the nervous system, the symptoms and signs of the disease can be quite varied. However, certain features are typical. Most PNDs have a subacute and progressive course. The neurologic symptoms typically develop over weeks or months, but can progress more rapidly (over a few days) in some cases. The median age of onset is around 65 years, but with a wide range. There is a strong female predominance (about 2:1) even when cases of gender-specific tumors (breast, ovary, and testes) are not considered.<sup>13,14</sup> In the majority of cases, there is no prior history of cancer, and the neurologic illness precedes the diagnosis of cancer. Misdiagnosis or delay in diagnosis of PND is common. The initial intensive search for malignancy may be unrevealing, which may put the diagnosis of PND in question. In some cases, non-specific symptoms (fever, fatigue, anorexia,

**FIGURE 1** Neuropathologic findings in paraneoplastic limbic encephalitis. The pathological changes in paraneoplastic disorders of the central nervous system are non-specific. Common findings regardless of the site of pathology include (A) perivascular lymphocytic infiltration, gliosis and (B) microglial nodules. The lymphocytic infiltrate is composed predominantly of T-cells. Similar findings can be seen in viral encephalitis. Adapted from Vernino et al.<sup>10</sup>

definite PND associations include gynecologic malignancies, arising from the breast, ovary, fallopian tube, and peritoneum, Hodgkin's and non-Hodgkin's lymphoma, testicular cancer, and neuroblastoma. PND occurs at a much lower frequency in patients with non-small cell lung, renal cell, uterine, and melanotic skin cancers. Many of the most common malignancies (adenocarcinoma of the colon or prostate, transitional cell bladder carcinoma, and skin carcinomas) are highly unlikely to be associated with PND. Case report associations of these cancers with neurologic disease could be coincidental due to the high frequency of these malignancies. When one of these tumors is found in a patient with suspected PND, the search for a second malignancy should continue. Alternatively, the pathology of the tumor should be carefully examined for the possibility of mixed pathology with small-cell neuroendocrine features. Common primary tumors of the adult nervous system (glioma or meningioma) are essentially never associated with PND—it would also be very difficult to dissociate paraneoplastic phenomena from direct effects of the tumor. All PND are rare, but several syndromes are distinctive enough to warrant specific attention.

**Paraneoplastic Cerebellar Degeneration**

Paraneoplastic cerebellar degeneration (PCD) begins as mild unsteadiness of walking, which progresses to a severe cerebellar ataxia over a few weeks or months. In some cases, a more acute onset may be misdiagnosed as brainstem or cerebellar stroke. More insidious onset may lead to a diagnosis of an inherited and degenerative cause. The typical presenting features are disabling incoordination of gait, trunk and limbs and an ataxic dysarthria. Often, severe vertigo and motion sickness with nausea, diplopia, nystagmus and oscillopsia are early complaints. As a result, within a few months, most patients will lose the ability to walk or even sit independently, lose the ability to write, or feed themselves, and lose the ability to communicate effectively.<sup>19,20</sup> Dramatic tremors of the limbs and head (titubation) are typical. However, the syndrome usually remains restricted to the cerebellum. Strength, sensation, and cognition are not affected. Symptoms often stabilize spontaneously, but unfortunately, the usual outcome is irreversible severe ataxia and loss of independence. Severe depression is a commonly associated comorbidity.

It is estimated that 50% of patients with subacute, severe, adult-onset ataxia have an underlying malignancy. Many of the non-paraneoplastic cases are probably idiopathic autoimmune disorders.<sup>26,27</sup> PCD is more common in women since the classical association is with ovarian or

breast carcinoma. Usually, the onset of symptoms precedes the diagnosis of cancer or heralds a cancer recurrence. Autoantibodies reactive against the cytoplasm of cerebellar Purkinje cells (Purkinje cell antibody-type I [PCA-1] or “anti-Yo”) may be found in the serum or cerebrospinal fluid (CSF) as markers of these tumors. Imaging of the breast and pelvis and measurement of tumor biomarkers should be performed but may be normal. Thus, when PCA-1 antibodies are found, exploratory laparotomy is usually warranted, even if imaging is negative.<sup>28</sup> A poorly differentiated adenocarcinoma may be identified involving the fallopian tube or peritoneal wall even if the ovaries are pathologically normal or surgically absent. PCD may also occur in the context of other malignancies (small-cell lung carcinoma or Hodgkin's lymphoma) with different antibody markers (Table 2). The pathological outcome of PCD is a near complete loss of cerebellar Purkinje cells. Early in the disease course, imaging of the cerebellum is usually unremarkable. Later, cranial MRI and CT show diffuse cerebellar atrophy which corresponds to permanent neuronal loss.

**Limbic Encephalitis**

Paraneoplastic limbic encephalitis (PLE) is characterized by the triad of short-term memory impairment, temporal lobe seizures and psychiatric symptoms (commonly depression, psychosis or a change in personality). Two-thirds of patients have overt seizures (usually complex partial temporal lobe seizures) that may be difficult to control, and all patients show abnormalities on electroencephalography.<sup>29</sup> The differential diagnosis includes primary psychiatric illness, viral encephalitis, Creutzfeldt-Jacob disease, vasculitis, and non-paraneoplastic autoimmune encephalopathies.<sup>30</sup> PLE may stabilize or partially improve following treatment of the cancer or treatment with immunomodulatory therapies, but most patients are left with residual memory impairment and seizures.

The pathology of PLE is focused in the anteromedial temporal cortex, hippocampus, and amygdala, although adjacent limbic structures (eg, the hypothalamus and insular cortex) may be involved, and the process may be quite asymmetrical.<sup>29</sup> MRI typically shows non-enhancing signal changes in the mesial temporal lobes (Figure 2). Later in the disease course, marked hippocampal atrophy is associated with permanent cognitive impairment and epilepsy.

The most common tumors associated with PLE are small-cell lung carcinoma (SCLC), testicular cancer, breast cancer, and thymoma. Again, the syndrome usually occurs when the cancer is occult and limited in stage. A variety of

and weight loss) and findings (such as hyponatremia, anemia, or elevated sedimentation rate) may support the suspicion of occult malignancy. In patients with a previous history of cancer, the neurologic illness may herald cancer recurrence. When found, the tumors tend to be limited in stage and respond well to treatment.<sup>15</sup> In fact, several reports suggest that patients with PND have a favorable cancer survival compared to those with identical tumors without PND.<sup>16–19</sup> On the other hand, the neurologic response to treatment tends to be poor (with some exceptions for specific syndromes) and patients are often left with significant neurologic disability.<sup>16,20,21</sup>

Overall, paraneoplastic neurologic disorders are quite rare (estimated at 0.01% of cancer patients).<sup>22</sup> Certain malignancies are more likely to be associated with PND. About 30% of patients with thymoma have some form of neurologic autoimmunity, mostly myasthenia gravis.<sup>23</sup> Small-cell carcinoma, most commonly arising in the lung, is associated with one or more PNDs in up to 3% of cases.<sup>24,25</sup> Other malignancies with

Table 2 Neuronal Paraneoplastic Autoantibodies

Antibody	Antigen(s)	Tumor	Associated syndromes
<b>Neuronal nuclear and cytoplasmic antibodies*</b>			
ANNA-1 (anti-Hu) <sup>13,21</sup>	HuD, HuC, Hel-N1	SCLC	Encephalomyelitis, sensory neuropathy, autonomic and sensorimotor neuropathies, ataxia

PCA-1 (anti-Yo) <sup>19</sup>	CDR34 and CDR62	Ovarian or breast cancer	Paraneoplastic cerebellar degeneration
Anti-Ma <sup>32</sup>	Ma1 and Ma2	Lung, breast or testicular	Limbic and brainstem encephalitis
Amphiphysin <sup>60</sup>	Amphiphysin	Lung or breast cancer	Encephalomyelitis, neuropathy, stiff-person syndrome
PCA-2 <sup>61</sup>	Unknown (280kD)	SCLC	Encephalomyelitis
ANNA-2 (anti-Ri) <sup>31</sup>	Nova	Lung or breast cancer	Ataxia, opsoclonus-myoclonus, neuropathy
PCA-Tr (anti-Tr) <sup>62</sup>	Unknown	Hodgkin lymphoma	Paraneoplastic cerebellar degeneration
ANNA-3 <sup>63</sup>	Unknown (170kD)	SCLC	Encephalomyelitis
Recoverin	Recoverin	SCLC	Cancer-associated retinopathy
<b>Ion channel antibodies</b>			
P/Q-type VGCC <sup>43</sup>	Neuronal Ca <sup>++</sup> channels	SCLC (60%)	Lambert-Eaton syndrome
N-type VGCC <sup>43</sup>	Neuronal Ca <sup>++</sup> channels	Lung or breast cancer	Encephalomyelitis, neuropathy
Muscle AChR <sup>23</sup>	Muscle acetylcholine receptor	Thymoma (15%)	Myasthenia gravis
Ganglionic AChR <sup>64</sup>	Neuronal acetylcholine receptor	SCLC (15%)	Autonomic neuropathy
VGKC <sup>65</sup>	Neuronal K <sup>+</sup> channels	Thymoma or SCLC	Neuromyotonia; limbic encephalitis
mGluR1 <sup>66</sup>	Metabotropic glutamate receptor	Hodgkin lymphoma	Paraneoplastic cerebellar degeneration

\* Alternate nomenclature is indicated in parentheses  
AChR = acetylcholine receptor; ANNA = antineuronal nuclear antibody; CDR = cerebellar degeneration related protein; CRMP-5 = collapsing response mediator protein antibody; mGluR1 = metabotropic glutamate receptor, type 1; PCA = Purkinje cell antibody; SCLC = small-cell lung carcinoma; VGCC = voltage-gated calcium channel; VGKC = voltage-gated potassium channel.

**FIGURE 2** Radiographic features of paraneoplastic limbic encephalitis. (A) Bilateral signal abnormality in the medial temporal/hippocampal cortex is the most typical finding. (B) The changes can be subtle, restricted and unilateral in some cases. The characteristic abnormalities are best appreciated on coronal fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging.<sup>29</sup> (C) Findings on axial FLAIR findings can be easily missed, as in this case, which shows swelling and mild signal change in the left mesial temporal lobe (arrowhead). (D) Gadolinium contrast enhancement is usually not conspicuous. When seen, the contrast-enhancing region (arrowhead) reflects only a small portion of the affected limbic cortex.<sup>29</sup>

autoantibody markers are associated with PLE, including antineuronal nuclear antibody-type 1 (ANNA-1) and anti-Ma (see Table 2). The autoantibody findings are very useful in directing the search for occult malignancy, but up to 30% of patients with PLE and cancer have negative antibody studies.<sup>29</sup> In those cases, a search for malignancy must be conducted according to the patient's individual cancer risk factors.

### Brainstem Encephalitis

This syndrome is characterized by prominent eye movement abnormalities (vertical gaze palsy, ophthalmoplegia, double vision, complex

nystagmus or other involuntary eye movements) often associated with disorders of sleep and wakefulness (including excessive somnolence or central sleep apnea). Other cranial nerve findings include ptosis, facial weakness, flaccid dysarthria, dysphagia, subacute hearing loss, and jaw or eyelid dystonia.<sup>31,32</sup> Symptoms of brainstem encephalitis may also occur in combination with those of PLE, PCD, or opsoclonus-myoclonus. Brain MRI may be normal or may show brainstem abnormalities involving the medulla, pons, midbrain, or even rostrally into the hypothalamus and medial thalamus. Several different cancers have been associated with this syndrome, including SCLC, testicular, and breast cancer.

### Opsoclonus-Myoclonus

Opsoclonus describes involuntary, random, high-amplitude, conjugate eye movements often associated with diffuse or focal myoclonus (involuntary brief muscle contraction causing jerks of the trunk or limbs). This syndrome was initially described in children with neuroblastoma (also known as “dancing eyes, dancing feet” syndrome). However, less than half of patients with opsoclonus-myoclonus have cancer. Other causes include viral encephalitis, drug intoxication and idiopathic autoimmune cause. Patients without cancer often make a good recovery and respond to treatment. Children with opsoclonus-myoclonus may also respond well to adrenocorticotropic hormone, prednisone and other immunomodulatory treatments. In children with neuroblastoma, the neurologic symptoms often improve following treatment of the tumor, and the cancer survival rate is excellent. However, many children are left with some degree of incoordination or other neurologic deficits. In adults, this syndrome may coexist with features of PCD, PLE or brainstem encephalitis. In this situation, the presence of underlying malignancy (lung or breast cancer) is much more likely.

### Paraneoplastic Chorea

Common movement disorders, such as essential tremor and parkinsonism, are very unlikely to occur as paraneoplastic neurologic manifestations of occult malignancy. However, the subacute onset of generalized or focal chorea may represent a paraneoplastic neurologic disorder.

Chorea (or choreoathetosis) refers to involuntary, random, and coordinated but purposeless movements of one or more parts of the body. The patient may be unconcerned by or even unaware of the movements, and observers may attribute the movements to simple restlessness. Choreic movements of the body and limbs are often described as writhing and are much slower than myoclonic jerks. Chorea of the face (orofacial dyskinesia) can consist of excessive pursing of the lips or blinking and may be associated with a strained voice. Chorea in adults can have many causes, but subacute onset in a patient over 60 years old and association with other neurologic symptoms (vision loss, limbic encephalitis or neuropathy) should strongly raise the possibility of a paraneoplastic disorder.<sup>10</sup> Additionally, unlike other causes, paraneoplastic chorea may present asymmetrically.

Paraneoplastic chorea appears to be the result of a “striatal” encephalitis. Cranial magnetic resonance imaging (MRI) may show characteristic transient non-enhancing signal abnormalities in the striatum, which consists of the caudate and putamen (Figure 3).<sup>10</sup> The most commonly associated malignancy is SCLC often associated with collapsing response mediator protein (CRMP-5) autoantibodies in serum and CSF.

### Paraneoplastic Vision Loss

Progressive vision loss can occur as a paraneoplastic phenomenon although the exact incidence is unknown since non-specific visual complaints

**FIGURE 3** Radiographic features of paraneoplastic chorea. In many cases of paraneoplastic chorea, cranial T2-weighted and fluid-attenuated inversion recovery magnetic resonance imaging demonstrates signal abnormalities in the striatum (caudate and putamen). These areas do not enhance with gadolinium and show no changes on diffusion-weighted imaging.<sup>10</sup>

in cancer patients are fairly common. Subacute unilateral vision loss in the elderly must raise the possibility of ischemic, infectious or non-paraneoplastic inflammatory optic neuropathy. Paraneoplastic vision loss can present in a similar way with painless generalized or scotomatous loss of acuity, abnormalities of color vision or photosensitivity. Most cases start as monocular vision loss that becomes bilateral within weeks or months. Two forms of paraneoplastic vision loss are recognized. Cancer-associated retinopathy (CAR) is associated with an abnormal electroretinogram and positive visual symptoms (sparkling lights, shimmering scotomata or color distortion). Classically, CAR is associated with SCLC and with antibodies against any of several retinal antigens (most commonly the photoreceptor protein recoverin). Paraneoplastic optic neuritis, on the other hand, is often associated with a swollen, leaky optic disc, SCLC, and CRMP-5 antibodies.<sup>33</sup>

### Encephalomyelitis with Rigidity

Stiff-person syndrome, first described in 1956,<sup>34</sup> is a rare disorder characterized by muscle rigidity and spasms characteristically affecting the axial muscles. Patients have an inability to relax their muscles, hyperlordotic posture due to involuntary back extension, and exaggerated muscle responses to cutaneous and auditory stimuli. This classic form of stiff-person syndrome is more common in women and often associated with antibodies against glutamic acid decarboxylase (GAD)<sup>35</sup> and with autoimmune diabetes. These patients usually do not have cancer and do not have any other paraneoplastic autoantibodies. They have a chronic disorder that may respond to immunosuppression or to treatment with high doses of benzodiazepines.

A similar disorder may occur in a paraneoplastic context. Various terms, including paraneoplastic stiff-person syndrome or encephalomyelitis with rigidity, have been used to differentiate this entity from the classic syndrome. The best described association is with breast cancer and autoantibodies against amphiphysin, although the syndrome can occur with other cancers, and antibody tests may be negative despite a paraneoplastic cause. Clinical features that should increase the suspicion of a paraneoplastic disorder include stiffness and spasms that affect one limb much more than the axial muscles (sometimes referred to as “stiff-limb” syndrome), presence of diffuse rigidity coexisting with brain or spinal cord signs (encephalomyelitis with rigidity), the absence of GAD antibodies, and the lack of a response to benzodiazepines.

### Sensorimotor Peripheral Neuropathy

Autonomic neuropathy and pure sensory neuropathy represent recognized paraneoplastic

syndromes of the peripheral nerves and ganglia and are discussed separately below. Signs and symptoms of a peripheral sensorimotor neuropathy (numbness in the feet and fingers or distal weakness) are very common in cancer patients. The incidence of paraneoplastic peripheral neuropathy, however, is unknown since cancer patients often have several plausible reasons to develop neuropathy including nutritional deficiencies and exposure to chemotherapeutic agents. Nevertheless, neuropathy may present well in advance of the cancer diagnosis and is arguably the most common paraneoplastic neurologic syndrome. In many cases, the characteristics of a paraneoplastic peripheral neuropathy are those of a mixed sensory and motor length-dependent axonal neuropathy indistinguishable from those of non-paraneoplastic causes that are commonly encountered in the neurology clinic. One study estimated that 4.5% of patients with unexplained adult onset axonal sensorimotor neuropathy have a malignancy.<sup>36</sup> A few clinical features should increase the suspicion of PND. The onset of paraneoplastic neuropathy tends to be more rapid, with progression of symptoms, signs, and electrophysiologic changes over weeks or months. Pain is typical, and there may be unusual manifestations (such as intense itching reported in association with breast cancer).<sup>37</sup> On electrophysiological studies, there may be evidence of more widespread nerve involvement affecting nerve roots as well as peripheral nerves. Analysis of CSF may show mild abnormalities.

Paraneoplastic peripheral neuropathy has been associated with a number of cancers (small-cell and non-small-cell lung cancer, breast cancer and thymoma) and with several autoantibody markers (see Table 2), notably ANNA-1, CRMP-5 and N-type calcium channel antibodies. However, antibody studies can be negative in many patients with paraneoplastic peripheral neuropathy.<sup>36</sup>

A demyelinating polyneuropathy occurs commonly in patients with the rare osteosclerotic form of plasmacytoma as part of the polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (POEMS) syndrome.<sup>38</sup> There are no specific antibody tests, although serum protein electrophoresis can detect the monoclonal protein, and a radiographic bone survey may reveal an osteosclerotic focus. Treatment of the tumor in these cases can lead to improvement in the neuropathy.

### Paraneoplastic Sensory Neuronopathy

Progressive neuropathy that exclusively affects the sensory nerves has been termed pure sensory neuropathy, sensory ganglionopathy, or sensory neuronopathy. About 20% of cases of sensory

neuropathy are paraneoplastic; the remainder are associated with systemic autoimmune disease (notably Sjögren syndrome) or toxin exposure or remain idiopathic. Initial symptoms may commence in the upper or lower extremity and consist of distal pain, numbness, and paresthesias, which can be asymmetric. Clumsiness and gait unsteadiness develops because of marked loss of joint position sense. This sensory ataxia is distinct from ataxia due to a cerebellar disorder; speech and eye movements are normal. When the patient closes the eyes, the loss of balance and coordination becomes much worse, and slow wandering movements of the digits or limbs (pseudoathetosis) may be seen. Muscle stretch reflexes are usually absent. Often, the disorder progresses relentlessly over weeks or months and leads to significant disability—inability to walk or attend to basic needs. Because of marked insensitivity, the patient may be unaware of serious injuries to the extremities.

The pathological correlate of paraneoplastic sensory neuropathy is destruction of neurons and inflammation in the dorsal root ganglia. Any of several paraneoplastic antibodies may be found, but the typical correlation is with ANNA-1 (anti-Hu) antibody. SCLC is the most commonly associated tumor. Typically, the neurologic syndrome precedes the diagnosis of cancer, and the detection of cancer is often delayed by over a year despite close surveillance.

### Paraneoplastic Autonomic Neuropathy

In other cases, paraneoplastic autoimmunity can specifically target the neurons and nerves of the autonomic nervous system and spare the motor and sensory nerves. The autonomic nervous system has myriad functions, including regulation of body temperature, blood pressure, heart rate, urination, digestion, and sexual function. Complete or partial autonomic failure can be a troublesome or even life-threatening problem. Autonomic dysfunction has many causes, but many cases of subacute autonomic failure have an autoimmune basis, and some of these patients have an underlying malignancy. Common symptoms are syncope (due to orthostatic hypotension), heat intolerance (due to anhidrosis), dry mouth, severe constipation, and vomiting. The latter symptoms are due to abnormalities of gastrointestinal motility. A common presentation of paraneoplastic autonomic neuropathy is unexplained gastroparesis or intestinal pseudo-obstruction. This presentation of PND may be unrecognized as the patient undergoes extensive and unrevealing gastrointestinal evaluations. When autonomic symptoms occur in concert with another neurologic syndrome (like PLE or sensory neuropathy), a paraneoplastic cause should be strongly suspected.

The most common association is with SCLC and ANNA-1 (anti-Hu) antibodies. Many patients with SCLC and autonomic failure who do not have ANNA-1 have antibodies against the neuronal ganglionic acetylcholine receptor.<sup>39</sup> Mild abnormalities of autonomic function (dry mouth and impotence) are also present in a majority of patients with the Lambert-Eaton syndrome.

### Myasthenia Gravis and Lambert-Eaton Syndrome

These two disorders differ from the disorders described above in two important respects. First, these diseases are directly caused by antibodies that are also a specific diagnostic marker, and second, patients often respond well to treatment. Myasthenia gravis (MG) is the prototypical autoimmune neurologic disorder. Patients present with fatigable weakness that usually affects the eyes (causing ptosis and diplopia). Antibodies against acetylcholine receptors (AChR) at the neuromuscular junction cause the disease and can be detected in the serum in about 85% of MG patients. MG is generally not thought of as a paraneoplastic disorder, yet up to 15% of patients with MG have thymoma. MG has also been rarely associated with SCLC. The possibility of thymoma should be considered in any patient with a new diagnosis of MG, and certain antibody results should increase the suspicion of thymoma.<sup>23</sup> The incidence of thymoma is highest when the onset of MG is at an older age. When present, thymoma can usually be detected with routine computed tomography of the chest. Although histologically benign, thymoma should be resected if possible since untreated thymoma can be invasive and locally metastatic. Unlike other PND, MG will usually respond to immunosuppressive drugs (such as steroids and azathioprine) and to symptomatic treatment with acetylcholinesterase inhibitor (pyridostigmine) to improve neuromuscular transmission. Most MG patients will need some form of long-term treatment for MG even after thymectomy. Paraneoplastic MG is very difficult to control unless the thymoma is removed.

Like MG, Lambert-Eaton syndrome (LES) is an antibody-mediated disorder. Antibodies against P/Q-type voltage-gated calcium channels on the motor nerve terminal lead to inefficiency of neuromuscular transmission. LES is a paraneoplastic disorder associated with SCLC in about 60% of adult patients. Patients with paraneoplastic LES usually present after age 40 with complaints of generalized weakness and fatigue. Back and proximal leg pain may be a prominent feature leading to a misdiagnosis of lumbar spinal stenosis. On examination, muscle weakness may be minimal and out of proportion to the patient's complaints. A consistent finding is decreased or

absent tendon reflexes. Many patients also have mild autonomic symptoms, consisting of dry mouth, constipation and impotence (in men). When LES is associated with SCLC, features of other neurologic syndromes may coexist, and other paraneoplastic antibodies may be detected in addition to calcium channel antibodies. If the cancer is found and treated, the symptoms of LES generally improve although rarely remit completely. Immunosuppression and other drugs (pyridostigmine and 3,4-diaminopyridine) are usually effective in improving strength.

### Laboratory Findings

Since PND usually predates the diagnosis of cancer, and routine laboratory tests in patients with these disorders are usually normal, diagnosis of PND depends on clinical suspicion. In some cases, mild elevation of erythrocyte sedimentation rate, C-reactive protein or antinuclear antibody may provide a non-specific indicator of ongoing inflammation and autoimmunity. Analysis of CSF may be normal or show only mild lymphocytic pleocytosis and elevated protein. Oligoclonal bands and increased CSF immunoglobulin  $\gamma$  synthesis rate are seen in a minority of cases. The advent and expansion of paraneoplastic serological testing in neurology has been a great help in diagnosing PND.

### Paraneoplastic Autoantibodies

The use and interpretation of antibody testing in suspected PND is an area of much confusion and intellectual debate. Furthermore, the number of antibodies associated with autoimmune neurologic disorders has been growing steadily. Many small laboratories offer testing for individual paraneoplastic antibodies, but the major reference laboratories have moved toward offering comprehensive testing panels to improve sensitivity and to relieve the clinician from the burden of having to keep up with this evolving field. Conceptually, it is useful to consider paraneoplastic antibodies in two distinct groups because the implications of testing differ.

### Antibodies against Neuronal Nuclear and Cytoplasmic Antigens

The first group consists of antibodies directed against intracellular antigens in the nucleus or cytoplasm of neurons (see Table 2). In some cases, the protein antigen has been definitively identified, and testing using Western blot against recombinant protein is available. In other cases, the antibody is defined descriptively based on the pattern of immunohistochemical staining of brain sections. In most cases, the antibodies have been shown to recognize antigens both in neurons and in the appropriate tumor cells. It is

unlikely that these antibodies are directly pathogenic since their specific antigens are intracellular and not readily accessible in living neurons. Furthermore, the antibodies often bind to a wide variety of neurons (ANNA-1, for example, binds to the nuclei of all neurons) even though the associated clinical syndromes are usually restricted to a specific region or cell type of the nervous system. These antibodies are important as surrogate markers of a specific immune response to cancer. Because of these characteristics, neuronal nuclear and cytoplasmic antibodies are highly specific for the presence of cancer and also predictive of the cancer type. Nearly 90% of patients with ANNA-1 antibodies have SCLC,<sup>13</sup> and over 90% of patients with PCA-1 have cancer (76% ovarian or related peritoneal tumors and 13% breast cancer).<sup>40</sup> Thus, finding a neuronal nuclear or cytoplasmic antibody in a patient with a neurologic syndrome should mandate a thorough evaluation for occult malignancy and close oncologic follow-up if cancer is not detected on the initial search. The antibody specificity helps direct the search for cancer by predicting the most likely cancer.

On the other hand, individual neuronal nuclear and cytoplasmic paraneoplastic antibodies are not very specific for a particular neurologic syndrome. These antibodies also may be found in a small but significant proportion of cancer patients who have no neurologic symptoms.<sup>41</sup> Each antibody can be associated with several distinct syndromes or with unique presentations in individual patients. For example, PCA-1 antibodies are usually associated with PCD, but can also be associated with motor neuropathy. ANNA-1 and CRMP-5 antibodies have been associated with nearly every recognized paraneoplastic neurologic syndrome.<sup>21,42</sup> Additionally, individual neuronal and nuclear cytoplasmic antibodies are not sensitive diagnostic tools. The most common paraneoplastic antibody, ANNA-1, is found in only 25% of patients with PLE and proven SCLC.<sup>29</sup> Even when the most complete battery of paraneoplastic antibodies is obtained, as many as 30% of patients with a subacute neurologic syndrome and cancer have no paraneoplastic antibody detected.<sup>14,29</sup> Thus, negative antibody tests cannot exclude a PND.

### Ion Channel Antibodies

The other group of antibodies that may be associated with PND are antibodies against neuronal ion channels (see Table 2). The implications of ion channel antibody results are very different than the nuclear and cytoplasmic antibodies described above. Ion channel antibodies are usually very sensitive and quite specific for a particular neurologic disorder, but not specific for paraneoplastic disease. For example, antibodies against neuronal P/Q-type voltage-gated calcium

channels are found in nearly all patients with the Lambert-Eaton myasthenic syndrome, but only about 60% of adult patients with LES have cancer.<sup>43</sup> Hence, the antibody is a marker of the disease but not a marker of cancer. Likewise, myasthenia gravis is highly associated with muscle AChR antibodies, but MG is a paraneoplastic disorder associated with thymoma in only 15% of patients.

Voltage- and ligand-gated ion channels are integral to the proper functioning of all neurons, but they are relatively low in abundance in the cell membrane. Thus, ion channel antibodies are generally not detectable using tissue immunohistochemistry. These antibodies are detected using more sensitive and quantitative methods. Ion channel antibodies are also unique in that they may be directly pathogenic. Muscle AChR antibodies are the cause of MG, and P/Q-type calcium channel antibodies cause LES.

### Evaluation and Treatment

The evaluation of a PND requires an initial clinical suspicion. These disorders usually precede a diagnosis of cancer, and the cancers are typically very limited in stage and usually asymptomatic. Some of the clinical syndromes should immediately raise the possibility of PND in the clinician's mind. However, many patients with PND have atypical, unusual, or multifocal neurologic complaints that are impossible to localize neuroanatomically. Thus, it is appropriate to consider a paraneoplastic cause in nearly every unexplained subacute neurologic syndrome. The presence of cancer risk factors or constitutional symptoms, such as unexplained weight loss, should increase the suspicion further.

Testing for paraneoplastic antibodies can help confirm the diagnosis of PND and help direct the search for occult malignancy. Negative paraneoplastic serology, however, cannot be used to "rule-out" a PND. If there is a prior history of cancer, specific cancer risk factors, or high suspicion based on the neurologic syndrome, one should proceed with cancer screening even without serological confirmation.

The cancer work-up starts with a detailed medical history and a complete medical examination, including palpation of lymph nodes, breasts, and testes, plus rectal and pelvic examination. The search for suspected lung cancer would start with computed tomography (CT) of the chest. If the chest CT is indeterminate or normal, positron emission tomography (PET) has been shown to be more sensitive for detecting small foci of malignancy (Figure 4).<sup>14,44</sup> If initial imaging studies are normal, repeat examination and chest CT should be performed at 3-month intervals. For suspected pelvic gynecologic malignancies, evaluation starts with bimanual pelvic examination, CT, or

ultrasonography of the abdomen and pelvis, and measurement of the serum CA-125 tumor marker. In some situations, it is necessary to proceed with exploratory laparotomy even if screening studies are normal. Breast cancer evaluation requires physical examination and mammography (supplemented by ultrasonography or MRI). Evaluation for testicular cancer includes physical and ultrasound examination of the testes, tumor markers ( $\alpha$ -fetoprotein and  $\beta$ -hCG) and CT of the abdomen and pelvis. Suspicious findings on the imaging studies should be subjected to biopsy to confirm the cancer diagnosis and guide treatment.

Tumor therapy is the standard approach to treating PND. A complete oncologic remission can be associated with stabilization or improvement in the neurologic syndrome.<sup>14</sup> Hence, early tumor diagnosis and prompt institution of therapy is critical. Even though these patients may have a poor performance score due to their neurologic deficits, aggressive tumor treatment offers the best chance of a favorable neurologic outcome. In addition to eliminating the tumor as the stimulus for the autoimmune syndrome, many chemotherapy regimens also provide direct immunosuppressive effects. These cancers are often found at a limited stage and are held in check by a vigorous anti-tumor immune response. Hence, the oncologic outcome in patients with PND is better than in patients with similar tumors.<sup>16-19</sup> Once a tumor remission is achieved, the serum titers of paraneoplastic antibodies tend to decline slowly over time but may never normalize. A relapse of neurologic symptoms or onset of a new unexplained neurologic syndrome may herald tumor recurrence. A rise in the paraneoplastic antibody titer can also signal the return of cancer, but monitoring of paraneoplastic serology over time is not efficient or reliable for this purpose. Standard oncologic follow-up and imaging studies according to the type of malignancy is important, especially if immunosuppression is used to treat the PND. Theoretically, treatments that impair cytotoxic T-cell function would facilitate tumor growth. However, immunosuppression has thus far not been associated with increased risk of cancer recurrence in small treatment studies for PND.<sup>16,45</sup>

In cases of PND where cancer cannot be identified, despite an exhaustive search, or where the neurologic symptoms progress despite cancer remission, immunomodulatory therapies can be applied.<sup>16</sup> These might include corticosteroids, immunosuppressants, intravenous immunoglobulin, or plasma exchange.<sup>45</sup> The role of these immunomodulatory therapies in combination with standard cancer treatment is not known.

Some PND syndromes typically respond to treatment better than others. Paraneoplastic disorders of the neuromuscular junction

**FIGURE 4** Positron-emission tomography detection of occult cancer. A patient with paraneoplastic encephalitis, PCA-2 and CRMP-5 antibodies, and a long smoking history was evaluated. (A) Computed tomography (CT) of the chest was unremarkable, but (B)  $^{18}\text{F}$ -fluorodeoxyglucose positron emission tomography (PET) revealed hypermetabolic foci in the right mediastinum lymph node chain (arrowhead). (C) With current technology, the PET abnormalities can be identified anatomically and coregistered with CT. In this case, directed mediastinoscopic biopsy revealed small-cell lung carcinoma.

(myasthenia gravis and LES) are antibody mediated disorders and respond well to plasma exchange, intravenous immunoglobulin or long-term immunosuppression (eg, prednisone, azathioprine). In general, other disorders of the peripheral nervous system (paraneoplastic neuropathies) are more likely to improve than those of the central nervous system.<sup>46</sup> Paraneoplastic sensory and sensorimotor neuropathies may stabilize or improve modestly after cancer treatment, but residual deficits are the rule. Paraneoplastic autonomic disorders can sometimes improve dramatically after treatment.<sup>39</sup>

Among common central nervous system paraneoplastic disorders, limbic encephalitis and opsoclonus-myoclonus are most amenable to treatment.<sup>11,46</sup> In combination with cancer treatment, high-dose steroid treatment may be useful in promoting recovery in these disorders. Typical paraneoplastic cerebellar degeneration, on the other hand, rarely responds to treatment.<sup>16</sup> Even with effective cancer treatment and adjunctive immunosuppression, the best outcome of PCD is an arrest of neurologic progression. Patients and their families need to understand the inherent difficulties in treating these disorders and set reasonable expectations. Median survival for PND of the central nervous system is 2 to 4 years from the onset of neurologic symptoms.<sup>14</sup>

Because PND is so devastating and because an autoimmune etiology is likely, immunomodulatory therapies are often utilized. However, very few prospective studies have been performed to establish the efficacy or futility of such treatments. Based on retrospective data, it is generally thought that immunomodulatory treatment is ineffective, and that treatment of the underlying malignancy is the only available treatment for these disorders.<sup>11,13,21,46,47</sup> Yet, there have been individual case reports of neurologic improvement using corticosteroids, intravenous immunoglobulin, plasma exchange, protein A immunoabsorption, rituximab, tacrolimus, mycophenolate mofetil,

or cyclophosphamide. Based on a few systematic prospective case series,<sup>16,45</sup> immunomodulatory treatments may lead to a stabilization or mild improvement of disability in patients who are still ambulatory, but offer little benefit to those with severe disability. Syndromes limited to the peripheral nervous system seem to be more likely to respond than those affecting the CNS.

Symptomatic therapies are also important for the management of patients with PND. Patients with PLE need anticonvulsants to control their seizures. Patients with myoclonus or chorea can benefit from clonazepam or neuroleptics.<sup>10</sup> Paraneoplastic neuropathies are often associated with significant pain that might benefit from analgesics, tricyclic antidepressants, or anticonvulsants (gabapentin or carbamazepine). Neuromuscular junction disorders can respond to acetylcholinesterase inhibitors (pyridostigmine) or 3,4-diaminopyridine (for LES). Most importantly, PND is psychologically devastating to patients and their families. Patients are faced not only with a progressive and disabling neurologic syndrome but also with a new diagnosis of cancer and an uncertain future. Severe depression is a common factor, which may interfere with the patient's treatment. This must be recognized and addressed. Finally, rehabilitation services are important. If the neurologic syndrome can be stabilized, physical and occupational therapies can help these patients reestablish some degree of independence.

## Summary

Paraneoplastic neurologic syndromes represent a rare, but severe immunologic complication of certain malignancies (most notably small-cell lung carcinoma, ovarian cancer, and thymoma). Clinical manifestations can be quite varied and multifocal in the nervous system. Several distinct clinical syndromes are recognized including sensory neuropathy, cerebellar degeneration,

limbic encephalitis, and Lambert-Eaton myasthenic syndrome. These disorders are usually associated with a subacute onset and significant disability. Typically, the neurologic presentation antedates the diagnosis of malignancy, and the cancer, when found, tends to be localized and responsive to treatment. Diagnosis depends on clinical suspicion, serology for paraneoplastic antibodies, and a focused search for cancer. Current treatments for the neurologic symptoms are effective in only a minority of cases. Optimum management includes early diagnosis, treatment of cancer to remission, immunosuppression, symptomatic therapies, and compassionate support.

# Neuropathic Pain

Leslie J. Blackhall MD, MTS

Neuropathic pain is defined as pain due to an injury to, or dysfunction of, the nervous system. In patients with cancer, neuropathic pain can occur from the tumor itself, infiltrating or compressing neural structures, or as a consequence of cancer treatment. The pathophysiology of neuropathic pain is complex, and may involve both peripheral and central mechanisms. For example, patients with peripheral nerve damage from chemotherapy may manifest hyperesthesia (hypersensitivity to noxious stimuli), allodynia (pain to stimuli that normally do not cause pain), and spontaneous pain (pain occurring in the absence of any stimulation). In these cases, damage to the sensory neurons may cause spontaneous ectopic activity, due to focal demyelination producing exposure of sodium channels<sup>1</sup> and accumulation of inflammatory mediators and cytokines that sensitize nociceptor terminals so that they respond to normally innocuous stimuli.<sup>2</sup> Neuroma formation in regenerating afferent nerves can cause an accumulation of sodium channels and an increase in ectopic activity. Peripheral nerve injury may cause disinhibition in the dorsal root ganglia through multiple mechanisms, including a reduction in GABA (down-regulated on injured nerves) and an up-regulation of cholecystikinin receptors. This disinhibition can lead to exaggerated or even spontaneous firing of dorsal horn neurons. Central neurons can become sensitized as well, as in the phenomenon known as “wind up” where repetitive C-fiber input causes increased central response to subsequent stimuli (mediated through the NMDA receptors). Finally, patients with phantom limb pain may have cortical reorganization as well.

The diagnosis of neuropathic pain in cancer may be obvious, or more subtle as part of a mixed pain complex in which nociceptive and neuropathic components are both present. In the latter case, neuropathic pain may be identified by the quality of the pain. Patients with this type of pain complain of burning, shooting, or radiating pain. Paroxysms of pain, often described as having an “electric shock” quality, may be present. Allodynia, hyperesthesia and paresthesias are characteristic of neuropathic pain, and patients may report a paradoxical feeling of numbness and pain in the same area.

## Treatment of Neuropathic Pain in Cancer

Cancer-related neuropathic pain is common, and may be more severe and difficult to treat than other types of cancer-related pain. Epidural spinal cord compression, leptomeningeal disease, brachial plexus infiltration and lumbosacral plexopathies are examples of neuropathic syndromes that will often require aggressive pain management. While treatment of the underlying disease with radiation, surgical decompression or chemotherapy may provide relief of pain, not all patients will respond to these treatments, and even those who respond may have a prolonged lag time before their pain improves. Radiation, surgery, and chemotherapy may themselves cause neuropathic pain (see “Treatment-Related Neuropathic Pain Syndromes” below for a discussion of treatment related pain). Finally, at the end of life, patients with these syndromes may not be candidates for further treatment of their primary disease. For these reasons, the symptomatic treatment of neuropathic pain is an important issue in cancer care. In the following section, we will discuss the pharmacologic management of neuropathic pain, with emphasis on medications specific for treatment of neuropathic pain. It is important to remember, however, that opioids, even those without specific efficacy for neuropathic pain, have an important place in the management of neuropathic pain, and will almost always be required in treating moderate to severe pain.<sup>3,4</sup> This is especially true because patients with cancer-related neuropathic pain will often have other types of cancer pain syndromes. Treatment-related pain syndromes may be a special case, and these are discussed in a later section (see “Treatment-Related Neuropathic Pain Syndromes” below).

As we discuss the medications commonly used for neuropathic pain, it should be noted that most of the evidence for the efficacy of these agents has been for nonmalignant conditions. In general, this section has been organized by class of drug (eg, antidepressant, anticonvulsant). However, another and potentially more useful way of thinking about medications for neuropathic pain is by mechanism of action.<sup>5,6</sup> Thus, mode of

action, where known, has been discussed in each section and is also shown in Table 1.

Although it is beyond the scope of this chapter to discuss neurosurgical and anesthetic techniques for the treatment of cancer-related pain, patients who do not respond to pharmacologic treatment, or who are unable to tolerate the side effects of treatment, may benefit from nerve blocks, epidural or intrathecal medications,<sup>7</sup> or even to neurosurgical approaches such as cordotomy.<sup>8</sup> Referral to a specialist in cancer-related pain syndromes is recommended in difficult cases like these.

## Tricyclic Antidepressants.

### Mechanism of Action

A tricyclic antidepressant (TCA) acts as a modulator of descending inhibitory pathways via inhibition of reuptake of norepinephrine and serotonin (imipramine, amitriptyline, clomipramine), or, in some cases, norepinephrine alone (desipramine and maprotiline).<sup>5,6</sup> Successful treatment of pain is independent of improvement of depression, and usually occurs at dosages below those prescribed for antidepressant effects.

### Efficacy in Specific Conditions

In studies of painful polyneuropathies (usually diabetic), TCAs have been shown to be effective, with a number needed to treat (NNT) (ie, the number of patients needed to treat to obtain at least 50% pain relief for one patient) of 3.0 across 13 separate studies.<sup>6,9</sup> Balanced reuptake inhibitors have generally been more effective for this condition than those inhibiting the reuptake of NE alone, with a NNT of 2.0 for the balanced reuptake inhibitors, versus 3.4 for the selective NE reuptake inhibitors. This situation may be reversed in postherpetic neuralgia, where data for effectiveness is fairly strong and the NNT overall is about 2.3. These agents, amitriptyline in particular, may be effective for both lancinating and steady pain, and may also be effective in neuropathic pain caused by peripheral nerve injury. Some caution is needed in generalizing the results of studies done mainly on benign peripheral neuropathy (primarily of diabetic origin) to cancer-related peripheral neuropathies (usually

**Table 1 Medications to Combat Neuropathic Pain NMDA = N-methyl-D-aspartic acid**

Location of Action	Mechanism of Action	Medication
Peripheral nervous system	Sodium channel blocker	Lidocaine (patch and systemic), mexiletine, lamotrigine, carbamazepine, oxcarbazepine, topiramate
Peripheral nervous system	Depletion of substance P	Topical capsaicin
Central nervous system (spinal cord)	Calcium channel blocker	Gabapentin, levetiracetam
Central nervous system (spinal cord)	NMDA receptor blocker	Ketamine, methadone
Central nervous system (brain, modulating descending inhibitory pathways)	Norepinephrine and/or serotonin reuptake inhibition	TCAs, venlafaxine, duloxetine, paroxetine, citalopram, bupropion, tramadol
Central nervous system (brain, modulating descending inhibitory pathways)	Opioid receptors	Opioids (including methadone), tramadol

Adapted from Beydoun A, Backonja M.<sup>5</sup>

caused by chemotherapeutic agents). Several studies on TCAs in the treatment of HIV-related peripheral neuropathy, for example, have failed to show benefit.<sup>10,11</sup>

Several studies have looked specifically at TCAs in cancer-related neuropathic pain. In a study of radiation-induced mucositis pain in head and neck cancer, the TCA nortriptyline hydrochloride provided effective relief in 8 of 19 patients; 11 of 19 required the addition of morphine to provide effective relief.<sup>12</sup> In a study of postmastectomy pain, 8 of 15 patients had more than 50% reduction in pain intensity with amitriptyline (average dose 50 mg). Unfortunately, most of the good responders did not wish to continue the medication because of side effects, especially sedation.<sup>13</sup> These authors suggested using a less sedating TCA.

### Side Effects

Side effects of TCAs are generally related to their anticholinergic effects and include sedation, dizziness, weight gain, orthostatic hypotension, dry mouth, urinary retention, constipation, arrhythmias and confusion. (Some of these side effects, in particular, weight gain and sedation, can be useful in cancer patients; and amitriptyline, in particular, may be prescribed at night for patients with neuropathic pain and difficulty sleeping). TCAs can lower the seizure threshold and should be used with caution in liver disease. Overdose can be fatal, usually secondary to cardiac complications. Drug interactions are common and include imidazoles such as Diflucan (increased blood levels of TCAs), carbamazepine (decreased blood levels of TCA and carbamazepine). The risk of dose-limiting side effect may be reduced in TCAs by choice of agent. Desipramine has fewer anticholinergic side effects but, as an NE inhibitor, it may be less effective than amitriptyline. If avoidance of sedation is desired,

then nortriptyline is a good choice. It is a major metabolite of amitriptyline and has fewer sedating side effects.<sup>14</sup>

### Other Antidepressants

Since the use of TCAs for pain control has been limited by the high incidence of side effects, the newer, better-tolerated antidepressants have been studied as treatments for neuropathic pain. Although there are far fewer data for SSRIs than for TCAs, it appears that they are relatively ineffective compared to TCAs for this indication,<sup>4,15</sup> although there is some evidence for paroxetine<sup>16</sup> and citalopram.<sup>17</sup> Bupropion has also shown some efficacy in the treatment of neuropathic pain syndromes.<sup>18,19</sup>

Two newer antidepressants that have shown particular promise in treating neuropathic pain are venlafaxine and duloxetine. Both of these agents inhibit reuptake of serotonin and norepinephrine, although venlafaxine affects the NE system more weakly and mainly at higher doses.<sup>20</sup> These agents presumably work through the same mechanisms as the TCAs, but have a better side effect profile. Several articles have presented evidence for the use of venlafaxine for diabetic neuropathy.<sup>20-23</sup> One article looked at the use of perioperative venlafaxine for the prevention of postmastectomy pain syndrome and found it to be effective in preventing postoperative chest wall, arm and axilla pain<sup>24</sup>; otherwise, reports have mainly focused on nonmalignant pain syndromes.

Duloxetine is an antidepressant related to venlafaxine, but with more robust NE inhibition and has been studied for the treatment of painful physical symptoms associated with depression.<sup>25,26</sup> Data on cancer-related neuropathic pain are lacking, but in theory, this agent is promising.

In summary, antidepressants, especially the TCAs have been the mainstay of treatment for

neuropathic pain for many years. More recently, however, TCAs have fallen out of favor because of their many adverse side effects. Judicious choice of TCA may allow them to be used effectively, however. Newer antidepressants, such as venlafaxine and duloxetine, show promise in treating neuropathic pain, with an improved side effect profile. More data are needed on their use in cancer-related pain.

## Gabapentin

### Mechanism of Action

The mechanism of action is still unclear for this agent, although evidence points to central mechanisms, perhaps at the level of the spinal cord, where it acts to inhibit the calcium channel current.<sup>5,6</sup>

### Efficacy in Specific Conditions

Early evidence for the effectiveness of gabapentin for neuropathic pain, in the form of case studies, led to randomized controlled trials of this agent for specific conditions. Well-designed studies have found gabapentin to be effective for diabetic peripheral neuropathy,<sup>27</sup> postherpetic neuralgia,<sup>28,29</sup> and other neuropathic pain syndromes.<sup>30</sup> Improvement has also been seen in phantom limb pain.<sup>31</sup> Doses used in one study, which showed a positive effect for gabapentin, were much higher than those used for the management of seizures, with patients requiring up to 3,600 mg/day.<sup>32</sup>

Because of the success of gabapentin in treating nonmalignant neuropathic pain, and its relatively favorable side-effect profile (see "Side Effects" below) it has become widely used in treating cancer patients with a variety of neuropathic pain syndromes.<sup>33</sup> One study looked at the efficacy of gabapentin as an adjuvant to opioid therapy in cancer patients with a variety of neuropathic pain syndromes, including brachial plexopathy, sciatic neuropathy, and radiculopathy from meningeal disease. In this uncontrolled trial, 20 of 22 patients experienced significant improvement following addition of gabapentin.<sup>34</sup>

### Side Effects

Gabapentin is generally well tolerated. The most common side effects of this medication are sedation, ataxia, and dizziness. Peripheral edema, abdominal cramping, and nausea are less common. The central nervous system (CNS) side effects of gabapentin mainly occur during the titration phase and may be ameliorated by starting with lower doses and titrating slowly.

In summary, gabapentin is increasingly used as a first line agent for cancer-related neuropathic pain, either alone or in combination with opioids. Because patients with advanced cancer are frequently debilitated and already suffering from

fatigue for a variety of reasons, it is our clinical experience that the aggressive titration schedules used in studies on nonmalignant neuropathic pain syndromes are not appropriate in this population. For these patients, tolerance to gabapentin-related sedation may be improved by starting at doses as low as 100 mg three times a day and titrating up each dose by 100 mg every day or two until pain is improved or intolerable side effects occur.

Lamotrigine is a newer antiepileptic agent that has been studied for its use in nonmalignant neuropathic pain syndromes. Its mechanisms of action are unknown although it probably acts as both a sodium channel modulator in the peripheral nervous system (PNS) and a calcium channel inhibitor at the level of the spinal cord.<sup>5</sup> Specific data on its use in cancer patients are lacking; however, it has been shown to benefit patients with trigeminal neuralgia,<sup>35</sup> HIV-associated neuropathy,<sup>36,37</sup> diabetic neuropathy,<sup>38</sup> and post-stroke pain.<sup>39</sup> Adverse effects are similar to those seen in gabapentin, including somnolence, dizziness, and ataxia, but are more common with this agent than with gabapentin. Rarely, severe rash—and even Stevens-Johnson syndrome—may occur. Slow titration is required to avoid the more severe CNS side effects.

Carbamazepine and oxcarbazepine have also been used for neuropathic pain. The mechanism of action is probably the same as that of lamotrigine. Carbamazepine is an agent that has long been used to treat trigeminal neuralgia and has been the drug of choice for that condition.<sup>40,41</sup> The use of this medication has been limited, however, by its side effects which commonly include sedation, dizziness, ataxia, and nausea, as well as rare, but potentially fatal, hematological effects. Oxcarbazepine is a metabolite of carbamazepine, which appears to have similar benefits, with an improved side effect profile.<sup>42</sup> As with many agents, data from patients with cancer-related pain are not yet available.

Other anticonvulsants, including pregabalin,<sup>43</sup> topiramate,<sup>44</sup> and levetiracetam<sup>45,46</sup> have also been used for neuropathic pain, and are likely to find increasing use for this indication. Clonazepam is probably not effective for neuropathic pain.<sup>47</sup>

## NMDA Receptor Antagonists

Ketamine is an anesthetic agent whose mode of action in the treatment of neuropathic pain is NMDA receptor antagonism, acting at the level of the spinal cord. The NMDA receptor is involved in central sensitization and in opioid tolerance, so NMDA receptor antagonists have been used as single agents for the treatment of pain and also to improve efficacy of opioid medications.

## Efficacy in specific conditions

Although ketamine has been studied for peripheral neuropathy,<sup>48</sup> post-amputation pain<sup>49</sup> and postherpetic neuralgia,<sup>50</sup> its utility for these conditions has been limited by the severe and near-universal side effects, including sedation and even hallucinations. However, this agent has found a niche in the treatment of intractable, opioid-resistant cancer-related pain. Most of the evidence for the use of ketamine in this setting is anecdotal, including case reports,<sup>51–54</sup> open-label audits,<sup>55</sup> and other uncontrolled trials,<sup>56</sup> with relatively few randomized controlled trials.<sup>57–59</sup> Like the case reports, those trials showed the efficacy of ketamine in cancer patients with neuropathic pain. Hallucinations and sedation, however, were frequently reported in all studies.

The importance of ketamine in cancer pain management becomes clear when one looks at the patients treated in the case reports. These patients were suffering from very advanced cancer nearing the end of life, with serious complications of their disease, such as spinal cord compression, which caused severe neuropathic pain. They were generally on very high-dose opioids and multiple adjuvant medications without significant relief, and their pain greatly improved, albeit at the frequent cost of sedation, with ketamine. One such report, for example, describes a patient with neuropathic pain from cervical cancer.<sup>52</sup> Despite 1,000 mg/day of oral morphine and 200 mcg/hr of transdermal fentanyl and numerous adjuvant analgesics, she was experiencing severe pain, reported as 8 to 9 out of 10 on a numeric rating scale. This patient responded to IV ketamine in conjunction with IV morphine. This patient is characteristic of many of the case reports concerning intravenous ketamine for patients near the end of their lives. Oral ketamine has also been used for cancer-related neuropathic pain, in the outpatient setting.<sup>56</sup> Seven of nine patients improved on oral ketamine in this study, although three withdrew because of side effects, including sedation and feelings of unreality.

## Side Effects

As discussed above, side effects include sedation, hallucinations, dizziness, and feelings of unreality. These side effects are frequent and may be severe. They appear to be dose-related. Several of these studies reported the concomitant use of haloperidol, diazepam, or midazolam to prevent or treat hallucinations or dissociative symptoms.<sup>52,58</sup> Dose reduction also generally results in improvement or elimination of these side effects.<sup>55</sup>

In summary, ketamine is an effective treatment for severe neuropathic cancer pain. For selected patients, it can be extremely beneficial, providing relief in desperate situations. Because of the potential for severe side effects, however,

IV ketamine should be reserved for those patients whose symptoms are refractory to other medications and should generally be given under the supervision of a clinician experienced in cancer pain management. The starting dose should be low: 0.1 to 0.15 mg/kg/hour continuously, with gradually increasing doses while monitoring for CNS side effects and using haloperidol, diazepam, or midazolam if necessary. For patients close to the end of their lives, especially those who are not expected to survive the hospitalization, a continuous infusion can be maintained intravenously or subcutaneously. Other patients may benefit from the transition to oral ketamine,<sup>53,54</sup> and there is evidence that, for some patients, a “burst” of IV ketamine may provide continued pain relief even after it has been discontinued.<sup>55</sup>

## Methadone

### Mechanism of Action

Methadone is an opioid finding increasing use for the treatment of neuropathic pain in cancer. It acts at both the  $\mu$ -opioid and  $\delta$ -opioid receptors. It also is an NMDA receptor antagonist, which has led to interest in its use in neuropathic pain. The methadone marketed in this country is a racemic mixture of the d and l isomer; it is the d isomer that blocks the NMDA receptor.<sup>60</sup> It may also inhibit the reuptake of norepinephrine and serotonin.<sup>61</sup>

### Efficacy in Specific Conditions

Because of its long, and highly variable half-life, methadone has been considered a second-line agent for the treatment of cancer-related pain. Recently, however, there has been increasing interest in this agent, especially for neuropathic pain. Methadone has the advantage of being inexpensive, well-absorbed orally, and dosed two or three times a day. Since it lacks neuroactive metabolites, it can be used in renal failure. Its mechanism of action has led to interest in its use for neuropathic pain; however, there is little evidence to support the idea that methadone is superior to morphine or other opioids for this indication, and scant data to suggest that methadone is more effective for neuropathic pain than for other types of pain.

Several studies on methadone have showed efficacy for cancer pain treatment comparable to morphine.<sup>62–65</sup> Other studies have shown methadone to be efficacious in patients with cancer pain who are poorly responsive to morphine.<sup>66,67</sup>

None of the studies cited above focused specifically on methadone's effect on neuropathic pain. One study, which attempted to examine this issue by looking retrospectively at the ratio of morphine and hydromorphone to methadone during opioid rotation for the treatment of cancer-related neuropathic and non-neuropathic

pain, did not find a difference in the equianalgesic ratios for these two indications, suggesting no greater efficacy for methadone in neuropathic cancer pain than in non-neuropathic pain.<sup>68</sup>

### Side Effects

Side effects are similar to those of other narcotics, including confusion, sedation, constipation, diplopia, dizziness, dry mouth, nausea, and respiratory depression with overdose.

In summary, methadone is increasingly used in the management of cancer pain, especially in patients with neuropathic pain, and is used by some clinicians as a first-line agent for that indication. There is currently a paucity of data to support its specific use for neuropathic pain as compared to other types of cancer-related pain. That said, it is an effective agent for cancer-related pain of all types, and may have particular utility in patients who are poorly responsive to morphine. It can be used safely as long as attention is paid to its unique characteristic, in particular its long and variable half-life, which makes equianalgesic conversion difficult.<sup>69,70</sup>

## Topical Agents

### Lidocaine 5% Patch

#### Mechanism of Action

Lidocaine is a sodium channel antagonist. Such antagonists have been shown to bind to abnormal sodium channels with high affinity, and reduce the frequency of ectopic discharges. The rationale for the use of the lidocaine patch is to deliver this drug locally to an area of nerve damage, while reducing or eliminating systemic side effects.

#### Efficacy in Specific Conditions

The lidocaine 5% patch has been mostly studied as an agent for postherpetic neuralgia. Several well-designed trials have found it to be safe and effective for this indication.<sup>71–73</sup> Other focal peripheral neuropathic pain syndromes can be treated by the lidocaine patch as well.<sup>74</sup> The NNT for this study was 4.4, which is comparable to other treatments for this condition. The major indication for this agent is a focal peripheral neuropathy, especially with a component of allodynia. In terms of cancer-related pain, it seems reasonable to consider this agent for postmastectomy pain and post-thoracotomy pain, as they fit this definition, despite a lack of specific studies for these indications.

#### Side Effects

Side effects are mild and mainly consist of local reactions to the patch, including rash, pruritus, and sweating.

In summary, the lidocaine 5% patch is an easy-to-use agent with few side effects. It is a first-line agent for the treatment of postherpetic

neuralgia, and may be combined with other agents for more severe pain syndromes. It effectively relieves allodynia, and should be considered for patients with postmastectomy, post-thoracotomy, and other postsurgical pain syndromes where focal peripheral neuropathic pain is present.

### Topical Capsaicin

#### Mechanism of Action

Topical capsaicin is an agent derived from red peppers whose mode of action is felt to be depletion of substance P from sensory fibers.

#### Efficacy in Specific Conditions

Capsaicin applied topically has been studied for postherpetic neuralgia in a 0.025% concentration.<sup>75</sup> In this open-label uncontrolled trial, 56% of 23 patients reported good or excellent pain relief after 4 weeks. A burning sensation after application of the drug was common, however, and led to a 1/3 drop-out rate. A randomized controlled trial of 0.075% capsaicin for this indication also showed significant improvement.<sup>76</sup> Studies on the efficacy of this agent for diabetic and other peripheral neuropathies have been mixed, with some reporting improvement<sup>77,78</sup> and others no improvement compared to placebo.<sup>79,80</sup> Several articles have specifically addressed the use of topical capsaicin for postmastectomy pain syndrome. Two open-label studies showed improvement with this agent.<sup>81,82</sup> A randomized controlled trial of 0.075% capsaicin had somewhat more mixed results, with no improvement in “steady pain,” but significant improvement in stabbing and overall pain, compared to vehicle cream.<sup>83</sup>

#### Side Effects

Side effects are mainly local in nature. The most common is a burning sensation, and it may be severe enough to cause discontinuation of the agent. Rash has been reported as well. Rarely, coughing and sneezing may occur.

In summary, capsaicin is a topical agent that may be effective in some types of cancer-related neuropathic pain syndromes. It is less useful as a topical agent than lidocaine only because of the burning sensation it frequently causes.

## Antiarrhythmics

### Systemic Lidocaine

#### Mechanism of Action

Lidocaine acts as a sodium channel blocker, suppressing ectopic discharges from injured nerve endings.

#### Efficacy in Specific Conditions

Intravenous lidocaine has been described for the treatment of neuropathic pain for many years.

Acute postoperative pain,<sup>84</sup> phantom limb pain,<sup>85</sup> and peripheral nerve injury<sup>86</sup> are conditions in which there is some evidence of efficacy for lidocaine. One randomized, double-blind study comparing a 30-minute infusion of intravenous (IV) lidocaine to saline for diabetic peripheral neuropathy showed a reduction in symptoms (such as pain and sleep disturbance) lasting from days to several weeks.<sup>87</sup> A similar trial comparing IV lidocaine to saline for postherpetic neuralgia showed reduction in pain as measured by visual analog scores in the lidocaine group, with efficacy similar to morphine.<sup>88</sup>

Case reports have documented efficacy of lidocaine in neuropathic cancer pain.<sup>89,90</sup> One recent paper reviewed the use of intravenous lidocaine in an inpatient hospice unit. Sixty-one patients who had pain characterized as opioid refractory (ineffective pain relief despite the equivalent of 200 mg/d of oral morphine or more) were studied. Most of these patients were diagnosed with neuropathic pain (78%). The underlying diagnoses of these patients are not discussed, although, nationwide, cancer patients make up the majority of those enrolled in hospice care. Of these patients, 80% were deemed to have a “major” response to lidocaine, usually delivered as a bolus, followed by continuous IV infusion if response to the bolus was noted. Major response was defined as a decrease of at least 3 points on an 11-point pain scale. In this group of terminally ill patients (78% of whom died prior to discharge), the major side effect was sedation. One patient died suddenly, although sudden in this context is a relative term, and the cause of death was not clear.<sup>91</sup>

#### Side Effects

Side effects may be severe, which is why this drug is not a first-line agent. They include confusion, sedation, disorientation, lightheadedness, and cardiac arrhythmias. CNS side effects are not uncommon, especially in older patients. These are less concerning if the medication is given as a “burst” and not continued indefinitely.

### Mexiletine Hydrochloride

The success of lidocaine in treating some types of neuropathic pain led to interest in other agents in this class. Mexiletine hydrochloride, a structural analog of lidocaine, which can be given orally, has received attention as a treatment for neuropathic pain.

The mechanism of action is the same as that for lidocaine.

#### Efficacy in Specific Conditions

Several studies found mexiletine hydrochloride to be beneficial for the treatment of diabetic peripheral neuropathy.<sup>92–94</sup> In at least one study, patients with stabbing and burning pain sensations were most likely to experience benefit from treatment

with this agent.<sup>94</sup> Other studies have not found mexiletine hydrochloride to be effective in the treatment of diabetic peripheral neuropathy,<sup>95</sup> and its use for the treatment of other peripheral neuropathies, such as those associated with HIV disease, has been disappointing.<sup>96,97</sup> Adverse effects were not uncommon in all studies, although serious cardiac side effects were quite rare, perhaps because they tended to exclude patients with cardiac histories, or even abnormal EKGs.

Aside from its general use in the treatment of peripheral neuropathies, mexiletine hydrochloride has been studied for cancer-related pain syndromes. One randomized, placebo-controlled study examined the use of intraoperative regional block and 6 days of oral mexiletine hydrochloride postoperatively, given alone or in combination, on immediate and chronic pain in patients undergoing surgery for breast cancer. While both regional block and oral mexiletine hydrochloride seemed to provide some immediate benefit in reducing postoperative pain, development of chronic postmastectomy pain syndrome was not affected by mexiletine hydrochloride or regional block given in this manner.<sup>98</sup> Open-label studies<sup>99</sup> and case reports<sup>100</sup> have had mixed results in the treatment of neuropathic pain in patients with advanced cancer.

#### Side Effects

As mentioned above, serious arrhythmias are a known side effect of drugs in this class, and, for this reason, they should generally not be used in patients with serious cardiac disease, including heart failure and known arrhythmias. Confusion, sedation, and dizziness are also side effects of this and similar medications. Gastrointestinal side effects, including nausea, diarrhea, vomiting, and abdominal pain, are common. Side effects tend to increase as dose increases. This is unfortunate, as at least some studies have shown dose-dependent improvement in pain.

In summary, lidocaine and its oral analog mexiletine hydrochloride are drugs that have shown some benefit in the treatment of neuropathic pain, including cancer-related neuropathic pain. Because of their potentially serious side effects, they are considered second- or third-line agents. Some would recommend a trial of intravenous lidocaine, and, if benefit is seen, continue ongoing treatment with mexiletine hydrochloride.<sup>101</sup>

### Tramadol

#### Mechanism of Action

Tramadol is a unique agent that is a relatively weak (compared to opioids) agonist at  $\mu$ -opioid receptors. It is also a relatively weak inhibitor of the norepinephrine and serotonin reuptake (compared to antidepressants). Because of the

latter property, this agent has attracted interest as a treatment for neuropathic pain.

#### Efficacy in Specific Conditions

Tramadol has shown benefit in the treatment of diabetic neuropathy,<sup>102,103</sup> postherpetic neuralgia<sup>104</sup> and other painful polyneuropathies.<sup>105</sup> The latter study is of particular interest because it showed not just generalized relief of pain but also specific relief of allodynia, a symptom that has been thought to be relatively opioid-resistant, perhaps indicating specific efficacy of this agent for neuropathic pain. With respect to cancer-related pain, one open-label, non-placebo controlled study on the use of a slow-release preparation of tramadol on cancer-related pain found that 71% of patients reported good to complete pain relief at 6 weeks.<sup>106</sup> Although this study looked at all types of cancer-related pain, more than 40% of these patients had a neuropathic cause of their pain. Two other studies compared morphine to tramadol for cancer-related pain.<sup>107,108</sup> Both studies found morphine to be more efficacious for this indication; however, neither looked specifically at neuropathic pain and therefore could not answer the question of whether tramadol might have specific action on cancer pain of neuropathic origin.

#### Side Effects

Side effects are similar to those of other  $\mu$ -receptor agonists, but less severe<sup>107,108</sup> including dizziness, sedation, confusion, constipation, nausea and vomiting, dry mouth, and urinary retention. Sweating is also common.

In summary, tramadol is an agent with a unique mode of action, with both opioid effects and effects related to NE and SE reuptake inhibition. It is a relatively weak opioid and, for this reason, is less likely to be effective for very severe cancer-related pain; however, there is some evidence it may have specific efficacy for neuropathic pain. Its side effect profile is relatively favorable, and it has a lower abuse potential than other opioids. Some of the studies cited above have used doses greater than the 400 mg/day generally recommended for this drug.<sup>106</sup>

### Treatment-Related Neuropathic Pain Syndromes

The following section will discuss neuropathic pain syndromes that are caused by treatments for cancer. Emphasis will be on mechanism of action, diagnosis and prevention, as well as general guidelines for treatment.

#### Post-thoracotomy Chest Pain

##### Cause and Incidence

Persistent pain following thoracic surgery for lung cancer (and other conditions) is probably

related to injury to the intercostal nerves, which produces a neurogenic pain syndrome, often including radiating pain, allodynia, and other sensory disturbances. Post-thoracotomy pain, defined as postoperative pain of at least 2 months duration where other causes of pain have been excluded,<sup>109</sup> is a common occurrence, with most studies finding an incidence of > 50% at 6 months<sup>110-112</sup> (although some studies have found lower rates).<sup>113,114</sup> Patients undergoing surgery for malignancy may be more likely to develop chronic pain than those have surgery for other reasons.<sup>115</sup> For most patients, the pain will be mild; however, a subset will have severe and difficult-to-control pain.<sup>114</sup>

#### Prevention

Several factors have been shown to correlate with an increased likelihood of chronic pain following thoracotomy, including increasing age and female gender. Intensity of acute postoperative pain has been shown to correlate with the presence of chronic pain in most studies.<sup>112,116</sup> This observation has led to studies on preemptive analgesia: attempts to improve or eliminate acute postoperative pain and to prevent the development of chronic pain. One study found that preoperative thoracic epidural analgesia (TEA) (using bupivacaine and morphine), combined with epidural patient-controlled anesthesia (PCA) postoperatively reduced perioperative and chronic pain, compared to postoperative pain control only using IV PCA.<sup>110</sup> Other studies have supported the clinical utility of preemptive analgesia to prevent post-thoracotomy pain,<sup>117</sup> while some have not.<sup>113</sup> Other aspects of the surgical procedure have been studied as well. Preemptive analgesia of the skin,<sup>118</sup> muscle-sparing surgery,<sup>119</sup> and video-assisted thoracic surgery (VATS)<sup>120,121</sup> have not been shown to reduce the incidence of chronic postoperative pain. One study reported that the use of intracostal sutures led to a decreased pain experience at up to three months postoperatively compared to the usual pericostal sutures.<sup>122</sup>

#### Treatment

Treatment of established chronic post-thoracotomy pain should be individualized; however, many would start with the lidocaine 5% patch<sup>74</sup>. Capsaicin cream is another possibility, as this agent has almost no systemic side effects; however, the local reactions to this agent are more severe than with lidocaine. If local agents are ineffective or incompletely effective, TCAs have been a first-line treatment (see “Tricyclic Antidepressants” above). However, because of the relatively unfavorable side-effect profile, many would now institute a trial of gabapentin. If the pain is severe or refractory enough to warrant a narcotic, tramadol is a reasonable first choice. It is important to note that post-thoracotomy pain usually begins

days to, at most, weeks following surgery, and pain that starts after this time frame, or that worsens after initially improving, should raise suspicion for recurrent disease.

## Postmastectomy Pain

### Cause and Incidence

The breast, axilla, and upper arm are innervated by a variety of nerves: the lateral cutaneous branch of the T2 (the intercostobrachial nerve), T3, and T4 provide innervation to the anterior chest wall and upper back, the torso, and nipple. Sympathetic innervation for the cutaneous structures of the breast is provided by the medial and lateral branches of the ventral ramus of the 3rd to 6th intercostal nerves.

Because of the number of different types of procedures performed on breast cancer patients (mastectomy, lumpectomy, sentinel node biopsy, axillary node dissection, reconstructive procedures etc.), as well as the frequent association of these procedures with chemotherapy and/or radiation, classifying the causes and incidence of pain following surgery for breast cancer is complex. While both nociceptive pain (due to damaged muscles or ligaments) and neuropathic pain can result in pain following surgery for breast cancer, neuropathic pain is more likely to persist long after wound healing has occurred. By all accounts, this type of pain is common following surgery for breast cancer.

One article distinguishes four pain syndromes: phantom breast pain, intercostobrachial neuralgia, neuroma pain, and other nerve injury pain.<sup>123</sup> Phantom breast pain is the painful sensation that a removed breast is still present (non-painful breast phantoms occur as well). One prospective study interviewed patients 3 weeks and 1 year after mastectomy with a prevalence of 13.3% for painful breast phantoms (PBP) at 3 weeks, and 12.7% at one year.<sup>124</sup> Other studies have found higher rates, up to 44%.<sup>123,125</sup> PBP is often described as knife-like, or shooting.

Intercostobrachial neuralgia, usually known as postmastectomy pain syndrome (PMP) consists of pain in the axilla, medial upper arm, and anterior chest wall, and is often caused by nerve damage during axillary node dissection.<sup>126,127</sup> Lumpectomy as well as mastectomy can result in damage to the intercostobrachial nerve. PMP is usually described as a continuous aching or burning, with intermittent shooting or shock-like sensations. Allodynia and hyperesthesia are common. It is often worsened by movement. Estimates of the prevalence of this syndrome vary widely. In one study, 20% of patients undergoing treatment of breast cancer at outpatient oncology centers had symptoms whose history and characteristics were consistent with postmastectomy syndrome.<sup>128</sup> Of those reporting pain, half reported that the pain interfered with daily chores,

and half reported sleep disturbances. A retrospective questionnaire found that 43% of responders reported an intercostobrachial-type (postmastectomy) pain syndrome.<sup>129</sup> Pain was severe enough to affect sleep in a third of these women. Younger women were more likely than older women to experience pain following breast surgery in this study.

Neuroma pain can occur in the scars from either mastectomy or lumpectomy, but may be more common in patients undergoing mastectomy and radiation than those who have had a modified radical mastectomy.<sup>130</sup> Estimates of the prevalence of neuroma pain range from 23 to 49%.<sup>123</sup>

Other nerve-injury pain can occur during surgery even when the intercostobrachial nerve has been spared; estimates of these types of injuries are not available. Breast reconstruction, especially procedures involving implants, seems to increase the risk of chronic pain following mastectomy for breast cancer.<sup>131</sup>

### Prevention

As with the post-thoracotomy syndrome and other postoperative pain syndromes, preemptive analgesia to prevent or diminish perioperative pain has been proposed as a means of decreasing the incidence of chronic pain following surgery for breast cancer. One study evaluated the use of a single 1,200 mg dose of gabapentin given preoperatively. Acute movement-related pain, and morphine consumption were reduced in the study group, but chronic postmastectomy pain was not evaluated.<sup>132</sup> One well-designed study found that venlafaxine given for two weeks perioperatively significantly reduced the incidence of PMP at 6 months. Interestingly, this effect occurred despite the fact that acute pain was not reduced in the study group.<sup>133</sup>

### Treatment of Established Postmastectomy Pain

Amitriptyline is effective in the treatment of PMP; however, as mentioned above, many women will not tolerate this medication because of its adverse effects.<sup>13</sup> If a trial of a TCA is desired, nortriptyline should probably be tried first because it is less sedating.<sup>14</sup> Venlafaxine has also been shown to be somewhat effective in the treatment of PMP.<sup>134</sup> As mentioned above, topical agents, such as lidocaine 5% patch<sup>74</sup> and capsaicin,<sup>81,82</sup> can be effective, usually with minimal side effects, especially in patients with allodynia. The use of other medications, including gabapentin and opioids, will need to be individualized, depending on severity of pain and the patient's tolerance of various side effects.

## Phantom Limb Pain

### Cause and Incidence

Phantom limb pain (PLP) is the sensation of pain in a limb that has been amputated. As compared

to stump pain, which is experienced at the site of the stump, the patient with phantom limb pain actually feels that the toe, or foot or other portion of the amputated limb is hurting. (This should also be distinguished from non-painful phantom sensations.) Incidence of this puzzling condition is from 50 to 80% in various studies.<sup>135-139</sup> The pain is usually intermittent and described in terms common in neuropathic pain, such as shooting, stabbing, and burning. It is usually perceived as being localized in distal parts of the amputated limb. Almost all patients with this syndrome develop pain within days of surgery.<sup>140</sup> It tends to decrease or disappear over time, and patients often experience a process known as "telescoping" where the phantom limb initially experienced as the full size of the missing part becomes smaller, with the most distal part (the foot or hand) shrinking back towards the stump. A minority, however, will have long-lasting, severe pain.<sup>141</sup>

The pathophysiology of phantom limb pain is complex and includes both peripheral and central factors. Because manipulation of the stump often causes pain in the phantom limb, some have theorized that neuromas formed at the site of severed nerve endings generate abnormal impulses in the CNS, leading to phantom pain. This theory is bolstered by the observation that phantom limb pain more often occurs in patients with observable stump pathology,<sup>142</sup> and may be improved by local injection of lidocaine into the stump.<sup>143</sup> Unfortunately, however, stump revision, including removal of neuromas, has had limited success in improving phantom limb pain, which suggests other mechanisms of action as well, including sensitization of dorsal horn neurons in the spine, mediated through NMDA receptors,<sup>144</sup> and cortical reorganization.<sup>145</sup>

Few consistent risk factors for the development of phantom limb pain have been found. Cause of amputation does not seem to correlate with development of painful phantoms; however, several studies have shown that pain in the limb prior to amputation is a risk factor for phantom limb pain after amputation.<sup>144,146</sup>

### Prevention

Preemptive epidural analgesia may reduce phantom limb pain,<sup>147,148</sup> underlining the need for patients undergoing amputation to have their pre- and perioperative pain control maximized. Ongoing tissue damage (such as that caused by residual or recurrent tumor) near the stump also seems to predispose to, and increase the severity of, PLP. Patients with increasing PLP syndromes should be evaluated for tumor recurrence.<sup>149</sup>

### Treatment

Treatment of established phantom limb pain may be difficult; however, several studies have been

published with positive results. Morphine and other narcotics have been used for this indication. One small but well-designed study comparing extended-release morphine to placebo for PLP showed that morphine reduced the intensity of PLP, and that this reduction was associated with a decrease in cortical reorganization, at least in some of the patients tested.<sup>150</sup> Ketamine was effective in one study, presumably through its effect on the NMDA receptor.<sup>144</sup> Calcitonin, given by infusion, was effective in one double-blind trial in reducing both the intensity and frequency of PLP, an effect which lasted for up to months after the infusion. Mechanism for this improvement is unclear, although it may be related to effects on serotonin receptors.<sup>151</sup> Nonpharmacologic methods, including TENS<sup>152</sup> and sensory discrimination training,<sup>153</sup> have shown promise in treating this condition as well.

## Post Radical Neck Dissection

### Cause and Incidence

Neuropathic pain following neck dissection for head and neck cancer is a well-known syndrome, occurring in perhaps 23 to 28% of patients.<sup>154-156</sup> One prospective study found that 25% of cancer-free patients had pain at 12 and 24 months postoperatively, although only 3 to 4% had severe pain.<sup>156</sup> Others have found lower levels of postoperative pain.<sup>157</sup> This pain is usually described as continuous, burning with hyperesthesia, allodynia, and intermittent paroxysms of “shock-like” pain. A myofascial component to this pain is often present as well. The neuropathic pain is apparently caused by damage to the superficial cervical plexus (C2-4),<sup>158</sup> and may be improved, at least temporarily, with nerve blocks to that area. Incidence of pain is not necessarily correlated with aggressiveness of the surgery or use of radiation.<sup>156,158</sup>

### Treatment

Specific treatment protocols for this syndrome have not been reported in the literature. One study reported effective relief with nonspecific combinations of narcotic and adjuvant medications (including gabapentin, TCAs and mexiletine hydrochloride) as is generally recommended for neuropathic pain, supplemented in some cases by nerve blocks.<sup>158</sup> Botulinum toxin injection into trigger points may improve pain in some patients as well.<sup>159</sup>

## Postradiation Pain Syndromes

Several well-described pain syndromes occur as a result of radiation. As with the postsurgical pain syndromes mentioned above, one of the main challenges is to differentiate pain caused by the treatment (radiation or surgery) from pain caused

by residual or recurrent tumor. Brachial plexopathy is the best described of these syndromes. It is more likely to occur with higher doses of radiation (greater than 6,000 cGy), and may appear months to years following completing of radiation. Clinical features of the pain syndrome, such as distribution and intensity, cannot reliably distinguish between malignant and postradiation plexopathy,<sup>160</sup> although plexopathies caused by recurrent cancer are more likely to be painful. Magnetic resonance imaging is probably the best modality for distinguishing brachial plexopathy due to tumor infiltration from radiation effects, especially in the classic delayed-onset injury,<sup>161</sup> with the finding of a discrete mass adjacent to the brachial plexus highly predictive of tumor infiltration. Less common causes of brachial plexopathy include chemotherapy, nerve entrapment from lymphedema, and occlusion of the subclavian artery.<sup>161</sup>

Radiation damage may cause other painful neurologic syndromes, including lumbosacral plexopathy<sup>162</sup> and radiation myelopathy.<sup>163</sup> Once again, patients with these syndromes need careful evaluation for recurrent tumor.

### Treatment

While specific treatment protocols have not been described, it is our experience that severe postradiation pain requires a narcotic, often in combination with adjuvant medications such as gabapentin. Symptomatic treatment will need to be individualized using the agents discussed above.

## Chemotherapy-Induced Peripheral Neuropathy

Many chemotherapeutic agents are neurotoxic. In particular, the taxanes, the vinca alkaloids and cisplatin are known to cause peripheral neuropathy, which may be very painful. In general, the neuropathy caused by these agents is dose-related (either to cumulative dose or dose intensity). Although peripheral neuropathy can occur in any patient, those with preexisting neuropathy due to diabetes mellitus or other causes may be at higher risk for the development of severe peripheral neuropathic complications of chemotherapy. Below we will briefly discuss the data regarding risk factors for, and prevention of, chemotherapy-related peripheral neuropathy. Research into neuroprotective agents will be discussed, although the use of these agents is, for the most part, still investigational.

### Cisplatin and Other Platinum Compounds

Peripheral neuropathy is common with cisplatin, starting with exposure to doses as low as 200 mg/m<sup>2</sup>, and is almost universal at doses

>400 mg/m<sup>2</sup>. Deterioration may start within a month after initiation of treatment and continue for up to 6 months after completion of treatment (a phenomenon known as “coasting”).<sup>164-166</sup> This is primarily a sensory neuropathy, with both negative (numbness, loss of vibration sensation, loss of tendon reflexes) and positive symptoms (paresthesias of varying intensities). The exact mechanism of this neuropathy is not completely clear; however, the drug appears to accumulate in the dorsal root ganglia. Oxaliplatin can cause both acute and chronic neurotoxic reactions. The acute reactions occur 30 to 60 minutes after infusion and resolve within days of treatment. They consist of paresthesias, allodynia, jaw and leg cramps, and, occasionally, visual changes,<sup>167</sup> and are related to infusion time and dose, and reappear with each infusion. Chronically, oxaliplatin causes a peripheral neuropathy similar to that caused by cisplatin. Carboplatin appears to be less neurotoxic than cisplatin; however, it can cause peripheral neuropathy as well.<sup>168</sup>

### Prevention of Platinum-Related Neuropathy

Because neurotoxicity is related to dose intensity and cumulative dose, reduction of dose and longer intervals between infusions may reduce the severity of neuropathic complications of cisplatin. Several neuroprotective agents have been studied for use with cisplatin, including a synthetic ACTH analog, which has had mixed results.<sup>169,170</sup> Amifostine, a thiol prodrug, showed benefit in preventing cisplatin neuropathy in one study<sup>171</sup>; however, subsequent studies have not been positive.<sup>172,173</sup> Glutathione showed some benefit in one study of patients with advanced gastric cancer.<sup>174</sup> Finally, nerve growth factors show some promise in both prevention and treatment of cisplatin peripheral neuropathy.<sup>175</sup>

Cumulative neurotoxicity from oxaliplatin is usually reversible after discontinuation of therapy, and may be managed by temporary cessation of treatment. One pilot study showed reduction of chronic neuropathy with administration of carbamazepine.<sup>176</sup> Some success has been seen with amifostine as well.<sup>177</sup>

### Taxanes

Paclitaxel causes peripheral neuropathy by promoting the rigid microtubules that act to inhibit axonal transport. Patients may develop neuropathy after even a single dose of paclitaxel, especially if used in combination with cisplatin, but the neuropathy is most common in doses >250 mg/m<sup>2</sup> and usually begins 48 hours after infusion.<sup>178,179</sup> Symptoms include paresthesias, numbness and pain in feet and hands, ataxia, and muscle weakness. Neuropathy may be the dose-limiting side effect, interfering with the ability to perform activities of daily living.<sup>180</sup> Docetaxel can

cause peripheral neuropathy, as well, in a dose-dependent way.<sup>181,182</sup> Both paclitaxel and docetaxel neuropathies may reverse after discontinuation of treatment, although permanent neuropathy can occur.<sup>183</sup>

#### Prevention of Taxane-Induced Neuropathy

Because neuropathy is dose-dependent, changes in dosing schedule may reduce or prevent this complication, especially in patients with diabetes mellitus.<sup>184,185</sup> Various agents, including glutamine<sup>186</sup> and an ACTH analog<sup>187</sup> have shown some promise as neuroprotective agents. Corticosteroids are probably not effective in preventing taxane-related neuropathy.<sup>188</sup> Amifostine has had mixed results but is probably not useful.<sup>189,190</sup> Nerve growth factors are under investigation.<sup>191</sup>

#### Vinca Alkaloids

Peripheral sensory neuropathies are very common in patients treated with vinca alkaloids, and are felt to be due to alterations in cellular microtubule structure causing edema of fast- and slow-conducting axons.<sup>192</sup> Toxicity is dose-dependent, and risk is increased with hepatic insufficiency.<sup>193</sup> Paresthesias and pain of the hands and feet are the initial symptoms of neurotoxicity; some patients will go on to develop muscle cramps and weakness. Autonomic insufficiency, including constipation (to the point of megacolon), bladder insufficiency, orthostatic hypotension, and impotence, may occur.<sup>194</sup> Most of the neuropathic side effects of these agents are reversible within a few months after discontinuing treatment.<sup>195</sup>

#### Prevention of Vinca Alkaloid-Related Neuropathy

Manipulation of dosing schedule by giving smaller doses per interval or longer intervals between doses may reduce the neuropathic symptoms of vincristine and related agents. Treatment is usually interrupted if patients experience more severe symptoms, such as muscle weakness.<sup>196</sup> Glutamic acid may reduce vincristine peripheral neuropathy.<sup>197</sup>

#### Treatment of Established Neuropathies

Treatment of established peripheral neuropathies has been extensively covered above in the section on medications for neuropathic pain. As noted in that section, however, much of the research on treatment of peripheral neuropathy has been done on patients with diabetic neuropathy. For patients with mild to moderate peripheral neuropathy, TCAs have generally been used as first-line agents; however, many would now use gabapentin first because of its more favorable side-effect profile. Carbamazepine may be

effective, especially for oxaliplatin-related neuropathies. Tramadol or opioids may be needed alone or in combination with adjuvant medications for more severe pain, and many would consider methadone when an opioid is needed because of its theoretical benefit for neuropathic pain. Specific treatments for chemotherapy-induced peripheral neuropathy that are still investigational include decompression of peripheral nerves<sup>198</sup> and ethosuximide.<sup>199</sup>

#### Postherpetic Neuralgia

##### Cause and Incidence

Although postherpetic neuralgia (PHN) is not a direct complication of cancer, it has been included here because herpes zoster infection, including disseminated disease, is a not an uncommon result of the immunosuppression that accompanies cancer and/or its treatment. Herpes zoster infection causes neuropathic pain during the acute infection (as a prodrome and for  $\approx$  30 days after the onset of the rash), subacutely (for 1 to 4 months after onset of the rash) and as a chronic painful condition known as postherpetic neuralgia.<sup>200</sup> Pathologic evaluation of patients with PHN reveals scarring of peripheral nerves, ganglion, and sensory roots, with damage (including inflammation and atrophy) at the level of the dorsal horn of the spinal cord, as well.<sup>201,202</sup>

Risk factors for the development of persistent pain include age  $\geq$  50, prodromal symptoms, rash severity, and moderate to severe pain during the acute phase of illness.<sup>203</sup> This means that patients with cancer, who are often elderly and are more likely have disseminated (and more acutely painful) disease, are at higher risk of chronic pain following acute infection.

##### Prevention of PHN

Prevention of PHN has been extensively studied. Most studies agree that treatment with antiviral agents (acyclovir, famciclovir, and valacyclovir), especially when initiated early, reduces the duration and likelihood of postherpetic neuralgia.<sup>204–208</sup> Because acute pain during zoster infection predicts the development of chronic postherpetic neuralgia, some have tried preemptive analgesia to prevent PHN. One study suggested that acute treatment with low-dose amitriptyline reduces the incidence of postherpetic neuralgia.<sup>209</sup> Anesthetic techniques, including sympathetic blocks<sup>210</sup> and epidural blocks,<sup>211</sup> have also been tried; while these techniques reduce acute pain, problems with study design make it difficult to say definitively that they reduce PHN.<sup>212</sup> Corticosteroids have also been advocated to prevent PHN, but results of clinical trials have not shown this to be effective.<sup>213,214</sup>

##### Treatment of Established PHN

TCAs have traditionally been the first-line agents for PHN.<sup>6,9,215</sup> Unfortunately, the side effects of these medications make them poorly tolerated, especially in elderly patients (although, as stated above, nortriptyline is better than amitriptyline in this respect<sup>14</sup>). For this reason, gabapentin (as discussed above) would be a first-line agent, used prior to TCAs, by most clinicians.<sup>28,29</sup> Lidocaine 5% patch is also a first-line agent once the open lesions are gone. It is easy to apply, works quickly and without a long titration schedule, and works especially well for the treatment of allodynia.<sup>71,72,73</sup>

For patients whose pain is not controlled with non-narcotic medications alone, opioids can be an effective treatment. Both morphine and oxycodone have been proven to be effective for this indication.<sup>88,216,217</sup> Tramadol is another reasonable choice for PHN.<sup>104</sup>

Combinations of several of the above medications may be necessary to achieve an acceptable level of pain control in many patients.<sup>218</sup> In particular, the lidocaine 5% patch is easy to combine with oral agents because of its lack of systemic side effects and its special efficacy for allodynia. Patients who do not respond to these agents may benefit from referral to a pain specialist for more aggressive therapy.

#### Conclusion

As patients with cancer survive longer, with a greater disease burden, helping them maintain an adequate quality of life becomes ever more crucial. In this setting, treatment of cancer-related neuropathic pain is an essential part of the overall palliative care plan. Careful assessment and individualized treatment are the keys to successful management of neuropathic pain in cancer. Patience and persistence are required, as trials of multiple different agents may be needed before a satisfactory regimen is determined. Because much of the work on neuropathic pain syndromes has been done on nonmalignant conditions, more research on cancer-related neuropathic pain is needed.

# Psychiatric Issues in Oncology

Gabrielle Marzani-Nissen, MD

Lora D. Baum, PhD

As the array of therapeutic options for oncologic patients increases, more individuals now live with, or have undergone treatment for, cancer. As such, more patients and clinicians are experiencing cancer as a chronic process. In 2003, it was estimated that 9.6 million people were living after a cancer diagnosis.<sup>1</sup> For these and others, issues related to quality of life and sustained health have taken on prominence. The impact of stress and mood has been shown to have direct effects on disease outcome. This is elucidated by the now 20-year-old field of psychoneuroimmunology.<sup>2-6</sup>

The most common psychiatric diagnoses seen by the internist are delirium, adjustment disorders, and depression. A classic study by Derogatis and colleagues found a 44% prevalence of psychiatric disorders in cancer patients.<sup>7</sup> Although the most quoted study, it is based on criteria from an older Diagnostic and Statistical Manual of Psychiatry, the DSM-III. It is now thought that clinically significant levels of depression and/or anxiety develop in 15 to 40% of cancer patients, and depend on the site of cancer and the stage of disease.<sup>8,9</sup> The incidence of delirium also depends on the stage of illness for cancer patients and ranges from 15 to 85%.

Throughout this chapter, emphasis is placed upon a combined approach using both pharmacologic management of mood or anxiety disorders with adjunctive psychotherapy. Although some cancer patients are initially too distressed to participate fully in psychotherapy as they contend with a life-threatening illness, once a medication or treatment begins to take effect, this experience changes. Patients often want to examine the way they look at the world, and many readily grasp the connection between their thoughts, emotions, and behaviors, and how changing one can impact another.

The goal of this chapter is to provide clinicians with practical information and strategies for the cancer patients they care for. It is also designed to assist practitioners with populations who may have special needs, such as those with schizophrenia and bipolar illness. It will cover delirium, frontal lobe syndromes, anxiety disorders, mania and bipolar illnesses, personality disorders,

schizophrenia, and, finally, depression and the assessment of suicide risk.

## Delirium and Cognitive Impairment Disorders

### Delirium

#### Clinical Manifestations

Delirium, characterized by a fluctuating disturbance in consciousness, is reported to affect 8 to 40% of inpatients at any given time.<sup>10</sup> Symptoms, which can be subtle, often occur abruptly, with an average onset of 3.3 days in the oncologic population (see DSM-IV criteria for delirium).<sup>11</sup> The incidence of delirium in the cancer population is cited at 13 to 25%, although up to 85% of terminally ill cancer patients are delirious.<sup>12</sup> Vulnerable populations include the elderly, brain injured, demented or cognitively impaired, those recovering from procedures or surgeries, and those who are very ill. The 3-month mortality is 23 to 33%.<sup>13,14</sup> In cancer populations, associated risk factors include advanced age, cognitive impairment, low albumin level, bone metastasis, hematologic malignancy, use of opioids, and alcoholism.<sup>11,15</sup> Family or nursing staff are often the first to notice delirium manifesting itself as restlessness, anxiety, change in attention, and easy distractibility. It can unmask old cerebrovascular events and cause memory impairment, disorganized speech, disorientation, misperceptions, illusions, change in sleep, aphasia, tremor, asterixis, myoclonus, and reflex and tone changes.<sup>13</sup>

Psychiatric symptoms and mimickers include mania, depression, tearfulness, personality changes, irritability, delusions, hallucinations, and psychosis. Subtypes include the hyperalert (agitated type), the hypoalert (lethargic type), and a mixed or alternating type.<sup>10,12</sup> The latter is often mistaken for depression—part of the reason that the most common consult for psychiatrist is “Evaluate for depression” while the most common diagnosis given is “Delirium.”

#### Pathophysiologic Manifestations

The earliest sign of delirium is a disruption of the sleep-wake cycle, which is controlled by the

suprachiasmatic nuclei of the anterior hypothalamus. As the sleep-wake cycle is normally synchronized with external environmental cues, a loss of light and unfamiliar hospital environments will promote delirium in vulnerable populations. The term “sundowning” is a misnomer; it is not related to light, but rather, the time of day (late afternoon). The neurotransmitter glutamate in the ascending reticular activating system (ARAS) in the brainstem, is involved in levels of consciousness and in maintaining wakefulness.<sup>16,17</sup> Dysregulation of other transmitters, such as acetylcholine, norepinephrine, and histamine have been implicated, with acetylcholine likely a major contributor.<sup>17,18</sup>

#### Etiology

The causes of delirium in the cancer patient are often different than in the general population. This is due to the nature of the disease and the modality of treatments. For example, intentional alkalinization of urine is produced to minimize the risk of tumor lysis syndromes. Table 1 reviews some of these features.<sup>10,12,18-20</sup> Even when mild, combinations of states such as anemia, and slight hypercalcemia may produce delirium in a vulnerable individual.

#### Diagnosis

The electroencephalograms (EEG) is often very sensitive and shows diffuse background slowing, although certain events such as delirium tremens and hyperthermia have a normal or increased amount of activity.<sup>18,21</sup> An EEG can rule out nonconvulsive status epilepticus, a mimicker of delirium. Although a Folstein Mini-Mental State score is often low, a normal result can occur in individuals with high premorbid functioning. Delirium can take up to 3 months to clear<sup>22</sup> in certain vulnerable populations; thus, internists will often care for those with resolving delirium. The evaluation for delirium involves the identification of an underlying medical cause and the removal of offending agents.

#### Pharmacologic Treatments

There are no medications approved by the United States Food and Drug Administration (FDA)

Table 1 Special Causes of Delirium in the Cancer Patient

**Medical Illnesses**

CNS: primary CNS cancer, secondary metastasis, stroke, post-operative state, whole brain radiation, non-convulsive status epilepticus  
 Hepatic: hepatic failure or dysfunction; hyperammonemia,  
 Hematologic: anemia  
 Metabolic: prophylactic alkalization in patients vulnerable for tumor lysis syndrome or other hypercarbia; metabolic disarray  
 Renal: renal disease or failure  
 GI: constipation, ileus  
 Endocrine: hypercalcemia from bone metastasis or paraneoplastic syndromes; hyper- and hypoglycemia, adrenal pathology or crisis, hypomagnesemia, thyrotoxicosis; SIADH, hyper- and hyponatremia  
 Deficiencies: B<sub>1</sub>, B<sub>12</sub> and niacin deficiency  
 Pulmonary: hypoxia from primary lung disease, infection, or pulmonary embolus  
 Infections: sepsis; infections in immunosuppressed or elderly individuals, meningitis, encephalitis, or opportunistic infections  
 Vascular: thromboembolic events such as deep venous thrombosis, disseminated intravascular coagulation  
 Withdrawal: alcohol, benzodiazepines, barbiturates, narcotics

**Medications that can cause Delirium in the Cancer Patient**

Antibiotics (particularly quinolones, penicillins, cephalosporins)  
 Antifungals  
 Anesthesia  
 Anticholinergic/antihistaminergic medications (including benzotropine mesylate, diphenhydramine, Phenergan, and tricyclic antidepressants)  
 Antihypertensives (especially  $\beta$ -blockers and clonidine),  
 Chemotherapeutic agents: L-asparaginase, bleomycin, cisplatin, cytosine arabinoside (ara-C), fludarabine, 5-fluorouracil, interferon, interleukin, ifosfamide, methotrexate (with high dose or intrathecal administration), prednisone, procarbazine, vinblastine, vinca alkaloids (vincristine)  
 Dopaminergic agents  
 Sedatives, such as benzodiazepines and other hypnotics such as zolpidem  
 Corticosteroids and other immunosuppressants such as azathioprine  
 Muscle relaxants  
 Opioid medications  
 Stimulants  
 Salicylates  
 Toxic levels of valproate, lithium, carbamazepine, digitalis

for the treatment of delirium except for alcohol withdrawal. However, the literature provides recommendations for agitated delirium. These consist of low-dose antipsychotics. Antipsychotics are divided into typical agents and atypical agents (see “Schizophrenia”). There are new warnings by the manufacturers on all atypical agents. Therefore, risks, benefits, and alternatives need to be discussed with the patients primary delirium maker prior to giving these medicatives, for the demented elderly.<sup>23,24</sup> These are due to four randomized controlled trials that found an association with increased cerebrovascular events and an increase in all-cause mortality with these agents. Low-dose quetiapine beginning at 25 mg/d and increasing by 25 mg/d up to 25 mg tid has been asked. Quetiapine is very sedating, so it is useful at night. Typical agents such as haloperidol at 0.5 mg to 1 mg bid can also be started and titrated slowly.<sup>12</sup> Haloperidol is not particularly sedating. In the elderly, some typical agents such as chlorpromazine are avoided because of their anticholinergic activity. The partial dopamine agonist aripiprazole, and the atypical agent ziprasidone have little data to

support their use in delirium. Akathisia is a common side effect of all antipsychotics, although it is seen more frequently in older agents. Higher doses have been recommended in some textbooks, but that brings the possibility of extrapyramidal side effects, such as dystonia and parkinsonism. Prolonged Q-Tc intervals, torsades de pointes, and neuroleptic malignant syndromes (discussed elsewhere), are also major concerns.<sup>25</sup> Vital signs should be monitored, an electrocardiogram (EKG) ordered, and Q-Tc intervals monitored for moderate to high doses.

If a person is severely agitated, some recommend a higher dose of haldol, such as 5 to 10 mg. Checking for acute hypoxia and other vital-sign abnormalities is important before doing so. As the delirium is resolving, plan to taper because there is a risk of tardive dyskinesia. Tardive dyskinesia is thought to be related to extrapyramidal side effects. Typical neuroleptics have a 25% incidence of tardive dyskinesia in the elderly at 1 year, which is often irreversible. The incidence of tardive dyskinesia is thought to be much lower in the newer agents, but quetiapine, which is thought

to have the least EPS of all the agents, is still reported to have 4 to 6% at low doses and 6 to 8% at high doses.<sup>26</sup>

Benzodiazepines should not be used for delirium unless it is due to alcohol or benzodiazepine withdrawal. It is critical to determine if this is delirium is due to alcohol or benzodiazepine withdrawal because all antipsychotic agents can lower the seizure threshold.

Recommendations for the treatment of agitated delirium are as follows.

- Check vital signs, rule out an acute medical process
- Rule out offending medications
- Rule out alcohol withdrawal
- Obtain a baseline EKG and Q-Tc (with a monitored bed if high doses of medication required)
- Begin with haloperidol 0.5-1 mg bid, or quetiapine 25mg at night, and titrate slowly
- Consider giving two-thirds of the total dose in the evening and one-third in morning, or morning and noon
- Consider the possibility that increased agitation is due to akathisia

**Psychological interventions**

Establishing a routine and providing visual cues with clocks, calendars, exposure to daytime sunlight, and the closing of curtains at night can help the confused patient reestablish a sleep-wake cycle.<sup>27</sup> Decreasing stimulation and activities at night will minimize and help prevent delirium. Providing familiar objects from home, such as a favorite pillow case or piece of music can assist with the reorienting process. Individuals with poor eyesight and hearing need their hearing aid and glasses to prevent misinterpretation of shadows and noises, which fosters delusions.<sup>18,28</sup> If a patient is in the hospital, a single room without undue distractions is helpful. Having consistent caregivers, who provide confident, consistent care will help reassure the frightened patient and help from feel safe. The family should be briefed on ways to help the patient, such as the calm repetition of information. Limiting the number of caregivers and restricting visitors to a few familiar people can be very helpful.

**Frontal Lobe Syndromes**

Frontal lobe syndromes occur with bilateral lesions. This may be due to a variety of insults including ischemia, mass effect such as tumor, and degenerative or demyelinating processes.<sup>29</sup> Individuals manifest these syndromes with a delay in processing information and retrieving information, poor judgment, and a decrease in curiosity. This social withdrawal or apathy can quickly shift to irritability, abrupt behavioral aggression, and disinhibition. An intact unilateral lobe does not generally produce this behavior. Lesions

of the frontal lobes have three presentations: changes in motor activities, personality changes, and cognitive dysfunction.<sup>30</sup> There are predictable responses to specific lesions. For example, damage to orbitofrontal regions is associated with behavioral disinhibition, lack of guilt, and poor insight. Dorsolateral regions affect higher functioning behaviors and produce mood disorders. Injury in the medial region causes lethargy, amotivation, and less spontaneous movements and use of language.<sup>29</sup>

For patients who have had primary brain tumors or secondary metastasis, personality changes may be evident. It is important to rule out offending medications, which can potentially worsen or cause other effects. For example, benzodiazepines may contribute to behavioral disinhibition. Although antipsychotic medications are often recommended and used for behavioral dyscontrol, parkinsonism often occurs. Seizures are not uncommon in this population. Levetiracetam (Keppra), which is often successfully used as an antiepileptic drug (AED), may worsen behavior in some individuals. In this case, other AEDs such as valproate (VPA), carbamazepine (CBZ), lamotrigine, and oxcarbazepine may be more appropriate. It is best to use an AED that has some mood-stabilizing properties, rather than phenytoin in this population. Additionally, delirium may also be very subtle in this population.

Families often need to be educated to understand that behaviors that appear to be laziness, depression, or antisocial behavior are due to frontal lobe injury. Depending on the needs and limitations of the individual, referrals to occupational therapy and physical therapy can be helpful.

## Anxiety Disorders

Anxiety *per se* is often a healthy and adaptive response to the diagnosis of cancer and its treatments.<sup>31</sup> In cancer patients, stressful periods occur at points of transition. These include a new cancer diagnosis, beginning any new treatment, waiting for test results, and preparing for medical procedures. In advanced cancer patients, the failure of treatment or a recurrence can produce anxiety.<sup>32</sup> Shock and disbelief commonly follow the diagnosis of cancer. Anxiety, intrusive thoughts, impaired attention, irritability, dysphoric mood, and vegetative symptoms such as loss of appetite and difficulty sleeping, will often occur but should slowly resolve over 7 to 10 days.<sup>32</sup> However, significant anxiety and depressive disorders can persist in between 25 to 48% of individuals.<sup>7,10,32-34</sup> About 4 to 5% of patients with cancer have preexisting anxiety disorders, which is the most prevalent psychiatric disorder in the general adult population. Adjustment disorders (see

DSM-IV chart on adjustment disorders), an exaggerated form of normal anxious response, are the most common type of disorder in cancer patients.<sup>35</sup> Anticipatory anxiety can occur before appointments or treatments and can become a conditioned response to the treatment setting.<sup>36</sup>

## Diagnosis

Standard screening instruments and criterion, including the DSM, may overdiagnose anxiety (see TWS is a charts?? for Generalized Anxiety disorder) and mood disorders in medically ill individuals because they include neurovegetative criteria that can artificially elevate the score of an individual who may have difficulty with sleep or appetite due to the cancer or the cancer treatment.<sup>32,34</sup> The Hospital Anxiety and Depression Scale (HADS) has been validated to assess patients with medical illnesses.<sup>32,37</sup>

Cancer is now considered a risk factor for the development of Acute Stress Disorder (ASD) and Post-traumatic Stress Disorder (PTSD) (see chart).<sup>38</sup> Acute stress disorder begins within 2 days of the event, such as the cancer diagnosis, and lasts up to 4 weeks (see TWS is a charts??).

If at that point symptoms continue, the criterion for post-traumatic stress disorder is met. Symptoms include the reexperiencing of the event, avoidance, a sense of numbing, detachment or lack of emotional responsiveness, reduced awareness of surroundings, derealization and impaired recall. PTSD includes nightmares and flashbacks (see DSM-IV criteria for PTSD). In this context, the individual may not hear critically important information. As a practical matter, a physician should write down important information, and ideally have a friend or family member in the room to assist with later recall. Many factors, including biologic vulnerability, prior trauma, and poor social supports play a role in the development of ASD and PTSD.<sup>38</sup> In the cancer population, other factors include youth, previous health, and dissatisfaction with the manner in which they were told about cancer.<sup>38</sup> The stage of illness affects the content of anxiety. For example, anticipated alopecia has been shown to be “the most disturbing factor” in 47 to 58% of women with cancer, while other body-image issues predominate in metastatic disease.<sup>39,40</sup> There is debate as to whether anxiety disorders predominate among different sites of cancer.<sup>32,41</sup>

The diagnosis or treatment of cancer can exacerbate generalized anxiety disorders, which are present in 1.5 to 3% of the population.<sup>42</sup> However, some cancers, such as pancreatic cancer, can produce anxiety, panic attacks and depression, and precede the diagnosis in up to 50% of patients.<sup>43</sup> Symptoms must cause “clinically significant” distress or impairment in an important area of functioning, last at least six months,

and not be due to a substance, medicine, or medical problem (see the chart from DSM-IV).

The Diagnostic and Statistical Manual of Psychiatry, Fourth Edition, text revision (DSM-IV-TR) requires that a primary anxiety disorder be excluded if the etiology is due to a substance, medication or medical illness that can cause the symptoms.<sup>44</sup> Therefore, any patient who has a sudden increase in distress should be evaluated for an acute medical or metabolic process. It is not unusual for a patient to who was on steroids, or given benzodiazepines for nausea or narcotics in the hospital to develop withdrawal that unwittingly occurred in the transition into or from the hospital. Clarifying which medications were given in the hospital, not just the discharge medications, can be very important. Patients may have been started on medications that produced anxiety as a side effect. These may include steroids or beta agonists. Acute anxiety in populations who have a statistically high association with alcohol, such as head and neck, esophageal, gastric, and pancreatic cancers should be thought to be possibly from alcohol withdrawal. Additionally, patients who are heavy smokers may have nicotine withdrawal.

In cancer patients, symptoms of anxiety should also prompt the clinician to consider brain metastases, pulmonary embolus, thyroid disease, rapid withdrawal from steroids, hypoglycemia, and adrenal disease as appropriate. Anxiety due to a medication should be considered. Akathisia, a subjective sense of motor restlessness that manifests as pacing, and inability to sit still, or skin crawling, is often associated with typical and atypical neuroleptics, Phenergan, Compazine, and selective serotonin reuptake inhibitors (SSRIs).<sup>18,45</sup>

## Medical Illnesses That Can Present as Anxiety

- Cardiac: ischemia, arrhythmias, systolic and diastolic failure and diastolic dysfunction, valvular disease
- Endocrine: carcinoid, adrenal crisis or disease, disorders of calcium, thyroid disease, pheochromocytoma
- Metabolic: potassium disorders, hypoglycemia, hyponatremia, uremia, hypercarbia from pain, and prophylactic alkalinization of urine
- Respiratory/Pulmonary: hypoxia, asthma/reactive airways, COPD, pneumothorax, pulmonary edema, pulmonary embolism
- Heme: porphyrias (anxiety and panic attacks), anemia
- Neurologic: delirium, brain tumor, infarcts (particularly left frontal lobe infarcts), traumatic brain injury, mass effects, epilepsy / seizures (particularly temporal lobe epilepsy), vertigo

- Gastrointestinal: acute or chronic bleeding (hypovolemia)
- Immunologic: anaphylaxis, transfusion reaction
- Substances: alcohol, barbiturate, or benzodiazepine withdrawal; amphetamines and sympathomimetic agents, caffeine and caffeine withdrawal, nicotine withdrawal, opioid withdrawal, akathisia from Phenergan, Compazine, typical or atypical antipsychotic agents, corticosteroids

## Pharmacologic Treatments

Medications FDA-approved and traditionally used for anxiety disorders include SSRIs, selective serotonin/noradrenergic reuptake inhibitors (SNRIs) such as venlafaxine hydrochloride, mirtazapine, tricyclic agents, monoamine oxidase inhibitors (MAO-I) and benzodiazepines. Tricyclic medications and MAO-Is are avoided as first-line agents due to their side effects and danger or lethality in overdose.

Generalized anxiety disorders have also been treated successfully with azapirone agents such as buspirone hydrochloride (Buspar).<sup>46–48</sup> Gabapentin and lamotrigine have some reported efficacy. SSRIs and SNRIs may induce nausea, but controlled release forms may avoid the stimulation of upper gastrointestinal serotonin receptors that mediate nausea. Although generally regarded as safe and first-line agents, SSRIs (and possibly SNRIs) may increase the risk of intraoperative bleeding.<sup>49</sup> For cancer patients, the clinician should be aware that these medications cause an SIADH-like hyponatremia, and lower the seizure threshold by about 0.1%.

The anxiety seen in cancer patients is associated with more autonomic hyperactivity than in other patients with anxiety disorders.<sup>32</sup> These patients may be more sensitive to the side effects of some medications such as the SSRIs, venlafaxine and buspirone. A clinical pearl in treating anxiety with SSRIs and venlafaxine is the recognition that there is often an initial burst of anxiety in the first days of use with this medications; this anxiety usually dissipates within a few days. Clinical effects take 2 to 4 weeks. Telling the patient to anticipate a small increase in anxiety is therapeutically reassuring and often allows them to better tolerate the initial days. Working patients may prefer to start the medication on a weekend to minimize stress. Slow titration at half the recommended starting dose, with a dose increase in a week can often minimize side effects. Although the dose required to treat anxiety is lower than that for depression, complete resolution of panic symptoms will often not occur until higher doses are used. All SSRIs and medications in the antidepressant family have now been given warnings about the increased risk of suicidal ideation. This is likely multifactorial, and will now likely require

a routine follow-up sooner than the usual 1-month follow-up as (recommendations are being formalized by consensus guidelines). So long as patients understand that they need to contact someone immediately if they feel suicidal, or proceed to the nearest emergency room, it is reasonable to prescribe these medications for anxiety, especially since depression and panic themselves carry a risk of suicidal ideation. Although many practitioners prescribe benzodiazepines for the initial days, this can promote dependence on these agents. If prescribing a benzodiazepine, a longer acting one, such as clonazepam (Klonopin) is preferred, as there is less of an initial “rush” and less tendency to become dependent on the instant relief of anxiety. Although not FDA-approved, psychiatrists will often use low doses of quetiapine 25 to 50 mg instead of benzodiazepines for sleep and anxiety.<sup>50</sup>

### Classes of Medications used for Anxiety Disorders

The following medications are for GAD, ASDs, and PTSDs. All SSRIs and SNRIs cause hyponatremia, and all can lower seizure threshold, as can Wellbutrin.

SSRIs are the most prevalent medications used for their safety profile and efficacy. The oldest agents have the most P-450 interactions, which is important for patients on complex medication regimens. They are fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), citalopram (Celexa), and escitalopram (Lexapro). The longer acting forms generally have less initial anxiety and gastrointestinal distress, but the medications with the long-acting (sustained release (SR), XR, XL forms (paroxetine, fluoxetine, venlafaxine) also have the most P-450 interactions. All of these medications cause sexual dysfunction and weight gain. Start at half of the recommended dose.

Bupropion (Wellbutrin) is generally avoided for panic disorder as it can worsen panic attacks. Although most notorious for lowering the seizure threshold, the long-acting forms have the same incidence as SSRIs and SNRIs. It has no sexual dysfunction associated with it. It may be activating, but also may have better effect on sleep architecture. The SR form may reduce fatigue in cancer patients<sup>51</sup>

Mirtazapine (Remeron) is good for cancer patients with nausea (it may stimulate appetite), and insomnia (lower doses are more sedating than higher doses), anorexia (causes weight gain), and it has a sol tab. It has P-450 interaction. Start at 15 mg and increase if the patient is too sedated.

Duloxetine: (Cymbalta) uses NE and serotonin simultaneously, and has efficacy for pain. It has more than 1,000 inactive metabolites,

and should not be used with renal or hepatic dysfunction. Start at 30 mg.

Venlafaxine, (Effexor XR form) at low doses acts like an SSRI, and at higher doses has NE effects (BP). It appears to have efficacy for pain. It has mild effects on blood pressure at higher doses (about 10 mm). Start at 37.5 mg, and titrate slowly by 37.5 mg increments.

Tricyclics are generally avoided because of anticholinergic and muscarinic side effects, and high lethality in overdose.

MAO-Is (eg, phenelzine) are generally avoided because of lethality in overdose and strict dietary requirements.

Buspirone (Buspar) is recommended for generalized anxiety disorders, and usually is not effective for patients who have a history of using benzodiazepines. Start at 5 mg at night and increase slowly in a bid or tid fashion. When taken with food, there is less of a side effect of dizziness.

Gabapentin (Neurontin, Micromedex, Inc.) is sedating, has no antidepressant properties, but may have efficacy for social phobia. Start at 100 mg at night and increase by 100 mg in a bid or tid fashion.

Atypical Antipsychotics such as quetiapine, olanzapine, risperidone are used at times for severe anxiety as an augmentation strategy, and are sedation. Quetiapine has the least extrapyramidal side effects, and can be started at 25 mg a night titrating rapidly by 25 mg doses.

Benzodiazepines are used with caution by many psychiatrists because of their risk of dependence. Longer acting medications, such as clonazepam are useful because there is less of an initial “rush” with the medication. Clonazepam additionally has few active metabolites, although it is long-acting so should be used with caution for patients with hepatic dysfunction. If used, Clonazepam should be initiated at 0.25 mg twice a day before beginning the SSRI or SNRI, and then removed within weeks.<sup>52</sup> Alprazolam is avoided by psychiatrists because of the “rush” associated with it and the risk of addiction with this short-acting agent.

There are open labeled studies with valproate, carbamazepine, and topiramate. Clonidine hydrochloride and propranolol have both been cited as helpful for anxiety, but both can cause depression in some individuals. Trazodone hydrochloride (Desyrel), a very weak antidepressant, is good for sleep architecture, and can be used for sleep augmentation. Early studies in Europe found that it compared well against diazepam; using 25 mg tid found the anxiolytic effect to be equivalent to diazepam (Valium) 5 mg tid for anxiety.<sup>52–54</sup> Trazodone has been associated with priapism. Other sedative hypnotics such as zolpidem tartrate (Ambien) can be helpful for short periods, as efficacy decreases with long-term use.

An elixir is available for fluoxetine, and a soluble tablet is available for mirtazapine.

For acute stress disorders and post-traumatic stress, SSRIs have been shown to be effective. Tricyclics and MAO-Is (phenelzine) have been shown to be efficacious, but for the reasons above, are generally avoided. Open label studies with valproate, carbamazepine, and topiramate have shown mixed or limited efficacy. There is one controlled trial with lamotrigine showing efficacy (note, however, the risk of rash). Additionally, there is preliminary evidence that olanzapine, quetiapine, and risperidone may be helpful. Propranolol may reduce the onset of post-traumatic symptoms, and clonidine hydrochloride may have effects, but both can cause depression. Benzodiazepines are anxiolytic, but, again, raise a concern for tolerance and addiction, as they act on the GABA receptor complex that is shared with alcohol.<sup>55</sup>

#### Drug Interactions

The cytochrome P-450 system is a hepatic enzyme system that has clinically significant interactions with psychotropic agents and chemotherapy. Medications that are metabolized by this system will often interact with one another. In a healthy general population on no other medications P-450 interactions are rarely an issue. However, in cancer populations, certain chemotherapeutic agents and other medications used for nausea and side effects will interact with this system. Medication catabolism can be increased or decreased. There are helpful resources that are free and available on the Internet (eg, <<http://medicine.iupui.edu/flockhart/table.htm>>) as well as books that can guide the practitioner. Additionally, pharmacists are a helpful resource. Many antidepressants and antipsychotic agents use the P-450 systems. A helpful rule of thumb for SSRIs is that the newer ones often have the least P-450 interaction. Even with interactions, these medications can be used. The key is to go slow. Some common substrates include antidepressants (eg, amitriptyline, imipramine, bupropion, all SSRIs, mirtazapine, venlafaxine), antipsychotics (typical and atypical agents including clozapine, haloperidol, olanzapine, perphenazine, risperidone, thioridazine) chemotherapeutic agents, (eg, cyclophosphamide, ifosfamide, paclitaxel, tamoxifen), anti-nausea agents (eg, ondansetron, metoclopramide) and pain medications, such as celecoxib and methadone.

The P-450 interaction can increase levels of these agents substantially and cause adverse events. For example, excess stimulation of central serotonin receptors are thought to cause serotonin syndrome. This causes autonomic dysfunction, similar to neuroleptic malignant syndrome, and includes tachycardia, fever, diaphoresis, hypertension, diarrhea and myoclonus. When extreme, it can lead to shock and death. Of note,

the chemotherapeutic agent procarbazine, a weak MAO-I, should be used cautiously with any medication that has tricyclic, serotonergic, or noradrenergic components because of the risk of hypertensive crisis and serotonin syndromes.<sup>56</sup> This would include many psychiatric medications.

#### Psychological Interventions

Many anxious cancer patients are reluctant to take more medication, especially if they are also taking chemotherapy. Cognitive and behavioral techniques are often quite effective and have the added benefit of the patient's active participation in their care, a factor that adds to feelings of self-efficacy (the confidence of a person in their ability to successfully complete a task) and increased control. This idea forms the basis for many of the cognitive-behavioral interventions that will be helpful to cancer patients. Recently, a meta-analysis of many studies found that psychological interventions for anxiety were effective even when offered preventively to cancer patients on the basis of their medical diagnosis, and not psychological distress.<sup>57</sup> Initial treatment involves education about the nature of anxiety, and then the teaching of relaxation techniques, guided imagery, self-hypnosis, or distraction. These techniques are useful for many of the treatment-related side effects of chemotherapy, such as nausea, vomiting, and fatigue, as well as for anxiety.<sup>58</sup> For instance, many patients can be taught to modify pain or nausea sensations through self-hypnosis, which can decrease their intake of medication, thus allowing them choices in how symptoms are managed.<sup>59</sup> Biofeedback may be used to help monitor training in these techniques, but is usually not necessary, since patients often experience subjective improvement rather quickly.

The experience of anxiety is often both cognitive and physical. Patients describe racing thoughts; obsessive, repetitive thoughts; and a future-oriented sensation of dread or impending doom. In addition, the physiologic sensations include a subjective feeling of tension (often in the stomach and chest) and muscle tension (usually in the neck and shoulders). Hand and jaw clenching can occur, even in sleep, which can leave muscles feeling fatigued. Cognitive-behavioral interventions for anxiety thus must be targeted to an individual's experience to achieve optimum symptom relief.

Interventions for anxiety can take many different forms. Most produce what Herbert Benson has termed a "relaxation response," which is characterized by a decreased sympathetic arousal.<sup>60</sup> Meditation, yoga, and exercise are examples of techniques that patients can pursue independently through community-based courses.<sup>61,62</sup> Many psychologists trained in behavioral

medicine techniques can teach patients diaphragmatic breathing, autogenics (a technique used to induce vasodilation or constriction through increasing or decreasing peripheral blood flow), progressive muscle relaxation, and self-hypnosis, all of which have been found helpful in reducing anxiety.<sup>63</sup>

Most patients with anxiety are aware of a mind-body connection, because they notice the somatic effects of anxiety. To take advantage of an anxious patient's propensity to imagine the worst, a statement such as, "I already know you have a good imagination because you're a great worrier" can be used. This comment provides a positive use for what can be perceived as a negative trait, and does so with compassion and humor. Here are two examples of easy-to-teach cognitive techniques, which can be taught to a patient in a few moments during an office visit.

*Thought Stopping* This technique serves as both a distraction and a focal point, which allows a cycle of obsessive thoughts to be broken and then redirected. The patient is asked to picture a big, red, stop sign and to focus on the octagonal shape, the red background with white letters. The stop sign's powerful influence in everyday culture is emphasized: everybody obeys stop signs. As the stop sign is envisioned, the thought process is interrupted, and the patient is directed to then focus on something pleasant and positive, such as a pleasant memory, or a place that recalls good feelings. Redirecting activity, such as moving to a different room, or taking a brief walk outside, can also serve to break the chain of obsessive thoughts.

*Worry Time* Worry can be framed as an inefficient use of free time, which does not change the outcome of a feared event, but does negatively impact quality of life. Therefore, the patient is directed to continue to worry (since they have undoubtedly failed at not worrying), but to do it at a prescribed time only. For instance, worrying for the first five minutes of each hour would be allowed, but worrying outside of this time is prohibited. Through this technique, patients will often realize that nothing bad happens if they miss their "worry time" and they might even enjoy life in the meantime.

One component of anxiety in cancer patients that is not addressed by some of the cognitive-behavioral interventions discussed here is the anxiety that is a part of having a life-threatening illness. For many, cancer is the first time that mortality has become a clear possibility. This existential anxiety is best addressed through the exploration of beliefs and fears about the dying process and what lies beyond. For instance, many patients fear a painful, lonely death. Allowing

a person to discuss what would constitute an optimal death experience can relieve some of the anxiety and fear associated with dying. Encouraging a patient to open a discussion with relatives about end-of-life planning can deepen relationships with significant others and lead to healing on many levels.

## Adjustment Disorders

Cancer patients who have clinically significant symptoms of anxiety or depression and do not meet criteria for other disorders often have adjustment disorders. In a study of patients referred to a psycho-oncology service, 40% had an adjustment disorder.<sup>64</sup> These individuals usually had good functioning before their diagnosis, and the stress of the cancer diagnosis or treatment engenders subjective feelings of distress, and difficulty coping or functioning at work or at home. Patients may or may not report these to their primary medical provider or oncologist, but because psychological distress is so common in cancer patients, it is important to inquire about overall coping when seeing them. In most cases, the level of psychological distress in adjustment disorders does not warrant psychotropic medication. Psychological interventions that are effective for adjustment disorders include supportive psychotherapy, group peer support, and group psycho-educational therapy.

Supportive psychotherapy targets specific symptoms, such as depression, anxiety or insomnia, and places the symptoms into a context that normalizes the reaction, given the extreme circumstances of a cancer diagnosis. Often, patients have never consulted a mental health professional and are now more open to it because having cancer is universally understood as a stressor. This can be an opportunity for a patient to gain support in a confidential, professional setting, and not to burden relatives with fears and concerns. Patients often look forward to leaving their troubles at the therapist or doctor's office so they can feel emotionally stronger around family. Small interventions, such as ways to improve sleep<sup>65</sup> and nutrition, can often improve physical and emotional functioning in tandem.

Peer group support is a good choice for those who prefer a community-based intervention, and fellow patients can provide a sense of authenticity missing from a purely professional encounter. The informal support that occurs as a result of exchanging tips for thriving through treatment help not only in the short term, but also in the relationships that often grow out of these groups. Social support has been found to be a key variable in successful adjustment to cancer,<sup>66</sup> and support groups provide this in many ways.

In 1989, David Spiegel and colleagues published a surprising analysis of data that showed

that weekly supportive group therapy with self-hypnosis for pain in women with metastatic breast cancer improved survival when compared to a randomized control group.<sup>67</sup> This article was based upon an intervention that was designed to test the effectiveness of their model to decrease pain and increase quality of life, which it also did. However, upon a retrospective analysis of the survival of the groups, Spiegel was surprised to notice that the women in the intervention group lived about twice as long as those in the control group. This finding swept through the cancer community, and soon patients were calling for support groups with the belief that, if they participated, they would live longer. Subsequently, other researchers, including those mentored by Spiegel<sup>68</sup> have provided a mixed outcome with regards to increased longevity. In an editorial,<sup>69</sup> Spiegel states that 5 of 10 published trials report that psychotherapy prolongs survival. He explains the trials that do not show this effect by the large changes in both medical care and the widespread demand for psychosocial support that have occurred since his original study was begun in the late 1970s. Regardless of whether longevity is increased, almost all trials demonstrate improvement in psychological functioning, with the more distressed patients benefiting the most.<sup>68</sup>

When recommending support groups for patients, it is important to distinguish between those that are completely peer-led and those that are professionally led. While peer-led groups can be helpful for those who are exhibiting mild symptoms, professionally led groups have the benefit of being able to provide specific skills training in coping techniques, relaxation therapy, and credible information. More distressed or more isolated patients can usually benefit from this increased level of monitoring and mentoring.

Lastly, exercise is an intervention that is often overlooked, yet can be very effective in preventing cancer related-fatigue, and improving mood.<sup>70</sup> In both breast cancer<sup>71</sup> and prostate cancer<sup>72</sup> patients, randomized trials of exercise in patients receiving radiotherapy found that patients who engaged in a moderate, home-based exercise program had no increase in fatigue from baseline, while patients who did not exercise had significant increases in fatigue. The exercise programs also improved overall physical functioning, which added to self-efficacy and self-esteem during a time when many patients feel discouraged. Pinto and Turnzo<sup>73</sup> found that, among breast cancer patients, those who exercised reported higher satisfaction with body image and better mood than sedentary patients. Overall, for patients with mild to moderate symptoms characteristic of adjustment disorders, significant improvements in quality of

life can be made by addressing symptoms such as mood, insomnia, and fatigue.

## Mood Disorders

### Major Depression

Rates of depression in cancer patients vary from 1 to 50%, depending on the type of malignancy and study.<sup>74-76</sup> Major depression likely affects about 25% of the cancer population.<sup>74,75,77,78</sup> In a study at Memorial Sloan-Kettering Cancer Center, 31% of patients seen by the consult psychiatry service had a major depressive disorder or an adjustment disorder with depressed mood.<sup>75</sup> Factors, including interferon, appear to be involved in certain types of depression. Thus, individuals treated with interferon therapy may be vulnerable.<sup>79-83</sup> The site of cancer has been associated with various levels of psychological distress.<sup>9</sup> The assessment of depression in the cancer patient is discussed in another chapter (see Chapter 9, "Cancer and Depression"). Before prescribing an antidepressant in any patient, a screen to rule out hidden bipolar illness, alcohol abuse, and suicidal ideation is warranted. This includes an assessment for hypomania, with questions such as: "Have you ever seemed to need less sleep than usual, felt rested or energized, with clarity of thought or racing thoughts?" All SSRIs and medications in the antidepressant family have now been given warnings about the increased risk of suicidal ideation. As discussed in the section on anxiety, this is likely multifactorial, and will now likely require a routine follow-up sooner than the usual 1-month follow-up as recommendations are being formalized by consensus guidelines. So long as patients understand that they need to contact someone immediately if they feel suicidal, or proceed to the nearest emergency room, it is reasonable to prescribe these medications, especially since depression carries its own risk of suicidal ideation and suicide. In using these medications, it should be noted that many interact through the P-450 pathway (see "Anxiety Disorders").

The pharmacologic treatment of depression depends on whether or not the patient is undergoing treatment with chemotherapy, radiation, or surgery. If none of those, the treatment of depression should be the same as for the general population. Traditional first-line agents for depression include SSRIs, venlafaxine, mirtazapine, and bupropion. Gender and age differences have been noted with these agents in the treatment of depression. This is thought to be related to the presence or absence of estrogen. In some studies, premenopausal women have better responses to SSRIs than men or postmenopausal women. There is some suggestion that venlafaxine may have more efficacy than SSRIs in men and postmenopausal women. For example, there was a 2.5 times greater trend in improvement

for women over 50 years old on venlafaxine compared with younger women on SSRIs.<sup>84,85</sup> A new agent, duloxetine (Cymbalta) appears to be very good for some pain syndromes. Optimizing side effects can be helpful in choosing an agent. For example, mirtazapine is helpful for nausea, weight gain, and sedation, and causes no sexual dysfunction. Bupropion is activating, weight-neutral, causes no sexual dysfunction, but has a risk of seizures in its warning label. The longest acting versions have the equivalent risk of seizure as SSRIs. Both of these agents interact with the P-450 system (see “Anxiety Disorders”). The newest SSRIs have the least P-450 interaction. SSRIs and venlafaxine appear to have efficacy for women for hot flashes, which can be useful for women who cannot be on estrogen replacement.<sup>86,87</sup> However, venlafaxine can also cause sweating. SSRIs and venlafaxine are associated with headache. Duloxetine tends not to cause headache. Second-line agents such as tricyclics and MAO-Is carry more side effects and can be lethal in overdose. For more details on the agents discussed above, the reader is referred to the section on anxiety and Table 2.

## Psychological Interventions

The treatment of depression using cognitive therapy has long been a mainstay in psychotherapy.<sup>88</sup> Beck described the “cognitive triad” as (1) a negative view of the self (as unworthy, inadequate, and bad); (2) a negative view of the environment (as unsatisfying, demanding, and difficult); and (3) a negative view of the future (as unchangeable, unfulfilling, and hopeless). The thoughts related to this triad are the key cognitions in depression. Cognitive therapy serves to correct

misconceptions and errors in judgment and generate an array of possibilities for the future through demonstrating that choices are available even in difficult situations. This approach was recently found to be effective in decreasing depression and increasing optimism in women with early-stage breast cancer treated with a 10-week, group cognitive-behavioral stress management intervention.<sup>89</sup>

When providing primary medical care to a depressed patient, practitioners can sometimes begin to feel hopeless. The faulty logic that characterizes some patients’ thoughts, as well as the subjectively difficult circumstances they have, can at times be hard to counter. However, maintaining professional distance while showing empathy, and continuous positive reframing of negative or irrational thoughts serves to model optimism.

Here are a few interventions that can be used to help remind patients that they do have some control over what can feel like a hopeless situation:

### Identifying Automatic Thoughts

Ask patients if they have thoughts that seem to repeat over and over, like a broken record. Many depressed patients will readily describe them when prompted. Some examples might be “I’m not going to survive this,” “I’m a terrible burden to my family,” or “Why should I bother with all this?” A short examination of the usually skewed perceptions, by refuting with logical information, can be helpful. Examples based on your knowledge of the patient’s situation can be helpful here, such as: “Just as you cared for your husband after his surgery, he now wants to help you through

this.” Patients can be surprised how unrealistic—yet pervasive—these thinking patterns can be when they identify and discard their negative automatic thoughts.

### Positive Reframing

Pessimism often only allows a glass to seem half empty, when in fact it is also half full. Language is an important framer of possibility. Illness can be seen to be an impediment or an opportunity for change with regard to interpersonal relationships, work, and recreation. If a patient continually verbalizes what they can’t do, ask, “What can you do now that you couldn’t before?” A pause in life, even a forced one, is still a break in routine, and allows for thinking and doing things differently.

### Identifying Dichotomous Thinking

Many depressed patients see only black-and-white outcomes. They are blind to the myriad possibilities that exist in the gray area in between. When you hear patients being very rigid in their dichotomous thinking, you can challenge them to generate more possibilities. (“Are the only two choices available to stay in bed or to jog your usual mile? What other activities could you pursue at this time?”)

The role of a primary medical doctor for the cancer patient with depression can seem daunting. However, what patients value as much as medical expertise is the human ability to understand. By providing a depressed patient with the correct ‘prescription’ to see clearly, they can take back control of a situation that can, at times, feel overwhelming.

## Suicide

In the general population, individuals with mood disorders have a 15% lifetime risk of suicide and account for 50 to 70% of successful suicides. There is a higher risk with anxiety or panic symptoms and alcohol abuse. Fifteen to 25% of suicides are due to alcohol dependence and other substance abuse. However, these individuals often have a comorbid depression and have experienced an “interpersonal loss.”<sup>90</sup> There is a correlation between low serotonin levels and suicidal behavior.<sup>91–93</sup>

In general, the risk factors for suicide are listed in Table 3.<sup>88,92</sup>

### Suicide in the Cancer Patient

Suicide should not be considered a “rational act” in the cancer patient.<sup>75</sup> It should be attributed to an underlying state, such as depression, delirium or pain.<sup>95</sup> Cancer patients have twice the risk of suicide than that of the general population.<sup>95,96</sup> The same risk factors, such as male gender, older age, marital status, and social isolation apply as

**Table 2** Selective Medications Used for the Treatment of Depression in Cancer Patients

SSRIs	starting dose in mgs	dose range in mgs	metabolized by	inhibitor	stimulator
Fluoxetine (Prozac)	10–20	20–80	2D6		
Paroxetine (Paxil)			2D6	++	-for both
Immediate Release	10	10–50			
Controlled Release	12.5	12.5–62.5			
Sertraline (Zoloft)	25–50	50–200	No for both	-for both	-for both
Citalopram (Celexa)	10	20–60	No for both	-for both	-for both
Escitalopram (Lexapro)	5	10–20	No for both	+2D	-for both
Bupropion (Wellbutrin)			No for both	++	-for both
Immediate Release	100	100–150	TI0		
Sustained Release	150	150–300			
Extended Release	150	300–450			
Venlafaxine XR (Effexor XR)	37.5	75–225	2D6	-for both	-for both
Mirtazapine (Remeron)	15	15–45	No for both	-for both	-for both
Duloxetine (Cymbalta)	30	30–60	2D6	++	-for both

+ = least interaction; ++ = moderate interaction; +++ = most interaction

**Table 3 Risk Factors for Suicide in the General Population**

Male gender
Social isolation
Social status (being divorced, widowed or single)
Unemployment, change in social or economic status, legal problems, moving
Psychiatric illness (particularly, major depression or bipolar illness), co morbid psychiatric illness, psychological turmoil, previous attempts, alcohol use, anxiety
Physical illness
Family history
Presence of firearms
Recent loss
Hopelessness
Psychosis (particularly with command hallucinations)
Older age
Presence of a specific plan, means available to carry out the plan, and rehearsal of the plan.

in the general population. For example, men with cancer who are in their 60s and 70s have a 1.55 to 2.3 times greater risk for suicide than that of the general population.<sup>97</sup> As with the general population, poor social support, personal or family history of mood disorders, or prior attempts at suicide increase the risk, as do drug and alcohol abuse. For patients, risk is highest in the first few months after diagnosis.<sup>97</sup>

Psychological distress and “existential suffering” are also related to suicide.<sup>98</sup> Greater physical impairment or dependency, transition states (treatment decisions, undergoing treatment), emotional stress related to the diagnosis of cancer, plus social and cultural attitudes have been found to increase the risk of suicide. Additionally, pain, change in physical appearance, terminal illness or anxiety due to a poor prognosis, and issues related to death and dying are risk factors for suicide.<sup>74,75,90,99</sup> Hopelessness is more significant than the diagnosis of depression in determining risk of suicide.<sup>75</sup>

Confounding variables such as metabolic abnormalities (eg, hypercalcemia) and medications, including steroids and  $\beta$ -blockers, should be identified to rule out medication-induced depression. Certain medications, such as levetiracetam (Keppra) have been associated with suicidal ideation in small numbers of individuals.<sup>100</sup> A diagnosis of cancer, particularly brain cancer, has been associated with a higher risk of suicide.<sup>101</sup> Others report the highest risk in head and neck,<sup>102</sup> gastrointestinal (GI),<sup>96</sup> genitourinary, lung, and other respiratory cancers.<sup>97</sup> Additionally, breast cancer has been associated with a higher risk of suicide compared to other types of cancer.

As noted above, comorbid substance abuse with alcohol in general increases the risk for

suicide. This may be one reason why suicide risk in head, neck, and GI cancers may be higher than with other cancers.

Assessment of depression and suicidality should include asking the patient if there have been periods of hypomania (bipolar II symptoms), as these individuals may be more likely to enter a “mixed state,” where they are energized and dysphoric, a highly dangerous combination. The most likely time to commit suicide is when the person has the energy to do it. Individuals naturally may go through a mixed state as the energy returns and they may look better, but still report severe depression. SSRIs have been associated with a risk of suicidal ideation, and this may be, in part, due to the temporary phenomenon of a mixed state. However, the risk of suicide in an unmedicated, depressed population is higher than that for a medicated one. Delirium, by producing a depressed affect, may induce suicidal behavior.<sup>75</sup> It is noted that, before committing suicide, 8 of 10 patients who were suicidal had asked for better pain control.<sup>78</sup> Medications such as interferon, steroids, and other agents that are contributing to the symptoms should be halted and reassessed.

Assessment of suicidal ideation in the cancer patient entails the following.<sup>75</sup>

- Be empathic
- Establish a relationship
- Identify depression, anxiety, or other psychiatric illness
- Evaluate for delirium
- Identify risk factors in the patient (demographics, family history of psychiatric illness and suicides, past depressions or anxiety, substance abuse, suicide history)
- Identify risk factors related to the cancer (prognosis, stage, pain)
- Identify social and other support systems (who they live with; where they live)
- Identify hopelessness
- Identify suicidal ideation
- If suicidal or hopeless, identify if there is plan
- Identify if it is possible to implement the plan (access to guns in the home, for example)

When in doubt, the patient should be evaluated immediately by a mental health professional to determine need for admission to a hospital. If admitted, a sitter with a psychiatric consult-service following should be assigned to the individual, or admission to a psychiatric service should be instituted as appropriate.

### Bipolar Disorder and Secondary Mania

Traditionally, when the term mania is used, it refers to the manic pole of a bipolar (or

manic-depressive) illness. Unipolar depression, also known as Major Depressive Disorder is described elsewhere. Bipolar disorders have two subtypes. Bipolar type I is associated with mania, mixed states, and depression, whereas bipolar type II has hypomania and depression. Hypomania by definition does not require hospitalization (see DSM-IV criteria for mania and hypomania).

### Etiology and Diagnosis

In cancer patients, mania can be a manifestation of a primary bipolar illness, a side effect of a medication, or a manifestation of an underlying condition, such as a brain tumor or delirium. Although it is debated as to whether one has to have a bipolar diathesis to become manic on medications, in vulnerable patients, mania can be induced with antidepressants, stimulants, steroids, INH, L-dopa, and caffeine.<sup>103–105</sup>

Cerebrovascular events and neuro-oncologic events can also precipitate mania or exacerbate a stable condition.<sup>104,106–109</sup> The role of the right side of the brain in secondary mania is well established,<sup>110</sup> although there are instances documented of left hemispheric injury.<sup>111</sup> A high index of suspicion should be used to assign a diagnosis of a new bipolar illness in a cancer patient. Substance abuse (including alcohol, amphetamines, cocaine), thyroid or other endocrine dysfunction, cerebrovascular events, partial complex seizures, and personality disorders can mimic bipolar illness.

### Pharmacologic Treatments

There is solid literature and expert consensus guidelines for the treatment of mania due to a bipolar I disorder. Drugs that are FDA-approved for bipolar mania include: lithium, valproate, olanzapine, risperidone, quetiapine, and anipir ziprasidone.<sup>112</sup> There is solid literature for carbamazepine and lamotrigine FDA-approved for maintenance in bipolar depression). Other off-label medications include oxcarbamazepine<sup>113</sup> and topiramate. Electroconvulsive therapy (ECT) is also recognized as a valid treatment for bipolar mania.

However, these guidelines neither automatically apply, nor should be reflexively used for secondary mania. Secondary mania does not appear to respond as well to lithium and may respond better to divalproex sodium or olanzapine.<sup>114</sup> In secondary mania, the first task, if possible, is to remove the offending agent.

For cancer patients, there are specific concerns with mood stabilizers, as some depress bone marrow functioning (VPA and CBZ) and have other important effects. For example, valproate (Depakote, Depakene) is bound to albumin. Any process that affects albumin alters the levels

of valproate. It is important, then, to check a free and total level of valproate, particularly in low-albumin states. Valproate interacts with many medications used in cancer patients, including antiemetics of the phenothiazine class (promethazine hydrochloride and prochlorperazine) and antipsychotic agents.

The choice of mood stabilizer varies for the type of bipolar disorder (eg., euphoric vs. mixed) (see DSM-IV criteria for mixed state) and is still actively debated in the literature. For euphoric mood or “classic” mania: lithium is considered to be the gold standard, although valproate is a first-line agent. For mixed episodes, dysphoric mood, or rapid cycling, the treatment of choice is VPA or CBZ, although some think that lithium is still a first-line agent (Table 4). When rapid loading is required, oral VPA at 10 to 15 mg/kg is recommended in a divided dose. When psychotic, antipsychotic medications are utilized, the FDA has approved antipsychotic agents for the treatment of mania. There are no consensus guidelines for the treatment of substance-induced mania.

Due to the complexity of these medication interactions, providers are strongly encouraged to check for them before prescribing these medications.

## Personality Disorders

In clinical practice, patients who have a diagnosis of a personality disorder, or traits of such, are deemed difficult, challenging, or even hateful.<sup>116</sup> One of the hallmarks in recognizing patients with personality disorders is the ability to evoke intense negative feelings in their caregivers. When this occurs in patients who have a medical illness, and especially a life-threatening disease such as cancer, the clinician is placed in a difficult bind: how to help with compassion while setting limits with a patient who demands attention.

According to the DSM-IV, a personality disorder is “an enduring pattern of inner experience and behavior that deviates markedly from the expectations of the individual’s culture, is pervasive and inflexible, has an onset in adolescence or early adulthood, is stable over time, and leads to distress or impairment.”<sup>44</sup> A review of the 10 specific personality disorders is beyond the scope of this text, but instead, certain traits of patients with borderline personality disorder (BPD) will be used to identify ways in which treatment by the primary care provider can contribute to an overall positive outcome.

About 2% of the general population carries a diagnosis of BPD,<sup>44</sup> and therefore these patients interact frequently with the medical system, where they often present with chronic pain, hypochondriasis, multiple somatic complaints, medication

sensitivity, and drug-seeking behavior.<sup>117</sup> Even though many have occasional, extreme episodes of psychiatric symptoms (such as brief psychotic episodes, dissociative episodes, impulsivity, and rage), often the diagnosis is missed because of a superficially intact ability to function in society. It is only under stress that intense feelings of abandonment can resurface, an issue in which the medical system can play an unwitting part. Characteristic office behaviors include boundary violations (premature familiarity, requesting

special treatment), medical neediness, atypical presentation (self-inflicted wounds), mediation-seeking behavior, and a lack of cooperation with medical treatment (nothing works, or there are reasons for why interventions can’t be tried, leading to an escalating and complex treatment plan). Often, the clinician is left with the sense that “I’m trying too hard and nothing is helping.” This is one of the classic binds of the BPD patient: “You must help me/You can’t help me.” Another, more complicated bind is when the clinician

Table 4 Guidelines for use of Mood Stabilizers\*

### Lithium

Used for classic euphoric mania

As a salt, is affected by sodium and medications that affect sodium (see below):

Has Effects on renal, thyroid, cardiac, neurologic (tremor, cognitive impairment) skin (acne), GI, metabolic (weight gain) systems

Lowers seizure threshold

Increases white blood cell count (demarginates white cells)

Toxicity and overdose: narrow therapeutic window) Has risk of check level at 12 hours after last dose

Increased by: Thiazides, spironolactone, triamterene, ACE inhibitors, indomethacin (as much as 60%), NSAIDs, calcium channel blockers, tetracycline

Note: aspirin does not increase lithium levels

Decreased by: NaCl and sodium bicarbonate, acetazolamide, psyllium, theophylline

### Valproate (VPA):

Used for mixed/rapid cycling

Is an Anticonvulsant

Can cause sedation, nausea, vomiting, diarrhea, tremor weight gain, LFT elevation and pancreatitis

Needs free and total levels 12 hours after last dose

Can be loaded

Has sprinkles that can be used

Is Protein bound, affected by low albumin states and competing medications

Affects bone marrow, often platelets more than other lines

Increased by: Phenobarbital, magnesium and aluminum hydroxide, aspirin, fluoxetine

Decreased by: CBZ

### Carbamazepine (CBZ):

Used for mixed/rapid cycling mania

Is an Anticonvulsant

Needs level at 12 hours after last dose

Structurally similar to TCAs, so consider when on other SSRIs or TCAs

Can affect bone marrow, cause transient leukopenia, mild thrombocytopenia, both idiopathic and dose related, elevated liver function tests including a cholestatic picture, and can cause a rash

SIADH

Multiple drug-drug interactions:

Increases levels of erythromycin, antiarrhythmics, diltiazem, cimetidine, verapamil, VPA (lowers VPA level)

Lowers levels of acetaminophen, alprazolam, amitriptyline, bupropion, clonazepam, cyclosporine, desipramine, fentanyl, fluphenazine, haloperidol, hormonal contraceptives, imipramine, neuroleptics, lamotrigine, methylprednisolone, phenytoin, theophylline, valproate, warfarin.

CBZ levels increased by allopurinol, cimetidine, clarithromycin, diltiazem, erythromycin, fluoxetine, and fluxoxamine, gemfibrozil, levetiracetam, itraconazole, ketoconazole, lamotrigine, loratadine, macrolides, nefazodone, Valproate, verapamil.

CBZ levels decreased by: doxorubicin, cisplatin, CBZ (induces own metabolism), phenytoin, valproate.

Interactions where no level was elevated: Levetiracetam/Carbamazepine, led to CBZ toxicity in 4 patients, no elevations of CBZ.<sup>115</sup>

CBZ/Quetiapine. Active metabolite of CBZ increased with addition of Quetiapine<sup>115</sup>

\*In general, recommendations for mood stabilizers include: check levels at trough 12 hours after last dose; check free levels of VPA and CBZ. All patients need to be aware that these medications have effects on fetal development, and that hormonal contraceptive levels are decreased by CBZ.

ACE = angiotensin converting enzyme; NaCl = sodium chloride; LFT = liver function test; NSAID = nonsteroidal anti-inflammatory drug; SIADH = syndrome of inappropriate antidiuretic hormone; SSRI = selective serotonin reuptake inhibitors.

becomes unwittingly enmeshed in the problems of the BPD patient, and ultimately becomes irritated with the demands, communicating a sense of frustration. The patient, exquisitely sensitive to rejection, becomes rageful, yet dependent: “I hate you/Don’t leave me.”

The first element in setting up a successful patient interaction between a medical professional and a patient with BPD is recognizing the disorder by using your own reactions as a guide. The following treatment guidelines will help.

- Structure the office environment to model consistency and clear communication;
- set limits and remain neutral emotionally;
- outline the limits of treatment and when referral might be necessary;
- incorporate mental health treatment into overall medical care;
- prescribe psychotropic medications for symptom relief.<sup>117</sup>

There is no defined medication regimen, but treating target symptoms of depressive effect, anxiety, impulsive behavior, or distorted thinking will often provide some relief.

In addition to the difficulty with interpersonal relationships by patients with BPD, the stress of cancer can reactivate some maladaptive coping strategies, the so-called “lower-level defenses” such as splitting or denial.<sup>116</sup> Splitting consists of unconsciously dividing caregivers into “the good ones” and “the bad ones.” These categories can shift around, and the staff can be lured into taking sides for or against a patient. Denial, in its most rigid form, can lead patients to avoid knowledge of their disease and of their treatment options, and to flee from the medical system. These defenses may seem unreasonable, but are merely attempts to manage an overwhelming reality. In summary, treatment of patients with personality disorders and cancer is a difficult task, requiring recognition by staff of a patient’s limitations, and a coordinated plan involving consistency, consultation, and caring.

## Schizophrenia

The incidence of cancer in the schizophrenic population is debated but appears to be the same as in the general population which is 1 to 1.5%.<sup>119</sup> Internists are caring for more and more patients with both illnesses. Important in caring for schizophrenic individuals with cancer is assessment of capacity. Assessing for capacity involves only the patient understanding the nature of the medical illness; the risks, benefits, and alternatives to procedures; and the ability to manipulate this information, not their psychiatric illness. Often, these individuals have family or case managers to aid in decision making. An individual may have limited capacity for one aspect of

care, but not be able to fully manipulate information. In the state of Virginia, two physicians must deem a patient to not have such a capacity, and then, a legally authorized representative is appointed. Other jurisdictions have other requirements. Assessment for capacity is a dynamic and fluid event. If an individual with schizophrenia, who previously had the capacity, has an acute change in behavior, one should consider the onset of delirium. For individuals with schizophrenia, familiar environments are important. It is best to have consistency of caregivers such as the same doctor and nurse.<sup>119</sup>

Medications used in schizophrenia, such as olanzapine, are often metabolized through the P-450 pathway (see “Anxiety Disorders”) and are affected by smoking. There may be a 40% decrease increase in metabolism if the patient suddenly stops smoking. Thus, a previously therapeutic dose may be excessive in the inpatient setting. It is very reasonable to have a psychiatric consult for these individuals to help guide their care, and aid in enhancing services such as case management during these periods of stress.

The type of schizophrenia an individual has is important. Those with paranoid schizophrenia are often highly functional. In fact, 15 to 25% of schizophrenics were found to have IQs in the normal to above average range.<sup>120</sup> This disease process manifests with delusions and paranoia more than with hallucinations. Men manifest the illness earlier so tend to be unmarried; women manifest later and tend to be divorced. Up to 55% of schizophrenics attempt suicide once in their lives.<sup>121</sup> The risk of suicide is high: 10 to 15% die by suicide.

## Pathophysiology

Schizophrenia is felt to be due to a disturbance in the level of dopamine (and serotonin) in the brain. There are four main regions of the brain that are of pharmacologic interest. These include the mesocortical (frontal lobes), mesotemporal (temporal lobes), nigrostriatal (basal ganglia) and tuberinfundibular region (involved in prolactin). The mesotemporal region is involved in the production of hallucinations and delusions, which are historically called positive symptoms. The mesocortical regions are involved in executive processing and motivation. PET scans demonstrate decreased frontal metabolism in individuals with schizophrenia. The oldest medications used for schizophrenia are called the typical antipsychotics (or neuroleptics). Examples of typical antipsychotics include chlorpromazine (Thorazine) which is also used for hiccups, fluphenazine (Prolixin), haloperidol (Haldol), and perphenazine (Trilafon)

Typical antipsychotics decrease the levels of dopamine across all four regions. Although there

is a decrease in hallucinations and delusions, there is also a further depletion in the already decreased frontal regions and a decrease in areas that require it for normal functioning. These include the basal ganglia, and the tuberinfundibular pathway. The classic profile of an individual on this medication is a “treated” schizophrenic with parkinsonism, amotivation, decreased cognitive functioning, with possible lactation (loss of tonic inhibition of prolactin). The atypical antipsychotics tend to maintain or increase the level of dopamine in the frontal cortices, thus allowing individuals to function at a higher level. However, for unclear reasons, some individuals do not respond as well to the atypical medications compared to the typical medications.

## Pharmacologic Treatment

Table 5 provides dosing recommendations and outlines side effect profiles of these agents drawn from affinity information.<sup>122,123</sup>

If an individual cannot take an oral tablet, olanzapine sol tabs (Zydis), the elixir, intravenous (IV) or intramuscular forms can be used. Elixirs are available for fluphenazine (Prolixin), haloperidol (Haldol), and risperidone (Risperdal). By report, there are fewer extrapyramidal effects with IV medications than oral medications. Side effects that must be recognized include akathisia, dystonic reactions, and neuroleptic malignant syndrome (NMS). Dystonic reactions are more common in young, muscular men. NMS is felt to be a spectrum illness that is associated with muscular rigidity and cogwheeling, manifested by elevated creatine kinase (CK), autonomic instability (fever, diaphoresis, tachycardia, hypertension), leukocytosis, and change in mental status including delirium. It can be subtle initially and, if unrecognized, can lead to coma and death. It usually begins within the first weeks of treatment, and is precipitated by dehydration, medical illness, high doses of neuroleptics, and in conjunction with other agents that act on dopamine blockade. Treatment is supportive, although dantrolene (a skeletal muscle relaxant) and bromocriptine are sometimes used.<sup>18,45</sup> In the cancer patient, it is important to note that clozapine, an atypical antipsychotic, has been associated with agranulocytosis and severe leukopenia and thus is monitored weekly when first begun. A psychiatrist should be involved in decision-making to determine how best to monitor this medication.

## Summary

Across the entire spectrum of patients with cancer, the most common psychiatric co-morbidities include delirium, anxiety disorders, adjustment disorders, and mood disorders. The prevalence of

Table 5 Dosing and Comparison of Typical and Atypical Antipsychotics

Atypical (year) *FDA for mania	Trade name Geriatric Dosing	Geriatric Dosing (mg)	Psychois in adult population	Schizophrenia (refractory)	D2 (EPS)	Severe H1 (Sedation)	M1 (Anticholinergic)	Alpha 1 (hypotension)
Clozapine (1974, 1989)	Clozaril	*not recommends	N/A	(400–600) weekly CBCs at first for agranulocytosis	0/+	+++	+++	+++
Risperidone (1994)*	Risperdal	*Warning for dementia 0.25–0.5 (5–1.5)	2–4	2–4 (4–8)	+++	++	0/+	+++

High potency = SE EPS, safer IM (less orthostasis) Low potency = SE drowsiness, dizziness, dry mouth *Warning for dementia (all atypicals now have warnings) **Newer data supports lower dosing with haldol based on receptor occupancy CBC = complete blood count; EPS = extra pyramidal signs; FDA = Food and Drug Administration; M1 = muscarinic receptor; M2 = histaminic receptor; 0 = none; + = least; ++ = moderate; +++ = most								

these conditions varies, depending upon the medical status of the patient population. Common issues that span these diagnoses are disturbances in body image, relationship problems, occupational concerns, issues of loss, and anticipatory grief. Treatments range from the purely medical to the essentially psychological, with a blend of therapies usually being most effective. Many cancer centers have developed multidisciplinary psycho-oncology services to help address these needs. These professionals are often helpful in providing individual assessment, therapy and referral for patients and their family members with cancer.

# Renal Failure and Renal Tubular Defects

John R. Foringer, MD  
Kevin W. Finkel, MD

Renal disease is a common and complex problem in patients being treated for malignancy. Cancer patients are often hospitalized for treatment of their disease or the complications that arise from such treatment and are therefore vulnerable to the same renal risks seen in the general hospitalized population. In addition, unique injuries may occur from the use of chemotherapy, immunosuppressant agents, hematopoietic stem cell transplantation, release of toxic intracellular constituents, or malignancy itself. The presence of preexisting renal disease in cancer patients is another complicating factor. The detection of an elevated serum creatinine may exclude participation in a chemotherapeutic trial or lead to its early termination. Furthermore, there is little data on the effects of dialysis on serum concentrations and therapeutic benefit of numerous chemotherapy agents. Finally, as survival rates of patients with cancer improve, an increasing number will develop end stage renal disease (ESRD) requiring chronic dialysis or renal transplantation. These patients will require additional expertise in care.

## Acute Renal Failure

### Background

Acute renal failure (ARF) is characterized by an abrupt decrease in glomerular filtration rate (GFR) over hours to days. It occurs in approximately 5% of all hospitalized patients and 30% of those in the intensive care unit (ICU).<sup>1</sup> The morbidity and mortality associated with ARF are well described. In ICU patients with ARF mortality rates approaching 60 to 80%.<sup>2-4</sup> Over the last 30 years, there has been little change in the mortality associated with hospital-acquired ARF. In 1979, the incidence of ARF was reported to be 4.9%, with an overall mortality of 29%. If the rise in creatinine was greater than 3 mg/dL, then mortality increased to 64%.<sup>1</sup> A more recent report in 1996 also looked at incidence and outcomes of ARF. Using the same definition for ARF as the previous study, the incidence of ARF was 7.4%.<sup>5</sup> The overall mortality rate was 19.4%, while the mortality in patients with sepsis and ARF it was 76%.<sup>5</sup> Acute renal failure significantly increases hospital length

of stay and cost of care.<sup>6,7</sup> Additional morbidity and cost result from chronic dialysis therapy needed by 5% to 30% of surviving patients.<sup>8</sup>

Equally important is the need to recognize that small changes in serum creatinine levels are associated with significant increases in mortality rates. In one study of over 4,000 patients who underwent cardiothoracic surgery with cardiopulmonary bypass, 21-day mortality was 30% in patients whose creatinine increased more than 0.5 mg/dL within 48 hours compared to 9% or less for patients with smaller or no increase in postoperative creatinine.<sup>9</sup> In a large cohort study of 5,000 patients who received intravenous radiocontrast, a 50% increase in serum creatinine within 48 hours was associated with a sixfold increase in 30-day mortality rates.<sup>10</sup> Therefore, early recognition and treatment of ARF may improve patient outcome.

### Defining Acute Renal Failure

To date, there is no standard definition for ARF. Acute renal failure is detected by a change in the serum creatinine concentration that serves as a surrogate for a change in GFR. However, no consensus exists on what degree of change in the creatinine level constitutes ARF. This variability in the definition makes it difficult to compare individual treatment or intervention trials. It also delays the recognition of ARF in the clinical setting. Typically, ARF is defined as a 50% increase in serum creatinine if the baseline is  $\leq 1.5$  mg/dL. A small increase in the serum creatinine level is clinically significant because it is an insensitive and delayed marker of decreased GFR. The discordance between changes in creatinine levels and GFR exist because creatinine excretion occurs through both glomerular filtration and proximal tubular secretion. As filtration of creatinine declines, tubular secretion will increase; thus, no measurable change in the serum creatinine develops until there is a profound decrease in the GFR. In addition, the nonsteady state of creatinine levels in ARF makes it impossible to accurately determine GFR with the use of 24-hour urine collections or the Cockcroft-Gault formula. The Cockcroft-Gault formula is accepted as a

standard method for estimating GFR only when the serum creatinine level is stable.<sup>11,12</sup>

$$\text{GFR} = (140 - \text{age}) \times \text{Pt weight} (0.85) \text{ if female} / (72 \times \text{SCr})$$

where Pt weight = patient's weight in kg and SCr = serum creatinine

The insensitivity in serum creatinine change as a marker for declines in GFR makes it difficult to identify early ARF and initiate timely intervention. A lack of sensitivity for identifying small declines in the GFR have led to attempts to develop biomarkers of tubular injury that are both sensitive and specific for early ARF. Recently described, kidney injury molecule-1 (KIM-1) is a novel protein that is expressed during tubular injury and acute tubular necrosis (ATN).<sup>13</sup> Urinary KIM-1 is being evaluated as a possible biomarker for the early diagnosis of ATN. Thus far, other urinary markers for the early detection of ATN have not been proven useful for clinical use.

### Evaluation of Acute Renal Failure

In the evaluation of ARF, the most useful clinical indices include the history, physical examination, and urinary output. Useful laboratory data are urinalysis, urinary specific gravity, examination of urinary sediment, and measurement of urine electrolytes. Under certain circumstances, evaluation of urine osmolality and staining for urine eosinophils are helpful. Measurements of the serum blood urea nitrogen (BUN) and creatinine are routine for following the progression of ARF. When assessing the hemodynamic changes in patients and evaluating the adequacy of renal perfusion, central hemodynamic monitoring is often required.

Although the first indication of renal hypoperfusion or tubular injury may be changes in urine output, urine output is an insensitive measure of renal perfusion pressure. Prerenal azotemia with intact tubular function results in increased tubular sodium reabsorption and decreased water excretion. The renal hypoperfusion can result in a fall in the urine output to less than 20 mL/hour. Oliguria, defined as a urine

output <400 mL/d, may ensue. Oliguria is present in approximately 50% of ARF cases, regardless of cause. In the evaluation of suspected prerenal azotemia, urine indices are predictable based on the effect of norepinephrine, angiotensin II, aldosterone, and antidiuretic hormone (ADH) on renal blood flow and sodium and water reabsorption. Typical urine indices are illustrated in Table 1. During low urine flow states, tubular reabsorption of BUN increases and the serum BUN-to-creatinine ratio is often elevated to >20:1. An increased BUN-to-creatinine ratio also develops with gastrointestinal bleeding, obstructive uropathy, and hypercatabolic states common in critically ill patients. With the increased avidity of the proximal and distal tubule for sodium, the urine sodium typically is <20 milliequivalent/L (mEq/L). An alternative measure to evaluate the kidneys' ability to conserve sodium during oliguric ARF is the fractional excretion of sodium (FENa). The FENa has been adopted to distinguish intact tubular function (prerenal) from compromised tubular function (acute tubular necrosis) in the oliguric patient. With simultaneous measurements of the plasma sodium and creatinine (PCr mg/dL) and the urinary sodium and creatinine (UCr mg/dL) the FENa is calculated as follows:

$$\text{FENa (\%)} = (\text{UNa} \times \text{PCr} \times 100) / \text{CPNa} \times \text{UCr}$$

where UNa is urinary sodium and PNa is plasma sodium.

The FENa is <1% (see Table 1) in healthy people, demonstrating that less than 1% of the daily sodium load filtered by the kidneys is normally excreted in the urine. In the face of suppressed atrial natriuretic peptide release and high serum levels of aldosterone during prerenal azotemia, the FENa is also <1%, indicating intact tubular function. In contrast, in ATN the FENa is usually >1%.<sup>14,15</sup> Although the FENa can be a useful tool in differentiating prerenal azotemia from ATN, there are many pitfalls to its use when confounding factors are present. In chronic renal disease, impaired sodium and water reabsorption can increase the FENa despite the presence of prerenal azotemia. Similarly, administration of diuretics, bicarbonate, and saline can also raise the urine sodium content. In contrast, there are

numerous reports of patients with ATN from radiocontrast, rhabdomyolysis, sepsis, transplant rejection, urinary obstruction, acute glomerulonephritis, and hepatorenal syndrome in which the FENa is <1%.<sup>16</sup> Therefore the utility of calculating the FENa to differentiate prerenal azotemia from ATN is dependent on the patient's clinical disease and the use of ancillary urine and serum tests.

Urinalysis and examination of the urinary sediment can help differentiate the underlying etiology of ARF. Prerenal azotemia is typically associated with a normal urinalysis or occasional fine granular and hyaline casts. In ATN, tubular epithelial cells, epithelial cell casts, and coarse granular casts are seen. Pyuria and white blood cell casts are indicative of glomerulonephritis, infection, or acute tubulo-interstitial nephritis (TIN). Staining for the presence of urine eosinophils can help identify TIN, although, their detection is not a finding exclusive to TIN. Eosinophils have been seen in patients with rapidly progressive glomerulonephritis, bacterial prostatitis, acute cystitis, and post-infectious glomerulonephritis.<sup>17</sup> Red blood cell casts indicate acute or rapidly progressive glomerulonephritis. Nephrotic range proteinuria suggests intrinsic glomerular disease. In hemoglobinuria and myoglobinuria, the urine dipstick is positive for large blood in the absence of red blood cells on microscopic analysis. The classification of ARF and the typical urine findings are listed in Table 2.

### Prerenal Azotemia

Prerenal azotemia accounts for approximately 50 to 60% of hospital acquired ARF.<sup>1,18</sup> It is a normal physiologic response to decreased renal perfusion pressure resulting in a hemodynamically mediated reduction in the GFR. No immediate injury occurs to the renal parenchyma, and the GFR rapidly returns to normal with reversal of the hemodynamic insult. Overt pathologic changes can occur if the renal hypoperfusion is sustained. The decrease in glomerular ultrafiltration pressure can be secondary to a true decrease in the arterial blood volume or a decrease in the effective arterial blood volume as in congestive heart failure, cirrhosis, capillary leak syndromes, and

sepsis. When the mean arterial pressure falls below 80 to 90 mm Hg there is a reduction in renal blood flow. Progression of the prerenal state can lead to ATN. Prerenal azotemia and ischemic ATN are manifestations of renal hypoperfusion. The severity and duration of the insult will dictate the likelihood of progression from prerenal azotemia to ischemic tubular damage.

In renal hypoperfusion states, GFR is maintained by the interplay of several neurohumoral systems. The renin-angiotensin axis increases the vasomotor tone of the efferent arteriole, while afferent arteriolar vasomotor tone decreases under the influence of nitric oxide, vasodilatory prostaglandins, and the kallikrein-kinin system. The sympathetic nervous system reacts to hypoperfusion with release of norepinephrine and ADH. With sustained reductions in renal blood flow, the ability of the kidney to maintain glomerular perfusion pressure is overwhelmed; the GFR declines, resulting in azotemia and cellular hypoxia with ischemic tubular damage.

Common causes of prerenal azotemia are listed in Table 3. In patients with cancer, prerenal azotemia is often the result of loss of extracellular fluid volume from vomiting, diarrhea, and poor oral intake during the treatment of cancer or as a complication of the malignancy itself. Capillary leak syndrome with an increase in third-space volume loss is a complication in cancer patients associated with bone marrow transplant and, in particular, interleukin-2 therapy as discussed later in this chapter (see "Chemotherapeutic Agents").<sup>19,20</sup> Other common causes of third-space fluid losses leading to intravascular volume depletion include ascites, sepsis, and peripheral edema secondary to lymphatic obstruction.

### Specific Causes of Prerenal Azotemia

#### Non-steroidal Anti-inflammatory Drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) can be divided into nonselective inhibitors of both cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2) or selective inhibitors of COX-2. Patients at greatest risk for NSAID-induced ARF include the elderly and patients with congestive heart failure, advanced liver disease, atherosclerotic vascular disease, or chronic kidney disease.<sup>21,22</sup> Special attention should be given to elderly patients treated with NSAIDs of any type. In a population-based study, the risk of ARF in the elderly increased by 58% with prescription NSAID use.<sup>23</sup> The nonselective NSAIDs are inhibitors of the prostaglandins responsible for vasodilatation in the kidney and can promote prerenal azotemia in susceptible patients. The selective COX-2 inhibitors also cause a similar renal vasoconstriction. The renal safety profile of celecoxib (a COX-2 inhibitor) is similar to ibuprofen. One selective COX-2 inhibitor, rofecoxib, was found

Table 1 Urinary Indices in the Differential Diagnosis of ARF

Index	Normal Value	Prerenal Azotemia	Acute Tubular Necrosis	Obstruction
Urinary volume	≥ 0.5 mL/kg/hr	≤ 0.5 mL/kg/hr	Variable	Variable
Urine specific gravity	1.003–1.025	≥ 1.020	1.010	Variable
Urinary sodium	Variable	< 20 mEq/L	> 40 mEq/L	< 40 mEq/L early > 40 mEq/L late
FENa	< 1%	< 1%	> 3%	< 1% early > 3% late
BUN/creatinine ratio	10:1	> 20:1	Variable	Variable

BUN = blood urea nitrogen; FENa = fractional excretion of sodium; mEq = milliequivalent

Table 2 Urinary Findings and Confirmatory Test in the Common Causes of AKF

<i>Prerenal Azotemia</i>			
<i>Common Scenarios in Cancer Patients</i>	<i>Suggestive Clinical Findings</i>	<i>Typical Urine Analysis</i>	<i>Confirmation</i>
Emesis Poor oral intake Ascites Heart failure Hemorrhage Capillary leak syndrome Diuretics NSAID ACE-I or ARB	Volume depletion Decreased EABV	FeNa < 1% UNa < 20 SG > 1.020	Rapid resolution of ARF with correction of renal hypoperfusion Invasive monitoring—CVP or PCWP
<i>Postrenal Azotemia</i>			
Obstruction from pelvic or ureteral cancer, metastasis, lymphoma, etc. Retroperitoneal fibrosis Hemorrhagic cystitis Nephrolithiasis	Abdominal or flank pain Palpable bladder Enlarged prostate Urinary frequency, oliguria, or anuria	Hematuria without dysmorphic red blood cells, RBC casts, or proteinuria Variable FeNa and UNa	Abdominal X-ray Renal ultrasound CT or MRI IVP Retrograde pyelography
<i>Intrinsic Renal Azotemia</i>			
<i>Common Scenarios in Cancer Patients</i>	<i>Cause of ARF</i>	<i>Typical Urine Analysis</i>	<i>Confirmation</i>
Initiation of a new medication with onset of ARF Recent NSAID use Recent blood transfusion	Acute tubulointerstitial nephritis Hemolysis	Positive urine WBC Urine eosinophils White cell casts Red blood cells Rarely red blood cell casts Urine supernatant is pink and heme + Hemoglobinuria	Peripheral eosinophilia Renal biopsy Biopsy of skin rash Elevated K <sup>+</sup> , PO <sub>4</sub> , and uric acid, LDH Hypocalcemia Peripheral smear with fragmented red blood cells
Six months to a year post BMT Use of tacrolimus or cyclosporine Radiation nephritis 24 to 48 hours after radiocontrast	Hemolytic uremic syndrome and thrombotic thrombocytopenic purpura Radiocontrast	Urine red blood cells Heme + Early FeNa < 1%, UNa < 20 Progression to FeNa > 1% and UNa > 20	Renal biopsy Peripheral smear with schistocytes and fragmented red cells Thrombocytopenia Temporal relationship to the contrast infusion
Severe hypophosphatemia after chemotherapy induced renal tubular injury	Rhabdomyolysis	Urine supernatant Heme + without red blood cells Myoglobinuria	Elevated creatine kinase, PO <sub>4</sub> , uric acid, K <sup>+</sup> Hypocalcemia Elevated serum myoglobin
Initiation of chemotherapy in any malignancy with a large tumor burden Autolysis of cells with an aggressive leukemia or lymphoma	Tumor lysis syndrome	Urate crystals	Elevated K <sup>+</sup> , PO <sub>4</sub> , uric acid Decreased Ca <sup>2+</sup>
Progression of prerenal azotemia Sepsis Hemorrhage	Ischemia	FeNa > 1%, UNa > 20 SG = 1.010 Muddy brown, granular, or tubule epithelial cell cast	Clinical assessment and urine findings usually sufficient

ARF = acute renal failure; ACE-I = angiotensin converting enzyme inhibitor; ARB = angiotensin receptor blocker; BMT = bone marrow transplantation; Ca<sup>2+</sup> = serum calcium; CT = computed tomography; CVP = ; EABV = effective arterial blood volume; FeNa = fractional excretion of sodium; IVP = intravenous pyelography; K<sup>+</sup> = serum potassium; MRI = magnetic resonance imaging; NSAID = non-steroidal anti-inflammatory drugs; LDH = ; lactate dehydrogenase; PCWP = ; PO<sub>4</sub> = serum phosphorous; RBC = red blood (cell) count; SG = urine specific gravity; UNa = urine sodium concentration; WBC = white blood (cell) count;

Hepatorenal syndrome

to have a higher incidence of renal toxicity than the nonselective inhibitors or celecoxib.<sup>24</sup> The renal toxicity of NSAIDs is increased when they are used in combination with other medications, with the potential to alter the kidneys' ability to autoregulate glomerular filtration pressure such as angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs). The renal vascular changes associated with NSAID use are typically reversible, although prolonged use can lead to permanent renal injury. Non-steroidal anti-inflammatory drugs are also known to cause acute TIN, in which case, there is often a sudden change in GFR that may persist for days to weeks.

### ACE Inhibitors and ARBs

The renin-angiotensin system contributes to the autoregulation of glomerular perfusion pressure, and inhibition of this system has the potential to induce prerenal azotemia. Angiotensin-converting enzyme inhibitors reduce blood pressure by inhibiting the proteolytic cleavage of angiotensin I to angiotensin II. Angiotensin receptor blockers occupy the angiotensin receptor. Much like the prostaglandin inhibitors, ACE inhibitors and ARBs increase the risk of ARF in the elderly, in patients using diuretics, and in patients with volume depletion, congestive heart failure, or diabetes.<sup>25,26</sup> Their use in conjunction with NSAIDs, cyclosporine, and tacrolimus puts patients at an even greater risk for ARF.<sup>25,27</sup> The incidence of ARF is also higher in patients with chronic kidney disease of any etiology. Patients with chronic kidney disease may depend on local angiotensin II production to maintain GFR in the face of decreased functional renal mass. Therefore, a decline in GFR when these patients receive ACE-inhibitors is not unexpected. The rise in serum creatinine is typically less than 30% and does not constitute ARF. More dramatic increases in serum creatinine suggest the presence of underlying renal vascular disease.

### Calcineurin Inhibitors

The calcineurin inhibitors cyclosporine A (CSA) and tacrolimus are widely used as immunosuppressants in bone marrow transplantation to prevent graft-versus-host disease (GVHD). Both CSA and tacrolimus cause ARF. Nephrotoxicity is the result of direct afferent arteriolar vasoconstriction leading to a decrease in the glomerular filtration pressure and GFR. The vascular effect associated with CSA and tacrolimus is reversible with discontinuation of the drug. A dose reduction is sometimes enough to reverse the prerenal affect. Chronic nephrotoxicity is a potential complication with more prolonged use of the calcineurin inhibitors. Proteinuria, tubular dysfunction, arterial hypertension, and rising creatinine are clinical findings consistent with chronic CSA or tacrolimus nephrotoxicity. It typically takes more than 6 months of therapy for the chronic changes to occur. Arteriolar damage, interstitial fibrosis, tubular atrophy, and glomerulosclerosis are found on renal biopsy specimens. The pathologic changes of the chronic nephrotoxicity are irreversible.<sup>28-30</sup> A rare complication of CSA and tacrolimus therapy is hemolytic uremic syndrome (HUS). The mechanism of CSA or tacrolimus-induced HUS is direct damage to the vascular endothelium in a dose-dependent fashion. With discontinuation of the drug, patients may have partial recovery.<sup>31-33</sup> Calcineurin inhibitors have also been associated with hyperkalemia, thought to be secondary to tubular resistance to aldosterone.<sup>34</sup>

### Hepatorenal Syndrome

Hepatorenal syndrome (HRS) is a unique cause of renal vasoconstriction with a decline in GFR in the face of normal renal histology that occurs in the setting of liver failure. The clinical picture associated with HRS is that of a prerenal azotemia. In true HRS without confounding renal injuries, the renal failure will resolve with liver transplantation. The pathogenesis of HRS is not completely understood. Systemic and splanchnic vascular resistance is decreased, leading to a decrease in the effective arterial volume and hypoperfusion of the renal vasculature. The compensatory response is an increase in the mediators of renal vasoconstriction, including increased renin-angiotensin-aldosterone activity, ADH levels, sympathetic tone, and endothelin levels. The renal response is an increase in salt and water avidity leading to worsening ascites and edema.<sup>35,36</sup> Clinically, HRS is characterized by oliguric ARF with very low urine sodium and bland urine sediment. The diagnosis of HRS is a diagnosis of exclusion. Other causes for the ARF should be ruled out, including causes of prerenal azotemia, intrinsic renal disease, and obstructive nephropathy. Major and minor criteria have been established for the diagnosis of HRS (Table 4). Liver transplant is the definitive therapy for HRS. However, patients who develop HRS prior to transplant have worse graft and patient survival.<sup>37</sup> Newer pharmacologic therapy with vasopressin analogs (eg, ornipressin and terlipressin), which are splanchnic vasoconstrictors, has shown some benefit. However, the major complication associated with these medications is mesenteric

ischemia.<sup>38-40</sup> Oral midodrine hydrochloride (a selective  $\alpha_1$ -adrenergic agonist) in combination with octreotide showed benefit in renal function in a small series of patients.<sup>41</sup> N-acetylcysteine was shown to increase renal blood flow without changing the hemodynamic derangements associated with HRS.<sup>42</sup> Several small studies have shown that transjugular intrahepatic portosystemic shunting (TIPS) has prolonged survival and improved renal function in patients with HRS.<sup>43,44</sup> Given the poor prognosis of HRS, in a patient with rapid onset of renal failure, dialysis is usually not instituted unless the patient is a candidate for liver transplant or has a chance of hepatic recovery.<sup>35,36,45</sup>

### Abdominal Compartment Syndrome

Abdominal compartment syndrome (ACS) may develop in patients with massive ascites or in the postoperative state. It was first reported in 1876 in a paper describing the reduction in urine flow associated with elevated intra-abdominal pressure (IAP).<sup>46</sup> Acute increases in IAP are deleterious for both intra-abdominal and distant organ function including the kidneys.<sup>47</sup> Acutely, the abdomen functions as a closed space; thus, any increase in the volume of its contents leads to a rise in compartmental pressure. Abdominal compartment syndrome is characterized by an acute rise in IAP coupled with evidence of organ dysfunction, usually reduced urine output. The pathogenesis of this reduction in urine formation is complex and attributed to three major factors: (1) compression of the great veins reduces venous return to the right heart, which manifests as relative volume depletion that is coupled with increased renal venous back pressure from high central venous pressures, as well as renal vein compression; (2) direct pressure on the renal cortex shunts blood away from the corticomedullary junction by altering renal vascular resistance and induces an ischemic injury; and (3) direct pressure on the ureters causing obstructive nephropathy. Regardless of the underlying cause, a reduction in urine output and azotemia in the presence of a measured IAP over 15 cm H<sub>2</sub>O is certainly cause for concern and should prompt intervention.

The causes of an increased IAP are listed in Table 5. Abdominal compartment syndrome should be managed with attention to preservation of underlying organ function, and is usually treated with urgent surgical decompression. This is a highly complex condition and skilled surgical intervention is required.

### Obstructive (Postrenal) Nephropathy

Urinary tract obstruction is a relatively common cause of renal failure in patients with malignancy

**Table 4** Diagnostic Criteria for Hepatorenal Syndrome

#### Major Criteria

Acute or chronic liver disease with advanced hepatic failure and portal hypertension

Depressed GFR with a serum creatinine > 1.5 mg/dL or a creatinine clearance < 40 mL/min

Absence of shock, ongoing bacterial infection, fluid loss, and treatment with nephrotoxic medications

No sustained improvement in renal function after withdrawal of diuretics and fluid resuscitation with 1.5L of isotonic saline

Proteinuria < 500 mg/d and no evidence of obstructive nephropathy on ultrasonography

#### Minor Criteria

Oliguria

Urine sodium < 10 mEq/L

Urine osmolality > plasma osmolality

Urine red blood cells < 50 per high-power field

Serum sodium concentration < 130 mEq/L

Adapted from Arroyo V, et al.<sup>45</sup>  
mEq = milliequivalent.

**Table 5** Causes of Increased Intra-abdominal Pressure

Reperfusion injury after bowel ischemia
Pancreatitis
Ileus or obstruction
Abdominal packing to control hemorrhage
Abdominal closure under tension
Severe ascites

and is discussed in detail in a later chapter (see Chapter 48, “Urinary Tract Infections”).

### Intrinsic Acute Renal Failure

Intrinsic ARF (Table 6) is associated with renal parenchymal injury. The most common cause of intrinsic renal failure is ATN. It accounts for approximately 85% of intrinsic ARF episodes in hospitalized patients.<sup>48</sup> The etiology of the tubular injury may be nephrotoxic (35%) or ischemic (50%) in origin. However, ATN is often a multifactorial process, developing in the setting of a critical illness with nephrotoxic medications, renal hypoperfusion, and sepsis all playing a role. With prolonged episodes of renal hypoperfusion, cortical necrosis can occur and lead to irreversible renal failure. The pathophysiologic abnormalities that result in a fall in GFR include intrarenal vasoconstriction, decreased glomerular filtration pressure, intra-tubular obstruction, transtubular back-leak of filtrate, and interstitial inflammation. The clinical course of ATN is divided into three components: initiation, maintenance, and recovery. The period in which a patient first experiences a renal injury is the initiation phase of ATN. The renal injury is potentially reversible if the precipitating insult is corrected. With progression of the injury, parenchymal damage ensues and abrupt changes in the GFR occur. The maintenance phase can last several days to weeks, during which the GFR remains depressed and the patient can have variable urine output. In the recovery phase, the GFR returns to normal as cellular regeneration and tubular repair occurs.

### Specific Causes of Intrinsic Renal Failure

#### Radiocontrast Nephropathy (RCN)

Ten percent of hospital-acquired ARF is the result of contrast-induced nephrotoxicity, making it one of the most common causes of ATN.<sup>5</sup> Patients at particular risk for RCN are the elderly, diabetics, and patients with chronic kidney disease, congestive heart failure or volume depletion. Contrast nephropathy often occurs in the cancer

patient with an early prerenal azotemia from volume depletion when the serum creatinine is still normal. Cancer-induced hypercalcemia is a particular risk factor for contrast-induced renal failure, and the calcium should be lowered to normal levels prior to contrast administration. Patients receiving NSAIDs, ACE inhibitors, ARBs, CSA, or tacrolimus are also at increased risk for RCN. In patients with multiple myeloma, a potential interaction between contrast agents and light chains has been found.<sup>49</sup> Contrast nephropathy causes ARF by renal

vasoconstriction and direct tubular injury.<sup>50,51</sup> The vasoconstriction associated with RCN has been linked to increased levels of vasoconstrictors, such as calcium, endothelin, and adenosine, and inhibition of the vasodilator nitric oxide. Oxidant injury through free radical oxygen species has also been implicated and has been a target of preventative measures.<sup>52</sup> Clinically, patients usually have an elevation in the serum creatinine 24 to 48 hours after the exposure to the contrast. The creatinine typically peaks at 3 to 5 days and returns to baseline in 7 to 10 days. The diagnosis of RCN is often based on the temporal relationship. It is common to see a FENa < 1% with RCN secondary to the renal vasoconstriction and a prerenal-like picture. Although RCN is typically a transient event, it is associated with a hospital mortality rate five times greater than in matched controls who receive radiocontrast but do not develop ARF.<sup>10</sup> Many trials have been done to evaluate the use of n-acetyl-cysteine, low-dose dopamine, and fenoldopam mesylate for prophylaxis against RCN and are discussed later in this chapter (see “Specific Measures”). The administration of intravenous fluid has become commonplace for the prevention of RCN. It has been shown that 0.45% sodium chloride significantly decreased the incidence of ARF when compared to the administration of intravenous fluid with either mannitol or furosemide.<sup>53</sup> Although radiocontrast is a renal tubular toxin, it also causes intense renal vasoconstriction, which may explain the salutatory effects of fluid administration. Another study suggests that a solution containing 0.9% sodium chloride is more efficacious in preventing ARF than one containing 0.45% sodium chloride.<sup>54</sup>

#### Aminoglycosides

Aminoglycosides cause intrinsic ARF in approximately 10% of patients who are treated with them for more than 2 to 3 days. The serum creatinine typically rises 7 to 10 days after the drug is initiated. Aminoglycosides concentrate in the proximal tubular cells causing cellular damage. Once overt nephropathy develops, the urinalysis shows tubular epithelial cells and tubular cell casts. Proximal tubular injury is evident by wasting of electrolytes such as potassium, magnesium, and calcium in the urine.<sup>55</sup> The FENa is typically > 2%. Aminoglycosides can also cause nephrogenic diabetes insipidus because the tubulointerstitial injury inhibits adenylate cyclase activity leading to ADH resistance.<sup>56</sup> Risk factors for aminoglycoside-induced ARF are advanced age, chronic kidney disease, volume depletion, liver disease, and prolonged use of the drug. Monitoring of aminoglycoside blood levels is important in preventing renal toxicity. Studies suggest that once-daily dosing of aminoglycosides decreases the risk of ARF without altering the antimicrobial efficacy.<sup>57,58</sup>

### Amphotericin B

Amphotericin B and its liposomal derivatives are a common cause of ATN, particularly in patients who have undergone bone marrow transplant. Eighty percent of patients who receive amphotericin B will develop some degree of renal impairment. The initial nephrotoxic injury from amphotericin B results from renal vasoconstriction of the preglomerular arterioles and predisposes the patient to an ischemic insult.<sup>59,60</sup> Direct tubular toxicity follows. As with many tubular toxins, amphotericin B results in tubular wasting of potassium and magnesium. A renal tubular acidosis (RTA) causing a hyperchloremic metabolic acidosis, as well as a nephrogenic diabetes insipidus from ADH resistance, are common findings.<sup>26,60,61</sup> The newer liposomal forms of amphotericin B lack the solubilizing agent deoxycholate that contributes to tubular toxicity. Such preparations reduce, but do not eliminate, the development of ATN.<sup>62</sup> Although the renal failure associated with amphotericin B is usually temporary and improves with discontinuation of the drug, reinstatement often results in recurrence of the ARF.<sup>63</sup> In the prevention of amphotericin-B-induced ARF, clinical studies have shown that hydration with normal saline prior to the amphotericin infusion provides some protection.<sup>64,65</sup>

### Pigmented Nephropathy

The principal cause of the pigmented nephropathies is rhabdomyolysis and hemoglobinuria from transfusion reactions or post-bone-marrow transplant. The majority of rhabdomyolysis cases are subclinical with mild elevations in the creatine kinase (CK), lactic dehydrogenase, or aspartate transaminase. In severe cases, ARF may ensue from myoglobinuria. Hemoglobinuria can be induced by the infusion of hemolyzed red blood cells.<sup>66</sup> Preservation of bone marrow with dimethyl sulfoxide (DMSO) will cause hemolysis of red blood cells present in the stored specimen, and subsequent infusion will result in hemoglobinuria. Mismatched blood products and transfusion reactions produce hemoglobinuria. Myoglobinuria as well as hemoglobinuria have been thought to cause ARF through three mechanisms: renal vasoconstriction, intratubular cast formation, and heme-mediated proximal tubular injury. It is also known that oxidant stress is increased with the release of heme proteins. Free heme proteins are suspected to reduce the formation of nitric oxide and increase endothelin levels leading to vasoconstriction and the decline in GFR. Intratubular obstruction occurs with the interaction of myoglobin and Tamm-Horsfall mucoprotein in an aciduric environment.<sup>67</sup> The diagnosis of myoglobin-induced nephrotoxicity is suspected on history and by a CK level greater than 10 times

the normal range. The urine dipstick is commonly positive for blood, with no red blood cells on microscopic examination. The FENa may be <1% despite tubular injury. Evaluation of the urine sediment typically reveals heme-pigmented casts. Serum electrolyte derangements are common, including hyperkalemia, hyperphosphatemia, hyperuricemia, and hypocalcemia. The majority of patients will experience recovery of renal function with resolution of the hemoglobinuria or myoglobinuria. In the recovery phase of rhabdomyolysis, hypercalcemia develops in 30% of patients secondary to increased levels of vitamin D and parathyroid hormone. Replacement of serum calcium should be withheld in asymptomatic patients to prevent severe hypercalcemia after recovery. To prevent and treat the ARF of rhabdomyolysis, aggressive hydration is effective. Alkalinization of the urine has also been advocated to increase the solubility of the heme proteins in the urine. Alkalinization may also reduce the production of reactive oxygen species, thus reducing the oxidant stress.<sup>68</sup>

### Chemotherapeutic Agents

#### *Cisplatin*

Nephrotoxicity is the most common dose-limiting side effect of cisplatin administration. The primary site for clearance of cisplatin is the kidney. The most common clinical scenario is the gradual onset of nonoliguric ARF; electrolyte wasting is seen, however, especially with high doses of cisplatin.<sup>69</sup> Apoptosis of renal proximal tubular cells is induced, resulting in wasting of electrolytes such as potassium, magnesium, calcium, and bicarbonate.<sup>69</sup> A common electrolyte abnormality is hypomagnesemia, which often occurs with prolonged exposure to the drug.<sup>70</sup> The direct tubular toxicity associated with cisplatin is exacerbated in a low-chloride environment. In the intracellular compartment, chloride molecules are replaced with water molecules in the cis position of cisplatin, forming hydroxyl radicals that injure the neutrophilic binding sites on DNA.<sup>71,72</sup> The decline in GFR associated with cisplatin toxicity usually occurs 3 to 5 days after the exposure.<sup>69</sup> Doses of cisplatin > 50 mg/m<sup>2</sup> are sufficient to cause renal failure. The renal injury is typically reversible, but repeated doses of cisplatin in excess of 100 mg/m<sup>2</sup> may cause irreversible renal damage.<sup>72</sup> Hydration with isotonic saline and avoidance of concomitant nephrotoxins is the most effective way to prevent cisplatin-induced nephrotoxicity. Amifostine has been shown to reduce cisplatin nephrotoxicity through promotion of better DNA repair and elimination of free radicals.<sup>73,74</sup> With the cessation of cisplatin therapy, the majority of patients will recover renal function. However, it has been reported that the GFR is reduced on average 15% in patients followed long-term for resolved ARF from cisplatin nephrotoxicity.<sup>75</sup>

#### *Ifosfamide*

Ifosfamide is an alkylating drug that causes renal toxicity either directly or through a metabolite. The metabolite of ifosfamide, chloroacetaldehyde, causes direct tubular epithelial cell damage.<sup>76</sup> The renal injury occurs throughout the kidney, including the glomerulus, proximal and distal tubule, and interstitium. The proximal tubule is most seriously affected, causing wasting of electrolytes similar to cisplatin. The degree of hypokalemia, hypophosphatemia, hypomagnesemia, and hyperchloremic acidosis experienced with ifosfamide toxicity can be severe. Patients can develop Fanconi syndrome with hypophosphatemic rickets and osteomalacia, as well as nephrogenic diabetes insipidus.<sup>77</sup> A potential marker for ifosfamide nephrotoxicity is increased urinary  $\beta_2$ -microglobulin excretion.<sup>78</sup> Risk factors for ifosfamide nephrotoxicity include previous exposure to cisplatin, chronic kidney disease, and a cumulative dose > 84 g/m<sup>2</sup>.<sup>79,80</sup> Recent data suggest that amifostine may have a protective role against ifosfamide, as well as cisplatin nephrotoxicity.<sup>81</sup> The majority of patients will recover from ifosfamide-induced tubular injury; however, there are reports of long-term complications. Ifosfamide has been attributed to chronic renal fibrosis with a decline in the GFR over time and, in one case, leading to end-stage renal disease.<sup>82,83</sup> In pediatric literature, the chronic and progressive nature of ifosfamide-induced renal toxicity is well documented.<sup>84</sup>

#### *Methotrexate*

Methotrexate (MTX)-induced ARF is caused by the precipitation of the drug and its more insoluble metabolite, 7-hydroxymethotrexate, in the tubular lumen.<sup>72,85</sup> At a pH of <5.5, the drug and its metabolite precipitate when their concentration exceeds  $2 \times 10^{-3}$  molar, whereas solubility increases with a urine pH of 7.<sup>86</sup> Acute renal failure occurs from intrarenal obstruction, direct tubule toxicity, and prerenal azotemia from afferent arteriolar vasoconstriction. Acute renal failure is reported in 30 to 50% of patients treated with high-dose MTX (> 1 g/m<sup>2</sup>).<sup>86</sup> For the prevention of renal toxicity, hydration and high urine output is essential. Isotonic saline infusion and furosemide may be necessary to keep the urine output > 100 mL/h. An increase in the clearance rate of MTX is seen when the urine pH is increased from 5.5 to 8.4, which can be accomplished with an isotonic solution containing bicarbonate.<sup>87</sup> Once ARF develops, the excretion of MTX is reduced, the systemic toxicity of MTX is increased, and treatment is mainly supportive. It may be necessary to remove the drug with dialysis. Hemodialysis, using high blood flow rates with a high-flux dialyzer is an effective method of removing methotrexate.<sup>88</sup> High-dose leucovorin therapy can reduce the systemic toxicity associated with MTX and ARF.<sup>89,90</sup> In the majority of

cases, MTX-induced ARF will resolve. Often the plasma creatinine will peak within one week and return to baseline at 3 weeks.<sup>91</sup>

#### Biologic Agents

Acute renal failure is well described with the administration of  $\alpha$ -interferon and interleukin-2.<sup>92,93</sup> Acute renal failure secondary to interferon- $\alpha$  (IFN- $\alpha$ ) therapy is uncommon and has been associated with and without massive proteinuria.<sup>94</sup> Renal biopsy in IFN- $\alpha$ -associated ARF has revealed glomerular lesions, including focal segmental glomerulosclerosis and minimal change disease.<sup>94-96</sup> Other renal lesions include acute tubular interstitial nephritis and acute tubular necrosis.<sup>97,98</sup> The ARF can be reversible with cessation of the drug; however, some patients may have CKD or require long-term dialysis. After recovery of the ARF, proteinuria may persist, and these patients should be monitored for progression of renal disease.<sup>94</sup> With interleukin-2-induced renal dysfunction, a systemic capillary leak syndrome occurs resulting in volume depletion, hypotension, and prerenal azotemia.<sup>19,20</sup> Unlike IFN- $\alpha$ , interleukin-2 produces a decreased GFR in the majority of patients who receive the drug, and the incidence of ARF is high.<sup>99</sup>

Imatinib mesylate is a protein-tyrosine kinase inhibitor that inhibits the BCR-ABL tyrosine kinase as well as the receptor tyrosine kinase for platelet-derived growth factor and stem cell factor c-kit.<sup>100</sup> Two reports in the literature described acute renal failure associated with Gleevec. One case reported renal failure requiring temporary hemodialysis with ATN found on renal biopsy.<sup>101</sup> Both cases reported recovery of renal function with the cessation of imatinib mesylate. It is now recommended that renal function be monitored closely during therapy with Gleevec.

#### Bisphosphonates

Bisphosphonates are commonly used to manage hypercalcemia of malignancy and to reduce skeletal complications in patients with bone metastases and multiple myeloma. All three generations of bisphosphonates have been shown to cause renal failure. The most common pathologic finding on renal biopsy is acute tubular necrosis. A recent study reports biopsy-proven toxic ATN in six patients treated with zoledronic acid, a potent bisphosphonate. Renal function recovered with cessation of the drug but did not return to baseline levels.<sup>102</sup> Pamidronate has been shown to cause ATN as well as the nephrotic syndrome from a collapsing variant of focal segmental glomerular sclerosis.<sup>103,104</sup> The exact mechanism of bisphosphonate-induced renal failure is not known; however, direct toxicity to the tubular epithelial cells is suspect.

## Renal Diseases Associated with Malignancy

### Multiple Myeloma

Fifty percent of patients with multiple myeloma (MM) will develop some degree of renal functional impairment, and 10% will require dialysis. The pathogenesis of MM-induced renal failure includes myeloma kidney, renal tubular dysfunction, light-chain deposition disease, amyloidosis, and plasma cell infiltration. Hypercalcemia can also complicate MM and induce renal failure. Patients with MM are at increased risk for other causes of renal failure, in particular contrast nephropathy. The overproduction of monoclonal immunoglobulin light chains is the primary factor associated with the renal disease of MM. The recommended diagnostic tool for identifying the presence of urinary light chains is urine protein electrophoresis with immunofixation. Light chains can combine with Tamm-Horsfall mucoproteins to form casts that cause intratubular obstruction. Factors that influence tubular cast formation include low tubular flow rate, acidity of the urine, radiocontrast infusion, and distal nephron sodium, chloride, and calcium concentration. The therapy of MM-induced renal disease is limited to treating the MM. In patients with high tumor burdens, acute renal failure may ensue. Partial recovery of the GFR may occur in up to 50% of patients who undergo treatment of the MM.<sup>105</sup> Small case series suggest that plasmapheresis improves renal survival in patients who require dialysis for ARF from myeloma kidney.<sup>106,107</sup> However, renal biopsy may be necessary to identify those patients likely to respond to plasmapheresis therapy. Given the limited clinical experience and need for biopsy, plasmapheresis for myeloma kidney has not gained wide acceptance.

Patients with MM are at increased risk for developing ARF from nephrotoxic injury, particularly radiocontrast. The incidence of contrast nephropathy in MM patients is 0.6% to 1.25%.<sup>108</sup> It is postulated that iodinated contrast enhances the precipitation of intratubular proteins leading to obstruction. Adequate hydration and avoiding low urine flow states is the best protection against ARF in MM patients.

#### Hypercalcemia Associated with Multiple Myeloma

Hypercalcemia complicates MM in 15% of patients at presentation. Hypercalcemia induces prerenal azotemia by causing nephrogenic diabetes insipidus, renal vasoconstriction, and intratubular calcium deposition.<sup>109</sup> When the serum calcium level is  $>13$  mg/dL, most patients will have some degree of volume depletion. Volume repletion and a saline diuresis are essential to the therapy. Isotonic saline should be infused intravenously in large volumes to increase

calcium excretion. Furosemide may be used to increase the calciuresis once volume depletion is corrected. Thiazide diuretics should be avoided because they decrease urinary calcium excretion. Bisphosphonates, pyrophosphate analogs with a high affinity for hydroxyapatite, may be necessary to control the serum calcium in severe cases.<sup>110,111</sup> Pamidronate and clodronate, two second-generation bisphosphonates, are commonly used preparations. Both drugs are potent inhibitors of osteoclast bone resorption without significant bone demineralization.<sup>112</sup> Pamidronate can be given as a single intravenous dose of 30 to 90 mg and may normalize the calcium for several weeks.<sup>111</sup> Calcitonin, derived from the thyroid C-cell, inhibits osteoclast activity. The onset of calcitonin is rapid but with a short half-life and is usually not given as a sole therapy.<sup>113</sup> Plicamycin (mithramycin) is an inhibitor of RNA synthesis and impairs osteoclast activity. It is an effective means to acutely lower serum calcium. However, the multiple toxicities associated with plicamycin have made its use uncommon. Glucocorticoids are also effective in the therapy of hypercalcemia in patients with hematologic malignancies. Hemodialysis with a low calcium bath is the preferred method of reducing serum calcium levels in patients with a severely depressed GFR.

### Tumor Lysis Syndrome

Tumor lysis syndrome is often a dramatic presentation of ARF in patients with malignancy. It is characterized by the development of hyperphosphatemia, hypocalcemia, hyperuricemia, and hyperkalemia. Tumor lysis syndrome can occur spontaneously during the rapid growth phase of malignancies such as bulky lymphoblastomas and Burkitt's and non-Burkitt's lymphomas that have extremely rapid cell turnover rates.<sup>114</sup> More commonly, it is seen when cytotoxic chemotherapy induces lysis of malignant cells in patients with large tumor burdens. Tumor lysis syndrome has developed in patients with non-Hodgkin's lymphoma, acute lymphoblastic leukemia, chronic myelogenous leukemia in blast crises, small cell lung cancer, and metastatic breast cancer.<sup>115</sup> In most patients, the ARF is reversible after aggressive supportive therapy including dialysis.

The pathophysiology of ARF associated with tumor lysis syndrome is related to two main factors, preexisting volume depletion prior to the onset of renal failure and the precipitation of uric acid and calcium phosphate complexes in the renal tubules and tissue.<sup>116</sup> Patients may be volume-depleted from anorexia or nausea and vomiting associated with the malignancy, or from increased insensible losses from fever or tachypnea. Therefore, it is important to establish brisk flow of hypotonic urine to prevent or ameliorate ARF associated with tumor lysis syndrome.

Hyperuricemia is either present before treatment with chemotherapy or develops after therapy despite prophylaxis with allopurinol.<sup>117</sup> Uric acid is nearly completely ionized at physiologic pH, but becomes progressively insoluble in the acidic environment of the renal tubules. Precipitation of uric acid causes intratubular obstruction leading to increased renal vascular resistance and decreased GFR.<sup>118</sup> Moreover, a granulomatous reaction to intraluminal uric acid crystals and necrosis of tubular epithelium can be found on biopsy specimens.

Hyperphosphatemia and hypocalcemia also occur in tumor lysis syndrome. In patients who do not develop hyperuricemia in tumor lysis syndrome, ARF has been attributed to metastatic intra-renal calcification or acute nephrocalcinosis.<sup>119</sup> Tumor lysis with release of inorganic phosphate results in acute hypocalcemia and metastatic calcification resulting in ARF.

Therefore, ARF associated with tumor lysis syndrome is the result of the combination of volume depletion in the face of urinary precipitation of uric acid in the renal tubules and parenchyma, and acute nephrocalcinosis from severe hyperphosphatemia. Since patients at risk for tumor lysis often have intra-abdominal lymphoma, urinary tract obstruction can be a contributing factor in the development of ARF. Given the aforementioned pathogenetic factors for ARF, patients who are undergoing treatment with malignancies likely to experience rapid cell lysis should receive vigorous intravenous hydration to maintain good urinary flow and urinary dilution. In addition, because uric acid is very soluble at physiologic pH, sodium bicarbonate should be added to the intravenous fluid to achieve a pH greater than 6.5 in the urine. Alkalinization can be achieved by the administration of 100 mEq/L of sodium bicarbonate in 1 liter of D<sub>5</sub>W (5% dextrose in water) at a rate of 200 mL/h. Since metabolic alkalosis can aggravate hypocalcemia, caution should be exercised when using alkali in patients with low serum calcium levels. It is advisable to stop the infusion if the serum bicarbonate level is greater than 30 mEq/L. Allopurinol is administered to inhibit uric acid formation. Through its metabolite oxypurinol, allopurinol inhibits xanthine oxidase and thereby blocks the conversion of hypoxanthine and xanthine to uric acid. During massive tumor lysis, uric acid excretion can still increase, despite the administration of allopurinol, so that intravenous hydration is still necessary to prevent ARF. Since allopurinol and its metabolites are excreted in the urine, the dose should be reduced in the face of impaired renal function. Urate oxidase has been recently approved for use in the United States. It converts uric acid to water-soluble allantoin, thereby decreasing serum uric acid levels and urinary uric acid excretion.<sup>120</sup> The use of urate oxidase may

obviate the need for urinary alkalinization, but good urine flow with hydration should be maintained given the probability of preexisting volume depletion.

Dialysis for ARF associated with tumor lysis syndrome may be required for the traditional indications of fluid overload, hyperkalemia, hyperphosphatemia or hyperuricemia unresponsive to medical management. There is some interest in using dialysis in patients at high risk of tumor lysis syndrome to prevent the development of renal failure. In a small trial in five children, continuous hemofiltration was started prior to administration of chemotherapy and appeared to prevent renal failure in 80% of the patients.<sup>121</sup> However, given that continuous dialysis is complicated, expensive, and not without risk, its routine use as prophylaxis cannot be recommended.

### Thrombotic Microangiopathy

Thrombotic microangiopathy (TMA) in the form of hemolytic-uremic syndrome (HUS) and thrombocytopenic purpura (TTP) is a disease of multiple etiologies manifesting as non-immune hemolytic anemia, thrombocytopenia, varying degrees of encephalopathy, and renal failure due to platelet thrombi in the microcirculation of the kidneys. Laboratory findings include elevated indirect bilirubin and lactate dehydrogenase (LDH) levels, depressed serum haptoglobin values, and schistocytes on peripheral blood smear. The characteristic renal lesion consists of vessel wall thickening in capillaries and arterioles, with swelling and detachment of endothelial cells from the basement membranes and accumulation of subendothelial fluffy material.<sup>122</sup> These vascular lesions are indistinguishable from those seen in malignant hypertension or scleroderma renal crisis.

Typically, HUS develops in children with hemorrhagic colitis from verotoxin-producing *Escherichia coli* infection associated with ingestion of undercooked meat.<sup>123</sup> Renal failure is pronounced, and altered sensorium is not consistently present. In contrast, idiopathic TTP is usually seen in adult women where encephalopathy is the predominant clinical feature whereas renal involvement is less severe. However, because of similar laboratory findings and the great overlap in clinical features, these syndromes likely share the same pathogenesis—endothelial cell dysfunction.<sup>124</sup>

In cancer patients, malignancy, chemotherapy, radiation, immunosuppressive agents, and bone marrow transplantation can induce endothelial dysfunction leading to TMA and renal failure (Table 7).

Treatment of renal failure and TMA in cancer patients is mainly supportive, with initiation of dialysis as necessary. Stopping any causative medications is advised. However, the role of

plasmapheresis remains controversial. Although all forms of TMA share the same underlying pathogenesis of endothelial cell injury and dysfunction, the actual inciting event may be different in each case and not amenable to plasmapheresis. As an example, plasmapheresis has not been found to be an effective therapy for HUS in children, despite its clear benefit in the treatment of idiopathic TTP.<sup>125</sup> In TTP, an autoantibody to the von Willebrand's factor-cleaving protease has been described.<sup>126</sup> Inhibition of the cleaving enzyme leads to unusually large von Willebrand multimers that may agglutinate circulating platelets at sites with high levels of intravascular shear stress and trigger TMA. Plasma infusion may provide an exogenous source of cleaving protease to compete with the autoantibody while plasmapheresis will remove the pathogenic antibody. In HUS, no autoantibody has been found and may explain the ineffectiveness of plasmapheresis in this disorder.<sup>127</sup> Reports on the use of plasmapheresis in cancer patients are confined to those with bone marrow transplantation (BMT) nephropathy. Most studies are small case series that are unable to clearly demonstrate true benefit. Nevertheless, when faced with a patient with the clinical characteristics of severe TTP after BMT, a trial of plasmapheresis is probably warranted.

### Bone Marrow Transplantation

Acute renal failure, defined as doubling of the baseline serum creatinine level, may occur in up to 50% of patients who undergo BMT, of which half will undergo hemodialysis.<sup>128</sup> Initially, it was assumed that the cause of ARF was multifactorial in nature, given the severity of illness and the amount of nephrotoxin exposure. Instead, three distinctive renal syndromes associated with BMT were described and are categorized according to the time of onset.<sup>129</sup> Renal complications are more prevalent in patients who undergo allogeneic

transplants. When autologous stem cell transplants became the predominant method of BMT, the incidence of these disorders decreased.<sup>130</sup>

Within the first few days after transplantation, ARF may develop from hemoglobinuria caused by infusion of hemolyzed red blood cells.<sup>66</sup> Preservation of bone marrow with DMSO will cause hemolysis of red blood cells present in the stored specimen, and subsequent infusion will result in hemoglobinuria. Three mechanisms are involved in the pathogenesis of hemoglobinuric ARF: renal vasoconstriction, direct cytotoxicity of hemoglobin, and intratubular cast formation. By scavenging nitric oxide and stimulating the release of endothelin and thromboxane, hemoglobin causes renal vasoconstriction. Hemoglobin is also toxic to renal tubular epithelial cells either directly or through release of iron, and by generation of reactive oxygen species.<sup>131</sup> Intratubular cast formation occludes urinary flow, thereby decreasing GFR, and prolongs cellular exposure to the harmful effects of hemoglobin. Another renal syndrome usually occurs 10 to 21 days after transplantation and is associated with the development of veno-occlusive disease (VOD) of the liver.<sup>129</sup> VOD of the liver is characterized by tender hepatomegaly, fluid retention with ascites formation, and jaundice. It is the result of fibrous narrowing of small hepatic venules and sinusoids triggered by the pre-transplant cytoreductive regimen, and is more common after allogeneic than autologous BMT. The ARF is similar in appearance to hepatorenal syndrome. Patients have hyperdynamic vital signs, along with hyponatremia, oliguria, and low urinary sodium concentration. The urinalysis shows minimal proteinuria and muddy brown granular casts as a result of bile salts and bilirubin in the urine. The patients are usually resistant to diuretics, and spontaneous recovery is rare. Risk factors for the development of ARF include weight gain, hyperbilirubinemia, use of amphotericin B, and a baseline serum creatinine level greater than 0.7 mg/dL. The development of ARF adversely affects survival. In patients who require dialysis, the mortality rate approaches 80%. Although VOD can be diagnosed by either direct measurement of sinusoidal pressures or liver biopsy, these procedures are difficult or hazardous in BMT patients. Therefore the diagnosis of VOD is usually made on clinical criteria. However, studies have shown that clinical criteria alone may not be sufficient to recognize or exclude a diagnosis of VOD.<sup>132</sup> Small trials using infusions of prostaglandin E, pentoxifylline, or low-dose heparin to prevent the development of VOD have been promising.<sup>133–135</sup> However, their use is not commonplace because of the associated risks of bleeding.

A late-stage renal manifestation of transplantation referred to as “BMT nephropathy” usually occurs more than 6 months after the procedure.

It is characterized by the development of ARF with microangiopathic hemolytic anemia, worsening thrombocytopenia, hypertension, and fluid retention. Hence, BMT nephropathy is a form of HUS.<sup>136</sup> Patients may also have varying degrees of encephalopathy resembling TTP. It occurs in patients who receive cyclosporine for prevention of graft-versus-host disease, as well as those who do not. Radiation may play a role because its incidence appears higher after allogeneic compared with autologous BMT.<sup>130</sup> Although plasmapheresis therapy is often successful in treating idiopathic TTP, the results in BMT nephropathy have been disappointing.<sup>137</sup> Prognosis of BMT nephropathy is variable. Those patients who present with a modest rise in creatinine concentration and normal level of consciousness may have either spontaneous resolution or slow progression to chronic hemodialysis. Those patients who present with a fulminant course of TTP uniformly do poorly, despite aggressive dialysis and plasmapheresis, and often succumb to the disease.

GVHD is a complication of BMT not typically associated with renal disease. Renal lesions associated with GVHD have been described, and the primary manifestation is proteinuria. Immune-complex-mediated glomerular disease is the predominant finding on biopsy, with membranous nephropathy the pathologic lesion most commonly found.<sup>138–140</sup> In the majority of cases, the proteinuria improved or resolved with treatment of the GVHD with steroids or cyclosporin A.<sup>139</sup>

### **ARF associated with Lymphoma and Leukemia**

#### **Lymphoma**

Infiltration of the kidneys by lymphoma cells may be detected in up to 90% of cases at autopsy. However, clinical renal disease as a result of infiltration is rare, most commonly seen in highly malignant and disseminated disease.<sup>141–144</sup> The diagnosis of renal failure resulting from lymphomatous infiltration is necessarily one of exclusion because more common explanations for renal failure usually exist. The diagnosis may be suspected from clinical features and imaging studies. Patients may present with flank pain and hematuria. Renal ultrasonography reveals diffusely enlarged kidneys, sometimes with multiple focal lesions. Although definitive diagnosis depends on renal biopsy, this procedure is often impossible because of the presence of contraindications. In such cases the following criteria support the diagnosis of renal failure as a result of lymphomatous infiltration: (1) renal enlargement without obstruction; (2) absence of other causes of renal failure; and (3) rapid improvement of renal failure after radiotherapy or systemic chemotherapy.

### **Cytotoxic Nephropathy/ Hemophagocytic Syndrome**

Hemophagocytic syndrome (HPS) is a reactive disorder that results from intense macrophage activation and cytokine release.<sup>145</sup> It has developed in patients with malignant lymphoma, severe bacterial and viral infections, and in patients receiving prolonged parenteral nutrition with soluble lipids. Patients present with fever, rash, respiratory failure, lymphadenopathy and hepatosplenomegaly. There have been recent reports of HPS in association with occult peripheral T-cell lymphomas causing severe ARF.<sup>146</sup> Renal biopsy specimens are characterized by an unusually severe degree of interstitial edema with limited interstitial cellular infiltrate. A number of cytokines, including interferon- $\alpha$ , tumor necrosis factor (TNF), interleukin-6, macrophage colony-stimulating factor, and CD-8 are up-regulated in HPS and may explain the marked macrophage activation and cytokine release. In patients with lymphadenopathy who develop unexplained multiple organ dysfunction, markedly elevated cytokine levels support the diagnosis.

#### **Leukemia**

Leukemic infiltration of the kidneys is present in 60 to 90% of patients with chronic lymphocytic leukemia (CLL). Although uncommon, many cases of renal failure attributable to leukemic infiltration are known.<sup>147–149</sup> Ultrasonography usually reveals bilateral renal enlargement. Chemotherapy often produces a dramatic improvement in renal function.

There are reports of patients with CLL who develop ARF from leukemic infiltration and are infected with polyomavirus.<sup>150</sup> Urine from patients demonstrates viral inclusions in tubular cells (“decoy” cells), and blood is positive for polyomavirus (BK type) DNA. Therefore, in leukemia patients with ARF considered due to leukemic infiltration, evidence for coexisting BK virus infection should be sought.

Patients with significantly elevated white cell counts can develop ARF from leukostasis. Leukemic cells occlude the peritubular and glomerular capillaries, thereby decreasing GFR. Patients may be oliguric but their renal function often improves with therapeutic leukopheresis or chemotherapy. Leukostasis has been described in both acute and chronic leukemia.

#### **Radiation Nephritis**

Renal failure and hypertension develop when the kidneys are exposed to more than 2,300 rads of radiation in fractionated doses over a period of 3 to 5 weeks.<sup>151</sup> A characteristic of radiation injury is the long latent period between radiation and overt nephrotoxicity. The effects of DNA damage

from radiation are not evident until cell division occurs. The latency period depends on the proliferation rate of a particular tissue. The recognition of radiation injury has led to treatment protocols that have significantly minimized exposure and the incidence of radiation nephropathy. In the past, abdominal radiation and total body irradiation for bone marrow transplantation were leading causes of radiation nephritis. Today, sequential radiosensitizing chemotherapy with radiation is a more prevalent mode.<sup>152</sup>

Five clinical syndromes of radiation injury to the kidney are described: (1) acute radiation nephropathy; (2) chronic radiation nephropathy; (3) asymptomatic proteinuria; (4) benign hypertension; and (5) malignant hypertension.

### Acute Radiation Nephropathy

Acute radiation nephropathy usually occurs after a latent period of 6 to 12 months.<sup>153,154</sup> Patients present with ARF accompanied by microangiopathic hemolytic anemia with schistocytes, thrombocytopenia, hypertension, and fluid overload with edema. Renal biopsy findings are not specific to radiation injury and are typical of HUS. The onset of ARF can be abrupt, and the degree of anemia and hypertension is severe. Although progression to chronic renal failure is the rule, there are reports of response to ACE inhibitor therapy in stabilizing the renal function.<sup>155</sup> The development of end stage renal disease (ESRD) is a poor prognostic event in these patients because survival on chronic dialysis is poor compared to that of age-matched, non-diabetic and diabetic patients.

Malignant hypertension as a complication of radiation to the kidney has been reported as a feature of acute radiation nephropathy, but also occasionally as an isolated late manifestation presenting 18 months to 11 years after irradiation. The incidence of this complication is much less with the availability of the new classes of antihypertensive agents, in particular, the ACE inhibitors.

### Tubulointerstitial Nephritis

Acute tubulointerstitial nephritis (TIN) is a common cause of ARF accounting for 10% of cases in hospitalized patients.<sup>156</sup> On renal biopsy, an interstitial cellular infiltrate is the hallmark of TIN. The infiltrate is predominantly mononuclear with T- and B- lymphocytes, macrophages, and natural killer cells.<sup>157</sup> Scattered neutrophils, eosinophils, basophils, and plasma cells are also present. The infiltrate results in interstitial edema, disruption of tubular basement membrane, and destruction of the interstitial architecture. Similar to glomerulonephritis, most forms of acute TIN are immune-mediated.<sup>158</sup> Although earlier investigations concentrated on humeral

mechanisms with deposition of antibody or antigen-antibody immune complexes in the tubular basement membrane, there is abundant evidence now to suggest that cell-mediated immune responses account for most cases of acute TIN.<sup>159–162</sup> Experimental studies demonstrate that renal tubular epithelial cells can process and present target antigens to T-cells, as well as strongly express Class II major histocompatibility complex (MHC) determinants when stimulated by pro-inflammatory cytokines such as interferon- $\gamma$  and tumor necrosis factor- $\alpha$ .

The clinical features of TIN are variable and in part depend on the inciting process.<sup>163</sup> In general, besides renal failure, disruption of the normal tubulointerstitial compartment will produce findings consistent with renal tubular dysfunction, including urinary concentrating defect, hyperchloremic metabolic acidosis, hypo- or hyperkalemia, and hypomagnesemia. Modest proteinuria can be present, but nephrotic range proteinuria is distinctly unusual and associated with use of only a few medications: NSAIDs, interferon- $\alpha$ , and methicillin.

### Drug-Induced Acute Tubulointerstitial Nephritis

Drug reactions are a major cause of acute TIN in patients with cancer because they are exposed to a large number of medications of different classes. The most commonly implicated agents are the penicillins, cephalosporins, and NSAIDs. It can be difficult to establish a direct link between a particular drug and ARF because patients typically receive a variety of potentially nephrotoxic medications, making it uncertain which is the responsible agent. Also, comorbid conditions that could cause renal dysfunction are usually present. Since renal biopsy to determine the etiology of ARF is not routine, the diagnosis of acute TIN is presumptive. Acute TIN occurs within days to a few weeks of exposure to a drug, and there is no relationship between its development and the cumulative dose. Most patients present with symptoms of edema, hypertension, diminished urine output, and renal failure. The classical manifestations of allergic phenomena such as skin rash, arthralgias, fever, and eosinophilia are present in only a minority of patients.<sup>164</sup> Occasionally, flank pain is a prominent feature of the presentation. The presence of urinary eosinophils is of limited utility in the evaluation of ARF.<sup>165</sup> The finding of eosinophils in the urine has a positive predictive value for diagnosing acute TIN of only 40%. Absence of urinary eosinophils is more helpful in excluding the diagnosis although the negative predictive value is still only 70%. Hansel (rather than Wright's) stain is the preferred method of detecting eosinophiluria.<sup>17</sup> Pyuria in the absence of an infectious organism (sterile pyuria) can be seen with acute TIN; however,

leukopenia can limit the appearance of white blood cells in the urine. Therefore, the diagnosis of acute TIN requires a high index of suspicion and knowledge of the potential causes. Clues to the presence of acute TIN are listed in Table 8.

Treatment of drug-induced acute TIN is cessation of the causative agent. Small case series have reported significant clinical response to corticosteroid administration.<sup>163,166,167</sup> There are no large, randomized, placebo-controlled trials to guide treatment. Given the potential side effects of corticosteroids, their use should be restricted to patients with progressive renal failure despite stopping the offending drug. Consideration of renal biopsy in these cases is strongly recommended because the clinical diagnosis of TIN is presumptive and the risks from corticosteroid use in critically ill patients are high. Drug-induced acute TIN has been associated with a wide spectrum of medications, as listed in Table 9.

#### Fluoroquinolones

All members of this class have been reported to cause acute TIN.<sup>164</sup> Typically, there is fever, rash, and eosinophilia, but no other systemic features of an allergic reaction. Granulomatous TIN has been reported, as well as necrotizing vasculitis of the skin, lung, bladder, and kidney.<sup>168</sup>

#### Vancomycin

Although the nephrotoxicity of vancomycin has been attributed to impurities in the older

RTA = renal tubular acidosis; TIN = tubulointerstitial nephritis.

preparations of the drug, there remains a small incidence of ARF associated with its use.<sup>169</sup> Vancomycin nephrotoxicity typically develops when administered in combination with other drugs, particularly aminoglycosides, and when given at higher-than-recommended doses. There may be some signs of a hypersensitivity reaction, such as skin rash and eosinophilia.

#### Rifampin

There are several reports of hypersensitivity reactions to rifampin associated with its intermittent use, manifesting as fever, nausea, diarrhea, and oliguric ARF.<sup>170</sup> Rifampin is associated with several immune-mediated phenomena. The drug acts as a hapten and results in antibody and immune-complex formation, and the subsequent development of interstitial nephritis with renal failure.<sup>171</sup>

#### Penicillins

Acute tubulointerstitial nephritis has been reported with all the penicillins.<sup>164</sup> Renal manifestations include hematuria, proteinuria, and oliguric ARF. Fever, rash, arthralgias, eosinophilia, pyuria, and eosinophiluria may also be present, particularly associated with the use of methacillin.

#### Cephalosporins

All generations of cephalosporins produce nephrotoxicity. Most cases involve direct toxicity to the renal tubular cells, resulting in ATN. In addition, cephalosporins can produce hypersensitivity reactions with skin rash, fever, eosinophilia, hematuria, and TIN.<sup>163,164</sup> In some reports, renal failure was the only finding. Cephalosporins are structurally similar to the penicillins, and cross-reactivity has been reported in 1 to 20% of patients.

## Infective Tubulointerstitial Nephritis

### Bacterial Infection

Bacterial pyelonephritis may result in ARF.<sup>172</sup> This occurs most commonly in the setting of an ascending urinary tract infection superimposed on obstructive nephropathy. In patients with urinary tract infection or pyelonephritis who develop ARF, urgent imaging of the kidneys and urinary tract is necessary to exclude the presence of obstruction. Acute renal failure as a result of pyelonephritis can also occur in the absence of urinary tract obstruction. Occasionally, renal involvement results from hematogenous spread. In such cases, blood cultures are frequently positive, and there may be evidence of overt sepsis. Clinical distinction from ATN secondary to septicemia and septic shock may therefore be difficult. Renal histopathologic findings reveal an acute polymorphonuclear infiltrate in the interstitium with microabscess formation.

The prognosis in acute bacterial TIN is significantly worse than for ATN. Whereas patients with ATN are expected to make full recovery, bacterial TIN often progresses to severe interstitial scarring and progressive chronic renal failure. Patients require prolonged antibiotic treatment to eradicate the infection and close monitoring to minimize chronic progressive renal damage.

### Renal Candidiasis

Mucosal ulceration and long-dwelling intravascular catheters are major risk factors for invasion of the blood stream by *Candida* species. Other important risk factors include prolonged hospitalization, prior exposure to antimicrobial agents, corticosteroid therapy, the postoperative state, surgical wounds, chronic indwelling urinary catheters, and underlying malignancy. The kidneys are particularly vulnerable to candidal invasion. The presence of hyphae in the urine does not have diagnostic significance, while the absence of pyuria does not rule out a diagnosis of renal candidiasis especially in the severely neutropenic patient. Therefore, a positive culture of *Candida* from urine in the septicemic patient is considered as proof of renal candidiasis.<sup>173</sup> The *Candida* organisms progressively penetrate the renal parenchyma, forming hyphae and microabscesses, especially in the cortical regions. Involvement of renal vasculature may result in renal infarction and papillary necrosis. Penetration of the organisms into the renal tubules may result in multiple sites of tubular obstruction, or the formation of large aggregates of fungi within the collecting system in the form of fungal balls or bezoars.<sup>174</sup> This complication should be suspected in the presence of flank pain and microscopic hematuria. *Candida* species differ in virulence capacity to involve the kidneys. *Candida albicans* and

*C. tropicalis* have the greatest propensity to cause widespread metastatic disease and renal invasion.

The patient with renal candidiasis usually presents with fever, candiduria, and unexplained progressive renal failure.<sup>175</sup> There usually are no symptoms referable to the kidneys, while there may be symptoms arising from involvement of other organs, including skin, mucosa, muscle, and eyes. Contrary to the case with bacterial urinary tract infections, there is no consensus as to the critical concentrations of candiduria required for a diagnosis of renal candidiasis. High colony counts may be a reflection of colonization rather than infection in patients with indwelling bladder catheters or nephrostomy tubes. Diagnosis is further complicated by the lack of any tests to localize infection to the kidneys. *Candida* casts are highly suggestive of renal infection but are an unusual finding. The presence of fungal bezoars in the upper urinary tract can be excluded with renal ultrasonography or other suitable imaging procedures. A useful diagnostic test in the catheterized patient with candiduria, bladder washings with amphotericin B will clear the urine of colonization but not renal candidosis.<sup>176</sup>

### Zygomycosis

Invasive zygomycosis (mucormycosis) occurs predominantly in immunocompromised patients. Patients present with bilateral flank pain, fever, hematuria, pyuria, and renal failure, with radiographic evidence of enlarged non-functioning kidneys.<sup>177</sup> Mortality is high, and nephrectomy is usually required along with systemic anti-fungal therapy.

### Adenovirus Infections

Opportunistic infections secondary to systemic adenovirus infection occur in immunocompromised patients. Adenovirus type II appears to have a predilection for urothelial membrane surfaces, and infections of the urothelium are frequent. As a result, adenovirus type II has been associated with urinary tract obstruction and hemorrhagic cystitis in this patient population. There are several reports of acute TIN with oliguric ARF in the setting of a severe of pneumonitis, hepatitis, meningoencephalitis, myocarditis, and hemorrhagic cystitis.<sup>178,179</sup>

### Polyomavirus (BK Type) Infection

Polyomaviruses are ubiquitous, usually acquired in childhood, and have a predilection for the urothelial surfaces. They have been associated with renal dysfunction and urinary tract obstruction from ureteral ulcerations and strictures. An acute TIN (BK nephropathy) has been reported in patients who received renal or bone marrow transplants.<sup>180</sup> The diagnosis of BK nephropathy

is suggested by the presence of inclusion-bearing cells in the urine (“decoy” cells) and the detection by polymerase chain reaction of BK virus DNA in the serum.

#### Epstein-Barr Virus Infection

Epstein-Barr virus (EBV) is associated with acute TIN and renal failure in both immunocompetent and immunocompromised patients.<sup>181</sup> Other renal lesions associated with EBV and infectious mononucleosis includes acute glomerulonephritis, hemolytic-uremic syndrome, and rhabdomyolysis-induced ARF.<sup>182</sup>

#### Disseminated Histoplasmosis

Immunocompromised patients can develop multiple organ failure from disseminated histoplasmosis. The disease usually follows a rapidly progressive course with a high mortality rate. Although uncommon, ARF does occur.<sup>183,184</sup> Biopsy specimens show aggregates of phagocytosed macrophages in the glomerular capillaries and the tubular interstitium.

### Prevention of Acute Tubular Necrosis

There currently exist no known therapeutic options to ameliorate ARF or hasten its recovery. Dialysis remains only a supportive measure to treat or prevent the metabolic and hypervolemic complications of renal failure. Therefore, prevention of ARF remains a keystone in the treatment of the critically ill patient.

#### Volume Resuscitation

Most cases of ARF are the result of multiple factors, including exposure to nephrotoxic agents and relative or frank renal hypoperfusion. Avoidance of potential nephrotoxins such as intravenous radiocontrast, aminoglycoside antibiotics, and anti-fungal agents, when possible, is prudent. Maintenance of adequate intravascular volume to preserve renal perfusion pressure is essential. Many cancer patients have capillary leak associated with the systemic inflammatory response syndrome (SIRS) resulting in severe interstitial edema and renal hypoperfusion. Often, these patients also are receiving intravenous vasopressor agents and positive pressure ventilation that further impair renal blood flow. How exactly to maintain effective arterial blood volume in such circumstances remains a contentious issue. Aggressive hydration with crystalloid solutions such as 0.9% sodium chloride can worsen interstitial edema and pulmonary function. Colloidal solutions, such as various starches and human albumin, might appear to be attractive alternatives, but there is little solid evidence that establishes their superiority in clinical trials.<sup>185–187</sup> Systematic reviews of randomized controlled

trials comparing crystalloids with colloids have yielded conflicting results. Some trials have found an increased mortality rate associated with the administration of human albumin and hydroxyethylstarch while others have not.<sup>188,189</sup> So despite the importance of fluid therapy in the prevention of ARF, the nature of the optimum fluid resuscitation regimen remains a disputed topic. For the time being, it appears that treatment of the underlying diagnosis, usually sepsis, and general supportive efforts, including ultrafiltration if necessary, are the mainstays of therapy.

In the critically ill patient, it is often difficult to predict when a potential insult to the kidneys will occur, making true prophylaxis difficult.

### Specific Measures

#### N-acetylcysteine

N-acetylcysteine (NAC) is an antioxidant and causes renal vasodilatation by generating increased levels of nitric oxide (NO). Based on these effects, NAC was used in several small human trials for the prevention of ARF from radiocontrast agents in high-risk individuals. The trials have shown that its administration results in a significantly smaller change in baseline serum creatinine values compared to changes in the placebo group.<sup>190,191</sup> However, whether or not NAC prevents severe ARF and the need for dialysis has not been determined. At this point, it is probably reasonable to provide NAC prior to radiocontrast administration in patients at risk for the development of ARF. However, no convincing data exist to support the routine administration of NAC in other clinical circumstances to prevent the development of ARF.

#### Low-Dose Dopamine

Low-dose dopamine administration (1-3 µg/kg/min) to normal individuals causes renal vasodilatation and increased glomerular filtration rate (GRF), and acts as a proximal tubule diuretic. Due to these effects, numerous studies have used low-dose dopamine to either prevent or treat ARF in a variety of clinical settings. It has been given as prophylaxis for ARF associated with radiocontrast administration, repair of aortic aneurysms, orthotopic liver transplantation, unilateral nephrectomy, renal transplantation, and chemotherapy with interferon.<sup>192,193</sup> Yet despite more than 20 years of clinical experience, prevention trials with low-dose dopamine all have been small, inadequately randomized, of limited statistical power, and with end-points of questionable clinical significance. Furthermore, there is concern for the potential harmful effects of dopamine, even at low doses. It can trigger tachyarrhythmias and myocardial ischemia, decrease intestinal blood flow, and suppress T-cell function.<sup>192–194</sup> It has also been shown to

increase the risk of radiocontrast nephropathy when given as prophylaxis to patients with diabetic nephropathy.<sup>195</sup> Therefore, the use of low-dose dopamine for renal protection should be abandoned.

#### Low-Dose Fenoldopam Mesylate

Fenoldopam mesylate is a pure dopamine type-1 receptor agonist that has similar hemodynamic effects to dopamine in the kidney without  $\alpha$ - and  $\beta$ -adrenergic stimulation. Limited trials suggest administration of fenoldopam mesylate reduces the occurrence of ARF from radiocontrast agents and from the repair of aortic aneurysms.<sup>196,197</sup> However, as in the case of low-dose dopamine, no randomized controlled trials exist to support its indiscriminate use and it should be restricted to well-designed clinical studies.

#### Diuretics

Furosemide is a loop diuretic and vasodilator that may decrease oxygen consumption in Henle's loop by inhibiting sodium transport, thus lessening ischemic injury. By increasing urinary flow, it may also reduce intratubular obstruction and backleak of filtrate. Based on these properties, furosemide might be expected to prevent ARF. However, few data support its use. Furosemide was found to be ineffective when used to prevent ARF after cardiac surgery, and was found to increase the risk of ARF when given to prevent contrast nephropathy.<sup>53,198</sup>

Mannitol is an osmotic diuretic that can also scavenge free-radicals. It may be beneficial when added to organ preservation solutions during renal transplantation and protect against ARF caused by rhabdomyolysis if given extremely early.<sup>199,200</sup> Otherwise, mannitol has not been shown to be useful in the prevention of ARF. In fact, mannitol may aggravate ARF from radiocontrast agents.<sup>195</sup>

#### Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP) causes vasodilatation of the afferent arteriole and constriction of the efferent arteriole resulting in an increased GFR. It also inhibits renal tubular sodium reabsorption. Most studies with ANP concern the treatment of established ARF. However, in two studies that administered ANP in renal transplant recipients to prevent primary renal dysfunction, no benefit was found.<sup>201,202</sup> As with low-dose dopamine and mannitol, one study suggested that ANP prophylaxis might worsen renal function in diabetic patients receiving radiocontrast material.<sup>195</sup>

#### Insulin-like Growth Factor-1

Insulin-like growth factor-1 (IGF-1) increases renal blood flow and induces cell proliferation

and differentiation. In addition, it reverses apoptosis. In animal models, it ameliorates renal injury associated with ischemia and may prevent injury following renal transplantation.<sup>203,204</sup> IGF-1 was given to a small group of patients in a single trial for prophylaxis of ARF following aortic aneurysm repair.<sup>205</sup> IGF-1 was started postoperatively in a randomized placebo-controlled fashion. It was well tolerated, and produced a modest increase in the creatinine clearance in the treated group compared to the placebo group. However, no patient developed ARF necessitating dialysis. Hence, the role, if any, for IGF-1 in the prevention of ARF remains unknown.

### Clinical Trials in the Treatment of Acute Tubular Necrosis

Effective treatment of ARF in critically ill patients is lacking despite substantial advances in the understanding of its pathogenesis at a cellular and molecular level. This lack of efficacy results from numerous factors: the multifactorial nature of ARF in the intensive care unit (ICU), reliance on changes in serum creatinine levels to detect changes in GFR, varying definitions of ARF, the high mortality rate of ICU patients in general, and the lack of consensus on the timing and appropriate form of acute dialysis. Although a wide variety of agents, including loop diuretics, low-dose dopamine, ANP, thyroid hormone, and IGF-1, are effective in animal models, they have not been effective in the treatment of ARF in the clinical setting.<sup>48,206</sup>

The reasons that these therapies have been highly effective only in animals remain speculative. Most human trials involve moderately or severely ill patients in the ICU with multiple organ failure, whereas animal models of ARF rely on a single mechanism of injury in otherwise healthy animals.<sup>207</sup> In addition, the time of the renal insult is known precisely in the models, allowing for early administration of the intervention. In clinical trials, on the other hand, therapy is delayed because of reliance on a change of the serum creatinine level to indicate ARF. By the time the serum creatinine concentration has increased, there has been a significant decline in the GFR and the renal injury has been present for a prolonged period. Timing of the intervention may be critical to its success. Very early in ARF, hemodynamic factors and oxidant injury may predominate, while, later, inflammation may play a more prominent role. Unfortunately, there still exists no easily available reliable marker of early ARF. Therefore, therapy of ARF remains primarily supportive.

### Low-Dose Dopamine

Numerous trials using low-dose dopamine to treat ARF suggest that its use is beneficial.<sup>192,193,208</sup>

However, most studies were either uncontrolled case series or small randomized trials with limited statistical power. More recently, a large randomized placebo-controlled trial in 328 critically ill patients with early ARF sufficiently powered to detect a small benefit was reported.<sup>209</sup> There was no effect of low-dose dopamine on renal function, need for dialysis, ICU or hospital length-of-stay, or mortality. These findings combined with the aforementioned potential deleterious effects of low-dose dopamine are strong arguments for abandoning its use entirely in ARF.

### Diuretics

In patients with ARF, several studies have found no benefit from loop diuretics.<sup>210–214</sup> Their use did not accelerate renal recovery, decrease the need for dialysis, or reduce mortality. It was shown that the mortality rate of oliguric patients who responded to furosemide with a diuresis was lower than those who did not.<sup>18,214</sup> However, the clinical characteristics, severity of renal failure, and mortality rates were similar in patients with either spontaneous non-oliguric ARF or patients who became non-oliguric after furosemide. This implies that those patients able to respond to furosemide are less sick and have intrinsically less severe renal damage than non-responders, rather than there existing any true therapeutic benefit to furosemide administration. Although administration of furosemide might improve fluid management if it induces a diuresis, a retrospective review of a recent trial in critically ill patients with ARF found diuretic use to be associated with an increased risk of death and non-recovery of renal function.<sup>215</sup> Most of the increased risk, however, was seen in those patients unresponsive to high doses of diuretics, implying they had more severe disease. Therefore, diuretics should be used with caution in critically ill patients. Diuretics should be withdrawn if there is no response. In patients who experience an increase in urine output, volume status must be closely monitored because the injured kidneys are susceptible to further damage from mild changes in perfusion pressure. To maintain the diuresis, a continuous infusion of drug is probably preferable to intermittent bolus administration.<sup>216</sup> Although there are no large randomized controlled trials, the overall evidence suggests that continuous infusion of diuretics as opposed to bolus administration is more effective and associated with less toxicity and delayed development of diuretic resistance.

### Atrial Natriuretic Peptide

ANP improved renal blood flow and GRF in an uncontrolled trial of 11 patients who developed ARF after cardiac surgery.<sup>217</sup> In an open-labeled trial, infusion of ANP to patients with ARF increased GFR and decreased the need for dialysis by nearly 50%.<sup>218</sup> Based on these results, a

randomized placebo-controlled trial of 504 critically ill patients with ARF was conducted.<sup>219</sup> Despite the large size of the trial, ANP administration had no effect on 21-day dialysis-free survival, mortality, or change in plasma creatinine concentration. Although a subgroup analysis of the study suggested that ANP might be beneficial in those patients with oliguric renal failure, a subsequent similar trial in patients with oliguric renal failure failed to demonstrate any benefit of ANP.<sup>220</sup> Hence, there is no convincing evidence to support the use of ANP in the treatment of ARF.

### Insulin-Like Growth Factor-1

Based on the positive effects of IGF-1 in animal models of ARF, a randomized placebo-controlled trial was conducted in 72 critically ill patients with ARF.<sup>221</sup> The results showed there was no difference in the two groups in post-treatment GFR, need for dialysis, or mortality. In anuric patients, IGF-1 administration was associated with a slower rate of improvement in urine output and GFR. So despite the ample evidence that IGF-1 accelerates renal recovery in animal models of ARF, there is no support for its use in humans.

### Thyroxine

The administration of thyroid hormone following the initiation of ARF in a variety of ischemic and nephrotoxic animal models was found to be effective in promoting recovery of renal function.<sup>222–225</sup> Based on these results, thyroxine was administered to 59 patients with ARF in a randomized placebo-controlled trial.<sup>226</sup> Patients were well matched in baseline characteristics. Administration of thyroxine had no effect on any renal parameter. However, the trial was terminated early because of a significantly higher mortality rate in the patients who received thyroxine.

### Renal Replacement Therapy

Dialysis initially entered clinical practice more than 50 years ago, yet there is no consensus on the appropriate timing for initiation of dialysis, the dose or intensity of dialysis, or the mode of dialysis (intermittent versus continuous) in patients with ARF. By tradition, clinical parameters such as severe electrolyte imbalance, pulmonary edema, intractable metabolic acidosis, azotemia (BUN > 100 mg/dL), and uremia are used as indications for starting dialysis, but these parameters may be inappropriate in the critically ill patient. No studies have clearly defined the optimal time to initiate dialysis. Retrospective trials done more than 30 years ago suggested that maintaining a BUN level below 150 mg/dL conferred a survival benefit.<sup>227,228</sup> In a later prospective trial, more intensive dialysis (maintaining the BUN level below 60 mg/dL compared to 100 mg/dL) did not

improve mortality.<sup>229</sup> Part of the problem is that the dialysis procedure itself may be harmful. Bleeding and infection from vascular access, and hypotension and arrhythmias from changes in volume, may complicate dialysis. Studies also show that the dialysis procedure may prolong the course of ARF.<sup>230</sup> Delayed recovery may result from hypotension or activation of an inflammatory cascade by the interaction of blood components with the dialyzer membrane.<sup>231</sup>

### Intensity of Dialysis

Once dialysis has been initiated, it has not been established how often and how long it should be prescribed. In other words, what is the optimal intensity of dialysis that provides the patient the benefits of the procedure without exposure to undue risk? Equally germane to the issue is identifying appropriate end-points to define “adequate” dialysis in an ICU patient. Survival rate appears most relevant. However, given the severity of the patients’ comorbid diseases, it may be unrealistic to expect that various intensities of dialysis will impact mortality, or at the very least, to expect clinical trials to be powered sufficiently to prove any effect. Currently there is interest in applying some form of measuring urea removal in patients with ARF to define dialysis adequacy analogous to the circumstance in chronic outpatient dialysis. The National Cooperative Dialysis Study demonstrated that morbidity and hospitalization rates were inversely related to the amount of urea removal per treatment in chronic, stable hemodialysis patients.<sup>232</sup> Whether such a relationship exists in acutely ill patients with higher urea generation rates because of hypercatabolism is unknown. Recent trials have begun to address this issue. A study from the Cleveland Clinic showed a link between dialysis intensity and outcome in ICU patients when underlying comorbidity was accounted for using the Cleveland Clinic Severity of Illness Score.<sup>233</sup> Dialysis had no effect on the outcome of patients with low or high severity scores, but a beneficial effect in those with intermittent scores. Higher delivery of dialysis as measured by the reduction of urea concentration was associated with a significant decrease in morbidity when compared to low dose delivery in patients with an intermediate severity score. A more recent study in 72 critically ill patients with ARF randomized to daily or alternate day dialysis reported improved survival with the more intense regimen.<sup>234</sup> However, in this study, the dose of dialysis per session was significantly lower than what would be considered adequate for a stable patient on chronic hemodialysis. It thereby proves that under-dosing dialysis in a critically ill patient is detrimental, but failed to define what should be considered adequate for such patients. Although one could take the position that more dialysis is better, given the aforementioned risks associated

with dialysis, that attitude may be cavalier. In fact, in a trial of chronic renal-failure patients, increasing the dose of dialysis beyond what is currently considered adequate conferred no additional benefit to patients.<sup>235</sup> Therefore, “excessive” dialysis in critically ill patients may only increase the exposure to risk without imparting any additional benefit. Until these issues are resolved by ongoing clinical trials, it seems prudent to rely on clinical parameters such as electrolyte and acid-base balance, control of volume overload, and avoidance of azotemia (maintaining the BUN below 60 mg/dL) to guide dialytic therapy.

### Mode of Dialysis

In the past, intermittent hemodialysis (IHD) was the treatment of choice for ARF. However, as a result of the rapid solute removal and large volume shifts associated with its use, patients with hemodynamic instability poorly tolerate it. Because of the risk of hypotension and the possibility of prolonging ARF, newer modes of dialysis to minimize hypotension have been devised. Continuous renal replacement therapy (CRRT) removes solute and fluid at a much slower rate than IHD, thus minimizing hypotension.<sup>236,237</sup> Use of CRRT was originally reserved for patients with hemodynamic instability or massive fluid overload who could not otherwise tolerate IHD. Although dialysis was usually successful in such patients, the mortality rate remained high due to the underlying severity of illness. Given the better hemodynamic profile of CRRT, as well as potentially better solute clearance and removal of inflammatory cytokines, it was thought that CRRT would lead to better outcomes in critically ill patients who could otherwise tolerate IHD.

CRRT and IHD have been compared in a number of non-randomized or retrospective trials that have championed CRRT as the modality of choice in critically ill patients. However, prospective or randomized trials comparing IHD and CRRT have not found CRRT to confer a better outcome.<sup>238,239</sup> This somewhat surprising finding may be the result of studying critically ill patients where multiple factors play a role in the ultimate outcome. For now, it appears that IHD and CRRT are equivalent methods of treatment for ARF in the ICU.

There is also interest in using CRRT for non-renal indications, including sepsis and acute respiratory distress syndrome (ARDS).<sup>240</sup> It is based on the assumption that dialytic removal of inflammatory cytokines such as TNF- $\alpha$  and interleukins improves survival.<sup>241</sup> Small trials suggesting CRRT is beneficial all have serious methodological flaws. In addition, although cytokines can be removed by filtration and/or absorption to the filter, the actual quantity is low compared to endogenous clearance.<sup>242</sup> Clearance is also indiscriminant and can remove cytokines that may be beneficial in the face of critical illness.

Until adequate clinical trials are completed, the use of CRRT for non-renal indications cannot be recommended.

### Summary

In cancer patients, renal failure has become a difficult problem to prevent, diagnose early, and ultimately treat. The number of cancer survivors is rising and chronic kidney disease is too often the result of ARF, especially from nephrotoxic injury sustained during chemotherapy. To date, there is little data supporting prophylactic measures against ARF except volume expansion to prevent toxic nephropathy from contrast and chemotherapy. Even less clinical data is available in the treatment of established ARF. It is important to understand dialysis is not a therapy for ARF but simply a therapy to control the metabolic and volume complications associated with ARF. Unfortunately, to date, there are no large randomized trials to help define when dialysis should be started, what type of dialysis should be used, or for how long dialysis should be done in this patient population. With this in mind, the prevention of ARF becomes the best hope of a successful renal outcome in the treatment of cancer patients. To this end, it is important to recognize the potential risk factors for ARF, to diagnose ARF quickly, and work towards a rapid resolution of the renal insult.

# Urinary Tract Infections

Diana I. Jalal, MD

B.V.R. Bhamidipati Murthy, MD

Urinary tract infection (UTI) is the most common bacterial infection in the general population and is also a common clinical problem in cancer patients. While UTI affects all ages, significant differences are seen in age prevalence between the two sexes. While it is common at all ages in females, it occurs mostly at extremes of life in males. Patients with structural or functional abnormalities of the urinary tract, patients who are immunosuppressed, such as transplant recipients and cancer patients on chemotherapy, are particularly susceptible to UTI. UTIs are classified either according to the anatomic site—bladder (cystitis) or kidney (pyelonephritis)—or into uncomplicated or complicated (Table 1). Although the definitions of uncomplicated and complicated UTIs vary depending on the source of the definition, most agree that an acute uncomplicated UTI is typically an episode of acute cystitis or pyelonephritis that occurs in a young, healthy, non-pregnant woman with no functional or anatomic abnormalities of the urinary tract. It is also reasonable to consider UTIs that occur in healthy, ambulatory, postmenopausal women as uncomplicated. Similarly, episodes of acute cystitis that affect healthy young men are classified as uncomplicated by some, although this is more controversial.<sup>1</sup> A complicated infection is associated with an underlying condition that increases the risk for acquiring a UTI or that is likely to be associated with failing antimicrobial therapy.<sup>2</sup> Considering this definition, UTI in cancer patients should be considered complicated when it occurs as a result of suppressed immunity. The epidemiology and prevalence of UTI in cancer patients are not established; it is believed that the pathogenesis and treatment issues of UTI in cancer patients are no different from those in the general population. Hence, this review will primarily discuss UTI as it occurs in the general population. In addition, unique urinary tract infections that occur in certain specific situations in cancer patients such as patients on intensive chemotherapy and bone marrow transplantation (BMT) recipients will be discussed in more detail.

Traditionally, infection of the upper urinary tract has been termed “pyelonephritis,” which indicates that there is inflammation of renal

parenchyma as well as pelvis of the kidney in this condition. However, from a clinical standpoint, this term refers to a disorder of the kidney resulting from bacterial invasion. While this simple characterization amply describes acute pyelonephritis, the role of bacterial infection in chronic pyelonephritis is more complex. It is unusual for bacterial infection alone to cause chronic damage to the kidney, and in almost all of these patients, there is either a demonstrable urinary tract abnormality such as vesicoureteral reflux (VUR) or an anatomic obstruction to the flow of urine. Since chronic pyelonephritis is not a common problem in cancer patients, this review will restrict the discussion of upper urinary tract infection to acute pyelonephritis. Similarly, the long-term effects of UTI, such as chronic renal disease, hypertension, or both, and its effects on longevity and survival will not be discussed. Urinary tract obstruction and its management as it relates to cancer patients are discussed in another chapter (see Chapter 49, “Urologic Disorders”).

## Epidemiology of UTI

Surveys of office practice and general hospital admissions in the United States estimate that approximately 7 million episodes of acute cystitis, and at least 250,000 episodes of acute pyelonephritis, occur per year.<sup>2,3</sup> After infancy, and until age 55, UTI is predominantly a female disease occurring most often in sexually active women.<sup>4</sup> The frequency of UTI after infancy and until 10 years of age is about 1.2%. Approximately 1 to 3% of women between the ages of 15 and 24 years have bacteriuria; the incidence increases by 1 to 2% for each decade thereafter, up to a level of

about 10 to 15% by the 6th or the 7th decades. Approximately 40 to 50% of women will have at least one UTI in their lifetime.<sup>5</sup>

The incidence of UTI in men under the age of 50 years is much lower than in women, ranging from 5 to 8 in 10,000 men annually.<sup>6,7</sup> As the aging process progresses and prostatic disease becomes more common, the frequency of UTI in men rises dramatically.<sup>5</sup> The frequency of bacteriuria in the elderly non-catheterized patient lies somewhere between 11 and 15%. Despite the fact that most of these resolve spontaneously, genitourinary infections are the second most common cause of infections in this patient population.<sup>4</sup> With the onset of chronic debilitating illness and long-term institutionalization, bacteriuria rates in both sexes reach 15 to 50%, the incidence in women here being only slightly higher than in men.<sup>5</sup>

Unfortunately, little data exist that can shed light on the epidemiology of complicated UTIs. UTIs are the most common nosocomially acquired infections, accounting for 42% of all nosocomial infections.<sup>8</sup> A recent European study reported a general incidence of nosocomially acquired UTI of 3.55 per 1,000 patient hospital days.<sup>9</sup> The most important identified risk factor for developing a nosocomial UTI is the presence of an indwelling urinary catheter. Catheter-related infections account for more than one million cases in hospitals and nursing homes.<sup>10</sup>

Other populations at increased risk include pregnant women, patients with paraplegia or quadriplegia as a result of spinal cord injuries, and recipients of kidney transplants. The reported incidence of a urinary tract infection in kidney transplant patients ranges between 35% and 79% if antimicrobial prophylaxis is not administered.<sup>11,12</sup>

## Pathogenesis of Urinary Tract Infections

### Microbial Virulence Factors and Host Defenses

Normally, the urinary tract is sterile and well protected against microbial infection. In the past, host susceptibility to UTIs has been studied in

**Table 1** Classification of Urinary Tract Infections (UTI) in Adults

Young women with acute uncomplicated cystitis
Young women with recurrent cystitis
Young women with acute uncomplicated pyelonephritis
All adults with complicated UTI
All adults with asymptomatic bacteriuria

patients with structural or functional abnormalities; however, most patients with UTIs have no such abnormalities. Recent research has focused on the host behavioral factors, in addition to genetically determined cellular mechanisms that predispose to sporadic and recurrent UTI.<sup>13</sup>

Most of the urinary pathogens enter the urinary tract by ascending through the urethra into the bladder. They typically originate from the fecal flora, although the importance of the vagina as a bacterial reservoir and a source of pathogens in women has recently become appreciated.<sup>13</sup> *Escherichia coli* is the most common pathogen, and hence, the best characterized. Not all strains of fecal *E. coli* are capable of infecting the urinary tract; certain distinctive properties are needed to enable these microorganisms to overcome the local host defenses and invade the urinary tract.

### Pathogen Factors

As mentioned above, few clones of *E. coli* that colonize the gastrointestinal tract possess the ability to spread to the urinary tract and to produce clinically notable disease, these clones are termed uropathogenic *E. coli* (UPEC).<sup>14</sup> They possess genes encoding a diverse array of specialized properties that are thought to contribute to virulence, the so-called “virulence factors.” Clinical isolates from patients with cystitis and pyelonephritis are commonly derived from *E. coli* groups that express a limited range of distinctive O, K, and H antigens.<sup>15</sup> O antigens (surface cell wall antigens) O1, O2, O4, O6, O7, O16, O18, and O75 are expressed in 80% of UPEC. The capsular polysaccharide (K antigens) particularly K1, K2, K5, K12, K13, and K51 are antiphagocytic.<sup>14</sup>

Gram-negative bacteria carry adhesins, most commonly fimbriae with lectin-like domains that recognize oligosaccharide epitopes on cell surface glycolipids or glycoproteins. The resulting specific adherence not only promotes colonization but has also been identified as the most important virulence factor these bacteria possess.<sup>16</sup> There is strong epidemiologic evidence linking the adhesins with disease severity.<sup>17,18</sup> Adherence to the uroepithelium allows bacteria to resist the flushing action of the urine flow and bladder emptying, as well as facilitates tissue attack and invasion.<sup>16</sup> It is also felt to be the primary enhancer of cytokine responses by the host cells.<sup>13</sup> Most *E. coli* adhesins are fimbrial, but some are amorphous fibers, or capsule-like. Irrespective of morphology, adhesins contain defined molecular regions that interact with specific host receptor epitopes. In most cases, the bulk of each fiber is composed of nonadhesive structural subunits, whereas the adhesin is attached to the tip of the fiber.

These adhesins are categorized according to receptor specificity to mannose-sensitive and mannose-resistant. The mannose-resistant adhesins are more diverse and further subdivided into various families. Mannose-sensitive adhesins

in *E. coli* consist of type 1 fimbriae, also known as common pili, since they are present in almost all *E. coli* and broadly among other Enterobacteriaceae.<sup>15</sup> Type-I pili are composite fibers consisting of a long thick cylindrical rod joined at the distal end to a short thin tip fibrillum (FimH).<sup>19</sup> Type-I pili bind to the mannose-containing glycoproteins present on the bladder epithelial surface and are critical to the establishment of cystitis.<sup>20</sup> Immunization against the type I fimbrial adhesin molecule FimH has been shown to be protective against experimental UTI in mice and monkeys.<sup>21,22</sup> Of the mannose-resistant adhesins, the best-known group is the P fimbriae family. They are named as such due to their ability to bind specifically to Gal(1-4)Gal B disaccharide galabiose, which is present within the antigens of the human P blood system.<sup>15</sup> These receptors predominate in the kidney. Consequently, P pili have been shown to be critical in the ability of *E. coli* to cause pyelonephritis. They also are associated with sepsis as well as the development of prostatitis.

Other virulence factors include siderophores (which allow for iron acquisition), toxins produced by the bacteria (such as alpha hemolysin), and protectin, a polysaccharide coating that interferes with phagocytosis and protects against complement-mediated opsonization or lysis.<sup>15</sup>

In addition to the different virulence factors, certain *E. coli* enzymes may contribute to bacterial virulence in nutrient-limited environments by allowing the biosynthesis of essential metabolites. Two examples are *guaA* and *argC*, which participate in the synthesis of guanine and arginine, respectively.<sup>23</sup> Due to its toxic effect, lipopolysaccharide (LPS) should be considered when discussing virulence factors. LPS, which is a structural component of *E. coli*, interacts with Toll-like and other receptors in the host cell initiating signal transduction cascades that stimulate cytokine and chemokine synthesis.<sup>15</sup>

### Local Defenses

In women, estrogen stimulates the vaginal mucosa to grow and proliferate, thereby providing a sloughing mechanism for the removal of the bacteria. It also results in conditions that aid the cultivation of lactobacilli in the vaginal vestibule. These organisms create an environment with an acidic pH, which is particularly hostile for the Enterobacteriaceae, and which inhibits bacterial proliferation.

Other vaginal factors include the presence of certain types of cell surface antigens, such as the Lewis blood group. This exists at two genetic loci: *Lea*, and *Leb*. Patients who are *Le(a+b+)* and *Le(a-b+)* are referred to as secretors and have a lower incidence of UTIs compared to the nonsecretors, who are *Le(a+b-)* and *Le(a-b-)*.

Local defenses in the male are different and appear to be more effective. The most notable is

length of the urethra and the mechanical action of urine flow.<sup>24</sup> In males who are circumcised, this mechanical clearing appears to be enough to prevent the occurrence of UTI.<sup>25</sup> In addition, the prostate gland elaborates several proteins that have significant antibacterial effects, such as prostate antibacterial factor (PAF), spermine and spermidine. When an inflammatory process overwhelms host defenses, these substances are reduced, and the risk of infection may be increased.

The urine itself possesses several characteristics that render it inhibitory to bacterial growth. Low osmolality inhibits bacterial proliferation, as does high osmolality coupled with a low pH.<sup>24</sup> Furthermore, certain substances in the urine, such as urea, inhibit bacterial growth and proliferation.<sup>13</sup> In addition, urine contains a variety of oligosaccharides and glycoproteins with receptor affinity. For example, Tamm-Horsfall glycoprotein is produced by the tubular cells in the ascending loop of Henle and the convoluted tubule and is secreted into the urine. It helps combat bacterial infections in the urinary tract via several mechanisms. It has a receptor for type I pili of *E. coli*, thus functioning as a mechanical barrier to bacterial binding and facilitating removal of the organism from the urogenital tract.<sup>26,27</sup> Additionally, Tamm-Horsfall protein binds to polymorphonuclear leukocytes (PMNs) enhancing their phagocytic function and complement expression.

The ureter also plays a role in protecting the urogenital tract from infection, namely through its peristaltic activity. The significance of this activity is evident when ureteral peristalsis is impaired, such as in pregnancy or obstruction. There are factors within the kidney itself that help protect the host against UTI; for example, 10,000 times the bacterial load needed to initiate infection in the renal medulla would be needed to initiate infection in the renal cortex when bacteria are directly injected into the kidney. This is thought to be due to the relatively reduced blood supply to the medulla and concomitant hypoxia, both of which reduce the immune response.<sup>24</sup>

The role of the immune system in protection against UTI is not well-characterized. Patients who are known to have an ineffective immune system, such as diabetics, transplant recipients, and patients receiving corticosteroids, have an increased number of UTIs.<sup>14</sup> The local immune response is primarily mediated by PMNs. Despite the fact that these cells play no role in the prevention of the initial phase of the infection, they do appear to limit tissue invasion. The adherence of the bacteria to the uroepithelium is followed by PMN activation and their immediate appearance in the urine. They are recruited by certain cytokines and other chemoattractants, after which they undergo transepithelial

migration to the site of bacterial colonization. Through the mannose residues on the surface of the PMNs, they are able to bind the bacteria leading to phagocytosis and removal.<sup>24</sup>

The protective role of the humoral immune response and that of acquired resistance is more controversial, despite the reported specific antibody response that accompanies UTI. This response is typically noted 7 to 10 days after the onset of the infection, with the magnitude of antibody appearance being greater in pyelonephritis than in cystitis. The main protective function of the antibodies applies to deep parenchymal bacterial infection in pyelonephritis, thus serving to reduce local tissue damage and prevent the spread of the bacteria.<sup>13</sup>

Although T cells are locally and systemically activated as a consequence of UTI, the role cell-mediated immunity plays in protecting against infection remains to be determined.<sup>14</sup>

### A Dynamic Interaction

The early phase of any bacterial infection is a battle between the innate defenses of the host and the virulence factors elaborated by the infecting pathogen.<sup>19</sup> The initial phase of cystitis involves UPEC adhering to the bladder surface epithelium. This incites a variety of events within the host uroepithelial cells. The first event involves the invasion process, which results from the direct interaction between FimH and host cell signaling cascades, leading to host cell cytoskeleton rearrangements and the internalization of the adherent *E. coli*.<sup>19,28</sup> The second event triggered by this interaction is exfoliation of the superficial bladder epithelial cells, which occurs via an apoptotic-like mechanism that involves activation of caspases and cysteine proteases and DNA fragmentation.

The bacterial cells, however, do not wait for their impending clearance by exfoliation; instead, they have been noted to replicate yielding disorganized bacterial clusters termed “bacterial factories.” UPEC can then flux out of the dying cell before the completion of exfoliation, thereby allowing bacteria to escape this innate host defense mechanism. This allows for persistence of the bacteria in the bladder for several months, without being shed in the urine.<sup>29</sup> In fact, these bacteria have been shown to form intracellular biofilms, creating pod-like protrusions on the bladder surface. These pods contain the bacteria encased in a polysaccharide-rich matrix surrounded by a protective shell of uroplakin. Thus, in addition to the intestine and the vagina, the bladder itself may serve as a reservoir for UPEC and a source of recurrent cystitis seen in a large portion of young women after the first episode of cystitis.<sup>30</sup>

The third series of events, which appears to be induced directly by the interaction between the bacterial adhesins and their specific cell-surface epitopes, is cytokine and chemokine production.

For example, the interaction between the P-fimbriae and their specific motif on the uroepithelial cell surface leads to activation of several signaling pathways, such as the ceramide signaling pathway, which is involved in the induction of cytokine responses. They also recruit Toll-like receptor-4 (TLR-4) and activate the accompanying signaling pathway. Whether LPS participates in triggering host response mechanisms remains unclear. There are studies supporting a role for LPS in epithelial cell activation, and others suggesting direct activation of these cells via the fimbriae independent of LPS. Among the evidence for P-pili-dependent activation of the host response, individuals were subjected to intravesicular inoculation with either a nonfimbriated asymptomatic bacteriuria strain or transformed asymptomatic bacteriuria strains expressing P-fimbriae. The latter group were found to have invariably higher Inter-Leukin (IL)-8 and IL-6 levels and greater neutrophil responses in the urinary tract as compared to the non-transformant group.<sup>31</sup>

On the other hand, type-I fimbriae *E. coli* are capable of activating the host cell responses, and have been shown more consistently to incite these responses through an LPS and TLR-4-dependent activation signal.<sup>16,32</sup> Of note, this was thought to occur despite the fact that epithelial cells are CD-14 negative and thus have a poor response to LPS.<sup>31</sup> Recently, however, there is evidence that CD-14 (which is part of the receptor complex for LPS) is expressed on the bladder epithelial cell surface, and is required in association with a TLR for these cells to respond to LPS and type-I fimbriated *E. coli*. This response appears to be mediated by the activation of nuclear factor kappa B (NF- $\kappa$ B) and p38 mitogen-activated protein kinase (MAPK) signaling pathways.<sup>20</sup> Regardless of the exact mechanism by which bacteria trigger the cascade of innate responses, once the intruder is recognized, proinflammatory cytokines and chemokines such as IL-1, IL-6, and IL-8 are produced and lead to the recruitment and the activation of inflammatory cells.<sup>19</sup>

As indicated in the prior section, neutrophils are crucial for bacterial clearance from the kidneys and the bladder.<sup>33</sup> In response to the chemotactic gradient, neutrophils leave the circulation, traverse the submucosa, and reach the epithelial barrier. The last step of exit to the lumen, transepithelial migration is aided partially by epithelial intercellular adhesion molecule 1 (ICAM-1), as well as by IL-8. A role for IL-8 in neutrophil recruitment was suggested by the strong correlation between the urinary IL-8 levels and the urinary neutrophils numbers in individual patients.<sup>34</sup> It is now appreciated that IL-8 is the main chemokine involved in neutrophils migrating across infected epithelial cells in vitro. In vivo studies in the murine UTI model have identified macrophage-inflammatory protein-2 as an epithelial IL-8 equivalent in the mouse urinary tract.

In the IL-8 receptor knockout mouse, neutrophils fail to cross the epithelial barrier and accumulate in the tissue in massive numbers resulting in abscess formation and extensive fibrosis.<sup>35,36</sup> Use of anti-IL-8 antibody reduces neutrophil migration across the epithelial cell layers indicating its central role in this process.<sup>34,37</sup> These interactions explain the emergence of leukocytes in the urine, known as pyuria, which is a clinically utilized sign in the diagnosis of UTI.

### Host Risk Factors Predisposing To UTI

The host factors predisposing to UTI are shown in Table 2. Each of these will be discussed in more detail here.

#### Obstruction

Obstruction to the urinary tract, whether acute or chronic, leads to an increased risk of UTI.<sup>38</sup> A noted increase in the incidence of UTI is associated with obstruction in male infants, female children, pregnancy, as well as with calculi, bladder neck obstruction, and extrinsic compression of the ureters (tumors or retroperitoneal fibrosis). All these conditions are accompanied by a high incidence of pyelonephritis.<sup>13</sup> Several proposed mechanisms may account for this, including that obstruction results in decreased urinary flow and reduced efficiency of micturition, impairing clearance of the bacteria from the genitourinary tract.<sup>38</sup> Bladder over-distention may interfere with local mucosal defense mechanisms. Increased residual volume also predisposes to, and maintains, bladder infection by providing a continuous pool of media suitable for bacterial growth, and thus may enhance multiplication of the bacteria in the urine, as well as increase the capacity of the bacteria to multiply in the renal parenchyma, allowing the infection to be transmitted from one part of the kidney to another. Proof for the importance of obstruction in the pathogenesis of UTI is derived from the animal model of experimental hematogenous pyelonephritis, in which the kidney appears relatively resistant to infection, unless the ureter is ligated.<sup>13</sup>

#### Diabetes Mellitus

Although it has been shown that bacterial growth is enhanced by high glucose content in the urine, patients with diabetes who have no neurologic complications affecting bladder function and

**Table 2** Host Factors Predisposing to Urinary Tract Infections

Urinary tract obstruction
Diabetes mellitus
Advanced age
Immune compromised state
Urologic interventions

who have not undergone instrumentation are not at greater risk for developing UTI. Following instrumentation, however, or in the presence of autonomic neuropathy, ascending infection is more common and usually more severe.<sup>13</sup>

#### Advanced Age

Aging is associated with an increased prevalence of bacteriuria, occurring in 10% of men, and 20% of women over the age of 65. Possible reasons for the higher incidence of UTI include poor bladder emptying, loss of bactericidal effect of the prostate in elderly men, uterine prolapse and cystocele in elderly women, neuromuscular disease, and the risk of increased instrumentation in both genders.<sup>13</sup>

#### Immunocompromised Host

When considering the susceptibility of different populations of immune-suppressed patients to a particular form of infection, it is important to realize that such susceptibility is not caused by one factor, but is likely due to several factors interacting in an individual patient. It is determined by the underlying disease, the dose and duration of the immunosuppressive therapy, and the presence or absence of granulocytopenia.<sup>39</sup> These factors may play an important role in the increased susceptibility, and hence increased incidence of severity, of UTI in cancer patients. The interaction of certain therapies with any pre-existing immune abnormality makes it extremely difficult to establish a pathophysiology underlying the types of infections encountered in these patients. However, some disease processes are felt to be associated with increased infection susceptibility due to immune defects associated with the disease itself rather than the therapy. One potential example of this is multiple myeloma, since almost all the episodes of gram-negative bacteremia in these patients seem to occur in non-granulocytopenic individuals.<sup>40</sup> Most infections occurring in such patients involve the urinary, as well as the respiratory, tracts. Globally, up to 55% of the nosocomial infections affecting this group of patients are urinary tract infections, with *E. coli* being the most frequently isolated microorganism.<sup>40</sup>

Although neutropenia in and of itself does not appear to predispose the individual patient to acquiring a urinary tract infection, it blunts the clinical manifestations of an acquired infection, and predisposes the patient to bacteremia.<sup>41</sup> In one report, out of 56 patients with underlying malignancy and vancomycin-resistant enterococcus (VRE) infection (90% of whom had hematologic malignancies), 71% had bacteremia, whereas only 14% had a urinary infection.<sup>42</sup>

Broad-spectrum antibiotics play an important role in the compromised host, since they can alter the normal bacterial flora in the periurethral

area suppressing the growth of the lactobacilli leading to a greater incidence of colonization with resistant pathogenic microorganisms. They also predispose to fungemia with hematogenous seeding of the urinary tract.<sup>41</sup>

Surgical trauma, drainage catheters, chemicals, and certain diseases can breach the integrity of the mucopolysaccharide lining of the bladder mucosa, providing a nidus for infection and a conduit for bacterial invasion.

Other factors, such as malnutrition, have been independently associated with an increased risk of nosocomially acquired infections.<sup>43</sup> In addition to uremia, hyperglycemia and the potential immunomodulating effect of certain viral infections (such as cytomegalovirus [CMV], Epstein-Barr virus, and human immunodeficiency virus [HIV]) may contribute to weakening the host defenses. Thus, it is not surprising that infection by low virulence microorganisms becomes much more common once the immune system and/or the integrity of the urinary tract is compromised.<sup>39</sup> In fact, most of the *E. coli* isolated from compromised patients with a urinary infection are negative for P-fimbriae.<sup>44</sup> Further, most *E. coli* strains isolated from patients with a catheter-related urinary infection do not carry the virulence genes that *E. coli* from patients with community-acquired UTIs carry.<sup>45</sup>

#### Urologic Procedures

Patients subjected to urologic procedures pose a special risk for developing UTIs. Any drain from the urinary tract to the external surface will increase the risk—the longer the catheter has been in place, the greater the risk.<sup>46</sup> The risk of infection varies further with the type of surgery; when the surgery is carried out on infected tissue or in a patient with an infected stone, then infection is almost inevitable. Deposition of implants such as stents and other foreign bodies also increases the risk.<sup>46</sup> Not surprisingly, the most commonly reported complication of urinary diversion procedures is urinary tract infection, occurring in 35 to 40% of patients undergoing such procedures.<sup>39,47,48</sup> This high rate is not surprising when taking into account the high likelihood of other complications associated with these procedures, such as ureteral strictures (11%), incontinence (9%), and urinary stone formation (7%).<sup>47</sup> The renal calculi that accompany such diversion procedures are usually composed of calcium and struvite, and the concomitant infection is classically due to *Proteus* spp.<sup>38</sup> Of note, urine cultures from these patients are difficult to interpret because of the interference from residual bowel flora.<sup>49</sup>

#### Microbiology

The spectrum of etiologic agents is similar in uncomplicated upper and lower UTI, with *E. coli*

being the causative pathogen in 80 to 85% and *Staphylococcus saprophyticus* in 5 to 20% of cases.<sup>50</sup> Occasionally, other Enterobacteriaceae, such as *Proteus mirabilis* and *Klebsiella* spp or enterococci are isolated. However, the spectrum of pathogens causing a complicated UTI is much broader than that causing an uncomplicated infection. While *S. saprophyticus* is rarely seen in patients with a complicated UTI, several microorganisms are relatively more common in this group of patients, including *Proteus*, *Klebsiella*, *Pseudomonas*, and *Serratia*, in addition to the *Enterococci*, *Staphylococcus*, *Citrobacter*, and certain fungi.<sup>1</sup> One report from Germany on nosocomially acquired UTIs found *E. coli* to be the most common pathogen accounting for 32% of these infections in 2001, followed by *Enterococcus* spp in 22% of patients, and coagulase-negative staphylococcus in 10%.<sup>51</sup> It has been noted that other microorganisms have become more common over the past two decades, such as yeast and *K. pneumoniae*.<sup>52</sup>

These uropathogens, including *E. coli*, are more likely to be resistant to the commonly used antibacterial agents in the immunocompromised host, where bacterial pathogens remain the most common cause of infection.<sup>8</sup> For example, with the advent of antimicrobials and the increasing use of cephalosporins, increasing rates of colonization and infections with *Enterococci*, particularly VRE, are occurring. These microorganisms typically colonize the intestinal tract, the respiratory tract, and vagina of otherwise healthy individuals. *Enterococcus faecalis* and *Enterococcus faecium* are responsible for 85 to 90% and 5 to 10% of infections in humans, respectively. UTI is the most common nosocomial infection caused by these microorganisms. VRE, especially *Enterococcus faecium*, is prevalent in hospitalized individuals across the United States. The reported prevalence of VRE colonization in the urine varies according to the center, ranging from 1 to 26% in one study, with *Enterococcus faecium* accounting for about 88% of all VREs isolated.<sup>53</sup>

## Clinical Syndromes and Diagnosis

### Asymptomatic Bacteriuria

Asymptomatic bacteriuria is defined as the isolation of bacteria from the urine in significant quantities consistent with infection (greater than or equal to 10<sup>5</sup> colony forming units (CFU)/mL) preferably on two occasions, but without the local or systemic symptoms and signs.<sup>4,54</sup> Although asymptomatic bacteriuria commonly precedes a UTI, with an estimated prevalence of 3.5% in the general population, it does not always lead to symptomatic infection. Certain factors increase the risk for asymptomatic bacteriuria, such as parity, diabetes in women, a history of UTI, and a lower education level. An estimated 4 to 10%

of pregnant women are diagnosed with asymptomatic bacteriuria.<sup>4</sup> During pregnancy, asymptomatic bacteriuria has been associated with progression to pyelonephritis as well as with preterm labor and cerebral palsy.<sup>55</sup> In most other populations, however, including the elderly, spinal cord injury patients, and patients with diabetes, asymptomatic bacteriuria does not denote increased risk of disease; hence screening and treatment are not recommended.<sup>4,10</sup>

### Acute Uncomplicated Cystitis

Acute cystitis is generally considered uncomplicated unless it is associated with a predisposing factor, such as instrumentation with a catheter, the presence of a bladder stone, bladder outlet obstruction by benign prostate hypertrophy, or an underlying malignancy.<sup>2</sup> At the time of presentation with symptoms of an acute UTI, it is usually difficult to classify patients as having a complicated or an uncomplicated infection. It is, however, generally safe to assume that a premenopausal, sexually active, non-pregnant woman with recent onset of dysuria, frequency, or urgency, who has not been recently instrumented or treated with antibiotics, has an uncomplicated UTI.<sup>2</sup>

In young, sexually active women presenting with acute dysuria, three possible causes would need to be considered: acute cystitis, acute urethritis (caused by *Chlamydia trachomatis*, *Neisseria gonorrhoea*, or *Herpes simplex*), and vaginitis. A distinction among these three entities can usually be made with a high degree of certainty after performing a good history and physical examination, and by reviewing the urinalysis findings.<sup>54</sup> The typical symptoms of acute cystitis are urgency, frequency, dysuria, and suprapubic pain. Vaginitis is more likely if patients have an associated vaginal discharge or odor, pruritus, or dyspareunia. Nearly all young women with acute cystitis have been shown to have pyuria, defined as 10 or more leukocytes per mm<sup>3</sup> on an unspun voided midstream urine specimen.<sup>2</sup> The leukocyte esterase test has a widely reported sensitivity of 75 to 96% for detecting pyuria associated with acute UTI.<sup>56</sup> Thus, for patients with symptoms suggestive of a urinary infection, a negative leukocyte esterase test does not exclude the presence of an infection, and should prompt a microscopic urinary examination as well as urinary culture. UTI appears to be more likely with the presence of hematuria, since about 40% of women with an acute urinary infection are noted to have hematuria.<sup>2</sup> Gram stain is usually not performed since pathogens with low counts (< 10<sup>4</sup> CFU/mL) are difficult to visualize.<sup>2</sup> In symptomatic young women with suspected acute cystitis, a urine culture demonstrating 100 or more CFU/mL of uropathogenic species is indicative of infection.<sup>54,56,57</sup> However, from a practical point of view,

obtaining urine culture is not necessary in young women with acute uncomplicated cystitis, since the causative microorganisms and their antimicrobial susceptibilities are predictable.<sup>2</sup>

### Recurrent Cystitis in Women

About 20% of young women with an initial episode of cystitis have recurrent infections. Occasionally, such recurrences are due to persistent infections, but most cases of recurrences are due to episodes of exogenous reinfection, typically months apart.<sup>58</sup> Most of these patients have no underlying anatomic abnormalities.<sup>54</sup> This increased susceptibility in certain individuals is of unclear etiology. In some patients, certain habits, such as the use of diaphragms and spermicides may account for some of the recurrences.<sup>59</sup> In others, there may be a genetic predisposition.<sup>54</sup> In postmenopausal women, the risk of recurrent UTI appears related to presence of factors that impair bladder emptying, such as cystocele and increased postvoid residual.<sup>60</sup> Recurrence should be documented by urine culture at least once, and then managed either by continuous or postcoital prophylaxis, or by therapy initiated by the patients at onset of symptoms. Topical estradiol may be of benefit in postmenopausal women.<sup>54</sup>

### Acute Uncomplicated Pyelonephritis

Acute pyelonephritis should be considered uncomplicated, as well, in an otherwise healthy host infected with a virulent uropathogen unless it is associated with an underlying predisposing condition similar to those mentioned above, even though the infection does involve the upper urinary tract. The presentation of pyelonephritis can vary, from mild to moderate illness, to a life-threatening illness with gram-negative septicemia.<sup>57</sup> The severity of an infection seems to be related to cytokine expression, especially IL-6 and IL-8 responses, both locally and systemically. These cytokine responses are influenced, as indicated earlier, by host and bacterial variables.<sup>61</sup> Acute pyelonephritis is suggested by flank pain, nausea and vomiting, fever > 38°C, or by costovertebral angle tenderness.<sup>2</sup> Urinary frequency occurs in up to 98% of the women with acute pyelonephritis, suggesting a concomitant cystitis.<sup>62</sup> As in acute uncomplicated cystitis, pyuria occurs in the vast majority of the patients with acute pyelonephritis, and hematuria can be similarly evident. Urine culture reveals > 10<sup>5</sup> CFU/mL of uropathogens in > 80% of the cases, although some patients may have colony counts as low as 10<sup>3</sup> CFU/mL. Contrary to acute uncomplicated cystitis, a urine culture and sensitivity should always be performed in patients with acute pyelonephritis, since there are potentially serious sequelae to the use of inappropriate antimicrobial therapy.<sup>1,63</sup> Blood culture obtained in patients with acute pyelonephritis who are admitted to the

hospital reveal that up to 20% of these patients may have a positive result; however, the presence of bacteremia is not likely to affect the choice of antimicrobial therapy in this particular group of patients.<sup>64-69</sup>

### Urologic Evaluation of Women with UTI

Most women with an episode of acute UTI, and recurrent uncomplicated cystitis have no underlying anatomic or functional abnormality, and, therefore, routine urologic evaluation would not be indicated in such patients.<sup>1</sup> For patients with two or more episodes of pyelonephritis, further evaluation is indicated. Typically, such an evaluation includes renal ultrasonography and/or computed tomography scan to rule out nephrolithiasis or obstructive uropathy. A complete evaluation, including cystoscopy and excretory urography, should be reserved for patients with persistent hematuria after eradicating the infection.<sup>2</sup>

### Acute Uncomplicated UTI in Young Healthy Men

Due to the infrequency of UTIs in men, it has been traditional to consider all such infections in men complicated.<sup>70</sup> However, it is now clear that a small number of men between the ages 15 and 50 years old may suffer from an acute uncomplicated UTI without associated urologic abnormalities. Risk factors associated with these infections include homosexuality, intercourse with an infected female partner, and the lack of circumcision.<sup>71,72</sup> The etiologic agents are similar to those in women, and the causative microorganisms seem to have the same susceptibility patterns.<sup>1</sup> As in women, dysuria, frequency, urgency, and suprapubic pain or hematuria are the typical symptoms in a patient presenting with cystitis; fever and flank pain would suggest pyelonephritis. The absence of pyuria suggests a non-infectious etiology. Urethritis must be considered in sexually active men; examination for penile ulcerations and evaluation of a urethral swab with gram stain to exclude *N. gonorrhoea* or *C. trachomatis* infections is important. A midstream urine culture using colony count criteria similar to that recommended for women is recommended to confirm the diagnosis.<sup>1</sup> Young healthy men presenting with an acute cystitis syndrome with no discernable complicating factors, who respond promptly to therapy, usually demonstrate no abnormalities on urologic evaluation; thus, routine urologic evaluation is not necessary in this clinical setting.<sup>54</sup> Urologic evaluation should probably be done routinely in adolescents, men with pyelonephritis, recurrent infections, or in the presence of a complicating factor.<sup>1</sup>

### Complicated Urinary Tract Infections

Complicated UTIs are those that occur in patients with functional, metabolic, or anatomic

abnormalities of the urinary tract; they also include infections caused by pathogens that are resistant to antibiotics (Table 3). The clinical spectrum is wide and includes asymptomatic bacteriuria, mild cystitis, pyelonephritis, and life-threatening urosepsis. As mentioned earlier, there are a vast number of diverse microorganisms that might be responsible for a complicated UTI.<sup>54</sup> It is important to take this into consideration when contemplating the different therapeutic options.

Urine and blood cultures must be obtained from individuals suspected of having a complicated UTI in order to identify the infecting pathogen and its potential susceptibility pattern. Correction of the underlying predisposing condition is necessary, when feasible, to prevent recurrence of the infection.

## Antimicrobial Treatment of Urinary Tract Infections

### Acute Uncomplicated Cystitis

Despite the fact that little change has occurred in the epidemiology of the causative microorganisms of acute uncomplicated cystitis, the management of these infections has become more complicated by the trend towards increased

antimicrobial resistance. In the United States, the prevalence of resistance to trimethoprim-sulfamethoxazole (TMP-SMX) among *Escherichia coli* strains causing cystitis varies by region, and is higher than 20% in some regions.<sup>73</sup> Nitrofurantoin and fluoroquinolones remain highly active against almost all strains of *Escherichia coli*, although resistant strains to the fluoroquinolones are being reported in the US and in other countries<sup>1</sup>. The prevalence of resistance among uropathogens to  $\beta$ -lactams is high, ranging from 26 to 38%; hence, they are not recommended for first-line empiric therapy.<sup>73</sup> TMP-SMX is the most studied therapeutic agent, effective at eradicating initial bacteriuria in up to 93% of cases. It is, according to the clinical practice guidelines for management of acute uncomplicated cystitis published by the Infectious Diseases Society of America (IDSA), the recommended current standard of therapy.<sup>74</sup> Based on multiple studies revealing that 3 days therapy of an antimicrobial is generally as effective as the same antimicrobial agent given for longer durations, 3-day regimens are advocated. Single-dose therapy, in general, is less effective and associated with higher recurrence rates; accordingly, it is not recommended. Ofloxacin is as effective as TMP-SMX, as are probably the newer fluoroquinolones, but they are recommended as initial empirical therapy only in communities with higher than 20% resistance rates to TMP-SMX.  $\beta$ -lactams in 3-day regimens are less effective than TMP-SMX or fluoroquinolones in eradicating the infections and should not be used as first-line therapy. The role of nitrofurantoin may become more prominent in the treatment of acute uncomplicated cystitis, especially with the increasing resistance to TMP and TMP-SMX.<sup>74</sup>

### Acute Uncomplicated Pyelonephritis

For decades, the traditional therapy for pyelonephritis has been hospitalization and treatment with intravenous antimicrobials for 6 weeks. This has recently changed, however, with the recent studies suggesting that, for most patients with an episode of acute uncomplicated pyelonephritis, an adequate outcome can be achieved with 2 weeks of therapy. Shorter durations (7 days) are likely feasible in patients with mild pyelonephritis. Due to the seriousness of an acute uncomplicated pyelonephritis, the high prevalence of resistance of the causative pathogens to TMP-SMX, and the high risk of failure when TMP-SMX is used for resistant bacteria, the recommended empirical antibiotic choice is an oral fluoroquinolone. TMP-SMX and  $\beta$ -lactams should not be used alone unless the organism is known to be susceptible to the particular agent being used. If the patient is suspected of having a gram-positive infection based on gram stain, amoxicillin or amoxicillin-clavulanic acid is recommended.

Nitrofurantoin should not be used to treat pyelonephritis since it does not achieve reliable tissue or serum levels.

If the patient requires hospitalization due to high fever, dehydration, vomiting, and/or sepsis, then he/she should be treated with parenteral antibacterial therapy. Several agents are considered effective in this setting. The IDSA recommends the use of an intravenous fluoroquinolone as first-line therapy here as well, but intravenous ceftriaxone or an aminoglycoside, with or without ampicillin, are also acceptable choices.<sup>74</sup> If Enterococcus is suspected, then ampicillin with gentamicin is a reasonable option.<sup>1,74</sup>

### Acute Cystitis in Postmenopausal Women

There are few studies of the treatment of acute cystitis in postmenopausal women. Three-day therapy with ofloxacin was shown to be superior to cephalexin for 7 days in one study.<sup>75</sup> Unfortunately, there are no studies comparing the same antibacterial agent for different durations in older healthy ambulatory women. It is likely that the 3-day regimen as described for younger females is effective in this group of patients as well.<sup>1</sup>

### Acute Uncomplicated UTI in Men

Data on the treatment of young healthy males with a UTI are lacking due to the low frequency of such infections in the group of individuals. Due to the potential of an accompanying prostatitis in this setting, most sources recommend the use of a fluoroquinolone for 7 days as first-line of empiric therapy since it provides the best antimicrobial spectrum and prostatic penetration. A 7-day course of TMP-SMX can also be used. Nitrofurantoin and  $\beta$ -lactams should not be used in young males with an acute UTI since they would not reach adequate tissue levels.<sup>1</sup>

### Complicated UTI

In order to ensure effective eradication of an infection, the antibacterial agent has to be directed against the causative pathogen. Identification of the microorganisms and their susceptibility patterns by conventional laboratory methods takes 2 to 3 days in most cases. Unfortunately, in the situation of a complicating UTI, therapy cannot be delayed for long, and is typically initiated empirically. The ideal agent would need to offer coverage to the broad spectrum of pathogens that might be responsible for such an infection depending on the clinical setting. Due to their broad antibacterial spectrum and their favorable pharmacokinetics, the fluoroquinolones (eg, ciprofloxacin, levofloxacin, gatifloxacin), which achieve high bioavailability in the urine, can be considered the agents of choice in patients with mild to moderate illness. For initial

empiric therapy in the more seriously ill hospitalized patients, the choice of antibiotic must offer good activity against pathogens such as *Pseudomonas aeruginosa* as well as most of the enterococci. Combination of agents such as ampicillin and gentamicin, piperacillin and tazobactam, imipenem and cilastatin sodium would be appropriate.<sup>8,54</sup> Once the infecting strain and the antimicrobial susceptibilities are known, therapy can be modified accordingly. Usually 2 weeks of treatment are recommended, and patients who are receiving parenteral antibiotics can be switched to oral therapy when they improve clinically. Naturally, eliminating the underlying complicating factor, if plausible, is of great importance in preventing recurrence of the infectious disease.

### Types of UTI More Common in Cancer Patients:

As mentioned earlier, very little information is available with regard to the epidemiology of UTI in patients with malignancy. However, certain types of UTI appear to be more frequently observed in cancer patients: for example, fungal UTI and viral hemorrhagic cystitis secondary to an immunocompromised state. It is reasonable to discuss catheter-related UTI in this context, although it is not specific to cancer patients, because of the high morbidity of these patients and the frequency with which it is observed in these patients. For these reasons, these three types of UTI will be discussed in more detail.

### Catheter-Related Infections

Between 15% and 25% of patients in general hospitals may have a catheter inserted at some point during the course of their stay.<sup>76</sup> Up to half the patients requiring an indwelling urethral catheter for 5 days or longer will develop bacteriuria or candiduria.<sup>77</sup> The urinary tract of the catheterized patient appears to be highly susceptible to infection, once a small number of microorganisms gain access. Low-level bacteriuria or candiduria has been shown to progress to  $> 10^5$  CFU/ml 96% of the time.<sup>78</sup> Catheter-related UTIs are the most common nosocomial infections in hospitals and nursing homes, constituting  $> 40\%$  of all institutionally-acquired infections.<sup>76</sup> The risk of bacteriuria with short-term catheterization is 5% per day.<sup>79</sup> Furthermore, Platt and colleagues observed that acquiring a urinary tract infection (defined as bacteriuria  $> 10^5$  CFU/mL in the study) during indwelling bladder catheterization is associated with nearly a threefold increase in mortality among hospitalized patients.<sup>80</sup> Less than 5% of catheter-associated bacteriuria will be complicated by bacteremia; however, due to the large number of catheterized patients, nosocomial UTIs are the source of up to 15% of nosocomial blood stream infections.<sup>81</sup>

### Risk Factors for Catheter-Associated UTI

The most important risk factor for acquiring a UTI in the setting of an indwelling bladder catheter is the duration of catheterization, particularly past 6 days. Other risk factors include female gender, lack of administration of systemic antibiotics during the period of catheterization, catheter insertion outside the operating room, being on a urology service, other active sites of infection, diabetes, and malnutrition.<sup>77</sup> The presence of azotemia (creatinine  $> 2$  mg/dL), ureteral stent, or use of the catheter to monitor urine output further increase the risk.<sup>77,79,82</sup>

### Definition of Catheter-Related UTIs

Most sources advocate considering the new appearance of  $> 10^3$  CFU/mL of bacteria or fungi to represent a catheter-acquired UTI.<sup>77-79</sup> Most of these infections are unimicrobial, although they have been reported to be polymicrobial in up to 15% of the cases.<sup>81</sup> The most commonly isolated microorganism is *Escherichia coli*. Other gram-negative pathogens such as *Klebsiella*, *Enterobacter*, *Citrobacter*, and *P. aeruginosa* are common, as well. In one report, up to 27% of catheter-acquired UTIs were caused by enterococci or staphylococci, and up to one-third of the isolates were *Candida* species.<sup>83</sup> Yeast UTIs are particularly common when antibiotics are in use, and are increasing in incidence.<sup>52</sup>

### Pathogenesis

Most catheter-associated UTIs are endogenous—that is, from the patient's own colonic flora. The indwelling catheter offers conduits for bacterial entry along its external and internal surfaces.<sup>81</sup> Organisms can gain access into the urinary tract in one of two ways. Extraluminal contamination may occur early, by direct inoculation when the catheter is inserted, or later by organisms ascending from the perineum by capillary action in the thin mucous film contiguous to the external catheter surface. Intraluminal contamination may occur by reflux of microorganisms gaining access into the lumen from failure of closed drainage or contamination of urine in the collecting bag.<sup>79</sup> Although these infections have been shown to occur by both extraluminal and intraluminal routes, they seem to derive preponderantly from organisms that gain access extraluminally.<sup>84</sup> Some suggest that the latter is of even greater importance in women, perhaps because of the shorter urethra and its closer proximity to the anus.<sup>85</sup>

Urinary catheters are tubular latex or silicone devices which, when inserted, may acquire biofilms on the inner or the outer surface.<sup>86</sup> The initial adherence occurs to the irregular surfaces surrounding the catheter eyeholes. Microcolonies form in the depressions on these surfaces and spread to cover the entire surface around the

eyeholes.<sup>87</sup> A distinguishing characteristic of biofilms is the presence of an extracellular polymeric matrix, containing open water channels and primarily composed of polysaccharides, surrounding and encasing the cells.<sup>88</sup> Most of the biofilm volume is actually composed of this layer rather than of pathogenic cells. Organisms contained within the biofilms seem to be well protected against antimicrobials and the urine flow.<sup>86</sup> Urinary catheter biofilms may initially be composed of a single microorganism, but longer exposure inevitably leads to the presence of multiple species.<sup>89</sup> Organisms commonly present in biofilms of bladder catheters are *S. epidermidis*, *Enterococcus faecalis*, *Escherichia coli*, *Proteus mirabilis*, and *Pseudomonas*, among others.<sup>86</sup> Other than biofilm formation, the catheter, as a foreign body, may lead to a complex defect in PMN function, which may be partially responsible for these patients' higher susceptibility to infection.<sup>81,86</sup>

### Clinical Features

Most patients with a catheter-acquired UTI are asymptomatic, with less than 10% of those with a microbiologically documented UTI reporting any symptoms. Placement of an indwelling urethral catheter can, in and by itself, cause dysuria or urgency; however, these complaints do not appear to denote an underlying infection. Neither fever nor peripheral leukocytosis has been shown to be predictive of a urinary infection in this setting. Continuous drainage by the catheter with the resultant decompression of the infected bladder may prevent the urgency and frequency that would be expected in the setting of cystitis.<sup>77</sup> Similarly, most patients do not demonstrate pyuria, even with a microbiologically documented, catheter-associated UTI when the catheterization was short-term.<sup>83</sup> The sensitivity of pyuria was calculated at merely 37% in this prospective study, and based on this study, pyuria should not be used as the sole criteria for obtaining a urine culture if UTI is suspected in catheterized individuals.<sup>83</sup> In any event, the importance of such infections stems from the fact that they comprise the largest institutional reservoir for antibiotic resistant pathogens such as *Enterococci*, *Klebsiella*, *Citrobacter*, *Pseudomonas*, and others.<sup>77</sup>

### Prevention

Several catheter-care practices are universally recommended to prevent, or at least delay, the onset of catheter-associated UTIs: avoid unnecessary catheterizations; consider other methods of bladder drainage, such as condom catheters or suprapubic catheters; and ensure a trained professional inserts the catheter under aseptic conditions. Maintenance of closed drainage with as little manipulation as possible, and maintenance

of dependant drainage by keeping the collecting tubing and bag below the bladder level, are important. However, it is of greater importance to limit the duration of catheterization by prompt removal of the indwelling catheter once deemed unnecessary. Other techniques, such as anti-infective lubricant, antireflux valves, and instillation of an antibiotic into the collection bag remain of unproven efficacy.<sup>79</sup>

Use of systemic antimicrobials, such as TMP-SMX or ciprofloxacin, appears to be effective in the prevention of catheter-related UTIs<sup>90</sup>; however, infections that occur despite prophylaxis are far more likely to be caused by antibiotic-resistant bacteria. Furthermore, since most of these infections are asymptomatic and rarely lead to bacteremia, it is difficult to justify the use of systemic antibiotics in every patient subjected to an indwelling urethral catheter.<sup>79</sup> An exception to this would be renal transplant recipients, where prophylaxis has been shown to be cost-effective in the prevention of UTI.<sup>11</sup>

#### Treatment

Treatment of asymptomatic bacteriuria in the setting of an indwelling bladder catheter is not generally recommended. There are, however, specific groups of patients in whom it appears necessary, for example, patients with granulocytopenia or other immune compromising conditions or those undergoing urologic procedures.<sup>79</sup> Removal of the catheter results in eradication of infection unless predisposing factors for UTI persist. Treatment should be directed at the specific microorganism isolated.

#### Fungal UTI

There appears to be a steady increase in the rate of nosocomial fungal infections, from 2.0 to 3.8 per 1,000 discharges in the United States, as reported to the Centers for Disease Control and Prevention (CDC) National Nosocomial Infections Surveillance (NNIS) system. High rates of infection are not limited to oncology wards and high-risk nurseries; they also occur on cardiac surgery, burn, and trauma wards.<sup>91</sup> In patients with an indwelling catheter, up to 27% of UTIs have been reported to be caused by fungi.<sup>82</sup> Table 4 shows the CDC criteria for diagnosis of nosocomially-acquired UTI. Since the majority of the renal fungal infections result from *Candida* sp, the remainder of this discussion will be focused on the clinical findings and the treatment of *Candida* infections of the urinary tract.

Candiduria is a rare finding in healthy, non-hospitalized individuals. In hospitalized patients, the prevalence of candiduria is variable, but seems to be most common in the intensive care unit. *Candida* UTIs represent 10 to 15% of all nosocomial UTIs.<sup>92,93</sup> Analysis of reports from the NNIS system showed that *Candida albicans* ranked

seventh among all hospital pathogens isolated from a major infections site in 1996.<sup>91</sup> More recently, it was reported as the fourth most common cause of blood stream infection in the United States.<sup>94</sup> Over the past decade, there has been a definite increase in the incidence of non-*albicans Candida* species causing serious disease in humans.<sup>95-97</sup> In one retrospective series by Abbas and colleagues that evaluated patients with underlying malignancies, *Candida krusei* accounted for 5% of fungemias during 1989 through 1992; the incidence increased to 10% during the period 1993 to 1996.<sup>97</sup> The major risk factor for of non-*albicans* infections, including *Candida krusei* and *Candida glabrata*, was fluconazole prophylaxis given to patients undergoing treatment for leukemia.<sup>95,97</sup>

Most nosocomial *Candida* infections are thought to be endogenous, arising from colonization of the mouth, colon, vagina, or skin. *Candida* typically gains access to the urinary tract by the ascending route; thus, it occurs more frequently in women<sup>98</sup>. Other risk factors associated with *Candida* infections are summarized in Table 5.

According to a prospective multicenter study by Kauffman and colleagues, *Candida albicans* is the most common agent isolated in the urine (52%), followed by *Candida glabrata* in 16% of the patients. Ten percent of the patients had more than one species of *Candida* present.<sup>99</sup> A common problem is determining whether the presence of *Candida* in the urine is indicative of infection or merely colonization. Although pyuria usually supports the presence of an underlying infection, it might also be the result of concomitant

bacteriuria. In any event, the presence of colony counts  $\geq 10^3$  CFU/mL would need to be interpreted according to the clinical situation and to the patient's symptoms.

Most patients with funguria are asymptomatic, with less than 5% reporting dysuria, frequency, urgency, or flank pain. Hematuria also appears to be uncommon. Fever occurs more frequently (up to 22%); however, in most cases, it is not clear whether it is due to the candidal infection itself or the underlying disease.<sup>99</sup> Asymptomatic candiduria is usually viewed as a benign condition that rarely leads to invasive disease.<sup>100</sup> When invasion of the upper urinary tract does occur, however, the clinical signs and symptoms are indistinguishable from those associated with bacterial infection. The formation of perinephric abscesses and fungal balls (bezoars) that commonly include sloughed renal papillae (papillary necrosis) can occur in the compromised host, especially in the presence of obstruction, and in diabetics.

In a prospective multi-center study, Sobel and colleagues randomized 316 patients with asymptomatic candiduria  $\geq 10^3$  CFU/mL to either fluconazole or placebo. In the untreated group, they demonstrated that candiduria resolved in 41% of patients merely upon removal of the indwelling bladder catheter. Higher eradication rates were noted in the treated group as compared to the placebo group, initially (63% vs. 35%). However, patients who had received either fluconazole or placebo had similar rates of candiduria two weeks after the completion of therapy.<sup>101</sup> Accordingly, treatment of asymptomatic candiduria is not recommended by the IDSA except in specific circumstances. Candiduria should be treated if the patient is symptomatic, neutropenic, a renal allograft recipient, or about to undergo urologic manipulation. Removal of the urinary instrument should be undertaken if feasible. Choices for therapy include fluconazole at 200 mg/d for 7 to 14 days, amphotericin B at 0.3 to 1.0 mg/kg/d for 1 to 7 days, or, in the absence of renal insufficiency, flucytosine at 25 mg/kg qid.

The latter may be especially effective in patients with non-*albicans* *Candida* species.<sup>102</sup> The management of perinephric abscesses, bezoars, and papillary necrosis requires invasive urologic procedures to ensure adequate drainage in addition to the systemic therapy.<sup>103</sup>

Candiduria may be a source of subsequent dissemination, as in patients with urinary tract obstruction, or a marker of acute hematogenous dissemination as in neutropenic patients.<sup>103</sup> Renal involvement was present in one study in 90% of patients who died of disseminated candidiasis, on autopsy.<sup>98</sup> Among the NNIS hospitals, there has been a dramatic increase in the rate of all nosocomial bloodstream infections caused by fungi—from 5.4% in 1980 to 9.9% in 1990, the most common fungus being *Candida* spp.<sup>91</sup> Increased susceptibility to invasive candidiasis is typically attributed to host factors such as a severe illness, immunocompromised status, or malnutrition. Unlike candiduria, disseminated candidiasis carries a grave prognosis, with an estimated crude mortality of 50 to 60%.<sup>91</sup>

In patients with known disseminated candidiasis, renal involvement has no specific treatment implications unless renal function deteriorates or the patient develops flank pain. In these settings, imaging studies of the kidney such as ultrasonography or computed tomography are needed to exclude obstruction, perinephric abscess, and papillary necrosis.<sup>102</sup>

Prophylaxis reduces the incidence of both superficial and deep candidiasis in high-risk populations. The best data on prophylaxis of fungal infections include two randomized controlled trials that compared fluconazole with placebo in bone marrow transplantation recipients.<sup>104,105</sup> Both studies observed that fluconazole was both safe and effective in preventing *Candida* infections caused by all species except *Candida krusei*, and both studies demonstrated improvement in morbidity. In the trial by Slavin and colleagues, the probability of survival was greater in the group receiving the prophylaxis.<sup>104</sup> In the guidelines for the treatment of candidiasis, the IDSA advocates prophylaxis for neutropenic patients in limited situations: standard chemotherapy for acute myelogenous leukemia, allogeneic bone marrow transplantation, and high-risk autologous bone marrow transplantation.

## Hemorrhagic Cystitis

Hemorrhagic cystitis (HC) is one of the frequent complications in bone marrow transplant (BMT) recipients.<sup>106</sup> The incidence of HC is reported to vary widely, from 6 to 38% of patients after bone marrow transplantation.<sup>107–111</sup> Two distinct clinical types of HC have been described in these patients: an early and a late type. The early type is principally from chemotherapeutic agents—busulfan, cyclophosphamide, and ifosfamide—which are used during the conditioning regimen

in these patients. This is usually mild, and can often be prevented by modifying the conditioning regimen<sup>107</sup>; occasionally, it can be severe. On the other hand, the late onset type is related to either graft-versus-host disease (GVHD) or viral infections.<sup>107</sup> This review will discuss HC as it relates to viral infections in bone marrow transplantation recipients.

Viruses that have been incriminated in causing HC include the adenovirus and polyomaviruses. HC caused by human polyomavirus is from two types, BK virus (BKV) and JC virus (JCV). BKV causes cystitis and nephropathy in immunosuppressed and renal transplant recipients, while JCV is uncommonly associated with renal disorders. A polyomavirus of simian origin, SV40, has been associated recently with HC after bone marrow transplantation.<sup>112</sup>

The clinical features of HC with either adenovirus or BKV infections appear to be similar. Based on clinical features, Bedi and classified HC into four grades as shown in Table 6.<sup>108</sup> Grades 0 to 2 are considered mild disease, while grades 3 and 4 are considered severe disease. Apart from hematuria and clot retention or obstruction, other clinical features include pain, dysuria, renal failure, and problems associated with disseminated disease, such as pneumonia, enteritis, and neurologic complications. In a study on children who underwent allogeneic bone marrow transplantation, Hale and colleagues observed that the prevalence of severe HC was 11%, the mean duration of symptoms was 73 days, and in a multivariate analysis, male sex and unrelated donor grafts were significantly associated with HC.<sup>113</sup> In a study from the M. D. Anderson Cancer Center in Houston, TX, where the study was also limited to allogeneic BMT patients, of the 105 patients with acute lymphocytic leukemia, 32 patients developed HC within the first year after transplantation with a cumulative incidence of 30%.<sup>114</sup> The median time of onset of HC was 23 days with only one patient developing HC after 100 days. The mean duration of symptoms of HC was 30 days. Grade 2 HC occurred in 56%, grade 3 in 31%, and grade 4 in 13%; 59% were attributed to polyomavirus, with 17% attributed to adenovirus. An interesting feature in this study was a high CMV reactivation rate (63%) among patients with HC. While polyomavirus infection was

similar in both younger and older patients, adenovirus infection was exclusive to patients younger than 25 years. The two main factors that were associated with HC included transplantation from a matched, unrelated donor, and age <26 years. Interestingly, the use of cyclophosphamide in the preparative regimen was not associated with HC.<sup>114</sup>

The published studies that have looked at HC in BMT recipients can be summarized as those associated with adenovirus infections or with BKV infections.

### Adenovirus-Associated HC

In another study from M. D. Anderson Cancer Center, 85 out of 2,889 (3%) of adult patients who received BMT were diagnosed with adenovirus infection.<sup>115</sup> Of the 85, 13% were diagnosed with HC. There was no significant difference in the incidence of HC between patients who received allogeneic versus autologous BMT. The mean duration of symptoms of patients with HC was 26 days, compared with 21 days for pneumonia and 60 days for disseminated disease. Overall mortality was 26%, but none of the patients with isolated HC died; 85% of patients with disseminated disease had GVHD. The predictors for disseminated disease in a multivariate analysis were GVHD (odds ratio [OR] 6.23) and treatment with  $\geq 2$  immunosuppressive drugs (OR 74.0).<sup>115</sup>

In a study from Japan, Akiyama and colleagues observed that HC was more common after allogeneic BMT, rather than after autologous or syngeneic BMT.<sup>116</sup> In addition, the preparative regime, GVHD prophylaxis, grade of GVHD, and use of mesna were significantly associated with HC. Adenovirus was responsible for HC in 60% of patients, and 85% of the adenovirus-associated HC were due to infection by type II.<sup>116</sup> The serological status of adenovirus was not a risk factor for subsequent development of HC among these patients. In most studies, asymptomatic shedding of adenovirus was not common in BMT recipients. In the study by Akiyama and colleagues, the prevalence of adenovirus in urine samples in patients without HC was 3%, compared with 60% among patients with HC.<sup>116</sup>

### BKV/JCV Infections

BKV and JCV, named after the initials of the patients from whom the viruses were first discovered, are common problems in BMT recipients. In the general population, infection with these viruses occurs early in childhood, and seroconversion occurs throughout childhood such that, by 10 years of age, 60% of children would have acquired the antibodies.<sup>117</sup> The prevalence of a prior infection among adults is 60 to 80%.<sup>118</sup> Asymptomatic viruria occurs in 0.3% of non-immunosuppressed patients, 3% of pregnant women, 10 to 45% of renal transplant recipients

**Table 6** Grading of Hemorrhagic Cystitis

Grade 0	No hematuria

Adapted from Bedi et al.<sup>108</sup>

and 50% of BMT recipients.<sup>119–121</sup> BKV is probably transmitted through the respiratory secretions, although isolation of the virus from respiratory secretions has not been easy. After replication and dissemination, BKV invades the renal and urothelial cells where it establishes a latent infection. Infection can also be carried to the recipient through the organ, particularly in solid organ transplant patients. In renal transplant recipients, BKV infection is identified with graft dysfunction and is often associated with rejection.<sup>122</sup> The degree of viremia was higher in patients with rejection and graft dysfunction than in those without.<sup>122</sup>

HC in association with BKV infection in BMT recipients has been shown in a number of studies.<sup>106–108,123–126</sup> While BKV infection does not always lead to HC in these patients, HC is four times more common among patients with BKV infection than among those without the infection.<sup>121</sup> HC and renal infections in association with BKV infection are also seen in severely immunosuppressed patients, such as patients with HIV or /acquired immunodeficiency syndrome.<sup>127–129</sup> BKV infection causing nephropathy or HC is likely to be a secondary infection or reactivation of a previous primary infection.<sup>122</sup>

Diagnosis of BKV infection is principally made by urine examination. Presence of decoy cells in the urine is a morphologic marker for viral replication. Decoy cells are caused by infection of urinary epithelial cells by BKV and can be identified by light microscopy.<sup>121</sup> The nuclei of these cells are enlarged, and nuclear chromatin is completely homogenized by viral cytopathic effect. Urine BKV deoxyribonucleic acid (DNA) polymerase chain reaction (PCR) is highly sensitive and specific for diagnosing the infection. BKV DNA PCR in the plasma is also highly sensitive and specific for diagnosing BKV nephropathy, but may also be useful in diagnosis of HC. The predictive value of BKV DNA PCR is limited in children because an incidental primary BKV infection that is common in childhood may not be differentiated from a secondary infection or reactivation of a prior primary infection in these immunosuppressed patients.

### Treatment

In most cases, the clinical course of HC is mild and requires only volume expansion (also termed hyperhydration). When the hematuria is severe, analgesics may be required to relieve the pain from passing clots. An indwelling catheter is useful to prevent clot retention and urinary obstruction, but this is likely to be more successful in adults than in children because of the small catheter lumen required in children.<sup>111</sup> Evacuation of blood clots can also be carried out with transurethral catheterization, particularly in adults. Suprapubic catheter insertion and/or

surgical removal of clots may have to be performed if clot retention cannot be relieved through transurethral catheterization. Many urologists prefer an open surgical procedure for suprapubic catheter insertion, rather than a blind procedure because of better hemostasis with the former, as many of these patients are thrombocytopenic.

Several other local treatments have been tried with varied success in controlling hematuria in HC. These include prostaglandin E2 and F2 $\alpha$ , alum irrigation, instillation of formalin, intravesical hydrostatic pressure, hyperbaric oxygen, and laser vaporization of the bleeding areas.<sup>110,130,131</sup>

Specific treatment of viral diseases causing HC are still evolving. Cidofovir has been tried for adenovirus infections, as well as in an occasional patient with BKV infection, with varying success.<sup>121,132–135</sup> Two studies showed promising results: one showed that all patients prospectively treated with cidofovir for adenovirus infections responded.<sup>134</sup> All adenovirus infections, pneumonia, enteritis, HC and disseminated disease, were included in this study. None of these patients had nephrotoxicity from the drug at the dosage of 1mg/kg/d given three times weekly, and continued until virologic remission is achieved. In the other study that included only BMT patients with HC, 10 of the 14 (71%) patients showed clinical improvement with cidofovir.<sup>135</sup> Seven patients had nephrotoxicity from the drug, despite the dosage being the same as in the above study, and in four of them, the drug had to be discontinued. No prospective randomized trials are yet available with cidofovir. Breakthrough infections with CMV and herpes simplex virus (HSV) have been observed while on treatment with cidofovir in these immunosuppressed patients.<sup>135</sup> Cidofovir for adenovirus-associated HC has generally been reserved for grade 3 and 4 HC, and the preliminary results are certainly promising.

Intravenous ribavirin has also been tried in adenovirus infections in BMT patients, including HC. However, the results have been disappointing. In a study from M. D. Anderson Cancer Center, intravenous ribavirin was tried in 12 of 85 BMT patients with adenovirus infection, with only one of them responding to the treatment.<sup>115</sup> Among these 12 patients, only one patient had HC, and that patient did not respond to ribavirin. So, at the current time, for adenovirus-associated high-grade HC, cidofovir may be the treatment of choice, despite its significant nephrotoxic potential.

There is no consensus on optimum antiviral therapy to date for BKV/JCV infections. It is not certain whether asymptomatic viruria needs treatment, and no trials exist that show prevention of symptomatic infections by preempted treatment of asymptomatic patients. Cidofovir

has not met with the same degree of success in BKV infections. One complicating feature is that BKV can cause nephropathy, particularly in renal transplant recipients, and cidofovir also is nephrotoxic. It has also not been established that treatment of BKV nephropathy improves the graft survival in these patients. The experience of treating BKV-associated HC with cidofovir is limited to two case reports. In one report, a successful clearance of viruria after treatment with cidofovir in a BMT recipient with HC was observed; the patient also had a simultaneous reactivation of CMV infection.<sup>133</sup> In another report, no response was observed with cidofovir in a patient with HIV infection and HC.<sup>127</sup> In an extreme case of HC with hematuria, intravenous vidarabine was used in a BMT patient with BKV-associated HC with improvement of symptoms, although viruria persisted.<sup>136</sup>

Thus, more prospective studies are needed to establish the optimum therapy in both adenovirus and BKV-associated urinary infections in these immunocompromised patients.

### Conclusions

Urinary tract infections remain among the most common medical problems encountered, both in the general population and in hospitalized individuals, including patients with an underlying diagnosis of cancer. There are multiple local and systemic factors that predispose this latter group of patients to such infections. Patients with malignancies of the abdomen and the pelvis are at high risk of developing obstruction by virtue of the mass itself, or as a result of radiation therapy. UTIs are the most commonly reported complication among patients undergoing diversion procedures.

Systemic immune deficiency may be secondary to the disease itself or, more commonly, a consequence of the introduced therapies. Neutropenic patients are more susceptible to infection with resistant microorganisms such as VRE. Although they typically do not develop dysuria or pyuria, they are at increased risk of septicemia once a UTI has occurred. Thus, the presence of bacteriuria and candiduria needs to be taken seriously and should warrant antimicrobial therapy in these immunocompromised patients.

Certain subsets of patients, such as those undergoing BMT, are at higher risk of viral hemorrhagic cystitis. They are particularly prone to adenoviral and BKV infections. Despite the advent of newer antiviral agents, their treatment continues to pose a clinical challenge.

Unfortunately, little effort has been made to define the incidence and the microorganism patterns of UTIs in this group of patients. Further, the potential impact of UTIs on morbidity and mortality of cancer patients remains to be explored.

# Urologic Disorders

Glenn A. McDonald, MD  
John R. Foringer, MD

## Urologic Complications in Cancer

Optimal care of patients with neoplastic disorders requires not only proper therapy but also the anticipation of complications from both primary disease and associated therapeutic interventions. Abnormalities of the urinary tract commonly herald the presence of a neoplastic process or result from its therapy. Common urologic complications associated with neoplastic disorders include hematuria, hemorrhagic cystitis, and urinary obstruction. The presence of these abnormalities is associated with significant prognostic implications as well as management challenges. This chapter will review the salient features of these disorders and their therapy.

## Hematuria

Hematuria is the presence of abnormal numbers of red blood cells (RBCs) in the urine. It may present with obvious discoloration of the urine, as in macroscopic (gross hematuria), or with visibly normal urine, as with microscopic hematuria. The pattern of hematuria may be intermittent or persistent. Clinically, hematuria can be divided into two distinct categories, asymptomatic isolated hematuria and symptomatic hematuria. Asymptomatic isolated hematuria presents in the absence of any evidence suggesting the cause or site of the hematuria. Symptomatic hematuria occurs in the presence of associated historical clues, physical signs and symptoms, or abnormal laboratory values. Distinguishing between asymptomatic isolated and symptomatic hematuria can help guide the diagnostic work-up.

Gross hematuria is always associated with urinary tract pathology and commonly presents as red-colored urine. However, red-colored urine is not always caused by hematuria. The ingestion of several foods (rhubarb, beets), drugs (phenolphthalein, phenothiazines, phenindione, phenazopyridine), or in the presence of porphyrins (as in porphyria) may lead to red-colored urine.<sup>1</sup> Thus, in gross hematuria it is necessary to confirm the presence of hematuria by urine dipstick and microscopic evaluation. The urine

dipstick is a colorimetric test to detect free heme. In addition to RBCs, the presence of free hemoglobin (intravascular hemolysis) and myoglobin (rhabdomyolysis) will result in a positive dipstick test.<sup>2</sup> Contamination with iodine-containing products (Betadine) or other oxidizing agents can result in false positive urine results. Ascorbic acid excretion and old (air-exposed) dipsticks have been associated with false negative results.<sup>3</sup> The limitations of the urine dipstick test demonstrate the necessity for microscopic evaluation of urine in the evaluation of hematuria.

Under normal circumstances, people excrete up to  $1.2 \times 10^6$  red blood cells per day. Hematuria is defined as the presence of RBCs in the urinary tract that exceeds the amount normally found in a fresh urine sample. Since it is impractical to quantitate the number of RBCs over 24 hours, clinically significant hematuria is defined as  $\geq 3$  RBCs per high-powered field in 2 of 3 properly collected urine specimens.<sup>4</sup> Once the presence of RBCs in the urine has been confirmed, the objective is to identify the site and cause of bleeding. The site of bleeding may originate from any location in the urinary tract, which can be divided into three broad categories: extra renal diseases, non-glomerular renal disease, and glomerular renal disease. The predominant causes of hematuria in cancer patients are most commonly attributed to extra-renal disease and non-glomerular renal disease.

## Hematuria Associated with Extra-Renal Disease

In the general population, extra-renal causes of hematuria account for approximately 65% of the cases of hematuria. This percentage is markedly increased in cancer patients. Extra-renal causes of hematuria include uroepithelial neoplasm, benign prostatic hypertrophy, urinary tract infections, and nephrolithiasis (Table 1).

### Extra-Renal Neoplasms

Uroepithelial neoplasms include transitional cell carcinoma and squamous cell carcinoma. The incidence of transitional cell carcinoma progressively increases above the age of 35. It is

the fourth leading cause of cancer in men aged 60 to 79 (behind prostate, lung, and colon cancer).<sup>5</sup> The risk factors that are associated with the development of transitional cell carcinoma include age, sex, race, amount of hematuria, tobacco use, toxic exposures, and parasitic infection (Table 2).<sup>6</sup> These tumors occur approximately four times more frequently in men than women and twice as likely in white versus black males. They account for approximately 15 to 20% of the cases of hematuria in adult white men.<sup>7</sup> These tumors are 10 times more likely to occur in the bladder than the renal pelvis. Involvement of the renal pelvis is suggested by the presence of hydronephrosis on renal ultrasonography. The diagnosis of transitional cell carcinoma should be considered in patients with hematuria and a history of heavy tobacco use or exposure to occupational toxins.<sup>8</sup> While transitional cell carcinomas account for the majority of tumors of the bladder, squamous cell carcinoma has been associated with chronic schistosomiasis.<sup>8</sup> Abnormal urine cytology is present in approximately 70 to 80% of the cases of bladder cancer, but is approximately 95% specific. The low sensitivity of urine cytology makes flexible cystoscopy the preferred test to evaluate for neoplasms of the bladder.

Adenocarcinoma of the prostate is a common cause of hematuria. In contrast to transitional cell carcinoma, the incidence adenocarcinoma of the prostate increases above the age of 45 and is the most common malignancy of the urinary tract in men above the age of 55 (National Cancer Institute (U.S.). Division of Cancer Prevention and Control., 1987 #23). Benign prostatic hypertrophy (BPH) is also associated hematuria.<sup>9</sup> BPH is so prevalent in elderly men that the presence of hematuria merits formal evaluation.

### Urinary Tract Infections

Infections of the urinary tract such as urethritis, cystitis, or prostatitis account for approximately 20 to 25% of all cases of hematuria in the general population. Cancer patients are at an increased risk for these infections from both the primary disease and the associated therapy. Three factors that predispose cancer patients to infections of the urinary tract include an obstructive process related to the primary tumor, immunosuppression from chemotherapeutic agents, and the presence of a foreign body (such as a Foley catheter or nephrostomy tube). These infections may present as microscopic or macroscopic hematuria and are associated with pyuria. The presence of hematuria and pyuria should raise suspicion for infection and necessitates obtaining a urine culture. Two infectious organisms that are commonly associated with negative urine cultures are *Chlamydia trachomatis* and *Mycobacterium tuberculosis*.<sup>10,11</sup> It is important to note that other diseases can present with hematuria and pyuria. Three disorders that should be considered are inflammatory glomerulonephritis, interstitial

nephritis, and multiple myeloma (myeloma kidney). Unlike infections of the urinary tract, these disorders are commonly associated with renal insufficiency.

### Nephrolithiasis/Crystalluria

Nephrolithiasis accounts for 20% of the cases of hematuria in the general population. The classic presentation consists of flank pain, associated with either microscopic or macroscopic hematuria and the presence of crystals in the urine. Cancer patients may develop hematuria associated with crystalluria as a toxic effect from a therapeutic agent. Medications that are associated with crystalluria include sulphadiazine, triamterene, acyclovir, and indinavir.<sup>12</sup> Additionally, a sudden rise in the serum uric acid from conditions such as tumor lysis syndrome has been associated with hematuria and uric acid crystalluria.<sup>13</sup>

### Non-glomerular Renal Causes of Hematuria

Hematuria in cancer patient may also result from non-glomerular renal disorders. These disorders most commonly arise from the primary neoplasm, such as renal cell carcinoma or a therapeutic intervention (Table 3). The most common causes of hematuria in this category include: renal cell carcinoma, metabolic abnormalities, such as hypercalcemia or hyperuricemia, and coagulopathies.

Drug induced acute interstitial nephritis

### Renal Cell Carcinoma

Renal cell carcinoma (RCC) represents approximately 20% of all urinary tract neoplasms. The incidence of RCC is about half that of transitional cell carcinoma, but has a poorer prognosis, with a 5-year survival of only 60%.<sup>5</sup> The classic triad of hematuria, an abdominal mass, and flank pain are found in less than 5% of cases. The most common presentation of RCC is as asymptomatic hematuria or an incidental finding on an imaging study. Risk factors for RCC include heavy metal, asbestos, and hydrocarbon exposures; tobacco use; and acquired cystic disease in patients with end stage kidney disease.<sup>14</sup> The majority of RCC cases may be part of an autosomal dominant disorder, the von Hippel-Lindau disease resulting from biallelic mutation of the VHL gene.<sup>15</sup> Other clinical features that are commonly associated with RCC include fever, hypertension, erythrocytosis, and hypercalcemia. Renal cell carcinomas are most commonly identified by renal ultrasonography as a solid mass or complex cyst. Computed tomography and magnetic resonance imaging are useful in determining local spread plus renal vein and inferior vena cava involvement, respectively.<sup>16,17</sup>

### Hypercalcemia and Hyperuricemia

Hypercalcemia and hyperuricemia have been demonstrated in cancer patients associated with the neoplasm or related therapeutic interventions.<sup>18</sup> If these conditions lead to hypercalcemia or hyperuricemia, this may manifest as hematuria.<sup>19</sup> Both conditions would predispose the patient to either calcium or uric acid nephrolithiasis. Treatment for the elevated urine uric acid or calcium (with allopurinol or hydrochlorothiazide, respectively) resolved the hematuria.<sup>19</sup>

### Other Causes of Hematuria

#### Disorders of Coagulation

Hematuria may present, associated with bleeding diathesis. Cancer patients commonly develop bleeding diathesis from abnormalities of the coagulation system related to the neoplastic disease or therapy, and for hypercoagulable states or thrombosis. Hematuria associated with coagulopathic states always requires further evaluation.<sup>20</sup>

### Evaluation of Hematuria

Hematuria commonly presents with signs, symptoms, or abnormalities on urinalysis, or with laboratory values that provide clues to the etiology. Thus, the first step in the evaluation of hematuria is a complete history and physical examination. The pattern of hematuria can give insight into the site of bleeding. Prominent hematuria associated with the initiation of the stream suggests a

urethral lesion, whereas hematuria at termination is consistent with a bladder bleeding. Hematuria that is present continuously throughout urination is consistent with bladder, ureteral, or renal bleeding. The pattern of hematuria can be confirmed by obtaining a split urine specimen. Features associated with hematuria can often provide clues to the site and/or cause of hematuria. Bleeding from the upper urinary tract may be associated with ureteral casts, which form long serpentine clots compared to broad clots associated with lower urinary tract bleeding. Lower urinary tract bleeding may also present as bright red blood that clears with urination.

Other constellations of symptoms can suggest specific causes of hematuria. The presence of urgency, urinary frequency, and dysuria are commonly present with urinary tract infections. The presence of hematuria with associated unilateral flank pain is suggestive of urinary tract obstruction from renal stone disease. People over the age of 50 who present with hematuria and flank pain should be evaluated for renal cell carcinoma. All men above the age of 50 who present with hematuria should be asked about hesitancy, inability to empty the bladder, and the quality of the urinary stream to investigate for prostatic disease. Finally, in women who menstruate, it is important to rule out the possibility of contamination with RBCs from menstrual blood.

A patient's family history can often provide important clues to the etiology of hematuria. Both polycystic kidney disease and glomerular basement membrane diseases are inherited renal diseases that may present as hematuria. Careful attention to the medication history can be important. Drug-induced interstitial nephritis, cyclophosphamide associated hemorrhagic cystitis, or the presence of anticoagulation may present as hematuria. On physical examination, the presence of a renal mass or evidence of prostate disease on rectal examination, are critical in the evaluation of hematuria. The combination of hypertension, edema, and hematuria are consistent with glomerulonephritis. Hereditary disorders of the glomerular basement membrane are associated with sensory-neural hearing loss and anterior lenticonus. Careful examination of the urine can aid in the evaluation of hematuria. The presence of dysmorphic RBCs (fragmented or distorted), RBC casts, and proteinuria is suggestive of a glomerular disease.

### Clinical Approach to Hematuria

Because of the arbitrary nature of the definition of hematuria, it is important to consider the clinical presentation and demographic data of the patient with established hematuria. In the absence of associated symptoms (asymptomatic isolated hematuria) the evaluation is directed by the

patient's age (Table 4). Hematuria in asymptomatic patients under the age of 35 years old is very different from those over the age of 35. Glomerular and metabolic disease account for the majority of asymptomatic, isolated hematuria in adults under the age of 35. The evaluation of all patients with isolated hematuria should include renal ultrasonography as an initial imaging study. In patients under the age of 35, a 24-hour urine collection should be obtained to evaluate for metabolic disorders such as hypercalciuria or hyperuricosuria. In the absence of a metabolic cause, the focus of the evaluation turns to glomerular diseases. Specific attention should be paid to the family history for any first-degree relatives with familial glomerular disease. Prior to obtaining a renal biopsy, intravenous pyelography (IVP) should be performed to exclude the rare case of medullary sponge kidney. The incidence of a neoplasm presenting as asymptomatic, isolated hematuria markedly increases above the age of 35. If the initial renal ultrasonography is normal, IVP with nephrotomography should be performed with attention to visualization of the renal pelvis and ureters. Radiolucent filling defects would indicate the presence of a tumor. In the event of an inadequate visualization of the collecting system, retrograde pyelography should be performed. In addition to visualizing the collecting system, cystoscopy is indicated to rule out bladder involvement. If the above imaging studies are normal, urine cytology should be obtained. Urine cytology is abnormal in only 75 to 80% of patients with bladder. If the above evaluation is normal, a work-up for metabolic and glomerular etiologies should be performed.

### Hemorrhagic Cystitis

Hemorrhagic cystitis is defined as acute or insidious diffuse vesicular inflammation with

hemorrhage.<sup>21</sup> The presence of associated bleeding diathesis due to the cancer or its treatment may exacerbate vesicular bleeding. Gross hematuria commonly requires emergency therapy and palliation. The majority of cases of hemorrhagic cystitis in cancer patients are due to metabolites of chemotherapeutic agents such as cyclophosphamide, bladder injury from radiation therapy, and viral infections in an immunocompromised host (Table 5). Other important causes of bladder hemorrhage that occur in cancer patients (but that will not be discussed) include hemorrhage due to the primary neoplasm; or bacterial, fungal, or parasitic infection associated with an immunosuppressed state.

### Drug-Induced Hemorrhagic Cystitis

The urinary tract is exposed to the toxic effects of many therapeutic agents and their metabolites. Many of these agents are concentrated in the urine and have prolonged exposure to the mucosa of the bladder. A prominent example is the oxazaphosphorine alkylating agents that include cyclophosphamide and ifosfamide. Initial experience with these agents was associated with bladder damage manifesting as dysuria, increased urinary frequency, urgency, and microscopic and macroscopic hematuria.<sup>22</sup> Similar effects were subsequently noted with ifosfamide.<sup>23</sup> The incidence of hemorrhagic cystitis in patients receiving high-dose cyclophosphamide therapy has been reported to be as high as 20%—and as high as 8% of those receiving ifosfamide. Hemorrhagic cystitis is associated with a high morbidity and may result in life-threatening vesicular hemorrhage, with reported mortality rates in bone marrow transplantation patients of up to 75%.<sup>24</sup> The toxic effects of these agents commonly occur at the time of, or shortly after, the administration of these agents. Bladder hemorrhage may present later in the course of therapy in patients who are on chronic oral therapy. Other complications with chronic therapy include the development of fibrosis and transitional cell carcinoma of the bladder.<sup>25,26</sup>

It was initially thought that these agents were directly toxic to the vesical mucosa. Work by

Philips and colleagues, demonstrated that there were no toxic effects with direct exposure of the bladder to these agents.<sup>27</sup> Systemic administration resulted in bladder toxicity within 24 hours of receiving the first dose. Furthermore, untreated animals developed cystitis when urine from treated animals was instilled into their bladder, suggesting the presence of a toxic metabolite. The animals developed transmural edema, mucosal ulceration, and necrosis within 24 hours of administration of cyclophosphamide. The toxicity was dose-dependent and abrogated by inducing a diuresis. Subsequently, the hepatic metabolite of cyclophosphamide, acrolein, has been implicated as the toxic agent.<sup>28,29</sup> In other studies characterizing histologic and cytology features of cyclophosphamide toxicity, edema and hyperemia was noted within 4 hours of administration of a single dose and persisted for up to 36 hours.<sup>25,26</sup> Both increased dosage and repeated exposure are associated with progressive fibrosis.

Patients commonly present with signs of bladder irritation that include dysuria, increased frequency, urgency, and microscopic or gross hematuria. In one study of 100 patients who developed cyclophosphamide-induced hemorrhagic cystitis, microhematuria was present in 93% of the cases; 78% presented with gross hematuria; and 45% had symptoms associated with voiding.<sup>30</sup> Hemorrhage severe enough to require transfusion occurred in 20% of the patients. Bladder hemorrhage occurred after a mean cumulative intravenous dose of 18 g or an oral dose of 90 g. Hemorrhagic cystitis occurred after one dose in three patients. Cystectomy was required in 9 patients, and 10 patients died from uncontrolled bleeding or a complication thereof.<sup>30</sup> The primary clinical risk factor for developing hemorrhagic cystitis is the presence of thrombocytopenia at the time of treatment.<sup>31</sup> It is clear that bladder toxicity is a major limiting factor with the use of these agents. Therefore, effort to prevent or limit this toxicity is of paramount importance.

As mentioned above, initial studies indicated that prehydration with associated diuresis decreased the incidence of bladder hemorrhage.<sup>24,32</sup> Prehydration decreases bladder toxicity by diluting and washing out acrolein, the toxic metabolite of cyclophosphamide. Subsequent studies evaluating the effects of hydration on cyclophosphamide toxicity have been mixed, specifically, in the setting of high-dose therapy and chronic oral therapy.<sup>24,33</sup> A different strategy to limit the toxicity of acrolein is to bind and neutralize its toxic effects. Mesna (2-mercaptoethane sulfonate) is an agent that binds acrolein, limiting its toxicity and thereby allowing maximum therapeutic efficacy of oxazaphosphorine alkylating agents.<sup>34,35</sup> An added benefit of preventing bladder injury will also prevent the subsequent development of transitional cell carcinoma associated with this therapy.<sup>36</sup> In addition to aggressive oral

hydration, mesna is given intravenously in doses of 800 mg/m<sup>2</sup> or 20 mg/kg at time of cyclophosphamide administration and every 4 hours for 2 to 3 subsequent doses. To protect against ifosfamide toxicity, patients should receive intravenous hyperhydration and an intravenous bolus of mesna 15 minutes prior to treatment that equals 20% of the ifosfamide dose, and every 4 hours for 2 doses. The total mesna dose should equal 60% of the ifosfamide dose. Mesna can be administered as a continuous infusion at 100% of the ifosfamide dose. Mesna should be continued 4 to 8 hours after the infusion of ifosfamide is complete. In the case of high-dose cyclophosphamide as used in bone marrow transplantation, mesna is given in doses ranging from 60 to 160% of the cyclophosphamide dose by continuous infusion or in 3 to 5 divided doses.<sup>36–39</sup>

### Radiation Cystitis

Radiation is a common therapeutic modality employed in the treatment of gynecologic, genitourinary, and rectal cancer. Approximately 20% of the patients who receive pelvic irradiation of these tumors experience some form of bladder toxicity.<sup>40,41</sup> Bladder toxicity most commonly manifests as dysuria, urgency, and increased frequency due to reduced bladder compliance and capacity. Unlike cyclophosphamide toxicity, hematuria may occur months to years after therapy, presenting as microscopic hematuria or life-threatening hemorrhagic cystitis.<sup>42</sup> Hemorrhagic cystitis has been reported in up to 9% of the patients who received full-dose irradiation for genitourinary cancer.<sup>43</sup>

The initial toxic effect of radiation on the bladder is on the vesical mucosa with the development of diffuse mucosal edema. This is followed by the development of vascular telangiectasia, submucosal hemorrhage, and interstitial fibrosis.<sup>21</sup> The long-term consequence of this process is a small fibrotic bladder that is noncompliant. As this process resolves, the greatest danger is the development of obliterative endarteritis leading to ischemia of the vessel wall and hemorrhage.<sup>44</sup> In addition to hemorrhagic cystitis, one study demonstrated that 85% of macroscopic hematuria post-radiation therapy was attributed to recurrent disease.<sup>40</sup> This observation underscores the importance of cystoscopy with any episode of hematuria post-radiation therapy.

### Viral Hemorrhagic Cystitis

Hemorrhagic cystitis in cancer patients associated with viral infection has been predominantly seen in the bone marrow transplantation population. Viral-induced hemorrhagic cystitis was initially noted in the mid-1970s, when an outbreak of adenovirus type II was associated with urinary

symptoms and gross hematuria in immunocompetent children.<sup>45,46</sup> Adenovirus II has been recovered from the urine of patients who developed hemorrhagic cystitis after marrow transplantation.<sup>47</sup> Additionally, the BK type of human polyomavirus has been implicated in the development of hemorrhagic cystitis in the bone marrow transplantation population.<sup>48</sup> BK virus is indigenous in the general population and persists in a latent form in the kidney following a primary infection.<sup>49</sup> Subsequent immunosuppression (bone marrow transplantation) activates the latent virus resulting in viruria.<sup>50</sup> In a prospective study of patients undergoing marrow transplantation, BK virus was found in the urine in 55% of patient with hemorrhagic cystitis, compared to 11% who had no cystitis.<sup>51</sup> Furthermore, Priftakis and colleagues demonstrated that greater than  $1 \times 10^4$  copies/ $\mu$ L by real time polymerase chain reaction was associated with an increased risk of hemorrhagic cystitis.<sup>52</sup> The use of cyclophosphamide in the preparation for transplantation has been associated with persistent BK viruria and hemorrhagic cystitis.<sup>53</sup> In light of the role of the BK virus in hemorrhagic cystitis in this patient population, DNA gyrase inhibitors such as vidarabine are being incorporated in the uroprotective regimen.<sup>54</sup>

### Treatment

The best treatment for any disorder is prevention. Appropriate uroprotective regimens, as outlined for cyclophosphamide-induced hemorrhagic cystitis above, are critical for optimal therapy. The two clinical issues in the treatment of acute hemorrhagic cystitis are urinary obstruction due to clot formation and ongoing bladder hemorrhage. Dissolution of formed clots is accomplished by intermittent or constant bladder irrigation with water, or antibiotic-containing saline or endoscopic clot evacuation. Ongoing diffuse hemorrhage after clot removal is an indication for either systemic or intravesical administration of various hemostatic agents. These agents include aminocaproic acid, silver nitrate, alum, prostaglandins, and formalin (Table 6). In extreme cases, vascular

**Table 6** Therapeutic Agents for Hemorrhagic Cystitis

Aminocaproic Acid
Silver Nitrate
Alum
Hyperbaric Oxygen
Formalin
Hypogastric artery embolization
Open cystotomy with bladder packing
Cystectomy with urinary diversion

embolization and emergency cystectomy are utilized to avoid exsanguination.

The initial therapeutic approach to hemorrhagic cystitis consists of clot evacuation with bladder irrigation. Commonly removing clots and decompressing the bladder will decrease or resolve bladder hemorrhage.<sup>55</sup> This process is usually carried out with a multichannel catheter with intermittent or constant irrigation with water or antibiotic-containing saline. Continuous bedside irrigation for recalcitrant clots can result in increased intravesical pressure and bladder rupture.<sup>55</sup> Clots that have been present for many hours may require mechanical disruption under direct visualization with an endoscope. Direct visualization offers the additional advantage of cauterizing any focal site of bleeding.

$\epsilon$ -Aminocaproic acid, an inhibitor of plasminogen activator substances, promotes hemostasis in hemorrhagic cystitis by inhibiting fibrinolysis.<sup>56</sup> Aminocaproic acid has the untoward effect of increasing the density of existing clots, further complicating their dissolution.<sup>57</sup> Thus, it is important to make every effort to remove any existing clots prior to treatment with this agent. It is administered either intravenously or orally, with a maximal effect seen at 8 to 12 hours. The use of this agent is contraindicated in patients with upper tract bleeding in the presence of ureteral reflux.<sup>58</sup> It has also been associated with severe hypotension.<sup>58</sup>

The intravesical instillation of silver nitrate has been used to treat diffuse bladder hemorrhage.<sup>59</sup> This agent is instilled for 10 to 20 minutes and may require several treatments. In one study, silver nitrate was associated with a 68% success rates in stopping bladder hemorrhage.<sup>60</sup> Unfortunately, follow-up studies have been associated with short-term efficacy with recurrent bleeding rates of up to 80% at 2 years. Additionally, precipitation of silver salts in the urinary tract has resulted in functional obstruction and renal failure.<sup>61</sup>

Alum is an ammonium or potassium salt of aluminum which can be administered without anesthesia for hemorrhagic cystitis.<sup>62,63</sup> Continuous irrigation of a 1% solution is used to chemically cauterize the bladder. Continuous infusion for an average of 21 hours is required to achieve optimal outcomes. Allergic reactions have been reported, requiring termination of therapy. Alum is reportedly not absorbed by the bladder mucosa but has been associated with increased serum aluminum levels with encephalopathy.<sup>63-65</sup> Prostaglandin  $E_2$  and  $F_{2\alpha}$  are normally present in the bladder and have been reported to improve healing of the microvasculature and epithelium, inhibit edema, and have a protective effect on mucosal ulceration.<sup>66,67</sup> When instilled in the bladder, both have been demonstrated to control intractable bladder hemorrhage.<sup>66,68</sup> Severe

bladder spasms have limited the therapeutic efficacy of these agents.

Hyperbaric oxygen is a noninvasive form of therapy for hemorrhagic cystitis. Successful treatment of radiation-induced bone necrosis initiated the evaluation of hyperbaric oxygen in radiation-induced hemorrhagic cystitis. In multiple studies, hyperbaric oxygen therapy has resulted in the reversal of hematuria in patients with radiation-induced cystitis.<sup>44,69</sup> In subsequent studies, this therapy has proven effective in cyclophosphamide-induced hemorrhagic cystitis.<sup>70</sup> Hyperbaric oxygen is thought to promote wound healing in areas of the bladder where perfusion is limited due to scar tissue.

Formalin, the aqueous solution of formaldehyde, is the most effective local treatment for intractable bladder hemorrhage.<sup>71</sup> It is used in tissue preparation for its ability to rapidly cross-link proteins and fix tissues. Intravesical administration of formalin rapidly crosslinks proteins on the bladder mucosa, preventing further tissue necrosis, breakdown, and bleeding. It has been reported to be effective in alleviating bladder hemorrhage in up to 80% of the cases.<sup>71</sup> Unlike alum and the prostaglandins, the administration of formalin requires general or regional anesthesia due to the pain associated with instillation. Adverse effects of formalin administration are related to its ability to fix tissue. Formalin is administered in the reverse Trendelenburg's position to decrease the chance of reflux of formalin in the ureters resulting in fibrosis and hydronephrosis.<sup>72</sup>

Selective vascular embolization has been utilized to control massive bleeding from the bladder. Bleeding from virtually any site involving the bladder or prostate can be addressed by

selective embolization of the hypogastric artery.<sup>73,74</sup> This approach is commonly used in patients with refractory bladder hemorrhage and in patients who are not operative candidates and are medically unstable. Occluding the hypogastric artery may result in transient ischemia of the gluteal muscles, transient unilateral lower limb paralysis, and bladder necrosis.<sup>75,76</sup>

In cases where the above modalities have failed to control the bleeding, open cystotomy with bladder packing or cystectomy with urinary diversion may be required to avoid exsanguinations.<sup>77,78</sup> Surgical intervention under these circumstances is associated with high morbidity and mortality rates due to hemodynamic instability at the time of the procedure. The primary goal of these procedures is to gain hemodynamic instability. While most patients who undergo surgical intervention for bladder hemorrhage require urinary diversion, every effort should be made to avoid cystectomy in favor of bladder reconstruction.

### Clinical Approach to Hemorrhagic Cystitis

The therapeutic strategy in hemorrhagic cystitis is predicated on the severity of the bleeding. Devries and Freiha suggested dividing hemorrhage in three categories: mild, moderate, and severe (Table 7).<sup>21</sup> Mild hemorrhage is controlled by simple measures, such as bladder irrigation with water or saline, silver nitrate, alum, and aminocaproic acid. Moderate bladder hemorrhage results in a decrease in hemoglobin requiring 6 units or less of packed red blood cells over several days. Urinary obstruction due to clot formation is a common complication of this level of bleeding.

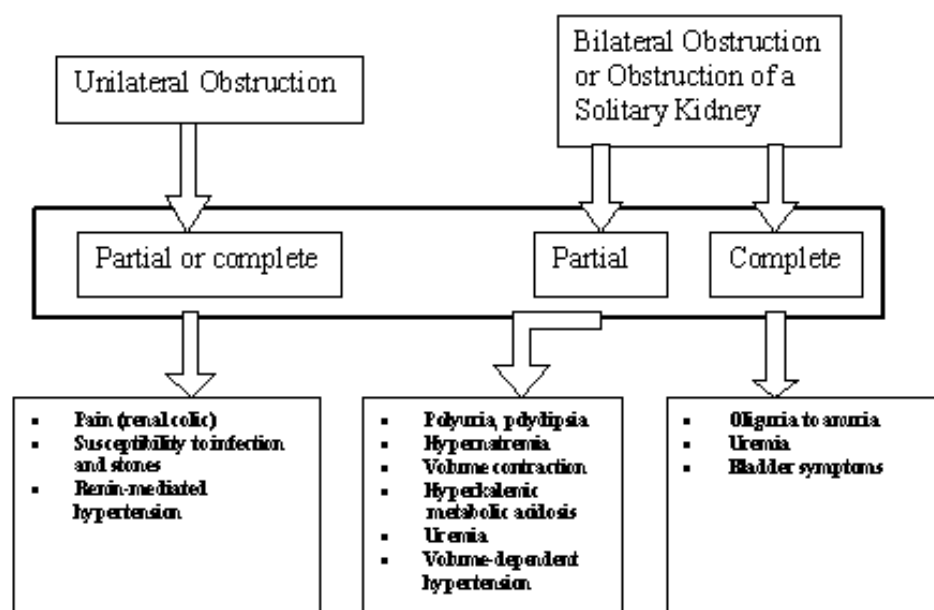

FIGURE 1 Adapted from Schrier R. Atlas of diseases of the kidney. Current Medicine, Inc.; 1999.

Aminocaproic acid
Formalin
<b>Severe hemorrhage</b>
Bladder irrigation/clot removal
Aminocaproic acid
Formalin
Hypogastric artery embolization
Surgical intervention

Evacuation and prevention of clot formation is the first goal of therapy. Intravesical instillation of aminocaproic acid, alum, or silver nitrate should be considered first-line agents to control this level of bleeding. In resistant cases, the instillation of a diluted formaldehyde solution or an open surgical procedure. Severe hematuria is defined as continued hemorrhage that does not resolve with simple irrigation, instillations, or aminocaproic acid, and requiring greater than 6 units of packed red blood cells. In this clinical setting, formalin appears to have the best chance of controlling intractable hemorrhage.

### Obstructive (Postrenal) Nephropathy

Urinary tract obstruction is a relatively common cause of renal failure in patients with malignancy. Regardless of cause, obstruction of urinary flow leads to renal impairment, which, early in the course of the condition, is reversible if the obstruction is alleviated. Tubular function is initially affected; however, prolonged obstruction leads to tubular damage and parenchymal atrophy. Seventy percent of the cancers that cause obstruction originate from the genitourinary tract.<sup>55</sup> Commonly encountered causes of urinary tract obstruction in cancer patients are listed in Table 8. Retroperitoneal fibrosis after radiation therapy can result in ureteral obstruction and can be a late complication. McIntyre and colleagues reviewed 1,784 cases for ureteral obstruction after external beam irradiation for the treatment of stage IB cervical carcinoma at the M. D. Anderson Cancer Center.<sup>79</sup> Ureteral obstruction occurred in 29 patients, with 2.5% of them surviving 20 years after developing a severe ureteral stricture. The authors recommend long-term surveillance for late onset ureteral obstruction.

Clinical manifestations of urinary tract obstruction vary, depending on the location, duration, and degree of obstruction. In patients with complete bilateral obstruction or with an obstructed solitary kidney, anuria (<50 mL of urine output in 24 hours) can be the presenting feature, whereas, in patients with partial obstruction, the urinary output can vary from oliguria to polyuria. In a review of 50 patients with acute renal failure secondary to bilateral ureteral obstruction, 76% had a malignancy as the cause, and half of these patients presented with uremia prior to the diagnosis of the cancer.<sup>80</sup> Although pain is more likely to be associated with acute blockage, obstruction may be totally asymptomatic and occur without overt clinical manifestations or suggestive laboratory findings.<sup>81</sup> Therefore, obstructive nephropathy should always be considered as a cause of renal failure when an obvious prerenal or intrinsic renal cause is not identified.

Diagnosis of urinary tract obstruction can be difficult. Anuria, flank pain with a palpable mass, or a palpable bladder are obvious clues. The laboratory evaluation can be helpful. Hyperkalemia with a non-anion gap metabolic acidosis is suggestive of a renal tubular acidosis associated with obstruction.<sup>82</sup> The urinary sediment may be bland or demonstrate crystals or hematuria depending on the etiology of the obstruction. Patients may have very dilute urine due to the presence

of an acquired form of nephrogenic diabetes insipidus.<sup>83</sup>

Ultrasonography is the most useful test to evaluate for the presence of obstruction. Although hydronephrosis is usually demonstrated, there are circumstances when hydronephrosis is not seen, despite urinary tract obstruction: (1) early in the course of obstruction (12 to 24 hours), when the collecting system is relatively noncompliant; (2) in the face of severe volume depletion, when glomerular filtration is severely depressed; and (3) when the collecting system is encased by retroperitoneal lymphadenopathy or fibrosis. Conversely, the finding of hydronephrosis on ultrasonography does not prove the presence of obstruction since it is also seen in high urinary flow states, such as diuretic use and diabetes insipidus, pregnancy, previous obstruction, and congenital megaureter. The lack of functional obstruction can be verified in these cases by a normal renal scan with furosemide-washout. In this test an intravenously injected radioisotope will collect in the dilated collecting system but be promptly excreted by the increased urinary flow induced by the diuretic.

Once obstruction is identified, it should be corrected with either percutaneous nephrostomy tubes or ureteral stenting, depending on local expertise and availability. The duration and severity of obstruction are the major determinants for the recovery of renal function after its correction. The longer the duration of obstruction, the less likely are the chances for complete renal recovery. In the past, open surgical procedures carried a high major complication rate, and now, both percutaneous and cystoscopic techniques are used to decompress obstructed kidneys with greater safety. Relative indications to proceed with percutaneous nephrostomy tube placement include large intravesicular tumors, large prostate tumors, tortuous ureters, more than one site of obstruction, or long occlusions.<sup>84</sup> An internal Double-J stent should be placed after decompression of the collecting system. Antegrade placement of the stent can be done using the nephrostomy tube. Metallic, self-expanding stents are now being used, often in conjunction with Double-J stents to avoid percutaneous nephrostomy tubes.<sup>85-87</sup> If the stent fails rapidly or cystoscopic management of the stent cannot be done, nephrostomy tubes may be permanent or an internal-external stent may be used.

Although renal function can be rapidly regained with percutaneous nephrostomy tubes or ureteral stents, the long-term prognosis for patients who develop obstructive uropathy from metastatic or locally advanced tumors is poor. Donat and Russo from the Memorial Sloan-Kettering Cancer Center reported the outcomes of 78 patients treated for ureteral obstruction from locally advanced or metastatic non-urolithic

tumors.<sup>88</sup> From the time of the first ureteral decompression, the median survival for all patients was 6.8 months. Fifty percent of the patients had a complication related to the placement of the percutaneous nephrostomy tubes or stents. In a report of 103 patients with advanced malignancies undergoing palliative urinary diversion, the average survival was 5 months with a complication rate of 63%.<sup>89</sup> It has been recommended that decompression procedures not be performed in patients with metastatic gastric and pancreatic cancer because the median survival is only 1.4 months after the procedure.<sup>55,88</sup>

## Post-Obstructive Diuresis

Post-obstructive diuresis occurs when there is correction of complete bilateral obstruction or complete obstruction of a solitary kidney. It involves the production of a large volume of urine that results from a defect in urinary concentrating ability, impaired reabsorption of urinary sodium, and solute diuresis from retained urea and intravenous administration of sodium-containing solutions. Patients with relief of complete obstruction who are at risk for developing post-obstructive diuresis should be carefully monitored. It has been recommended, for patients without pulmonary edema, congestive heart failure, or altered consciousness from uremia, that urine losses be replaced by oral intake.<sup>90</sup> Replacement fluids are given only if the patients develop orthostatic hypotension, tachycardia, hyponatremia, or a urine output more than 200 mL/hr. On the other hand, in high-risk patients with altered sensorium, congestive heart failure, or pulmonary edema, replacement of half the hourly urine output with half-normal saline has been recommended. If the patient is hyponatremic, normal saline should be used instead.<sup>55,90</sup>

# Ischemic Heart Disease in Cancer Patients

Atiar M. Rahman, MD, PhD

Table 1 Definitions

Acute coronary syndromes	A spectrum of clinical conditions encompassing ST segment elevation and non-ST segment elevation (unstable angina and non-Q wave myocardial infarction) myocardial infarction
Unstable angina	Ischaemic-type chest pain which is of recent origin; is more frequent, severe, or prolonged than the patient's usual angina; is more difficult to control with drugs; or is occurring at rest or minimal exertion; cardiac enzyme concentrations are not raised
Non-Q wave myocardial infarction	Myocardial infarction (increase in cardiac enzyme concentrations to greater than twice the upper limit of normal) occurring without the subsequent development of new Q waves on the 12 lead electrocardiogram
ST elevation myocardial infarction	Myocardial infarction with ST segment elevation on the presenting electrocardiogram

## Epidemiology

Collectively, cardiovascular disease, and cancer account for approximately two-thirds of all deaths in the United States.<sup>1</sup> Coronary artery disease (CAD) is the leading cause of death in the Western world, being responsible for about 1,400,000 annual deaths in the United States alone.<sup>2</sup> Similarly, cancer is second only to cardiovascular diseases as a cause of mortality and accounts for about one-quarter of all deaths in developed countries. In the United States, more than 563,700 people died from cancer in 2004.<sup>3</sup> About 1.37 million new cases of cancer would have been diagnosed in 2004 alone not including in situ (pre-invasive) cancer or the more than one million cases of non-melanomatous skin cancer. Cancer and CAD are true global health problems, although both disease states have often been regarded as a problem belonging principally to the developed world. In reality, more than half of all cancers occur in developing countries; and more than 80% of the global burden of cardiovascular disease occurs in low-income and middle-income countries.<sup>4</sup> The lifelong probability of developing cancer is 45% for men and 38% for women,<sup>5</sup> while the lifelong probability of developing CAD is 49% for men and 32% for women.<sup>6</sup> Indeed, cancer will become the leading cause of death in many countries early in this century. Worldwide there will be more than 30 million people living with cancer by 2015. The increasingly long survival of cancer patients raises a question as to whether there might be an associa-

tion between coronary disease and different types of cancer, since, as with many cancers, the prevalence of CAD is age-dependent, and these different diseases share some of the same risk factors (such as smoking). The attributable risk of age to coronary heart disease and cancer is significant and increases with age: the annual rate of first cardiovascular events in men aged 35 to 44 years of 7 in 1,000 increases almost tenfold to 68 in 1,000 for those aged greater than 85 years (for women, comparable rates occur 10 years later in life).<sup>6</sup> Although no definitive relationship is known to exist between cancer and CAD, in one retrospective autopsy study of 1,642 cancer patients, the incidence of MI was noted to be 6.5%, with significantly higher rates noted in patients with squamous cell cancers.<sup>7</sup> An emerging concept is that cancer is a manageable disease, similar to hypertension or diabetes, and requires early detection, periodic surveillance, and coordinated therapeutic decision-making. It is therefore critical for cancer survivors to limit comorbid illnesses. Many cancer survivors will actually be at as great a risk from cardiac disease as from recurrent cancer.<sup>8</sup>

## Economic Impact of Cancer and Heart Disease

According to the American Heart Association (AHA) and the National Center for Chronic Disease Prevention and Health Promotion, the cost of cardiovascular disease in the United States in 2005 was \$393.5 billion (US), of which CAD

contributes \$142 billion (US) equally split between direct medical costs and indirect costs, such as lost productivity. The National Institutes of Health (NIH) estimated that the overall costs for cancer in 2004 were at \$190 billion (US), including \$69 billion (US) for direct medical costs and \$121 billion (US) for indirect costs, such as lost productivity.<sup>6</sup> However, Americans' risk of dying from cancer continues to decline, and survival rates for many cancers continue to improve. Overall observed rates from all cancers dropped 1.1% per year from 1993 to 2001. The age-adjusted death rates for heart disease (ie, coronary heart disease) have decreased from 307.4 in 1950 to 134.6 per 100,000 persons (standardized to the 1940 population) in 1996. These data reflect progress in prevention, early detection, and treatment of both cancer and CAD. Paradoxically, however, this decline in mortality and resultant increased survival from both disease states combined with graying of the population would more likely translate into more patients with concurrent disease.

CAD and cancer are among the most significant contributors of health care spending in the US. Average monthly health care costs for cancer ranges from \$2,187 (US) for each patient with prostate cancer to \$7,616 (US) for those with pancreatic cancer, compared to the average health care costs for individuals without cancer of \$329 (US) per month.<sup>9</sup> This calculation excludes the average monthly indirect costs for cancer patients estimated at \$954 (US), attributed to an average loss of two working days and five days with short-term disability each month. Eisenstein and colleagues calculated that mean 10-year discounted inpatient medical costs of an acute coronary syndrome (ACS) patient were \$45,253 (US) (\$23,510 [US] acute phase and \$21,819 [US] post-acute phase) with similar figures for unstable angina and myocardial infarction patients.<sup>10</sup>

## Risk Stratification in Suspected CAD

Extensive clinical and statistical studies have identified several risk factors for coronary artery disease. Most of our knowledge about prevalence of coronary artery disease and its risk factors are mainly derived from studies done in populations

of European origin,<sup>11</sup> and data from studies in populations of non-European descent suggest that there may be variations in risk factors between different ethnic populations for coronary heart disease. Hypertension and hyperlipidemia do not represent a similar risk in south Asian<sup>12</sup> and Chinese populations.<sup>13</sup> Although commonly known risk factors (smoking, hypertension, hyperlipidemia, and diabetes) have been claimed to account for only half the risk of a myocardial infarction,<sup>14</sup> evidence from a recent large global case-control study (15,152 cases and 14,820 controls, undertaken in 52 countries in five continents) showed that easily measurable risk factors (including smoking, abnormal lipids, psychosocial factors, hypertension, diabetes, and abdominal obesity) are associated with more than 80% of the risk of an acute myocardial infarction (AMI).<sup>4</sup> The role of these attributes is verified by the fact that a strategy to reduce traditional cardiovascular risk factors through public awareness against smoking, by lowering low-density lipoprotein cholesterol and blood pressure, and by promoting a healthy lifestyle has contributed significantly to the decline in CAD-related deaths in the developed countries. In large cohorts from the United States, those without abnormal electrocardiogram (ECG) results, diabetes, a smoking habit, high cholesterol, and high blood pressure had an 80 to 90% lower risk of coronary heart disease compared with the rest of the population.<sup>14</sup> Similarly, in European studies, non-smokers with low blood pressure and low cholesterol had an age-adjusted relative risk of 0.09, which was much lower than for the average population (relative risk 1.0).<sup>4,15</sup> The latest data show smoking—a common risk factor for many cancers—as one of the most important risk factors, accounting for about 36% of the worldwide attributable risks of acute myocardial infarction. Additional factors including apolipoprotein ratios (ApoB/A1—marker of the balance of atherogenic and antiatherogenic particles),<sup>16</sup> and psychosocial factors,<sup>17</sup> may add substantially to traditional risk factors.

### Risk Stratification in ACS patient

Once a patient presents with ACS, a different approach of risk stratification becomes an integral component in the decision-making for such patient. Several such risk stratification tools are available; however, one that is frequently used is the Thrombolysis in Myocardial Infarction (TIMI) risk score (Table 2).<sup>18,19</sup> This tool combines seven variables (age  $\geq 65$  years;  $\geq$  three risk factors for CAD; prior coronary stenosis of  $\geq 50\%$ ; ST-segment deviation on ECG at presentation; at least two anginal events in prior 24 hours; use of aspirin in prior 7 days; and elevated serum cardiac markers) in an evenly weighted scale that can predict short- and long-term risk based on the calculated score<sup>20,21</sup> and identify

**Table 2** TIMI\* Risk Score for Unstable Angina and Non-ST-Segment Elevation

Age $> 65$ yr
Three or more risk factors for coronary artery disease
Prior coronary stenosis of 50%
ST-segment deviation on presenting ECG
Use of aspirin in prior 7 days
Elevated serum cardiac markers
Two or more anginal events in previous 24 hr

\*One point per risk factor: 5 to 7 points—high risk; 3 to 4 points—intermediate risk; 0 to 2 points—low risk  
TIMI = thrombolysis in myocardial infarction

patients that would benefit most from an early invasive strategy.<sup>22,23</sup> Other important predictors in stratifying the early delivery of appropriate treatments in Non ST elevation acute coronary syndrome (NSTEMI-ACS) patients include hemodynamic instability, signs and symptoms of heart failure, renal insufficiency, elevated levels of C-reactive protein and natriuretic peptides.<sup>24–27</sup>

### Coronary Complications of Cancer Therapy

There has been dramatic progress in cancer therapy in recent years, and the therapeutic options now include increasingly complex combinations of medications, radiation therapy, and surgical intervention. While a clear-cut link between cancer and CAD has not been established, many of the cancer treatments have important ischemic cardiac effects and are likely to have significant effects on patient outcomes. Several patient-related factors, including advanced age, preexisting coronary disease, concomitant radiation therapy, and metabolic abnormalities, increase the risk for chemotherapy-induced ischemic cardiac events in these patients. Additionally, each chemotherapeutic agent has the ability to potentiate the adverse effects of other agents. In one prospective study, cancer alone was associated with a fourfold risk of thrombosis, whereas chemotherapy increased the risk by 6.5 times.<sup>28</sup> Radiation therapy also plays an important role in magnifying cardiac toxicity (see below). It is, however, important to bear in mind that cancer patients undergoing intensive therapy are often severely ill, and cause-and-effect relationships of cardiac ischemia and therapies are often not very clear.

Coronary ischemia associated with chemotherapy agents are listed below according to drug class (Table 3).

#### Anthracyclines/Anthraquinolones

Anthracycline is the most studied of the anticancer drugs related to drug-induced cardiotoxicity, which is probably related to its ability to cause direct myocardial injury via formation of free

**Table 3** Adverse Cardiovascular Events Associated With Chemotherapeutic Agents

Raynaud phenomenon: vinblastine  
Autonomic neuropathy: vincristine  
Pulmonary fibrosis: bleomycin  
Endomyocardial fibrosis: busulfan

radicals.<sup>29</sup> Acute cardiotoxicity may manifest as nonspecific ST-segment and T-wave abnormalities, a common feature with chronic CAD. Anthracycline-induced cardiac toxicity has a dismal prognosis, but it can be greatly altered by early recognition and treatment.

## Alkylating Agents

These may cause endothelial and myocyte injury mediated through a toxic metabolite<sup>30</sup> resulting in hemorrhagic myocardial necrosis.<sup>31</sup> The toxic effects can last up to 6 days, but long-term effects are not usually seen in those who survive.<sup>32</sup> Ifosfamide may cause a dose-related incidence of arrhythmia.<sup>33</sup> Cisplatin infusion may be associated with chest pain, palpitations, and, occasionally, elevated cardiac enzymes indicative of myocardial infarction (MI).<sup>34</sup> Cisplatin is unique in that it can cause late cardiovascular complications such as hypertension, myocardial ischemia, and MI as long as 10 to 20 years after the remission of metastatic testicular cancer.<sup>35</sup> Mitomycin may adversely affect the heart via formation of superoxide radicals under aerobic conditions.<sup>36</sup>

## Antimetabolites

5-fluorouracil (5-FU), widely used in the treatment of many solid tumor treatment protocols, has been well described to induce cardiac ischemic syndrome,<sup>37</sup> which varies clinically from angina pectoris to acute MI. A “rechallenge” with 5-FU frequently reproduces the cardiac events. The ischemia is usually reversible on cessation of the 5-FU and implementation of anti-ischemic medical therapy. Although ischemic events can occur in patients without underlying CAD (incidence, 1.1%), the incidence is higher in patients with known CAD (4.5%).<sup>38</sup> Capecitabine, currently used in the treatment of breast and gastrointestinal cancers, has been associated with inducible angina or MI,<sup>39</sup> arrhythmias, and ischemic ECG changes.

## Antimicrotubule Agents

Paclitaxel is used extensively in the treatment of many solid tumors and is increasingly being used in coated stents for coronary interventions. Post-intervention intracoronary thrombosis is a known complication of coated stents, and require extended antiplatelet therapy in patients with CAD.<sup>40</sup> Paclitaxel is also known to cause sinus bradycardia, heart block, premature ventricular contractions, and ventricular tachycardia.<sup>41</sup> In a large study of approximately 1,000 patients, the incidence of cardiac toxicity was 14%, and most incidents (76%) were grade I asymptomatic bradycardia.<sup>42</sup>

Vinca alkaloids are used primarily in the treatment of leukemia and lymphoma. Vinorelbine-related ischemic cardiac events, including angina with ECG changes,<sup>43</sup> and myocardial ischemia and MI<sup>44</sup> are more likely to occur in women than in men.<sup>45</sup> The occasional clinical presentation of Prinzmetal’s angina and reversible ECG changes has led to the hypothesis of ischemia induced by coronary spasm.<sup>43</sup>

## Monoclonal Antibodies

Monoclonal antibodies are being increasingly used to manage many hematologic malignancies and solid tumors.<sup>46-49</sup> Infusion of these agents may result in massive release of cytokines leading to hypotension, dyspnea, hypoxia, or even death.<sup>49,50</sup>

## Cytokines

### Interleukins

High-dose interleukin-2 (IL-2), a T-cell growth factor, used for the treatment of metastatic renal cell carcinoma and melanoma may result in vascular leak syndrome,<sup>51</sup> cardiac arrhythmias, MI, and myocarditis.<sup>52</sup> Improvements in patient selection and treatment protocols may substantially reduce IL-2-treatment-related cardiac ischemic events.<sup>53</sup> Denileukin diftitox (Ontak), an IL-2/diphtheria toxin fusion protein used in the treatment of T-cell lymphoma, may predispose to arterial thrombosis in cancer patients,<sup>54</sup> which may also translate into ischemic symptoms.

### Interferon

Interferon, produced by macrophages and lymphocytes and approved for the treatment of many types of cancer, may cause hypotension or hypertension, tachycardia,<sup>55</sup> and, in severe cases, angina and MI.

## Miscellaneous Agents

### All-*trans* Retinoic Acid

This is a vitamin A derivative and is used in the treatment of acute promyelocytic leukemia. Fatal MI and thrombosis are known complications following use of all-*trans* retinoic acid<sup>56</sup> and may result in substantial decline in the LV ejection fraction<sup>57</sup>.

### Arsenic Trioxide

Arsenic Trioxide is used in the treatment of refractory or relapsed acute promyelocytic leukemia. Arsenic is commonly known to cause ECG abnormalities. Soignet observed significant prolongation of the QT segment in ≈50% of patients with acute promyelocytic leukemia.<sup>58</sup> They also noted sinus tachycardia, nonspecific ST-T changes, and torsades de pointes. Other reported cardiac complications include complete heart block<sup>59,60</sup> and sudden cardiac death.<sup>61</sup> In all these situations, the infusion of arsenic trioxide had been completed 7 to 22 hours before the events.<sup>61</sup>

### Pentostatin

Pentostatin, a purine analogue used in the treatment of hairy cell leukemia and other hematologic malignancies, may induce myocardial infarction and arrhythmias,<sup>62</sup> especially when

given with high doses of cyclophosphamide in preparation for bone marrow transplantation.<sup>63</sup>

### Thalidomide

Thalidomide is currently used to treat a variety of hematologic and solid malignancies,<sup>64</sup> is relatively safe with regard to coronary complications, and is generally well tolerated. Cardiotoxic effects of thalidomide include sinus bradycardia and deep venous thrombosis.<sup>64</sup>

### Etoposide

Etoposide used in the treatment of refractory testicular tumors and small-cell lung carcinoma has been reported to cause myocardial ischemic symptoms and MI.<sup>65</sup> The risk of myocardial ischemic events is significantly increased in patients who have previously undergone chemotherapy or mediastinal radiation.<sup>66</sup> Concomitant chemotherapy with other agents may also increase the risk for MI.<sup>65</sup>

### Homoharringtonine

Most often used in the treatment of leukemia, homoharringtonine can be associated with severe hypotension. This dose-related effect is probably related to its calcium-channel-blocking activity.<sup>67</sup> Although not directly linked to coronary artery related complications, ventricular tachycardia and atrial fibrillation have been reported after administration of homoharringtonine,<sup>68</sup> which may complicate management in a known CAD patient.

## Radiation Therapy

Radiation therapy is commonly used in the treatment of many types of cancer, particularly breast cancer and Hodgkin’s lymphoma. Meta-analysis of randomized clinical trials confirmed increased cardiovascular mortality among patients treated for early breast cancer<sup>69</sup> and Hodgkin’s lymphoma.<sup>70</sup> The precise incidence of radiation-induced accelerated atherosclerosis is difficult to confirm, but it has been reported in patients who did not have the traditional risk factors for CAD.<sup>71</sup> Radiation to the thorax can damage coronary arteries in addition to its toxic effect on the pericardium, myocardium, and cardiac valves. Despite its promise to reduce in-stent restenosis, intracoronary irradiation therapy has been almost abandoned because of a high incidence of late thrombosis and an increased risk of myocardial infarction.<sup>72</sup> The morphologic changes observed in radiation-induced coronary artery disease are similar to those observed in spontaneous atherosclerosis.<sup>73</sup> The exact mechanisms by which radiation produces atherosclerosis are not known, but endothelial injury from radiation has been suggested as the initiating factor. Ionizing energy accelerates the deposition of cholesterol in the

arterial wall, contributes to intimal and adventitial proliferation, as well as plaque ulceration, all of which may lead to acute coronary thrombosis.<sup>74</sup> Ionizing radiation also produces reactive oxygen species, including superoxide anion, hydrogen peroxide, and hydroxyl radicals that increase oxidative stress to the endothelium and to circulating lipoproteins. The oxidized lipoproteins, in turn, recruit inflammatory monocytes and macrophages into the arterial wall<sup>75</sup> starting the cascade of inflammatory process that leads to ACS. Endothelial damage from radiation reduces the bioavailability of nitric oxide resulting in impaired arterial vasodilatation, increased platelet aggregation, and leukocyte adherence. The smaller baseline size of radiated coronary arteries may be a result of increased apoptosis, which in turn, is a result of decreased availability of nitric oxide.<sup>76</sup> The higher the doses of radiation therapy, the higher the incidence of radiation-induced heart disease. The incidence of cardiac toxicity is also higher in patients who undergo concurrent therapy with doxorubicin.<sup>77</sup> Patients with preexisting CAD are especially vulnerable. The mean interval for developing CAD after radiation therapy is approximately 82 months.<sup>78</sup> However, vascular injury from radiation therapy can be silent, with as high as 50% of asymptomatic patients demonstrating new myocardial perfusion defects.<sup>79</sup> Sudden cardiac death has also been reported in patients treated with radiation therapy,<sup>80</sup> which may be attributed to diffuse intimal hyperplasia of coronary arteries or from discrete left main stenosis.<sup>71</sup> Endothelial cell involvement is an early sign of radiation-induced vascular damage.<sup>81</sup> Radiation-induced vascular injury often involves long segments of an artery.<sup>82</sup>

Management of radiation-induced CAD is difficult but not different than that of non-radiation-induced CAD. Both percutaneous coronary intervention and coronary artery bypass grafting have been used for revascularization.<sup>71</sup> However, concomitant radiation-induced mediastinal fibrosis may render surgical bypass grafting more difficult in these patients.<sup>71</sup>

### Cancer Prevention, Cyclooxygenase-2 and Cardiovascular Complications

The identification of cyclooxygenase-2 (COX-2) as a promoter of intestinal tumorigenesis led to the concept that COX-2 inhibitors would prevent premalignant colorectal adenomas.<sup>83-87</sup> This looked especially attractive since neither prior clinical trials nor observational studies had reported a clearly increased risk of cardiovascular events with celecoxib use.<sup>88-93</sup> However, in a large prospective, randomized, double-blind, multicenter trial, celecoxib use was associated with a significant dose-related increase in serious

cardiovascular events, including myocardial infarction and death.<sup>94</sup> In addition, the number of venous thromboembolic events also increased. Similar observation of an increased incidence of death from cardiovascular causes, myocardial infarction, or stroke among patients receiving rofecoxib in the Adenomatous Polyp Prevention on Vioxx trial resulted in early termination<sup>95,96</sup> and voluntary withdrawal of the drug from the market. Use of other selective COX-2 inhibitors, including valdecoxib, and parecoxib, has also been associated with an increased rate of cardiovascular events.<sup>97,98</sup> The reason for increase in cardiovascular risk associated with the use of COX-2 inhibitors is uncertain. One possible mechanism involves the effects of COX-2 inhibitors on blocking the production of prostacyclin without affecting the synthesis of thromboxane A<sub>2</sub>,<sup>95</sup> thereby potentially creating a prothrombotic state. Significant increase in cardiovascular thromboembolic events were also noted when parecoxib and valdecoxib were used for pain control in the immediate postoperative period after coronary artery bypass surgery.<sup>99,100</sup>

### Cancer and the Prothrombotic State

Cancer appears to cause a prothrombotic or hypercoagulable state through an altered balance between the coagulation and fibrinolytic system. However, for reasons presently unclear, arterial thromboembolism is much less common than venous thrombosis in cancer. This dichotomy may be partly explained by the large amount of fibrin, which is excessively formed in the large venous thrombi, compared to the relatively small amount of fibrin in arterial clots. The pathogenic mechanisms of thrombosis in cancer patients are multifactorial. A major mechanism involves activation of factor VII at the extrinsic coagulation system by tissue factor, which is expressed by most tumor cells.<sup>101</sup> Another important mechanism is triggered by cancer procoagulant, a cysteine protease which directly activates factor X and is expressed by certain human tumor cells.<sup>102</sup> An association between arterial disease and disturbances in hemostasis, thrombosis, and vascular function, have also been reported to be present in cancer.<sup>103</sup> Tumor cells may be directly prothrombotic by generation of excess thrombin and procoagulant proteins, such as tissue factor, fibrinogen, and plasminogen activator inhibitor. Cancer cells can also activate the coagulation system through interactions with platelets, thus shifting the balance to induce a prothrombotic state. In cancer, monocytes may also be activated by immune complexes or cytokines, such as tumor necrosis factor<sup>104,105</sup> and certain malignant cells,<sup>106,107</sup> whereas other cells, including those of sarcoma, melanoma, neuroblastoma, lymphoma, and acute promyelocytic leukemia, can express

tissue factor per se.<sup>108</sup> Concentrations of several other proteins within the coagulation cascade are also abnormally raised in cancer, and this is often associated with a fall in the activity of anticoagulant factors<sup>109,110</sup> leading to a prothrombotic or hypercoagulable state. Although these mechanisms play major roles in venous thromboembolism, their exact roles in ACS are unknown; they might contribute to a rapid transition of a vulnerable plaque from a subintimal lesion to a thrombotic occlusion.

Clinical manifestations of arterial thromboembolic phenomenon in cancer may include localized arterial occlusion, nonbacterial thrombotic endocarditis (NBTE), disseminated intravascular coagulation, and thrombotic thrombocytopenic purpura. This variety of clinical syndromes may appear prior to diagnosis of cancer, in the course of overt malignant disease, or following initiation of chemotherapeutic agents. Although certain tumors (such as mucous carcinoma of the pancreas, lung, and gastrointestinal tract) have been traditionally associated with thromboembolism,<sup>111</sup> other solid neoplasms as well as hematologic malignancies are often associated with thrombosis. Notably, NBTE (which is not uncommon in patients with solid tumors<sup>112</sup>) is particularly prevalent in patients with myeloproliferative disorders in whom it may be associated with systemic thrombosis.<sup>113</sup>

### Pathogenesis of ACS

ACS encompasses unstable angina (UA), non-ST-segment elevation myocardial infarction (NSTEMI) and ST-segment elevation myocardial infarction (STEMI). STEMI is a distinct clinical entity, which results from an occlusive thrombus. UA/NSTEMI, on the other hand, is the combination of two closely related clinical entities (ie, a syndrome), characterized by decreased myocardial perfusion resulting from nonocclusive thrombus formation subsequent to disruption of an atherosclerotic plaque.

Views of the pathophysiology of atherothrombosis have evolved substantially over the last two decades. Insights into the pathophysiology have advanced beyond the notion of progressive chronic occlusion of the coronary artery, to the recognition that plaque disruption and superimposed thrombus formation are the leading causes of acute coronary syndromes (ACS). The term ACS was used, instead of acute myocardial infarction, in the 1996 guideline publication of the American College of Cardiology/American Heart Association (ACC/AHA) to emphasize this emerging concept of disruption of a vulnerable or high-risk plaque during myocardial ischemia.<sup>114</sup>

Plaque composition rather than luminal stenosis, has become the major focus of the pathophysiologic process of ACS. Plaques consist

of inflammatory and smooth muscle cells, cellular debris, and fatty deposits trapped within the vessel wall. Depending on the composition, they are classified into either “stable” (with little risk of acute rupture) or unstable (or “vulnerable”—ie, likely to spontaneously rupture and trigger clot formation initiating ACS). There are two aspects to the transition from vulnerable plaque to acute coronary event: one is associated with characteristics of the atheromatous subintimal lesion, and the other involves factors that make it likely that an obstructive thrombus will form at the site of the atheroma (the “vulnerable patient”).

Histologically, stable coronary plaques are rich in collagen and have thick fibrous caps. In contrast, vulnerable or rupture-prone lesions consist of a large number of inflammatory cells, including macrophages, foam cells, monocytes, granulocytes, and lymphocytes, reduced numbers of vascular smooth muscle cells (SMCs), and a thin fibrous cap (<65 μm) of collagen type I, with an underlying necrotic lipid-filled core occupying approximately 35% of the lesion.<sup>115</sup> Therefore, they are less stable and have a higher propensity to rupture. Typically, the underlying cross-sectional luminal narrowing is less than 50%. Plaque disruption usually occurs at the weakest point (the “shoulder”), frequently where the cap is thinnest and most heavily infiltrated with inflammatory cells.<sup>116</sup>

Characteristics of the patient that increase vulnerability include evidence of systemic inflammation (eg, increased levels of C-reactive protein, intercellular adhesion molecule 1, or vascular cell adhesion molecule 1) and hypercoagulability (elevated levels of fibrinogen, D-dimer, and factor V Leiden) as well as decreased anticoagulation factors such as protein S and C, thrombomodulin, and antithrombin III.<sup>117</sup>

Once the cap covering a vulnerable plaque erodes or is disrupted, the highly thrombogenic lipid-rich core, abundant in tissue factor, is exposed to the bloodstream, activating the clotting cascade. This triggers the formation of a superimposed thrombus that leads to vessel occlusion and subsequent ischemic symptoms distal to the occlusion.<sup>118,119</sup> These changes in the plaque are a result of a combination of internal and external influences. Overall plaque burden is greater in the symptomatic than in the asymptomatic patients.

### Endothelial Dysfunction

Endothelial dysfunction is a reversible systemic disorder characterized by a reduction of the bioavailability of vasodilators, in particular nitric oxide (NO), and an increase in endothelium-derived vasoconstrictor factors.<sup>120,121</sup> A dysfunctional endothelium promotes lipid and cell permeability, lipoprotein oxidation, inflammation, SMC proliferation, extracellular matrix

deposition or lysis, platelet activation, and thrombus formation<sup>122</sup> and generates a proatherogenic environment by creating a proinflammatory, proliferative, and prothrombotic milieu that favors atherogenesis.<sup>123</sup> Endothelial dysfunction is also involved in the recruitment of inflammatory cells into the vessel wall and in the initiation of atherosclerosis. Monocytes migrate into the subendothelium, where they transform into macrophages and modulate inflammatory reactions and the secretion of chemoattractants. Activated macrophages and smooth muscle cells in the atheroma then release lytic enzymes that can degrade the fibrous cap,<sup>124,125</sup> resulting in rupture of the lesion.

Many of the cardiovascular risk factors, as well as cancers, are associated with increased oxidative stress, and it is considered to be a major mechanism involved in the pathogenesis of endothelial dysfunction and may serve as a common pathogenic mechanism of the effect of risk factors on the endothelium.<sup>126,127</sup>

### Inflammation and Atherothrombosis

There is a strong link between inflammation and atherothrombosis.<sup>128</sup> Early in atherogenesis, patches of arterial endothelial cells, in particular vascular cell adhesion molecule-1 (VCAM-1), begin to express on their surface selective adhesion molecules that bind to various classes of leukocytes. Once they are in the arterial wall, the blood-derived inflammatory cells participate in and perpetuate a local inflammatory response which not only promote initiation and evolution of atherosclerosis, but also contributes decisively to acute thrombotic complications of atheroma. The activated macrophages produce proteolytic enzymes (eg, matrix metalloproteinases [MMP]) which degrade the collagen in the plaque’s protective fibrous cap, rendering it thin, weak, and vulnerable to rupture.<sup>129,130</sup> Indeed, the predictive value for coronary events of high levels of C-reactive protein may be a manifestation of such systemic phenomenon.<sup>131</sup>

### Tissue Factor

Tissue factor (TF) is a potent initiator of coagulation cascade, and is a key determinant of the vulnerability of the atherosclerotic plaque. The presence of abundant tissue factor<sup>132</sup> and apoptotic microparticles<sup>133</sup> in the shoulder region and in the acellular, lipid-rich core of the plaque suggests that they’re the thrombogenic potential in disrupted atherosclerotic plaque. Circulating tissue factor is strikingly increased in patients with cancer<sup>134</sup>; hence, it may also play a role in the formation of the thrombus upon atherosclerotic plaque disruption. Infective intracellular organisms have also been proposed as major contributors to plaque inflammation, activation,

and vulnerability.<sup>135</sup> Overall plaque burden is greater in symptomatic than in asymptomatic patients, and rupture of the plaques is associated with a sudden increase in the intralumenal pressure. This increase can occur if there is a loss of integrity of vessels in the vasa vasorum resulting in intraplaque hemorrhage.<sup>136</sup>

### Microembolization and Microvascular Obstruction

In the setting of acute MI, the presence of distal microembolization is evident clinically by “no-reflow” phenomenon following reperfusion. Microvascular obstruction, however, is demonstrated very early in the course of ACS, and is most likely caused by embolization rather than by edema or reperfusion injury.<sup>137</sup> One of the postulated mechanisms suggests that plaque rupture results in the release of prothrombotic materials into the coronary circulation, which embolize the microvascular bed. Evidence for the role of distal embolization in the pathogenesis of ACS is found in autopsy studies demonstrating the presence of platelet/fibrin microemboli in the cardiac tissue of up to 50 to 80% of patients with fatal MI.<sup>138</sup> These platelet aggregates contain thrombus overlying a ruptured atheromatous plaque and are located distal to epicardial coronary arteries, making it highly likely to represent emboli rather than mere platelet hyperactivity.<sup>138</sup> A prothrombotic milieu in cancer will likely exacerbate this phenomenon.

### Role of Risk Factors and Cancer

In about one-third of the cases of sudden coronary death, there is no significant disruption of atheromatous plaque except for some superficial erosion of markedly stenotic and fibrotic plaque.<sup>139</sup> In such cases, thrombus formation may depend on a hyperthrombogenic state triggered by systemic factors including elevated LDL cholesterol, cigarette smoking, hyperglycemia, and altered hemostasis<sup>140</sup>. Poorly controlled diabetics<sup>141</sup> as well as cancer<sup>142</sup> patients are known to have hyperthrombogenicity.

### Role of Platelets in Acute Coronary Syndrome

The role of the platelet and the endothelium in the pathogenesis of atherosclerosis and subsequent ischemic events has been the subject of extensive investigation.<sup>140</sup> The role of platelets is especially important in the context of ACS in cancer patients since patients with malignancy often have thrombocytopenia and are denied antiplatelet therapy, which forms the cornerstone of management in ACS patients (Table 4).

Platelets play a key role in thrombotic vascular occlusion at the ruptured coronary atherosclerotic plaque; and also interact with both

**Table 4 Predisposing Factors of ACS in Cancer Patients**

Coronary atherosclerosis

the coagulation and fibrinolytic systems in the pathogenesis of thrombosis. Multiple synergistic stimulations of platelet receptors by the corresponding ligands are involved in the process of platelet activation. Following plaque disruption or endothelial injury, platelets attach to the exposed subendothelium, releasing thromboxane A<sub>2</sub>, serotonin, adenosine diphosphate, platelet activating factor, oxygen-derived free radicals, activated thrombin, and tissue factor, which promotes further platelet aggregation and dynamic vasoconstriction that in turn lead to transient or permanent coronary artery thrombosis.<sup>143</sup> The von Willebrand factor-GP Iba interaction and the collagen-GP VI interaction are the two most important receptor-ligand interactions in the process of platelet thrombus formation on the surface of collagen.<sup>144</sup> In addition, both embolization of platelet aggregates and direct, receptor-mediated platelet adhesion to the post-ischemic microvascular surface result in obstruction and impairment of coronary microcirculation. Such microvascular disturbance may lead to significant additional tissue injury and aggravate myocardial contractile dysfunction. Platelets play another important role in conversion of chronic stable coronary disease to acute unstable process. Platelets inhibit the production of endogenous inhibitors of platelet aggregation and vasoconstriction including prostacyclin, endothelium-derived relaxing factor (nitric oxide). Tissue plasminogen activator is reduced at the sites of endothelial injury, resulting in a vasoconstrictive and prothrombotic environment with conversion from chronic to acute coronary syndromes.<sup>145</sup> Furthermore, new investigations have demonstrated that platelets not only contribute to acute thrombotic vascular occlusion but also participate in the inflammatory and matrix-degrading processes of coronary atherosclerosis itself.<sup>143</sup> Platelet-endothelial-cell interactions at lesion-prone sites might trigger an inflammatory response in the vessel wall early in the genesis of atherosclerosis and contribute to destabilization of advanced atherosclerotic lesions.<sup>146</sup>

## ACS in Cancer Patients

Patients with cancer have a prothrombotic milieu: endothelial damage from radiotherapy and chemotherapy.<sup>147</sup> The possible mechanisms responsible for radiation-induced CAD have been described above. Although not clearly defined, it is thought to have a synergistic role with other traditional risk factors.<sup>148</sup> High-dose radiation may damage the vascular endothelium, resulting in fibrosis or medial degeneration in the coronary arteries.<sup>149</sup> Case studies have been reported linking coronary spasm, acute vascular toxicity, and thromboembolism to various chemotherapeutic agents, notably 5-fluorouracil (and its analogue capecitabine), cisplatin, vinblastine, bleomycin, and cyclophosphamide.<sup>150-154</sup> Insulin resistance and metabolic disturbance in patients with bone marrow transplantation<sup>155</sup> and chemotherapy-induced early menopause may predispose them to premature coronary atherosclerosis.<sup>156</sup> The exact mechanism behind these vascular events is unknown, but activation of clotting factors following disturbances of microcirculation caused by the release of toxic substance from necrotic tissue and/or malignant cells has been thought to play a leading role. Details of various cardiotoxic events have been described above.

In cancer patients, gross mismatch in myocardial supply and demand may also contribute to initiating coronary syndromes. Increased myocardial oxygen demand in the prolonged perioperative setting, fever, and tachycardia, combined with reduced coronary perfusion in hypotension, anemia, and hypoxemia are common in cancer patients.

Patients undergoing radiation therapy of mediastinal tumors such as lymphoma<sup>157</sup> and seminoma<sup>158,159</sup> may experience accelerated CAD. This is especially true for patients who are also treated with chemotherapy.<sup>160</sup> Other mechanisms involved in accelerated CAD include chemotherapy-induced premature menopause, which is a recognized risk factor for coronary artery disease.<sup>161</sup> Meta-analyses of randomized clinical trials<sup>162,163</sup> and studies of population-based cancer registry data<sup>164-166</sup> show an increased risk of cardiac death in breast cancer patients exposed to radiation therapy, more so among those who received treatment to the left side. The risk of radiation-induced heart disease correlates with radiation-dose volume<sup>163</sup> and fractionation.<sup>167</sup> This risk is further compounded because hormone replacement therapy is not generally recommended for patients with breast cancer. Better prognosis and increased survival these days from better management of cancer patients make them more vulnerable to this radiation-induced heart disease over the long term. However, recently published data from our institution, which comprised improved radiation techniques and dosage,

failed to replicate these earlier claims of increased risk of myocardial infarction among breast cancer patients treated with radiation therapy.<sup>168</sup>

Other causes of tumor-related ACS are listed in Table 4 and include coronary embolization due to papillary fibroelastomas<sup>169</sup> and atrial myxomas,<sup>170-172</sup> and leukemic infiltration into the myocardium or pericardium.<sup>173</sup>

## Presentation of ACS in Cancer Patients

The classic or typical symptoms of acute coronary syndromes are substernal or left-sided chest pain, or discomfort that the patient often describes as pressure or heaviness, which may radiate to the left arm, neck, jaw, or shoulder. The discomfort associated with acute MI usually lasts at least 20 minutes, but may be shorter in duration. The discomfort is not positional in nature, nor is it affected by deep inspiration or movement. Unexplained nausea and vomiting, persistent shortness of breath secondary to left ventricular failure, and unexplained weakness, dizziness, lightheadedness, or syncope (or a combination of these) should arouse suspicion. This is more important in light of recent studies evaluating people presenting with AMI symptoms, which show that up to 43% of patients had atypical elements in the description of their chest pain or pressure,<sup>174</sup> and as many as 33 to 47% of all patients having an AMI will present without chest pain.<sup>175,176</sup> In a recently published, large study of 20,881 patients with ACS, more than 8% presented without any chest pain, of whom one in four were not initially recognized as having an acute coronary syndrome.<sup>177</sup>

Because symptoms like dyspnea, pleuritic chest pain, fatigue, weakness, discomfort in the upper abdomen and between the shoulder blades, palpitations, and confusion, are so common in cancer patients, it could easily be confused with symptoms of thoraco-abdominal involvement in preexisting malignancies. The differential diagnosis of chest pain is listed in Table 5. Consequently, these complaints may go unrecognized or may be erroneously labeled as those related to the cancer. Additionally, many cancer patients may not consider them serious enough to seek immediate assistance, therefore delaying prompt recognition and leading to delay in treatment—or misdiagnosis and inappropriate treatment. Therefore, it is imperative to be aware of patients who are at high risk for ACS in order to facilitate diagnosis and treatment. Often, more cases are identified from the “routine” blood test that follows complaints of any of these “atypical” symptoms. However, these “infarctlets” allow appropriate secondary prevention leading to reduced costs for subsequent cardiac care. In contrast to these small MI/“infarctlets” (identifiable by elevation of cardiac troponin alone), the patient with

classic “large myocardial infarction” may often present with heart failure, cardiogenic shock, or life-threatening arrhythmia. Finally, myocardial necrosis may also occur without any symptoms and might be detected only by an ECG or cardiac imaging.

## Diagnosis

Today, ACS is detected by several different modalities, including ECG changes, measurement of biochemical markers, and imaging studies such as echocardiography and myocardial perfusion imaging.<sup>178,179</sup> Each of these techniques is able to quantify the extent of damage, from minimal to small to large myocardial infarction. However, the sensitivity and specificity of each of these techniques to quantitate the extent of necrosis accurately differ significantly. Pathologically, infarcts are usually classified as focal/microscopic necrosis, small (< 10% of the left ventricle [LV]), medium (10 to 30% of the LV) or large (> 30% of the LV).

## Electrocardiography

ECG remains the time-honored and single most important tool in the diagnosis of ischemic heart disease. ECG criteria have emerged as one of the most powerful tools for the diagnosis and treatment of ACS. By using data from clinical and pathoanatomical correlative studies, significant accuracies and complex algorithms have been developed for standard 12-lead ECG to diagnose evolving MI. In the absence of QRS confounders

like bundle branch block, left ventricular hypertrophy, Wolff-Parkinson-White syndrome, ST segment elevation signifies acute myocardial injury in the right clinical setting. Tall and peaked “hyperacute” T waves may precede these changes during early phases of acute MI. Similarly, ST segment depression and/or T wave abnormalities, noted in two or more contiguous leads on two consecutive ECGs several hours apart, indicates ongoing ischemia. However, in cancer patients, ST segment elevation is more often indicative of pericarditis or myopericarditis (Table 5). In pericarditis, there is absence of reciprocal changes and depression of the PR segment. However, since biochemical markers enable detection of myocardial necrosis too small to be associated with QRS abnormalities, many patients will have a normal or unchanged ECG during microinfarcts. Newer ECG techniques with higher sensitivity and specificity may also be useful for the noninvasive detection of coronary artery disease.<sup>180</sup>

## Biochemical Markers of Myocardial Necrosis

Myocardial infarction is diagnosed when specific biomarkers are increased in the setting of acute ischemia.<sup>181</sup> Different myocardial proteins are released into the circulation due to the damaged myocytes: myoglobin, cardiac troponins T and I, creatine kinase, lactate dehydrogenase, as well as many others. These biomarkers merely reflect myocardial damage and not the mechanism of injury. As mentioned above, myopericarditis is relatively common in cancer patients. Therefore, an elevated value in the absence of clinical evidence of ischemia in a patient with cancer should prompt a search for causes, such as myocarditis, or myopericarditis.

Because total creatine kinase (CK) has wide tissue distribution, its measurement is not commonly used for the routine diagnosis of acute MI except when combined with a more sensitive fraction, such as creatine kinase myocardial band (CK-MB) or troponins. The latter is the most preferred biomarker for detection of myocardial injury because of its high tissue specificity and sensitivity. CK-MB is more tissue-specific than total CK but less tissue-specific than cardiac troponin. However, the data documenting its clinical specificity for myocardial necrosis are more abundant. A trend from two or more successive blood samples of CK-MB or troponin is used to diagnose MI. For most patients, these serial enzymes are obtained every 4 to 6 hours but may need to be extended beyond 12 hours if, despite high clinical index of suspicion, the earlier samples are negative. For patients with low suspicion and in need of an early diagnosis, a rapidly appearing biomarker, such as myoglobin, may help to rule out myocardial injury. Although no formal grading system of infarct size exists, the

level of biomarker elevation is often used to quantify extent of myocardial damage (small, medium, or large). In the past, markers like Serum glutamic oxaloacetic transaminase, Alanine Amino transferase, Aspartate Aminotransferase and Lactate Dehydrogenase (Glutamic-oxaloacetic transaminase, aspartate amino transferase, lactate dehydrogenase and lactate dehydrogenase isoenzymes) were used to diagnose ACS. However, these have been substituted by the newer biomarkers (CK-MB, troponin) and are no longer used in the diagnosis of MI.

It is important to remember that cardiac troponin values may remain elevated for 7 to 10 days or longer after myocardial necrosis, especially in cancer patients with renal insufficiency. This may make it difficult to time the initial event accurately and influence subsequent management decisions. In such cases, a high cardiac troponin value on presentation or on first sample should be correlated to CK-MB or myoglobin and to very recent clinical events.

## Imaging

Echocardiographic and myocardial single-photon emission computed tomographic (SPECT) perfusion imaging techniques have revolutionized identifying ischemic from nonischemic causes in cancer patients. Although commonly used in the cardiology outpatient setting for evaluation of inducible ischemia, both may be helpful to rule out or confirm the presence of myocardial ischemia in the acute setting, specially when ECGs are nondiagnostic or uninterpretable. Furthermore echocardiography allows assessment of frequent nonischemic causes of acute chest pain in patients with cancer (eg, perimyocarditis, pulmonary embolism, valvular heart disease like aortic stenosis, and aortic dissection). Echocardiography is also the diagnostic procedure of choice for identification of mechanical complications of MI, namely coexisting valvular dysfunction, infarct expansion, mural thrombus and decrement in left ventricular ejection fraction. While both techniques can determine the localization and extent of infarction, it should be emphasized that a normal echocardiographic exam does not exclude myocardial infarction, since injury involving > 20% of myocardial wall thickness is required before a segmental wall motion abnormality can be detected. Similarly > 10 g of myocardial tissue must be injured before perfusion defect is obvious on a radionuclide perfusion image. Advances in contrast echocardiography hold promise for the routine assessment of myocardial perfusion. Vasodilator stress in conjunction with contrast echocardiography will likely play an important role in the noninvasive evaluation of myocardial perfusion and coronary blood flow reserve.<sup>182</sup>

Several new techniques in cardiovascular (CV) imaging like computed tomography (CT)

angiography and magnetic resonance (MR) are extensively used in the diagnosis and follow-up of cancer patients. Newer techniques to image high risk/vulnerable atherosclerotic plaques are appearing on the horizon.<sup>183</sup> CT imaging of the coronary arteries, using either electron beam tomography or multidetector row CT, offer possibilities to assess coronary atherosclerosis and visualization of noncalcified plaque. Coronary calcium imaging may be clinically useful in young cancer patients at intermediate risk for coronary artery disease.<sup>184</sup>

CT pulmonary angiogram (CTPA) is increasingly used for the detection of pulmonary embolism (PE) in cancer patients. Most patients investigated have pathology other than PE as a cause of their symptoms. Careful analysis of CTPA allows assessment of not only the pulmonary arteries for embolism, but the heart as well. Potentially life-threatening, coexistent, underlying or incidental cardiac disease in a patient with chest symptoms can be reliably identified. Pathologies of the myocardium, including hypertrophic cardiomyopathy, pericardial disease, valvular disease, coronary artery disease, and intracardiac abnormalities, are demonstrated. It is important to have a clear understanding of the features of cardiac disease that may be seen on a CTPA.<sup>185</sup> Cardiac MR is also emerging as a powerful imaging technique in Ischemic Heart disease.<sup>186</sup> It is extremely capable of showing infarcted myocardium even in the presence of normal coronaries.<sup>187</sup>

## Treatments

### Non-ST-Segment Elevation Acute Coronary Syndrome (NSTEMI-ACS)

Acute coronary syndrome in a cancer patient presents a difficult challenge. There is no evidence-based guideline addressing specifically the management of cancer patients with ACS although there is no reason why general guidelines (Table 4) should not be applicable in the majority of cancer patients.

### Aspirin

An optimal antiplatelet regimen for patients with NSTEMI-ACS remains to be defined. Aspirin irreversibly inhibits platelet activation and aggregation by inhibiting cyclooxygenase-1 (prostaglandin H synthase) in platelets and megakaryocytes, which is a key enzyme in the pathway of synthesis of thromboxane A<sub>2</sub>, a potent vasoconstrictor and platelet aggregant.<sup>188</sup> Only the parent form of aspirin (acetylsalicylic acid) has any significant effect on platelet function. The inhibited platelets are unable to regenerate cyclooxygenase, therefore, the immediate antithrombotic effect of aspirin remains for the lifespan of the platelet. Following discontinuation of aspirin therapy, normal hemostasis is restored when approxi-

mately 20% of platelets regain normal cyclooxygenase activity,<sup>189</sup> making daily intake of aspirin necessary for useful platelet inhibition.

Aspirin reduces the incidence of death and nonfatal MI in patients with unstable angina<sup>190,191</sup> or acute MI,<sup>192</sup> with only a minor increase in the risk of major bleeding (0.2%). Since higher doses of aspirin do not provide greater benefit,<sup>192,193</sup> dosages > 75 mg daily may be less desirable in cancer patients due to increased susceptibility to bleeding, especially when combined with clopidogrel. It is important to remember that non-aspirin non-steroidal anti-inflammatory drugs, which are often used by many cancer patients, may attenuate the antiplatelet effects of aspirin.<sup>194–196</sup>

### Adenosine Diphosphate Receptor Antagonists

The thienopyridine derivatives (clopidogrel and ticlopidine hydrochloride) are metabolized in the liver to active compounds that covalently bind to the adenosine phosphate (ADP) receptors on platelets and dramatically reduce platelet activation. Clopidogrel is as safe as aspirin, but is more expensive. It is an appropriate alternative to aspirin for long-term secondary prevention in patients who cannot tolerate aspirin, have experienced a recurrent vascular event while taking aspirin, or are at very high risk of a vascular event (> 20% per year). An oral loading dose of 300 mg clopidogrel produces detectable inhibition of ADP-induced platelet aggregation after 2 hours, which becomes maximal after 6 hours.<sup>197,198</sup> If a loading dose of clopidogrel is not used, repeated daily oral doses of 75 mg clopidogrel are required to achieve a steady-state maximal platelet inhibition, which is comparable with that produced by 250 mg ticlopidine hydrochloride orally, twice daily.<sup>199</sup> In the Clopidogrel vs Aspirin in Patients at Risk of Ischemic Events trial,<sup>196</sup> there was a modest relative risk reduction in adverse CV events (5.3% vs 5.8%,  $p=.04$ ) with clopidogrel in known atherosclerotic vascular disease patients compared to aspirin. However, addition of clopidogrel to aspirin reduces the risk of serious vascular events among patients with non-ST-segment elevation acute coronary syndromes by 20%, and patients undergoing percutaneous coronary intervention by 30%, compared with aspirin alone. Therefore, cancer patients with NSTEMI-ACS who are considered to be at low bleeding risk may be started on dual antiplatelet therapy and continued for up to 12 months<sup>200,201</sup> for additional benefit in all-cause mortality, cardiovascular death, MI, and/or stroke. Cancer patients on clopidogrel undergoing surgery may be at increased risk of bleeding if the drug is administered within 5 days of surgery.<sup>202,203</sup> Accordingly, clopidogrel should be withheld 5 days before planned surgery.

### Glycoprotein IIb/IIIa Inhibitors

Short-term addition of an intravenous infusion of a glycoprotein (Gp) IIb/IIIa antagonist to aspirin prevents vascular events in high-risk patients having a percutaneous coronary intervention (PCI), and those with NSTEMI-ACS, but causes increased bleeding. For patients undergoing an early conservative strategy, the benefit of Gp IIb/IIIa inhibitors is less pronounced. However, based on their ability to prevent ischemic complications following PCI, Gp IIb/IIIa inhibitors may be used in NSTEMI-ACS patients managed with an early invasive strategy.<sup>114</sup> There may even be a paradoxical worse outcome with longer infusions of abciximab in patients for whom PCI is not planned.<sup>204</sup>

### Anticoagulation

Unfractionated heparin reduces ischemia in NSTEMI-ACS through its potentiation of circulating antithrombins and its ability to inhibit clot propagation.<sup>205</sup> However, heparin requires frequent monitoring and can be associated with delays in achieving therapeutic anticoagulation.<sup>206</sup> Low molecular weight heparin (LMWH) provides better bioavailability, more predictable pharmacokinetics, a longer half-life, and is associated with less platelet activation and heparin-induced thrombocytopenia. Regardless, many oncologists have been hesitant to use LMWH because of concerns of reduced efficacy, increased bleeding, and an inability to easily monitor anticoagulation. In two recent large trials in patients with NSTEMI-ACS, major bleeding episodes were more common with LMWH compared to heparin.<sup>207,208</sup>

### Thrombolytics

Despite the role of thrombosis in UA/NSTEMI, thrombolytic agents have not been shown to provide benefit in patients with UA/NSTEMI; in fact, the outcome may be worse with thrombolytics.<sup>209–211</sup> Consequently, thrombolytic agents are contraindicated for use in the treatment of patients who have UA/NSTEMI.

### Angiotensin Converting Enzyme Inhibitors

Angiotensin converting enzyme (ACE) inhibitors have emerged as standard care for most patients with atherosclerosis, diabetes mellitus, and left ventricular systolic dysfunction. However, they have not been evaluated in placebo-controlled trials of patients with NSTEMI-ACS. Nonetheless, support for their long-term outpatient use has come from the Heart Outcomes Prevention Evaluation trial<sup>212</sup> and the European Trial on Reduction of Cardiac Events with Perindopril in Stable Coronary Artery Disease,<sup>213</sup> which showed approximately 20% relative risk reduction in the

combined end point of cardiovascular death, MI, and stroke or cardiac arrest ( $p < .001$  for all) for the ACE inhibitor arm. In low-risk patients, however, ACE inhibitors do not provide the same benefit.<sup>214</sup>

### Angiotensin Receptor Blockade

There is no reason to change the current practice of choosing ACE inhibitors as first-line treatment for these conditions. If ACE inhibitors cannot be used, AngiotensinII receptor blockers represent an acceptable alternative.<sup>215</sup>

#### $\beta$ -Blockers

$\beta$ -blockers reduce cardiac workload and myocardial oxygen demand, and their use in the acute setting may yield a 13% relative risk reduction in the rate of progression to an acute MI<sup>216</sup> and a 29% relative risk reduction in death among high-risk individuals with a threatened or evolving MI.<sup>217</sup> When used in patients following an MI,  $\beta$ -blockers also produce significant reductions in adverse CV events.<sup>218-220</sup> For low- to intermediate-risk patients with angina and for all high-risk patients, intravenous  $\beta$ -blockers should be given in the setting of chest pain, followed by long-term use.

### Blood Pressure Control

Because high blood pressure (BP) increases myocardial oxygen demand, its treatment remains an important goal in the management of patients with NSTEMI-ACS. Although current guidelines recommend a BP of less than 130/85 mm Hg (reserving  $< 130/80$  mm Hg for patients with diabetes or chronic kidney disease,<sup>221</sup> recent evidence suggests that the optimal level may be even lower (ie, 125/75 mm Hg) in patients with stable CAD.<sup>222,223</sup> Either ACE inhibitors and  $\beta$ -blockers or amlodipine may be used for BP reduction in those with stable CAD.

### Cholesterol Treatment

The 3-hydroxy-3-methylglutaryl coenzyme-A reductase inhibitors (statins) inhibiting the rate-limiting step in cholesterol synthesis, and have become standard care for most patients with NSTEMI-ACS. Their sustained use results in a significant reduction in the level of low-density lipoprotein cholesterol (LDL-C), along with more modest but favorable effects on levels of other serum lipids. Based on a recommended LDL-C goal of less than 70 mg/dL (1.8 mmol/L),<sup>224</sup> nearly all patients with NSTEMI-ACS should begin treatment with a high-dose, potent statin during their hospitalization. The benefits of statins are seen as early as 30 days after treatment.<sup>225</sup> Because of comorbid conditions in cancer patients, including hepatic metastasis, all patients treated with a high-dose, potent statin should have creatine

kinase and transaminase levels closely monitored, with dose adjustment or discontinuation of medication as needed.

### Smoking Cessation

All smokers with ACS should be encouraged to quit smoking since abstinence has been found to greatly lower the risk of future coronary events.<sup>226,227</sup> Behavioral support,<sup>228,229</sup> as well as bupropion with or without nicotine replacement,<sup>230</sup> have been shown to have the greatest efficacy in helping patients quit, and thus should be offered to all cancer patients to improve long-term smoking cessation.

### Diabetes Management, Diet, and Exercise

All patients with diabetes should maintain strict glycemic control with a glycosylated hemoglobin level of less than 7.0%.<sup>231</sup>

### STE-ACS

Treatment strategies for STE-ACS in cancer patients remains suboptimal due to the perceived complexity, and a lack of guideline and agreement on the aggressiveness of therapy. There is no evidence-based guideline addressing specifically the management of cancer patients with STE-ACS, although there is no reason why general guidelines should not be applicable in the majority of cancer patients. This lack of consensus for the optimal reperfusion strategy in cancer patients with STE-ACS stems from the exclusion or non-representation of cancer patients in large clinical trials.

In the clinical setting, two key concepts are of profound importance when considering optimal treatment for STE-ACS. The Reimer and Jennings wavefront hypothesis of evolving infarction has driven the entire field of reperfusion therapy for almost last 3 decades<sup>23</sup>; and there is a very strong relationship between time to treatment and extent of myocardial salvage. Whether the therapy given is primary PCI or fibrinolytics depends on the policy of an individual institution, but speed is of the essence. Emphasis should be on restoring arterial patency as soon as possible, especially in high-risk cardiac patients (Table 7). The main concern for use of either strategy in cancer patients is the risk of major bleeding. Whether benefit outweighs risk depends largely on the duration of symptoms or ischemia and the nature of adjunctive therapy (ie, full- or reduced-dose fibrinolytics, platelet inhibitors, or heparin alone). As in elderly persons, patients with hypertension, and those with low body weight,<sup>232</sup> the risk of intracranial bleeding must be considered in cancer patients in the context of multiple preexisting comorbidities (eg, low platelets, presence of metastasis and associated hepatorenal

dysfunction). However, in the elderly who are also at a high risk of bleeding, multiple clinical trials and observational studies indicate improved survival and low risk of stroke with primary PCI compared with thrombolysis with STEMI. Since many cancer patients are managed at facilities without advanced cardiac interventional capability, thrombolytics are viable alternatives if transfer to a tertiary care center is delayed. Survival is greatest when reperfusion by thrombolytics is obtained within the first 3 hours of the onset of symptoms, and incremental delays thereafter do not yield significant additional mortality effect.<sup>233</sup> Moreover, the benefits of thrombolytics late after symptom onset are decreased and the risk of myocardial rupture may be increased.<sup>234,235</sup> However, because thrombolytic therapy requires, on average, 45 to 60 minutes before reperfusion occurs,<sup>236</sup> a case can be made for transfer for PCI without preceding fibrinolytic therapy in patients presenting relatively late (ie,  $\geq 3$  hours after symptom onset).<sup>237</sup> Moreover, given the altered hemostatic milieu in cancer patients, the efficacy of thrombolytic agents may be unpredictable. Access-site hemorrhage following PCI may be a major issue in cancer patients. It is not clear whether data from studies in patients  $> 75$  years showing an increased risk of intracerebral bleeding with combination of a fibrin-specific agent and a glycoprotein IIb/IIIa receptor antagonist may be extrapolated to the cancer population. Clearly, different approaches to reperfusion therapies need to be placed within the context of the presence of other comorbid conditions in cancer patient presenting with STE-ACS.

Large-scale targeted clinical trials are needed to evaluate the relative merits of available reperfusion strategies as well as newer antithrombotic adjunctive therapies in cancer patients presenting with STEMI.

### Summary

Acute coronary syndrome in a cancer patient presents a difficult challenge. The pathogenic mechanisms of ACS in cancer patients are multifactorial. A major mechanism involves activation of the coagulation system by components expressed by most tumor cells. Another important mechanism is triggered by changes in platelet volume and functions in cancer. There is no evidence-based guideline specifically addressing the management of cancer patients with ACS, although there is no reason why general guidelines should not be applicable in the majority of cancer patients. The main concern for use of primary PCI or fibrinolytics, platelet inhibitors, or heparin in cancer patients is the risk of major bleeding. Nevertheless, many cancer patients with ACS would qualify for the same management as others without cancer. However, a significant

**Table 7** The ABCDE Mnemonic for Treatment of ACS

A = Antiplatelet agents— <i>aspirin</i> Adenosine diphosphate receptor inhibitor <i>Clopidogrel</i> —in patients who cannot tolerate aspirin
B = $\beta$ -blocker in patients without contraindications Blood pressure control
C = Converting enzyme inhibition in patients with congestive heart failure, left ventricular dysfunction (ejection fraction below 40%), hypertension, or diabetes Cholesterol lowering agent— <i>statin</i> Cessation of smoking
D = Diabetes control Diet (heart-healthy)
E = Early invasive approach (cardiac catheterization) in high risk patients and those in whom conservative management fails

**Table 8** Determinants of short-term high risk of fatal or nonfatal myocardial infarction

Prolonged (> 20 min) ongoing pain at rest
Pulmonary edema, most likely related to ischemia
Angina at rest, with dynamic ST-segment changes > 1 mm
Angina with new or worsening mitral regurgitant murmur
Angina with S3 or new or worsening rales
Angina with hypotension

number of patients pose a challenge in their management because of several comorbid conditions (specifically, profound thrombocytopenia and metastatic lesions). A subset of high-risk patients may not be candidates for any of the conventional treatments; potential alternatives and a conservative therapeutic modality of treatments may have to be taken into consideration in this setting. An approach of intensive observation and aggressive pain control may of paramount importance in such cancer patients.

With increased complexity of effective cancer therapy, it is important to identify the subset of cancer patients at high risk for cardiovascular events, particularly those with no clinical history of coronary disease. Using novel and improved diagnostic techniques, it is possible to detect coronary artery disease at a much earlier stage, which can be managed with optimized medical therapy. Additionally, an increasing population of older, more deconditioned cancer patients with many comorbidities are under consideration for major surgery. Many such major surgeries are performed before or after chemotherapy and/or radiation, which increases the risk of cardiac ischemic events. Many chemotherapeutic agents have important ischemic cardiac effects, while others have the ability to potentiate the adverse effects of other agents and are likely to have significant effects on patient outcome. It is therefore very important to take into account several patient-related factors, including advanced age, preexisting coronary disease, concomitant radiation

therapy, and metabolic abnormalities in these patients.

# Cardiac Manifestations of Malignancy

Joseph Swafford, MD, FACC  
S. Wamique Yusuf, MD, FACC

The cardiac manifestations of cancer are actually quite rare. Many times these clinical entities are found on routine surveillance; sometimes they are found as a result of clinical symptomatology; and most of the times, the malignant manifestations of these disorders cancer involvement of the heart carry a poor prognosis. We will review metastatic malignancies of the heart, and then briefly, primary tumors of the heart. Sometimes these tumors have a higher prevalence for different cardiac chambers and entrance points to the heart (Figure 1). This chapter will conclude with a discussion of amyloidosis, which can be found in multiple myeloma patients. We will initiate our discussion with the clinical presentation and diagnostic techniques for patients with cardiac tumors.

## Clinical Presentation of Cardiac Tumors

Cancer patients may very well have constitutional symptoms consisting of fever, weight loss, fatigue, and malaise. These are not very helpful symptoms in focusing to suggest cardiac involvement. There are several categories of clinical presentation for cardiac tumors: (1) arrhythmias, (2) valvular and chamber obstructive symptoms, (3) congestive heart failure, (4) cardioembolic presentation events, and (5) cardiac tamponade.

## Arrhythmias

Depending on the size of the cardiac tumor and its location, there may be various arrhythmias that are manifested.<sup>1</sup> Most patients will complain of palpitations, or ectopy is found on

routine electrocardiogram. Patients can have either tachyarrhythmia or bradyarrhythmia. The important thing to remember, particularly in the cancer patient, is that these arrhythmias should warrant some workup, further investigation, keeping cardiac tumors as part of the differential diagnosis of the underlying cause. Cancer patients with arrhythmias routinely should have echocardiography. That, which serves as one of the best screening tests to determine if there is cardiac involvement from cancer.<sup>2,3</sup>

Tachyarrhythmias may include atrial fibrillation, atrial flutter,<sup>4</sup> and ventricular tachycardia. On rare occasions, patients can present with sudden cardiac death from ventricular fibrillation.<sup>5</sup> Patients can also have bradyarrhythmias that may manifest as syncope, near syncope, or extreme dizziness with palpitation. These bradyarrhythmias may result from invasion of the conduction system, such as the atrioventricular (AV) node resulting in the heart block<sup>6</sup> or the bundle branches causing right and left bundle branch block, or can result in sinoatrial node destruction with sinus arrest.

## Obstructive Symptoms

Obstructive symptoms can be either the result of impaired filling or outflow obstruction.

The size of some intracardiac masses and tumors can cause obstructions of the valve orifice or major blood vessels, resulting in sudden cessation of cardiac output and resulting syncope. If cardiac tumors are particularly large, limiting cardiac filling, sudden decreases in intravascular volume in these cancer patients, such as with severe hemorrhage or dehydration, can also precipitate syncope more readily. Some cardiac tumors are on a pedunculated stalk and, therefore, can prolapse across different valvular structures. It is with this clinical scenario that you can find the classic tumor plop on auscultation.<sup>7,8</sup> When patients lie in different positions, they may facilitate obstructing one of the cardiac valves, resulting in positional syncope. An example of this is a patient with a left atrial tumor, such as a myxoma,<sup>9</sup> who can have their tumor prolapse across the mitral valve orifice. When lying on the left side, there is a greater tendency to occlude

**FIGURE 1** An illustration showing the common locations of the most frequent primary tumors and the entrance point for some metastatic tumors by direct extension into the heart.

that mitral valve orifice, resulting in positional syncope.

### Congestive Heart Failure

Patients also can have congestive heart failure as a result of chamber or valvular obstruction. With large masses, there is a decrease in the ability to empty cardiac chambers, resulting in elevation of intracardiac pressures and resulting in classic congestive heart failure. This would be very similar to stenotic valvular lesions.<sup>10</sup> Depending on if the tumors are in the left cardiac chambers, you may get symptoms of left heart failure with pulmonary vascular congestion and pulmonary edema. If the tumors involve the right heart chambers, you can get hepatic congestion, ascites, and peripheral edema.

In addition to the obstructive mechanism for the development of congestive heart failure, there may be enough myocardial infiltration by tumors to cause actual pump failure in the form of a restrictive cardiomyopathy.<sup>11</sup>

### Cardioembolic Symptoms

Tumors can very frequently be friable<sup>12,13</sup> and can result in the presence of changes in flow pattern within the cardiac chambers, can result in thrombus development. There can be some surface clot that develops over the tumor surface. Any of these factors can result in thromboembolic phenomena lead to thromboembolism. When cardiac tumors in left heart chambers are involved, they can result in stroke,<sup>14</sup> coronary embolization with acute myocardial infarction, renal embolization with renal failure, peripheral arterial embolization<sup>15</sup> with gangrene, or mesenteric embolization with an acute abdomen. There has even be a report of cutaneous embolization from a cardiac myxoma.<sup>16</sup> The right-sided embolic phenomena usually manifest a pulmonary embolus.<sup>17</sup>

### Cardiac Tamponade

Cardiac tamponade is a frequent clinical presentation for patients with cardiac tumors. Patients will complain of constriction feelings within the chest; they may be restless or have a depressed sensorium because of decreased cardiac output. On physical exam, they may be hypotensive with a pulsus paradoxus, tachycardic, or tachypneic with a respiratory alkalosis. On cardiac auscultation, you can frequently hear a pericardial friction rub. This clinical scenario is often the initial presentation for patients with primary cardiac tumors.<sup>18–20</sup> The great majority of these presentations are the result of associated pericardial involvement; however, there can be cardiac rupture of tumors through the myocardium into the pericardial sac.<sup>21</sup>

### Diagnostic Work-Up

Chest X-rays are nonspecific for the diagnosis of cardiac tumors. You may see the enlarged globular cardiac silhouette for those patients that develop cardiac tamponade. Many tumors are intracavitary and therefore won't be picked up by this technique. A higher index of suspicion for cardiac tumors should be maintained for the patient who has primary lung tumors or metastatic tumors to the lung.

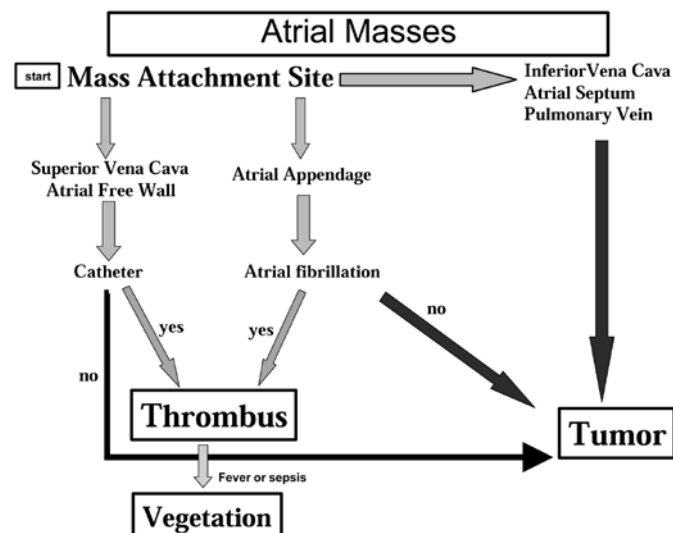

Echocardiography can be one of the best screening and most portable imaging techniques for identifying intracardiac masses. The discovery of an intracardiac echodensity on echocardiography can also create a significant diagnostic dilemma, as these densities can represent a primary cardiac tumor, a metastatic tumor, a portion of a thrombus, large vegetation, or an ultrasound artifact. Often, localizing the source or defining the tissue character of the image can be difficult, since echocardiographic images are generated from reflected or refracted ultrasound waves. The probable diagnosis of an intracardiac density can depend upon the clinical situation under which the echocardiogram was performed (Figure 2 and 3). In the cancer patient, echocardiography is ordered to evaluate coexisting cardiac disease, baseline assessment, follow-up of cardiotoxic chemotherapy, or for evaluation of a cardioembolic event such as a pulmonary embolus or stroke. In this clinical decision tree, the type of cancer must be considered, as certain cancers are more likely to metastasize to the heart or produce thrombus. Predisposing factors to development of thrombus, such as the presence of a central venous catheter or recurrent atrial fibrillation, is also important clinical information. The recent development of gas-filled microbubbles allows opacification of left-sided chambers. These bubbles are very small (4 to 10 microns) and can traverse the pulmonary

capillary bed. The main use for this new technique is left ventricular opacification to enhance endocardial definition. Contrast perfusion echocardiography<sup>22</sup> might be indicated, as many cardiac tumors are vascular and will be enhanced by microbubbles, just like the myocardium in myocardial contrast echocardiography.<sup>23,24</sup> Often, a mass found on transthoracic echocardiography (TTE) needs further evaluation by transesophageal echocardiography (TEE) to help exclude the presence of artifact and determine the attachment site of the intracardiac tumor. It is important to remember that this technique is contraindicated for patients with esophageal cancer or head and neck irradiation.

Additional imaging techniques include computerized tomography (CT), magnetic resonance imaging (MRI), and positron emission tomography (PET).

The use of CT and MRI can be most helpful in looking at the relationship of mediastinal or lung masses and how they relate to an intracardiac tumor. These techniques may help delineate invasion through a myocardial wall or an extension from one of the great vessels into the heart. MRI has the additional properties of soft tissue characterization, and that often gives the needed information to decide whether a mass is tumor versus thrombus. Contrast enhancement with gadolinium provides assessment of tumor vascularity. PET imaging has proven useful for tumors in the right atrium, right ventricle, and the left atrium. Tumors are usually hypermetabolic and can be demonstrated with a metabolic tracer. It may be more difficult to image smaller tumors in the left ventricle because the myocardium is thicker and shows metabolic properties of its own.

Endomyocardial biopsy by a transvenous catheter-based biptome has rarely been performed.<sup>25,26</sup> There are a few cases of percutaneous needle biopsy.<sup>27,28</sup> In the cancer patient, it is most

**FIGURE 2** A decision tree to help facilitate whether an atrial mass could be tumor versus thrombus. Begin by determining the attachment site of the mass.

**FIGURE 3** A decision tree to help determine whether a ventricular mass is likely to be tumor vs. thrombus. Begin by determining whether there is an right ventricular or left ventricular wall motion abnormality.

probably related to their primary malignancy. If the patient has a reasonable prognosis, then resection not only provides diagnostic pathology, but helps to avoid the clinical consequences mentioned earlier, such as embolism, congestive heart failure, and obstruction. Coronary angiography may be helpful if this will change the surgical approach or identify additional disease that need to be addressed.

### Metastatic Cardiac Tumors

Although autopsy studies have shown that metastatic disease to the heart and pericardium can be found in 10 to 20% of patients who died of malignancy; many cases of malignant tumors in the heart remain clinically silent. Metastasis to the heart occurs nearly 100 times more frequently than do primary cardiac tumors.<sup>29</sup> Metastasis may result from direct extension, lymphatic spread, or hematogenous spread into the heart. In absolute numbers, metastasis from lung cancer,<sup>30,31</sup> lymphoma,<sup>32</sup> and breast cancer<sup>33–35</sup> are the most common metastatic tumors. Of all tumors, malignant melanoma has the greatest propensity to metastasize to the heart.<sup>36,37</sup> Such lesions are found in nearly 71% of melanoma patients at autopsy. The most likely site of metastatic disease is the pericardium, although disease spread to the myocardium and/or endocardium is not rare. Because they are so frequently asymptomatic, the tumors can often be found as incidental finding on echocardiography while patients are being evaluated for other reasons. When symptoms do occur, they are frequently those of congestive heart failure, dysrhythmia, or increasing pericardial effusion leading to cardiac tamponade.

Tumor progression through the inferior vena cava may also involve the heart. In adults, this

phenomenon is seen in 4 to 10% of patients with renal cell carcinoma (Figure 4).<sup>38</sup> Other tumors that may spread to the heart through the inferior vena cava included hepatocellular carcinoma<sup>39</sup> and leiomyosarcoma<sup>40</sup> and, in children, Wilms' tumor. Such spread is usually diagnosed with a combination of echocardiography, computed tomography, and magnetic resonance imaging.<sup>41</sup> Most patients with these tumors do not have cardiac symptoms, but they may demonstrate an onset of hypertension or lower extremity edema without other finding of congestive heart failure.

Although these next two examples are not classic metastatic malignancies to the heart, these entities occur in the clinical setting of hematogenous malignancy.

### Leukemia

There have been descriptions of cardiac masses inside the cardiac chambers in association with different leukemias and were thought to be due to leukemic infiltration.<sup>42–44</sup>

**FIGURE 4** Transesophageal echocardiogram done intraoperatively showing a renal cell carcinoma tumor thrombus in the inferior vena cava (white arrow). Borrowed from the case files of Dilip Thakar, MD. IVC = inferior vena cava.

### Hypereosinophilic Syndrome (Löfller's Endocarditis)

Elevated eosinophil levels from any cause, including leukemia and other neoplastic disorders, can result in myocarditis, cardiac infiltration, or cardiac mass development.<sup>45,46</sup> The pathologic cardiac involvement consists of biventricular apical endocardial thickening, frequently with laminar mural thrombosis that contains eosinophils as part of the thrombus. The clinical scenario is congestive heart failure with hemodynamics similar to other restrictive cardiomyopathies (see Chapter 53, "Pericardium in the Cancer Patient"). Patients can develop embolism from the bilateral mural thrombi. Treatment include routine therapy for CHF, chemotherapy with hydroxyurea and imatinib,<sup>47</sup> and, late in the clinical course, surgical extraction of the fibrotic thrombus can ameliorate symptoms.

### Primary Cardiac Tumors

Malignant and benign primary cardiac tumors are extremely rare, with an incidence in autopsy series reported to be between 0.001% and 0.03%.<sup>48</sup> The occurrences of primary benign and malignant tumors of the heart are unique entities to diagnose and manage.

### Benign Primary Cardiac Tumors

Seventy-five percent of primary cardiac tumors are benign; myxomas comprise about one half of this group. Most myxomas are found in the left atrium (75%) and in decreasing frequencies in the right atrium, right ventricle, and left ventricle. The incidence of myxomas peaks at 40 to 60 years of age; they are more common in women, with a female-to-male ratio of 3:1.<sup>49</sup> They are generally friable and tend to fragment, which gives them the potential of embolizing.<sup>50</sup> Most myxomas occur sporadically. Some are familial, and, occasionally, have been described in relation to a particular syndrome called Carney's complex, an autosomal-dominant condition associated with cardiac myxomas, myxomas in other regions (cutaneous or mammary), hyperpigmented skin lesions, hyperactivity of the adrenal or testicular glands, and pituitary tumors.<sup>51–53</sup> Carney's complex occurs at a younger age, and should be considered when cardiac myxomas are discovered in atypical locations in the heart.<sup>54</sup>

In children, the most common benign cardiac tumors are the rhabdomyomas, usually found in the ventricles. One-third of patients with these tumors also have tuberous sclerosis and a much poorer prognosis; death is frequently the result of unstable dysrhythmias. Rhabdomyomas that occur as an isolated finding have a much better prognosis.

Other benign primary tumors of the heart include fibromas (also located in the ventricles),

which may be intramural and may become calcified. Lipomas, also seen in the heart, are histologically the same as those in other locations in the body. They usually occur in the left ventricle or the right atrium but may be found anywhere in the heart as well as the pericardium. Although frequently asymptomatic, they may grow large enough to cause obstructive symptoms.

Papillary fibroelastomas, which usually occur on cardiac valves, are often found incidentally (Figure 5). They may result in embolic phenomena,<sup>14</sup> and, when situated on the aortic valve, can cause coronary ostial occlusion.<sup>55</sup> Mesotheliomas<sup>20</sup> of the atrioventricular node, which is now called the cystic tumor of the AV node have the distinction of being the smallest tumor that may cause sudden cardiac death, death resulting from complete heart block, or, occasionally, ventricular fibrillation.

**FIGURE 5** Transesophageal echocardiogram showing a pulmonic valve papillary fibroelastoma (arrow) which was found incidentally during thoracic surgery. Borrowed from the case files of Dilip Thakar, MD. AoV=aortic valve, RVOT=right ventricular outflow tract, MPA=main pulmonary artery.

Paragangliomas (pheochromocytomas)<sup>20</sup> may be found as intrapericardial tumors. The very rare hemangiomas are usually found postmortem; they are identified sometimes in vivo during coronary angiography where they may cause a characteristic “tumor blush”.

### Malignant primary cardiac tumors

Primary cardiac malignancies are of connective tissue origin and are classified as sarcomas.<sup>56,57</sup> There is no gender predilection, and the mean age of presentation is approximately 40 years. Angiosarcomas, the most common type of malignant cardiac tumors, usually occur in the right atrium (Figure 6) and present clinically as hemopericardium or with right-sided congestive heart failure. Eighty percent of these tumors have metastasized at the time of diagnosis, often to the lungs, liver, bone, or lymph nodes.

**FIGURE 6** Computed axial tomography scan of the heart demonstrating an angiosarcoma in the right atrium. White arrow demonstrates the tumor actually infiltrating the right atrial wall.

Malignant fibrous histiocytomas<sup>58</sup> and fibrosarcomas are most frequently found in the left atrium, and both have a poor prognosis (Figure 7). Occasionally, these tumors are confused with left atrial myxomas.

### Treatment of Cardiac Tumors

The optimal treatment for cardiac tumors is resection of the tumor. This obviously has a much better prognosis if the tumor is a benign cardiac tumor. Primary malignancies of the heart can recur, and chemotherapy or radiation therapy may be helpful in controlling them, depending on the histology of the tumor.<sup>40</sup> Metastatic tumors of the heart can be resected, but chemotherapy and bioimmunotherapy may help to control disease. Surgical resection will help avoid obstructive symptoms or cardioembolic events. Cases that involve extensive myocardial infiltration may require explantation of the heart with resection of the tumor, reconstruction of the chambers and valves, and subsequent autotransplantation of the heart.<sup>59-61</sup>

**FIGURE 7** A magnetic resonance imaging scan showing a malignant fibrous histiocytoma in the left atrium (white arrow). LV=left ventricle, LA=left

### Cardiac Amyloidosis

The term amyloid was introduced in 1984 by German physician scientist Rudolph Virchow.<sup>62</sup> Amyloid is the term used for the predominantly extracellular deposition of a group of chemically diverse, abnormal proteins that are arranged to a greater or lesser extent in specific beta-pleated fibrils. Amyloidosis is a systemic disorder characterized by tissue deposition of amyloid protein in a wide variety of clinical settings. The conclusive diagnosis of organ involvement with amyloid is with biopsy specimens which, under light microscopy and standard tissue stains, appear as an amorphous, eosinophilic, hyaline-like extracellular substance.<sup>63</sup> To differentiate amyloid deposition from other hyaline deposits like collagen and fibrin, Congo red stain is commonly used which, under ordinary light, imparts a pink or red color to the tissue, and under polarizing microscopy, gives a green birefringence of the stained amyloid.<sup>63</sup> When stained with Congo red, all forms of amyloid appear the same, but biochemically, the fibrils are different. The electron microscopy shows non-branching fibrils of indefinite length and a diameter of approximately 7.5 to 10 nm, and electron microscopy features are identical in all types of amyloidosis.<sup>63</sup>

### Classification of Amyloidosis

The classification of amyloidosis is based on the nature of the precursor plasma protein that forms the fibril deposits (Table 1).<sup>64</sup> According to this classification, the amyloid protein is designated A, followed by the protein designation in abbreviated form without any space after first letter A. Thus, the former primary amyloidosis is now AL amyloidosis. The distinction between systemic and localized (organ or tissue limited) is avoided. This is because some amyloid deposits, which may appear to be localized, may represent a predilection site of systemic amyloidosis.

In clinical practice, amyloid deposition may be systemic (generalized) or localized to an organ like the heart or kidney. For clinical practice, the systemic type can be classified as primary (AL type), which is commonly associated with immunocyte dyscrasia, or secondary (AA type), which occurs as a complication of chronic inflammatory process.<sup>63,65,66</sup>

In AL amyloidosis, the  $\kappa$  or  $\lambda$  immunoglobulin light chain is the precursor protein. In AA type, the AA protein (which forms the AA amyloid protein) is derived from circulating acute phase reactant serum amyloid A (SAA), which in itself is synthesized in hepatocytes under the influence of cytokines such as IL-6 and IL-1.

SAA is common in most inflammatory conditions, but an increase in SAA in itself is not sufficient for deposition of amyloid.

**Table 1** Characteristics of Common Types of Systemic Amyloidosis

TYPE	Fibril Composition	Precursor Protein	Underlying Disorders
AL(primary)	Monoclonal immunoglobulin light chain	$\lambda$ or $\kappa$ light chain (ratio of $\lambda$ to $\kappa$ ,3:1)	Plasma cell dyscrasia
ATTR (familial)	Transthyretin	Variant form of transthyretin	Inheritance
AA(reactive)	Serum amyloid A protein(SAA)	Chronic inflammatory disorders	
A $\beta$ 2M	$\beta$ 2 microglobulin	$\beta$ 2 microglobulin	Long term dialysis

Adapted from Ikeda S. Cardiac amyloidosis: heterogeneous pathogenic backgrounds. Intern Med 2004;43:1107–14.

The hereditary or familial group includes a heterogeneous group with a variety of clinical manifestation.<sup>65</sup> The most common form in this group is ATTR amyloidosis (previously called pre-albumin), in which the precursor protein is a mutated transthyretin (TTR) and is a normal protein that binds thyroxine and retinol. Hence the name Trans Thy-Retin.

Senile systemic amyloidosis refers to systemic deposition of amyloid in elderly patients. Because of the dominant involvement of the heart, it was previously called “senile cardiac amyloidosis”. The amyloid in this form is composed of normal transthyretin molecule.

### Cardiac Manifestations:

The amyloid deposits in the extracellular space eventually cause pressure atrophy of the myocardial fibers.<sup>63</sup> The degree of cardiac compromise and subsequent clinical manifestations depend on the extent and location of amyloid deposition. Involvement of conduction system leads to ECG abnormalities, whereas involvement of a large area of myocardium will lead to heart failure.

The cardiac conduction system can be involved in all areas of the conduction system. Particularly, there can be involvement of the sinus node.<sup>67</sup>

Cardiac involvement is a prominent feature of AL amyloidosis,<sup>68</sup> whereas in secondary (AA) amyloidosis, involvement of the heart is found only rarely.<sup>66</sup>

The clinical manifestation of cardiac amyloidosis may be nonspecific, like fatigue, or the patient may present with a wide range of symptoms, from congestive heart failure, coronary insufficiency, heart block, valvular dysfunction, or pericardial effusion.<sup>68</sup> In patients with AL amyloidosis, fatigue and weakness are the most common systemic symptoms noted in more than 56% of patients, followed by weight loss, ecchymosis, and petechiae.<sup>68,69</sup> In these patients, multiorgan involvement should raise the suspicion of cardiac involvement. In one study of AL amyloidosis, heart involvement in the absence of clinical evidence of other system involvement (except the underlying plasma cell dyscrasia) was present in less than 4% of the patients.<sup>68</sup> In these patients, symptoms of left heart failure are

predominant followed by fatigue and weakness. Despite predominant symptoms of left heart failure, clinical signs of right heart failure predominate, with jugular venous distention and ankle edema (> 80% of cases).

In some patients, angina pectoris may be the first cardiac manifestation of systemic amyloidosis, and months later, they will develop the full scenario of systemic amyloidosis. These patients have normal coronary angiograms but abnormality of coronary flow reserve.<sup>70</sup> Chest pain is present in about 25% of patients with cardiac amyloidosis, and of those who underwent catheterization, greater than 80% had a normal cardiac catheterization.<sup>68</sup> Chest pain in these patients may be due to small vessel disease. Amyloidosis is known to infiltrate the intramyocardial vessels.

Similarly, another group of patients with angina and amyloidosis had normal epicardial coronary vessels.<sup>71</sup> In one study of primary systemic amyloidosis, the majority of patients did not have severe coexisting coronary atherosclerosis but had amyloid involvement of the epicardial coronary vessels which was nonobstructive.<sup>72</sup> The majority of these patients had intramural coronary amyloidosis. Even of these patients, more than 50% had microscopic changes of myocardial ischemia.<sup>72</sup> In patients with amyloidosis, histologic sections of coronary artery have shown various degrees of diffuse stenosis of the small coronary arteries by amyloid deposition that occurs mainly in the media of the vessels with maintenance of normal intramural epicardial coronary vessels.<sup>71</sup>

Postural hypotension is a predominant feature of cardiac amyloidosis, found in about 40% of patients.<sup>68</sup> In a minority of the patients, chest pain may be preceded by episodes of orthostatic hypotension.<sup>71</sup> Other nonspecific features of cardiac amyloidosis include: syncope (20%), palpitations (17%), hypotension (14%) and hypertension (2.6%).<sup>68</sup> Syncope in these patients may be related to postural hypotension, ventricular arrhythmias or heart block. Patients may also have stress-induced syncope. The prognosis of patients with stress-precipitated syncope is worse when compared to those who do not have stress-induced syncope.<sup>69</sup>

There are no distinguishing clinical features that may differentiate patients with systemic senile amyloidosis (senile cardiac amyloidosis) from those with immunoglobulin-derived amyloid (AL).<sup>73</sup>

Heart failure due to amyloidosis is commonly due to the result of restrictive cardiomyopathy. Progressive deposition of amyloid within the heart leads to thickening of the walls, resulting in small ventricular chambers, noncompliant myocardium, and reduced stroke volume. Eventually, it leads to a diminished cardiac output, which is exacerbated by any increase in the heart rate. Initially, the main problem is diastolic dysfunction rather than systolic dysfunction. In the presence of coexisting hypertension, when clinical suspicion of amyloidosis is low, amyloid cardiac disease can be misdiagnosed as hypertrophy due to hypertension. Amyloid heart disease can mimic hypertrophic cardiomyopathy and remain undiagnosed until development of systolic heart failure.<sup>74</sup>

### Investigations

On noninvasive evaluation, cardiac amyloidosis may be confused with hypertrophic cardiomyopathy and other causes of left ventricular hypertrophy. Electrocardiogram (ECG) and echocardiogram findings may be helpful to differentiate a combination of symptoms from other causes of left ventricular hypertrophy. A list of investigations are detailed below and summarized in Table 2.

### Electrocardiogram

ECG abnormalities are found in the majority of patients with cardiac amyloidosis. In a study of AL cardiac amyloidosis, about 96% of patients had some ECG abnormality, with low voltage and pseudo-infarct pattern being the most common abnormalities found in >70% of patients (Figure 8).<sup>68</sup> Conduction abnormalities are found in about 36% of patients. The ECG and echocardiographic features of heart involvement in AA amyloidosis resemble those of AL amyloidosis.<sup>66</sup> In another study in which low voltage (56% of cases) and pseudo-infarct pattern (60%) were the most common ECG findings in biopsy-proven cardiac amyloidosis, it was found that, if an ECG finding of low voltage was present and the echocardiogram showed an intraventricular septum thickness >1.98 cm, the diagnosis of cardiac amyloidosis can be made with a sensitivity of 72% and a specificity of 91%.<sup>75</sup> In another study, ST depression was found in 70% and T wave changes in 85% of patients with AL Amyloidosis.<sup>71</sup>

### Echocardiogram

The most common echocardiogram findings in cardiac amyloidosis are normal LV end diastolic

**Table 2** Clinical Evaluation Of A Patient With Suspected Amyloidosis

<b>Clinical Evaluation</b>	Heart ( Heart failure, fatigue, syncope, chest pain, murmur, postural hypotension, palpitations) Other Systemic Features ( macroglossia, neuropathy, hepatomegaly, malabsorption, diarrhea, proteinuria or frank nephrosis, skin papules or plaques, periorbital ecchymosis, arthritis, carpal tunnel syndrome, pleural effusion due to amyloid heart disease or pleural amyloid deposition)
<b>ECG</b>	Low voltage, pseudoinfarct pattern, heart block
<b>CXR</b>	Heart: Usually normal cardiac silhouette. In later stage Cardiomegaly. Lungs: Pulmonary edema, pleural effusion
<b>Echocardiogram</b>	Normal Left ventricular end diastolic dimension, thickening of septum and posterior wall, distinctive sparkling/granular appearance of the myocardium, restrictive physiology.
<b>Holter</b>	Conduction abnormality, Heart rate variability
<b>Blood</b>	Albumin, LFT's Creatinine, electrolyte, Coagulation, Thyroid function. BNP and Troponin ( in cardiac involment)
<b>Urine</b>	Proteinuria, Creatinine clearance

BNP = brain natriuretic peptide; CXR = chest x ray; ECG = electrocardiogram; LFT = liver function tests.

**FIGURE 8** A two dimensional echocardiogram showing the parasternal long axis view. The white arrow shows the increased echodensity of the interventricular septum correlating with amyloid deposition compared to normal echocardiographic appearance of the posterior wall of the left ventricle shown by the red arrow.

RV = right ventricle, LV = left ventricle, Ao = aorta, LA = left atrium.

dimension, thickening of both right and left ventricular myocardial walls, restrictive physiology on Doppler, and sparkling/granular appearance of the myocardium (Figure 9 and 10).<sup>75</sup> In cardiac amyloidosis, there is infiltration by amyloid protein, which initially leads to a restrictive diastolic dysfunction, and the left ventricular ejection fraction starts to fall only late in the course of the disease, unless the patient has concomitant coronary artery disease or other etiology for dilated cardiomyopathy.

### Chest Roentgenograms

The cardiomyopathy in amyloidosis is restrictive in nature, hence the cardiac silhouette may not be enlarged. In senile systemic amyloidosis, cardiomegaly is noted in a majority of patients

with associate pleural effusions in >35% of cases.<sup>73</sup>

### Nuclear Scintigraphy

Abnormal cardiac uptake of <sup>99m</sup>Tc-3, 3-diphosphono-1, 2-propodicarboxylic acid (<sup>99m</sup>Tc-DPD) may help differentiate TTR-related cardiac amyloidosis from the AL type of cardiac amyloidosis.<sup>76</sup>

### Serology

Serum N-terminal pro-brain natriuretic peptide (BNP) has been found to be a sensitive marker of myocardial dysfunction in patients with AL amyloidosis.<sup>77</sup> In asymptomatic patients with cardiac amyloidosis, BNP levels may be elevated and may help to distinguish between those with or without heart failure.<sup>78</sup> This raises the

**FIGURE 10** A transthoracic two dimensional echocardiogram showing increased echodensity and thickening of the myocardial walls and valves. This also demonstrates the sparkling and granular appearance of the walls.

LV = left ventricle, RV = right ventricle, RA = right ventricle.

possibility that elevation of BNP levels in cardiac amyloidosis could be direct myocyte damage due in addition to a rise in left ventricular end diastolic pressure.

In a small study, troponin levels were elevated in all patients with amyloid cardiomyopathy, of which 70% had values above the threshold used for the diagnosis of cardiac ischemia. In this study only 15% of patients had severe coronary artery disease. Amyloid deposition within the intramural epicardial coronary artery was found in all patients, and 38% had obstructive findings with greater than 60% obstruction. Interestingly,

**FIGURE 9** A 12 lead EKG demonstrating a pseudo-infarct pattern with Q waves in leads I, aVL, V1 and V2.

troponin I elevation was higher in patients with no or mild coronary artery disease. In this study, no statistical correlation was noted between troponin elevation and left ventricular ejection fraction, left ventricular wall thickness, pulmonary artery wedge pressure, or pulmonary artery pressure. This suggests that, in amyloid cardiomyopathy, elevation in troponins may be due to amyloid infiltration of the heart.<sup>79</sup>

## Diagnosis

The diagnosis of cardiac amyloidosis should be considered in any patient who has unexplained cardiomyopathy, in particular in the setting of conditions known to be associated with amyloidosis. Although secondary (AA) amyloidosis rarely causes cardiac involvement, a high index of suspicion is needed in these cases as well. Patients who have amyloid involvement elsewhere, (eg, those with proteinuria or GI involvement with amyloidosis), should have an ECG and an echocardiogram as baseline investigations. In those with a high clinical suspicion of cardiac amyloidosis, the next step would be to establish a diagnosis by cardiac biopsy. When a cardiac biopsy is not possible, then a biopsy of the subcutaneous abdominal fat can be obtained.<sup>80</sup> Once a positive tissue diagnosis is obtained, the next step is to find out the type of amyloidosis. AL amyloidosis is the most common type, and the next step is to search for plasma cell dyscrasia by immunofixation electrophoresis of the serum and urine or by a bone marrow biopsy with immunohistochemical staining of plasma cells for kappa or lambda light chains.<sup>65</sup> The bone marrow biopsy will also help exclude myeloma or other conditions like Waldenström's macroglobulinemia as a cause of amyloidosis. If these are negative, then the next step, even in the absence of a family history of amyloidosis, is to look for a mutant TTR protein in serum, a mutant TTR gene in genomic DNA or both.<sup>65</sup>

Although there may be no clinical features to differentiate senile cardiac amyloidosis from the AL type, the absence of abnormal M protein in serum and urine plus the presence of cardiac amyloidosis in patients greater than 60 years of age with no extracardiac manifestation of primary amyloidosis, raises the possibility of systemic senile amyloidosis (senile cardiac amyloidosis).

## Treatment

Treatment of cardiac amyloidosis should not be limited to those with clinical cardiac presentations, as treatment of concomitant disease (such as myeloma, nephrotic syndrome, and neuropathy or Gastrointestinal symptoms) is essential to the general well-being of the patient.

Angina should be treated with standard anti-anginal medications, albeit with cautious use

of  $\beta$ -blockers and calcium channel blockers. In a small group of patients with AL amyloidosis, chest pain on exertion was promptly relieved by nitrates, but recurred frequently despite long-term use of these drugs.<sup>71,81</sup> Due to the recurrence of chest pain despite long-term nitrates, some have advocated the use of anti-anginal medications like nicorandil (not available in the US) which, in a study of normal population, was found to cause a dose-dependent increase in coronary flow velocity and a decrease in coronary vascular resistance, following intracoronary injection.<sup>82</sup> In one case report, despite use of diltiazem and nicorandil, the patient developed recurrent angina with ECG changes.<sup>83</sup>

There is not enough data available to make any firm recommendations on ideal medication for patients with angina and amyloid, but nitrates seem to be the logical and most prevalent choice made in these patients.

Treatment of congestive heart failure is with standard heart-failure medications, which include diuretics, angiotensin-converting enzyme inhibitors (ACE inhibitors) and  $\beta$ -blockers, although these medications have not been systematically studied in any large group of patients with amyloid cardiomyopathy.

ACE inhibitors should be used cautiously because of the potential for causing or exacerbating postural hypotension. This category of drug should be started in small doses, and increments made gradually and cautiously. Calcium channel blockers theoretically have been beneficial in diastolic heart failure,<sup>84</sup> and along with  $\beta$ -blockers and ACE inhibitors have a class 2b indication for treatment of patients with heart failure and normal left ventricular ejection fraction.<sup>85</sup> Calcium channel blockers should also be used cautiously in patients with amyloidosis because they have been reported to precipitate and worsen heart failure even in the presence of normal left ventricular ejection fraction.<sup>86</sup> Discontinuation of verapamil in this case was followed by clinical and echocardiographic improvement with normalization of left ventricular systolic function.<sup>86</sup> Digoxin should be avoided, as it avidly binds to amyloid fibrils,<sup>87</sup> which may lead to toxicity.

Indications for pacemakers are the same as in the general population.<sup>88</sup> However, when there is extensive involvement of the heart by amyloid tissue, successful insertion of pacemaker may still not be life-saving.

Clinical and echocardiographic improvement has been reported with thalidomide treatment in a patient with primary (AL) amyloidosis with cardiac involvement.<sup>89</sup> In a study of primary amyloidosis, for patients with cardiac involvement (21% of the study population), treatment with melphalan improved survival compared to colchicine.<sup>90</sup>

Heart transplantation is a last resort because there is a recurrence of amyloid deposition in

transplanted hearts, and, therefore, only provides short-term benefit because it does not influence the underlying disease process.<sup>91</sup> It may have a role in a selective group of patients who are considered to be cured of the primary disease with high-dose chemotherapy and stem cell transplant.

## Prognosis

In patients with primary amyloidosis, the presence of cardiac involvement is associated with a worse outcome, and the majority of deaths are cardiac-related.<sup>90</sup> Cardiac amyloidosis is associated with variable prognoses, depending upon the presence of other disease and concomitant involvement of other organs. In patients with primary amyloidosis (AL), the most common cause of death is due to either sudden cardiac death or congestive heart failure.<sup>68</sup> The median survival in the 232 patients following a diagnosis of AL amyloidosis was 1.08 years (range 0.83 to 1.25), and from the date of the index echocardiogram, median survival was 0.50 years (range 0.42 to 0.66).<sup>68</sup> In this study, patients with congestive heart failure median survival from diagnosis was 0.75 years (range 0.59 to 1.00), which was significantly shorter when compared to patients with heart involvement but no congestive heart failure, where median survival was 2.34 years (range 1.58 to 2.92).<sup>68</sup> In patients with systemic amyloidosis, elevated troponin and BNP levels also provide important prognostic information and are predictors of mortality in these patients.<sup>92</sup>

Patients with senile systemic amyloidosis with cardiac amyloidosis, despite being older and exhibiting greater left ventricular wall thickness, appear to have a survival advantage and better prognosis when compared to patients with AL amyloidosis involving the heart.<sup>93</sup>

Amyloid infiltration may affect the geometry of the ventricles in a discordant fashion, and when right ventricular dilation occurs greater than the left ventricle, it is associated with a poor prognosis with a median survival of only 4 months.<sup>94</sup> Right ventricular dilatation in these patients may be due to elevated left ventricular end diastolic pressure or elevated pulmonary vascular resistance and pulmonary hypertension from amyloid involvement of pulmonary arterioles.

# The Pericardium in the Cancer Patient

Steven M. Ewer, MD  
Michael S. Ewer, MD, JD

Heart disease and cancer are the two most common causes of death in developed countries. While primary cardiac malignancy is relative rare, involvement of the heart either by malignant spread of the tumor, or as a sequel to the various treatment strategies, occurs much more frequently. The pericardium is of especial interest to those treating patients with cancer, as it is the cardiac structure most frequently affected by tumor spread, and it is the cardiac structure most sensitive to the effects of ionizing radiation. Pericardial disease and cancer are therefore two closely related fields of interest.

Approximately 9% of patients who eventually succumb to malignancy have direct cancerous involvement of the pericardium, and for 80% of these patients, their pericardial involvement will contribute to their demise.<sup>1</sup> An even greater number develop pericardial disease via other mechanisms that are related to their malignancy. Likewise, 7% of patients presenting with acute pericardial disease have a neoplastic etiology,<sup>2</sup> and 35% of procedures performed for pericardial disease are done on cancer patients.<sup>3</sup> Usually, pericardial disease in the cancer patient presents well after the diagnosis of cancer has been established. Typical questions that arise include: (1) what aspect of malignancy or its treatment are the cause; (2) what are the implications for prognosis and further cancer treatment; and (3) what is the best way to manage the pericardial disease. In rare cases, however, a patient with no history of cancer may present with malignant pericardial disease as the first manifestation. Sometimes, pericardial involvement during life remains unsuspected and is an incidental finding at autopsy.

Historically, malignant pericardial disease was relegated to a medical curiosity and was diagnosed almost exclusively on autopsy. With the advent of imaging technology in the 20th century, ante mortem diagnosis became possible, but prognosis remained grim and little could be offered to patients besides occasional brief palliation. Currently, even earlier diagnosis of malignant pericardial disease is possible, and a much greater number of treatments are available for the

systemic and local management of their malignancy, as well as management of treatment-related pericardial disease. These advances have rendered pericardial disease in the cancer patient increasingly relevant in modern medicine. Despite these accomplishments, however, quality evidence for optimizing diagnostic and therapeutic strategies for these conditions has lagged, and we are left with a considerable degree of uncertainty as to the ideal management of an exceedingly complex group of patients.

Malignant disease and its treatment affect the pericardium in a variety of ways. While primary pericardial tumors are very rare, metastases are quite common. Nearly all cancers (with perhaps the exception of primary brain tumors) are capable of metastasizing to the pericardium through either direct extension (ie, lung, esophageal), retrograde lymphatic spread (ie, lung, breast), or hematogenous seeding (ie, melanoma, lymphoma, leukemia). Other causes of pericardial abnormalities in the cancer patient that do not involve direct invasion include adjacent inflammation, interruption of lymphatic or venous drainage, infection, hypoalbuminemia, congestive heart failure, renal failure, toxicities of chemotherapeutics, and chest irradiation. Many cases of pericardial disease in the cancer patient are idiopathic, and it should be recognized that the pericardial disease is often unrelated to the underlying malignancy. The etiology of a pericardial abnormality in a cancer patient is thus critical to his or her management, having important implications for prognosis and treatment. The possibility that the etiology of a sanguineous pericardial effusion in a lung cancer patient may be caused by tuberculosis, for example, cannot be overemphasized.

Symptoms of pericardial disease are often vague and nonspecific, and can mimic disease in many other organ systems, which are often also affected by the malignancy. Diagnosis can be very challenging, and even after diagnosis, treating existing pericardial disease does not ensure relief of an individual's symptoms. The clinician must approach these patients with a broad view of clinical medicine in order to minimize the possibility of incorrect diagnoses and inappropriate interventions.

Despite the fact that the diagnosis of pericardial problems may be difficult, the management of such problems may be tremendously gratifying. The improvement experienced by a patient following drainage of pericardial fluid in the setting of cardiac tamponade is one of the most dramatic and rewarding interventions that we as internists or cardiologists can undertake. As cancer treatments continue to improve, we will have increasing opportunity to offer our patients both quantity and quality of life through management of their pericardial disease.

After a brief discussion of normal pericardial structure and function, this chapter will examine the spectrum of primary and metastatic tumors of the pericardium, pericardial sequelae of chest radiation, and other aspects of malignancy and its treatment that affect the pericardium. We will then review the more common manifestations of pericardial disease as it pertains to the patient with diagnosed or undiagnosed malignancy. Mechanisms, diagnosis, and treatment of these entities, including acute pericarditis, pericardial effusion, tamponade, and pericardial constriction will be discussed.

## Normal Pericardial Structure and Function

The pericardium consists of a fibrous sac that contains the heart. There are two pericardial layers: the inner visceral pericardium, attached directly to the surface of the heart, and the outer parietal pericardium, separated from the visceral pericardium by the pericardial space. The pericardial space contains a small amount of serous fluid. The two layers meet at or near the origin of the great vessels (the superior vena cava, aorta, pulmonary artery, and pulmonary veins), and these attachments serve to anchor the pericardium and heart within the mediastinum. The two layers thus completely enclose the pericardial space, which is often considered a "potential space" because, while usually containing a minimal amount of fluid between the two adjacent surfaces, this space can greatly expand in pathologic states, holding more than two liters of pericardial fluid in some cases.

From an embryologic perspective, the visceral pericardium is a monolayer of mesothelial cells on the surface of the epicardium, which also consists of some connective tissue, adipose tissue, the coronary blood vessels, nerves, and lymphatic vessels. The parietal pericardium consists of a monolayer of mesothelial cells along with a thicker serosa, which is made of fibrous connective tissue including collagen and elastin. The normal thickness of the parietal pericardium is 1 to 3.5 mm, depending on variations in the serosa.<sup>4</sup> The thickness of the parietal pericardium increases with most pericardial disease states, including those related to malignancy, and, indeed, is the primary abnormality in the case of constriction.

Most references to “the pericardium” as a tissue structure are understood to imply the parietal pericardium; the visceral pericardium usually is included as part of the epicardium. While this convention has the potential for confusion, the meaning is usually clear from the context. Metastases to the pericardium, however, may involve both the parietal and visceral layers.

Innervation of the pericardium is derived from the phrenic nerve anteriorly and the esophageal plexus posteriorly, both carrying fibers derived from the vagus nerve. These fibers are the source of chest pain in acute pericarditis. Myocardial innervation is supplied by the same nerves, which helps explain the similarities of anginal pain and pericardial pain when prominent pleuritic features are absent. Lymphatic drainage is to the anterior and posterior mediastinal lymph nodes, and retrograde spread through these vessels is an important source of metastatic tumor spread, especially for cases of breast and lung cancers that involve mediastinal lymph nodes. Obstruction of lymphatics by tumor is also a mechanism for pathologic accumulation of pericardial fluid that does not require invasion of the pericardium per se.

The pericardial space normally contains 15 to 50 mL of fluid, which is continuously secreted by the mesothelial cells of the visceral pericardium. This fluid is essentially a plasma ultrafiltrate and serves to lubricate the movements of the heart. Pericardial fluid is resorbed via lymphatics and veins. When secretion is increased (eg with inflammation) and/or resorption is decreased (eg tumor obstruction), fluid can accumulate abnormally in the pericardial space and is then referred to as an effusion. Three major sinuses, as well as several minor ones within the pericardial space, serve to store accumulated fluid without affecting cardiac function or causing symptoms: the transverse sinus lies between the superior pulmonary veins and the main pulmonary artery; the oblique sinus lies between the right and left pulmonary veins behind the left atrium; and the superior sinus surrounds the base of the

ascending aorta. When preclinical (but nevertheless pathologic) pericardial effusions are present, these sinuses can be seen to be enlarged with various imaging modalities, including computed tomography (CT), magnetic resonance imaging (MRI), and transesophageal echocardiography. Because of their location, the pericardial sinuses are not typically seen on transthoracic echocardiography.

In addition to lubricating the movements of the heart, the pericardium serves many other physiologic functions. The relatively fixed volume and inherent elasticity combine to keep the pericardial sac under tension, which contributes to diastolic pressures within the heart and helps maintain the classic pressure-volume relationships of cardiac physiology. For instance, under conditions that increase left ventricular volume, a condition commonly encountered in the cancer patient (eg, anthracycline cardiomyopathy, renal dysfunction), the structural integrity of the pericardium helps take on some of the burden of increased wall stress. Within the pericardial space, there is a small negative pressure ( $\approx 3$  mmHg) that serves to augment diastolic filling.<sup>4</sup> Other functions include a physical tethering of the heart within the mediastinum, a barrier against infection and inflammation, participation in the cardiac autonomic reflexes, and paracrine functions (releasing mediators such as endothelin and prostacyclins). When cancer results in a diseased pericardium, any of these functions can be altered or disrupted, often leading to complex pathophysiology with subtle, multi-faceted contributions to morbidity.

### Primary Tumors of the Pericardium

Primary pericardial tumors are extraordinarily rare. The reported incidence of all cardiac tumors ranges from 0.001% to 0.28% in autopsy series,<sup>5</sup> and pericardial tumors make up only a fraction of these cases. (By comparison, the incidence of pericardial metastases is approximately 2.5% in a similar general autopsy series.) Both benign and malignant pericardial tumors will be addressed. A list of primary tumors of the pericardium is shown in Table 1. Relative incidence as a percentage of all primary pericardial tumors is shown where possible.

Five tumor types make up the vast majority of primary pericardial tumors, accompanied by a longer list of very rare entities (see Table 1). Approximately 25% of primary pericardial tumors are malignant. In general, the benign lesions present more commonly in infancy or childhood, and malignant tumors are seen more frequently after the third decade. The exceptions are slow-growing benign tumors such as lipomas, which may also present later in life. We will briefly discuss some of the more common pericardial tumors below, including pericardial cysts,

**Table 1** Primary Tumors of the Pericardium

<i>Benign</i>	
Pericardial Cyst (62%)	
Teratoma (11%)	
Bronchogenic Cyst

Thymoma	
Primary Cardiac Lymphoma	
Hodgkin's Lymphoma	
Malignant Nerve-Sheath Tumors	
Hemangioepithelioma	
Liposarcoma	
Pheochromocytoma	

teratomas, mesotheliomas, and angiosarcomas. Other tumors are found in the literature only as isolated case reports and very small series and will be mentioned briefly. The bulk of epidemiologic data regarding primary cardiac tumors comes from a series of 533 such cases by the Armed Forces Institute of Pathology,<sup>6</sup> and was summarized and updated more recently.<sup>5</sup>

### Pericardial Cysts

Pericardial cysts are the most common primary pericardial tumor.<sup>21</sup> They consist of a lining of mesothelial cells surrounded by a layer of fibrous connective tissue, much like the structure of the pericardium itself. Occasionally, hyperplasia of the mesothelium is found, and rarely, inflammatory cells may also be present. The interior of the cyst contains a clear, straw-colored fluid, and may communicate with the pericardial space. Pericardial cysts usually contain only small amounts of fluid (less than 10 cc) and are usually less than 3 cm in their widest dimension. They can, however expand considerably, and may achieve maximal dimensions of up to 15 cm.<sup>5</sup> The most common location is along the right heart border.<sup>5</sup> Pericardial cysts can present at any age, but the majority are diagnosed before the age of 30. They have also been noted as incidental findings at autopsy. Only one-third of patients present with

symptoms, which consist primarily of chest pain, but can also include dyspnea and arrhythmias.<sup>4</sup> More typically, an abnormality is seen on chest X-ray obtained for other reasons, which then leads to the diagnosis of a cardiac tumor. More detailed imaging can be obtained with echocardiography, computed tomography, or magnetic resonance imaging. Treatment consists of surgical excision, percutaneous drainage, or thorascopic drainage. Pericardial cysts do not have malignant potential, and the prognosis is excellent.

### Teratoma

Teratomas are composed of tissue derived from all three germ layers. They are usually, but not always, benign. Pericardial teratomas arise from the base of the pulmonary artery or aorta, which often complicates their surgical removal. Approximately 80% occur in the pediatric population,<sup>5</sup> typically in infancy or in utero.<sup>7,8</sup> There is a remarkable female-to-male preponderance. Clinical presentation is far more dramatic than for pericardial cysts. Because of their location and size, compression of the right atrium is the rule, and right ventricular compression is not uncommon. Furthermore, pericardial teratomas are frequently accompanied by a large pericardial effusion, which exacerbates tamponade physiology. Presentation includes hydrops fetalis, fetal pericardial effusion, and dyspnea, cyanosis, cardiomegaly, cardiac murmurs, and sudden cardiac death in the neonatal or pediatric patient. Treatment includes surgical excision, and a non-trivial operative mortality exists for these patients. Occasionally, fetal pericardiocentesis is also necessary.<sup>9</sup> After recovery from surgery, the prognosis is excellent and recurrences are uncommon. Rarely, teratomas can undergo malignant transformation, invading adjacent structures, including the myocardium. In these unfortunate cases, surgical excision is not feasible and the prognosis is poor; death usually occurs within weeks of the diagnosis.

### Mesothelioma

Mesothelioma is the most common primary malignancy of the pericardium. It usually presents in middle age, with males affected twice as often as females.<sup>10</sup> It is unclear from the scant literature available if exposure to inhaled asbestos is a significant risk factor for pericardial mesothelioma as it is for its pleural counterpart, but several cases without any apparent asbestos exposure have been documented.<sup>4,11</sup> Another series, however, found no difference in asbestos exposure in patients with pleural versus pericardial mesothelioma,<sup>12</sup> implying an association. Additionally, the issue is confused by the fact that some mesotheliomas thought to be of pericardial origin are actually derived from the pleura with local

invasion into the pericardium. Some evidence implicates simian virus 40 as well as asbestos in the pathogenesis of mesothelioma; this virus has been found in up to 80% of patients with mesothelioma, and has been found to cause mesothelioma in animal models.<sup>13</sup>

Although localized nodules can exist, mesothelioma usually spreads uniformly throughout the pericardial space. Invasion occurs locally and includes spread to the pleura, mediastinum, mediastinal lymph nodes, and occasionally, through the diaphragm to the peritoneum. Invasion to the deep myocardium or endocardium is rare, in contrast with other pericardial malignancies. Distant metastases are also notably uncommon, but have been found in the brain.<sup>14</sup> Clinical presentation spans the spectrum of pericardial disease, including acute pericarditis, chronic or recurrent pericardial effusions, and constriction. Constitutional symptoms are also common.

Diagnosis of mesothelioma is confirmed by cytologic evaluation of the fluid or pericardial biopsy along with suggestive clinical features. Pathologic distinction between mesothelioma and reactive mesothelial hyperplasia (seen in response to inflammation) can be challenging.<sup>5</sup> Treatment is mainly palliative, and consists of radiation, chemotherapy, and local measures to control pericardial symptoms. Given the behavior patterns of this malignancy, surgical resection is generally impossible. The very high operative mortality makes surgical intervention prohibitively risky, including treatment of pericardial constrictive disease due to mesothelioma. Prognosis is poor with or without surgery, with one series reporting a 60% 6-month mortality.<sup>5</sup>

### Angiosarcoma

Angiosarcoma is the second most common primary pericardial malignancy after mesothelioma, and is the most common cardiac sarcoma overall. Angiosarcomas originate in either the right atrium or pericardium in 80% of cases.<sup>5</sup> Patients usually present as young or middle-aged adults, and as is the case with mesothelioma, men are more susceptible than women. Unlike mesothelioma, however, angiosarcoma commonly invades the myocardium and endocardium, and can present with intracardiac masses or valvular obstruction. Distant metastases are possible and occur in approximately one-quarter of all cases,<sup>5</sup> with a predilection for the central nervous system. Symptoms and clinical findings include those of acute pericarditis, pericardial effusion, congestive heart failure (especially right-sided failure resulting from obstruction of the superior or inferior vena cava, or the tricuspid valve), arrhythmias, and constitutional symptoms. Pericardial effusions are typically hemorrhagic. Surgical resection may be possible in selected patients, but treatment is generally palliative, and includes

chemotherapy and radiation. The prognosis is generally poor.

### Other Primary Pericardial Tumors

Pericardial lipomas resemble lipomas found elsewhere in the body. They are slow-growing benign tumors that are asymptomatic until they begin to compress adjacent structures. Unlike teratomas, there is no significant inflammatory reaction, and effusion is usually absent. If not compressing critical structures, they can grow to giant proportions—nearly 5 kg in one case report.<sup>15</sup> They are often confused with the more common pericardial cysts, in part because of their homogenous, low-density signal on various imaging modalities. Surgery is curative, and offered only when symptoms warrant intervention or diagnostic uncertainty remains. As with lipomas elsewhere, there is an exceedingly low rate of malignant transformation to liposarcoma. Liposarcomas can recur after surgical resection, and repeat surgery can be an effective way to manage such cases.<sup>16,17</sup>

Occasionally, thymomas can arise from the parietal pericardium without evidence of anterior mediastinal involvement. Tumors can be benign or malignant, and do not appear to be associated with myasthenia gravis. Hemangiomas and lymphangiomas can occur in the pericardium, often mimicking pericardial cysts. Intrapericardial pheochromocytoma is a rare but well-documented phenomenon. Diagnosis includes measurement of active metabolites in the blood and urine, and imaging with MRI or targeted nuclear scanning. Pericardial neurofibromas have been described in the context of von Recklinghausen's disease. Primary cardiac lymphoma is usually of B-cell origin and tends to involve both the myocardium and pericardium simultaneously. Treatment is similar to extracardiac lymphoma.

### Metastatic Disease of the Pericardium

In several large autopsy series, 10% of all patients who die because of cancer have metastases to the heart. Of these, approximately 85% have pericardial involvement.<sup>18</sup> Not only is malignant pericardial disease fairly common, it contributes to death in the majority of cases.<sup>1</sup> Pericardial metastases outnumber primary pericardial tumors by about two orders of magnitude, and thus are by far the more important clinical entities. Nearly all cancers have been found to metastasize to the pericardium, but only a handful of these are seen with any meaningful frequency. Table 2 shows a list of these more common pericardial metastases with their relative frequencies.<sup>19–21</sup> Lung cancer, breast cancer, and hematologic malignancies together account for approximately two-thirds of

**Table 2 Metastatic Cancers to the Pericardium**

Lung Cancer 33% (includes roughly equal numbers of squamous cell, adenocarcinoma, and small cell carcinoma)
Breast Cancer 19%
Hematologic Malignancies 13%
Gastrointestinal Carcinomas 7.7% (includes adenocarcinoma and squamous cell carcinoma)
Malignant Melanoma 4.6%
Prostate Cancer 3.5%
Thyroid Cancer 3.5%
Pancreatic Cancer 3.5%
Gynecologic Malignancies 3.5%

pericardial metastases. In some series, this group accounts for 80%.<sup>18</sup>

Of equal relevance is the likelihood of a given malignancy to metastasize to the pericardium. Melanoma is the most likely to do so, with up to 70% of metastatic cases involving the pericardium.<sup>18</sup> Leukemia and lymphoma are found to involve the pericardium in approximately 33% of cases. Breast cancer metastasizes to the pericardium in approximately 21% of cases, and lung cancer in 19%.<sup>1</sup>

Cancer can metastasize to the pericardium in one of three ways: direct extension, lymphatic spread, and hematogenous spread. All three mechanisms are fairly common and clinically relevant. Direct extension to the pericardium is facilitated by aggressive tumor behavior and proximity to the heart. Malignancies in this category include lung cancer, esophageal cancer, and, to a lesser degree, breast cancer. (The mid-esophagus is separated from the left atrial cavity by as little as 3 mm of tissue in some locations!) Often overlooked members of this category are primary cardiac tumors that originate elsewhere in the heart and invade the pericardium, such as rhabdomyosarcoma and fibrosarcoma. Angiosarcoma is a unique, albeit confusing, example, in that it can originate in either the myocardium or pericardium and then proceed to invade adjacent structures.

Lymphatic spread is probably the most common mechanism of metastatic spread to the pericardium. As noted above, lymph node groups that receive drainage from the heart are the anterior and posterior mediastinal nodes, and cancers that metastasize to these nodes, most notably breast and lung cancer, can reach the pericardium via retrograde lymphatic spread. Careful histologic study has confirmed this mechanism in the majority of cases involving pericardial metastases.<sup>22-24</sup> Note that invasion and obstruction of these lymphatics is also likely to be the main contributor to malignant and non-malignant pericardial effusions in this group.

Leukemia, lymphoma, and melanoma most commonly seed the heart, including the pericardium, through the blood vessels. Hemorrhage

often accompanies metastases in this category, contributing to the pericardial effusion. It is interesting that these malignancies are precisely the ones most likely to involve the pericardium, implying perhaps that this route of metastasis is more efficient than lymphatic spread or direct extension.

Presentation of metastatic pericardial disease is highly variable. Some cases are asymptomatic and are diagnosed incidentally on autopsy, while others present as life-threatening catastrophic events such as pericardial tamponade. Most patients with pericardial metastases are symptomatic however, and as noted above, pericardial involvement very often leads to their demise.<sup>1</sup> The most common presentations, namely acute pericarditis, chronic effusion, tamponade, and constrictive disease, all occur in cancer patients and will be discussed in detail below. In general, malignant pericardial disease presents more often as chronic pericardial effusions or tamponade, and less often as acute pericarditis. Pericardial constriction can be seen following chest irradiation. However, it is worth mentioning that patients rarely present in classical textbook fashion. Sorting out pericardial disease in the setting of malignancy can be extremely challenging.

Case series have been collected that specifically look at symptoms and signs of metastatic pericardial disease. One study reports dyspnea in 91%, cough in 67%, pleural effusion in 53%, and venous distension in 30%.<sup>25</sup> Another reports tachycardia in 46%, pleural effusion in 44%, dyspnea at rest in 40%, and abnormal chest X-ray in 32%.<sup>19</sup> Other findings include rales, pulsus paradoxus, distant heart sounds, and abdominal symptoms related to congestion. Many of these are nonspecific and can mimic other diseases, especially lung disease, which is frequently coexistent as the primary site of malignancy, another site of metastasis, or pneumonia. Arrhythmias are a common manifestation of malignant pericardial disease,<sup>26</sup> and a new arrhythmia in a cancer patient should raise suspicion for cardiac metastases if this has not previously been diagnosed. Congestive heart failure can present similarly, but symptoms include orthopnea and paroxysmal nocturnal dyspnea, which are usually not present with symptomatic pericardial effusions. Because symptoms are relatively nonspecific, or even misleading, and the differential diagnosis in these patients is always broad, the clinician must have a high index of suspicion to detect clinically relevant pericardial involvement. The adage that pericardial disease can act as a masquerader is especially true in the cancer patient.

Once pericardial disease is suspected based on history and physical examination, the most useful initial test is the transthoracic echocardiogram because of its high diagnostic yield, ready availability, and noninvasive nature. Echocardiographic findings for specific entities

will be discussed below. Chest X-ray may reveal cardiomegaly, pleural effusions, and mediastinal lymphadenopathy, but is not definitive. Electrocardiography may reveal several aspects of pericardial disease, and these will also be considered below. CT and MRI can be helpful adjuncts, especially useful because of their expanded field of view (including lungs, pleura, mediastinum, and great vessels), which helps put malignant pericardial disease in a broader perspective. Indeed, pericardial effusions are often discovered incidentally on chest CT scans done for other indications, such as to rule out pulmonary metastases or thromboembolic disease. Additionally, MRI is especially able to visualize cardiac masses due to its excellent contrast resolution.<sup>27</sup> Melanoma has unique features on MRI because of the ability of melanin to bind paramagnetic metals. This gives melanoma a bright appearance on T1-weighted images, in contrast to other tumors.<sup>27</sup> Both MRI and CT can help determine pericardial thickness if constriction is being considered.

Pathology, including cytology of pericardial fluid and tissue from surgical specimens, is an important aspect of diagnosis. The finding of malignant cells in pericardial fluid or in tissue samples of parietal or visceral pericardium help make the diagnosis of malignant pericardial effusion, which may be defined as an effusion associated with any evidence for malignant invasion of the pericardium. Not all pericardial effusions in a patient with cancer are necessarily malignant. Other mechanisms for effusion in these patients include adjacent inflammation, interruption of lymphatic or venous drainage, infection, hypoalbuminemia, congestive heart failure, renal failure, toxicities of chemotherapeutics, and chest irradiation. The pericardial space has even been found to be a site of extramedullary hematopoiesis in cases of chronic myeloid leukemia,<sup>28,29</sup> and amyloid accumulation in multiple myeloma.<sup>30</sup> Effusions can also be idiopathic, seemingly unrelated to malignancy. In addition to cell morphology, fluid and tissue analysis with chemistry and microbiology may help to diagnose some of these other entities, and will be discussed in more detail below.

Treatment of malignant pericardial disease involves two parallel strategies—local control of the pericardial disease and, where feasible, systemic treatment for the underlying malignancy. Since the overall prognosis of patients with pericardial metastases from any cancer is generally poor, palliation is usually the goal. Tumor type and aggressiveness influence treatment. As with any treatment in oncology, quality and quantity of life must both be considered when choosing a therapeutic strategy. In general, the more definitive procedures carry a higher risk of morbidity and mortality, and less burdensome strategies may sometimes be more prudent. Good communication between the cardiologist, oncologist,

primary care physician, patient, and family is essential to arriving at a medically reasonable and appropriate treatment strategy that can be accepted by the patient and his decision-makers.

### Malignancy-Related Pericardial Disease

It has been estimated that nearly two-thirds of patients with malignancy who present with pericardial disease do not have direct pathologic invasion of the pericardium by the tumor.<sup>3</sup> In many cases, pericardial disease is related indirectly to the malignancy or its treatment; radiation pericarditis and opportunistic infections are examples of this phenomenon. In some instances, pericardial disease is entirely unrelated to the malignancy. We will discuss some of the non-malignant but malignancy-related conditions here.

### Radiation-Induced Pericardial Disease

It has been well established that external radiation to the thorax is associated with cardiac sequelae. All three cardiac layers can be involved, but the pericardium is the most radiosensitive; the myocardium and endocardium are post-mitotic tissues, and thus are less susceptible.<sup>5</sup> Radiation-related cardiac disease depends mostly on radiation dose, volume of the heart exposed, and specific techniques used, but other factors play a role, including age at the time of exposure (younger patients are at higher risk) and even genetic susceptibility, as discovered by examination of certain single nucleotide polymorphisms.<sup>31</sup>

The most common malignancies treated with chest radiation, and thus associated with cardiac disease, are lung cancer, breast cancer, and lymphoma. Other relevant malignancies are esophageal and thyroid cancers. Radiation doses typically associated with cardiac disease start around 25 gray (Gy) (or 2,500 Rads), with disease quite common at doses above 40 Gy. One study found acute pericarditis in over 30% of patients who received greater than 40 Gy to the heart.<sup>5</sup> The incidence of cardiac sequelae also increases when more than 50% of the volume of the heart is contained in the radiation field.<sup>32</sup>

The mechanism of cardiac damage from radiation is not well understood, but is thought to consist of microvascular destruction, including lymphatics, and apoptosis from direct cellular injury.<sup>33</sup> Inflammation from necrosis of tumor cells and hypersensitivity reactions may also play a role.<sup>5</sup> Over time, fibrosis and/or pericardial effusion can form, and pericardial thickening is usually a late manifestation. One theory explaining late development of pericardial disease (over 20 years after exposure in some cases) involves an increased susceptibility or an exaggerated response to infection conferred upon an irradiated peri-

cardium,<sup>4</sup> but little evidence is yet available to support this hypothesis. Although pathologic changes can be found in many patients exposed to radiation, symptoms occur in only a small number of cases.

The exact incidence of radiation-related pericardial disease is difficult to discern because of the potentially long delay between radiation exposure and the development of late pericardial disease. Furthermore, improvement in radiation techniques over the last 30 years have led to remarkable reductions in the incidence of disease, making older epidemiologic studies obsolete. One study examined the burden of cardiac irradiation in all patients with pericardial disease and found radiation to be the cause in 7.3%. This was further broken down, and radiation was implicated in 11% of cases of constriction, 7.5% of pericardial effusion, and 9.1% of acute pericarditis.<sup>20</sup>

Hodgkin's and non-Hodgkin's lymphoma have the highest incidence of radiation-related cardiac disease, attributable to disease prevalence, a younger patient population, and to anatomic considerations. The relative risk of fatal cardiac events has been reported as high as 7.2 after treatment for Hodgkin's lymphoma.<sup>34,35</sup> A typical regimen includes 30 to 39 Gy at 1.5 to 1.8 Gy/fraction over 4 to 5 weeks. Mantle radiation (parallel opposed A-P and P-A fields) is given to the mediastinum, although the heart is usually shielded for part of the treatment. Total radiation dose to the heart depends on the location of the malignancy within the mediastinum. Mantle radiation is associated with a higher incidence of pericarditis than radiation for lung or breast cancer because the total dose to the heart is higher. In one study of 48 long-term Hodgkin's survivors with an average 14-year follow-up and a median dose of 40 Gy, all patients studied were found to have pericardial thickening, and one was found to have constriction.<sup>36</sup> An autopsy study of young patients who received over 35 Gy to the heart found pericardial thickening in 15 of 16 cases, and clinical evidence of tamponade was present in 5 cases prior to death.<sup>37</sup> In the largest cohort to date of patients with mediastinal radiation for Hodgkin's lymphoma, 2.2% of 590 patients developed clinical pericarditis.<sup>38</sup>

Breast cancer is typically treated with 50 Gy at 2 Gy/fraction over 5 to 6 weeks. The radiation field is tangential, such that no more than 2 cm of lung or chest wall tissue is involved. External beam radiation is also sometimes applied to the internal mammary chain of lymph nodes, which is focused at a prescribed depth. The heart is nearly completely shielded during radiation of right-sided breast cancer, and is minimized with the above techniques during left-sided radiation. One study found the mean radiation dose to the heart for left-sided disease to be 3.8 Gy for tangential field alone, and 6.4 Gy when external

beam to the internal mammary chain was included.<sup>39</sup> Respiratory gating with breath-holding techniques can further reduce cardiac irradiation.<sup>40</sup> Significant cardiac toxicities of radiation for breast cancer are fairly uncommon, including pericardial disease. One study found no increase in cardiac mortality when comparing patients with left and right-sided breast cancer treated with radiation and followed for 12 years.<sup>41</sup>

Radiation therapy for lung cancer is usually palliative. Regimens consist of 60 Gy to the hilum or mediastinum at 1.8 to 2 Gy/fraction over 7 to 8 weeks. Radiation is usually administered only to active macroscopic lesions, rather than comprehensive inclusion of all potentially involved tissues. Extent of heart involvement thus is highly dependent on location of mediastinal disease. The heart can be fairly effectively shielded during left hilar radiation. Prognosis is generally very poor in this group of patients, so manifestations of late pericardial disease are decidedly rare. Acute pericarditis is possible, but infrequent.

Clinical manifestations of radiation-induced pericardial disease are highly variable. Patients can present acutely during their treatment, subacutely weeks or months later, or as late as decades after radiation exposure. Presentations include acute pericarditis, chronic pericardial effusion, cardiac tamponade, and pericardial constriction. The peak incidence of pericardial sequelae occurs 5 to 9 months after radiation exposure,<sup>32</sup> but all patients are indefinitely susceptible, with incidence increasing with the duration of follow-up.<sup>4</sup> Interestingly, acute disease does not seem to predispose a higher risk of late chronic disease.<sup>32</sup>

Acute pericarditis is an early manifestation and presents with chest pain, fever, a pericardial rub, and electrocardiographic changes. Effusion may or may not be present. The differential diagnosis includes other causes of chest pain, especially pulmonary embolism, which can cause pleuritic chest pain similar to pericarditis, and myocardial infarction, which is also found with increased prevalence after radiation. Malignant pericardial disease is much less likely to present with classic acute pericarditis. Treatment consists of nonsteroidal anti-inflammatory drugs, and corticosteroids are sometimes necessary for refractory cases. Radiation can usually be continued once anti-inflammatory treatment has been initiated. Prognosis is excellent for this form of pericardial disease, but late sequelae may be more frequent in those who experience a significant initial inflammatory reaction.

Subacute or chronic pericardial effusion is the most common manifestation of radiation-induced pericardial disease. Symptoms are similar to other causes of pericardial effusion. Although tamponade is possible with radiation, this entity should raise suspicion for malignant

pericardial disease, which is a much more likely cause for tamponade. Effusions range from serous to hemorrhagic, and over time become more fibrinous with evidence of adhesions. Increased protein and lymphocyte count are seen on fluid analysis, and are similar to other inflammatory conditions. The diagnosis is one of exclusion, and diagnostic pericardiocentesis may be required to rule out malignant effusion. Another helpful clinical finding is the absence of metastatic disease elsewhere; if no other metastases are found with appropriate testing, radiation is much more likely to be the cause.<sup>11</sup> Treatment includes anti-inflammatory drugs, with drainage as needed. Definitive surgical procedures are rarely needed, as the condition generally responds well to conservative management. Prognosis is generally good, although some patients do go on to develop constrictive disease.

Pericardial constriction is the feared outcome of chronic radiation-induced pericardial disease. Although its incidence is uncommon, the prognosis is grave. Clinical manifestations of constriction will be discussed below, but a few points specific to radiation disease will be considered here. Although other causes of pericardial constriction (eg, tuberculosis, post-cardiac surgery) typically involve diffuse pericardial calcification, radiation disease tends to be non-calcific.<sup>3</sup> A diagnostic dilemma with this entity is in distinguishing it from myocardial fibrosis, which may also result from cardiac irradiation. Myocardial radiation damage presents as a restrictive cardiomyopathy, which is difficult to distinguish from constriction. In fact, both entities can be present in patients with chest radiation. The distinction is critical, because performing pericardiectomy on patients with predominantly restrictive disease leads to increased operative mortality. Some authors advocate endomyocardial biopsy at the time of catheterization for any patient suspected of having radiation-induced cardiac disease to rule out restriction preoperatively.<sup>4</sup> Even with predominant constriction, operative mortality is very high—21% in one study, with a 5-year survival of only 1%.<sup>3</sup>

A variation of pericardial constriction in the setting of radiation is effusive-constrictive disease, which involves substantial pericardial effusion in addition to the presence of constrictive physiology. This is typically discovered at the time of pericardiocentesis for tamponade, after which constriction becomes evident.

Lastly, a known complication of chest irradiation is the development of secondary malignancies. These can arise from virtually any tissue exposed to the radiation, including the pericardium in very rare instances. Cases involving “primary” pericardial lymphoma,<sup>42</sup> pericardial angiosarcoma,<sup>43</sup> and pericardial mesothelioma<sup>44</sup> have been described, occurring years after

radiation therapy to the chest for the initial malignancy.

### Chemotherapy-Related Pericardial Disease

Several antineoplastic or related agents have been implicated in pericardial disease,<sup>45</sup> and are summarized in Table 3. The incidence of chemotherapy-related pericardial disease is rare, and the mechanisms are generally poorly understood. They are important, however, in the context of the differential diagnosis of pericardial conditions in the cancer patient. Chemotherapy-related pericardial disease is usually self-limited, and may be treated with anti-inflammatory drugs and removal of the offending agent when practical. In very rare cases, pericardiocentesis may be necessary to treat tamponade or as a diagnostic intervention to help rule out malignant effusion or infection.

Anthracyclines can cause pericarditis (more specifically myopericarditis) as a manifestation of their early cardiotoxicity. These effects are not related to cumulative dose, although the relationship with later cardiac dysfunction has been suggested. The recognition of pericarditis alone, however, should not be considered sufficient grounds for altering the anthracycline-containing chemotherapeutic regimen in patients who are otherwise stable.<sup>46</sup>

All-*trans* retinoic acid is used for induction and maintenance of remission in patients with acute promyelocytic leukemia. The main toxicity of this agent is retinoic acid syndrome, which consists of fever, weight gain, interstitial pulmonary infiltrates, pleural and pericardial effusions, hypotension, and acute renal failure. It is seen during induction in approximately 25% of cases, but has not been observed with maintenance therapy. Pleural and pericardial manifestations occur in about one-third of patients with the

syndrome.<sup>47</sup> The mechanism involves the differentiation and extravasation of leukemic cells into affected organs, which causes a brisk inflammatory response and capillary leak. Mortality ranges from 5 to 30%, but cause of death is not usually related directly to the pericardial effusion.<sup>47</sup> Treatment involves early recognition and administration of dexamethasone 10 mg intravenously twice daily. Development of retinoic acid syndrome does not preclude further treatment with this agent, but prophylactic steroids and close monitoring are required.

### Infectious Pericardial Disease

Of all pericardial disease with a recognized cause, infections make up the largest category. A long list of potential pathogens exist, including viruses, bacteria, rickettsia, fungi, and parasites.<sup>4</sup> Cancer patients are a uniquely susceptible group as their disease or its treatment routinely causes immunosuppression, leukopenia, multisystem organ disease, and loss of tissue integrity (and hence loss of normal barriers to infection). Frequent hospitalizations and long-term intravascular access catheters add to the infectious burden. Thus, infections should routinely be included in the differential diagnosis of malignant pericardial disease. During any pericardial drainage procedure, samples should always be collected for cell count, Gram stain, and culture, with additional microbiologic studies obtained if indicated. Because treatment is usually curative, correct diagnosis is essential.

Cancer or complications of its treatment can lead to suppurative infections of the pericardium via fistula formation. Given the close proximity of the esophagus to the heart, esophageal cancers can invade locally and create esophagopericardial fistulas with resulting purulent pericarditis.<sup>48–50</sup> Gastric cancer has likewise created fistulas to the pericardium in rare cases.<sup>51</sup> Metallic stents placed into the esophagus for an obstructing tumor can also lead to fistula formation.<sup>52</sup>

Tuberculous pericarditis is especially important in the cancer patient because of this organism's predilection for immunocompromised hosts and the elderly, and because clinical features can often mimic malignant disease. Although *Mycobacterium tuberculosis* can present with the entire spectrum of pericardial syndromes, the most common presentation is an insidious chronic effusive pericarditis, which has a tendency to progress to calcific constrictive disease. Chronic fevers and cachexia are frequent. Interestingly, most patients do not have coexistent pulmonary infection.<sup>4</sup> Diagnosis is challenging because many tests, including acid-fast staining, culture, and tuberculin skin testing all have relatively low sensitivity. Polymerase chain reaction (PCR) to test for mycobacterial DNA is

**Table 3** Antineoplastic Agents Associated with Pericardial Toxicity

Medication	Comment
Cytarabine (Ara-C)	Pericarditis, effusion
Cyclophosphamide	Pericarditis
Ifosfamide	Pericarditis
Anthracyclines	Myopericarditis, early toxicity, not dose-related
Sargramostim	Effusion, constriction
Busulfan	Tamponade, pericardial fibrosis
Cisplatin	Pericarditis at high doses
Methotrexate	Pericarditis, effusion, possibly immune-mediated
Imatinib	Effusion
All- <i>trans</i> Retinoic Acid	Effusion (Retinoic Acid Syndrome)

increasingly being used. Treatment includes multidrug regimens based on local susceptibility patterns as well as pericardiocentesis or surgery as needed. If pericardiectomy is necessary for constriction, earlier intervention leads to better outcomes.<sup>4</sup>

Since human immunodeficiency virus (HIV) is classically associated with certain malignancies and also causes pericardial disease, it is of special interest; HIV can lead to pericardial disease via direct effects, secondary infections, and malignancies. Other cardiovascular sequelae include myocarditis, heart failure, pulmonary hypertension, and premature coronary artery disease.<sup>53</sup> Before the era of highly active antiretroviral therapy (HAART), the incidence of pericardial effusion was found to be 11% per year and was associated with a poor prognosis.<sup>54</sup> Typically, pericardial effusions are small, asymptomatic, and sterile, and do not lead directly to death. Tamponade and constrictive disease are possible, however. Notable secondary pericardial infections include typical and atypical mycobacteria and fungi. HIV-related malignancies such as primary cardiac lymphoma, metastatic lymphoma, and Kaposi's sarcoma have all been known to involve the pericardium.

## Pericardial Syndromes in the Cancer Patient

Pericardial disease in the cancer patient can present with a diverse group of clinical syndromes. This spectrum includes acute pericarditis, pericardial effusion, cardiac tamponade, and pericardial constriction. The boundaries between these syndromes are somewhat arbitrary, however, and much overlap is seen in actual practice. Despite its limitations, it is helpful to organize one's approach to pericardial disease within this framework.

### Acute Pericarditis

Acute pericarditis is a syndrome of chest pain caused by inflammation of the pericardium and surrounding structures. At least some component of myocarditis is almost universally present and accounts for many of the clinical findings; some authors prefer the term "myopericarditis" for this reason. A clinically apparent pericardial effusion may or may not be present. Of the many possible etiologies, viral infections make up a large segment, and indeterminate etiologies grouped as "idiopathic" constitute a major portion, as well. Many of the less common causes are associated with previously well-established diagnoses or obvious clinical scenarios. The causes of acute pericarditis are summarized in Table 4.

In the general population (ie, without previous diagnosis of malignancy), acute pericarditis is very rarely the first presentation of a malignancy.

**Table 4** Causes of Acute Pericarditis

Idiopathic
Viral (Coxsackie viruses, echoviruses, influenza, HIV, etc.)
Tuberculous
Lyme Disease
Other Infections (includes bacterial, fungal, parasitic)
Collagen Vascular Diseases (systemic lupus erythematosus and others)
Drug Reactions
Hypothyroidism
Myocardial Infarction (coexistent or up to months later)
Post-pericardiectomy
Uremia and Renal Dialysis
Neoplastic Pericarditis
Radiation
Trauma

In one series, of 387 patients with acute pericarditis without tamponade, 9 (2.3%) were ultimately found to have occult malignancy as the cause.<sup>2</sup> In this series, features that increased the likelihood of malignancy included the presence of a large effusion and the lack of response to NSAIDs. Of the malignancies that presented with acute pericarditis as the first manifestation, almost all cases were primary lung cancers.

Even in the patient with known malignancy, idiopathic and viral etiologies are still the most likely. Malignant pericarditis moves higher in the differential diagnosis, however, and serious consideration must be given to this entity. In addition to the clinical clues mentioned above, a reasonable search for other metastatic disease is helpful, as the pericardium is very seldom the only site of metastatic spread. Radiation, chemotherapy, renal failure, and post-pericardiectomy, for example, are possible etiologies in the appropriate setting. Infections are also more likely in the cancer patient, given the relative immunosuppression sometimes imposed by malignancy or its treatment.

Acute inflammation of the pericardium presents primarily with chest pain. Other symptoms include fever, dyspnea, and cough. The chest pain is classically located over the left precordium, is sharp in quality and demonstrates pleuritic features. The pain is also positional, worsened by lying supine, and relieved with sitting up. Alternately, the pain can mimic myocardial ischemia with a dull or pressure-like quality and radiation to the jaw, left shoulder, and left arm, a feature probably attributable to the myocarditic component. Onset can be abrupt. Rapid, shallow breathing or splinting are commonly present with pleuritic pain, and can be confused with true dyspnea.

Physical examination findings of acute pericarditis can include low-grade fever, tachycardia, and a pericardial rub. The classic three-component rub is derived from audible movements of the heart within the pericardium. Its phases are timed with systole, early diastole, and atrial contraction, but not all three components of a pericardial rub may be audible. Rubs are characteristically transient and are often positional, and may not be heard at all. Thus, while the presence of a pericardial rub is generally specific for pericarditis, it is not a very sensitive finding. While rubs are more common in cases of pericarditis without significant effusions, they may still be present with large or even hemodynamically significant fluid collections.

Electrocardiographic findings of acute pericarditis are generated by the superficial myocarditis that is almost always present. A current of injury similar to acute ischemia is seen, but it is more generalized as to location and does not correspond anatomically to the distribution of a single coronary artery. A progression of stereotypical electrocardiogram (ECG) changes over the hours and days following the onset of symptoms has been carefully described,<sup>4</sup> but patients can also present with atypical electrocardiographic features or an entirely normal ECG. Initially, ST elevation and PR depression are present in the inferior, anterior, and lateral leads (Figure 1). These changes are the most characteristic of acute pericarditis when they occur. Over hours or days, the ST and PR segments return to baseline, and the T waves flatten and then become inverted. Given more time, the T waves return to normal. Both the ST and T wave changes can mimic acute myocardial ischemia; a helpful feature is the presence of similar ECG changes in leads I and II in pericarditis, which does not correspond to a typical coronary distribution. Diffuse T wave inversions are nonspecific; other features must be used to support the diagnosis.

Echocardiography is useful, especially in the emergency setting, where myocardial infarction is often in the differential diagnosis of acute pericarditis. Echocardiography can rule out significant segmental wall motion abnormalities, and it also detects the presence or absence of pericardial effusions. Even in the hemodynamically stable patient with acute pericarditis, impending cardiac tamponade is occasionally discovered. Earlier diagnosis and prompt treatment of this entity in a controlled setting is far more preferable than waiting until hemodynamic compromise is overt. Echocardiography is also useful for imaging pericardial masses, which are sometimes seen in cases of malignant pericarditis (Figure 2). Fibrinous exudates are sometimes seen, as well, with or without malignant involvement.

Other findings include leukocytosis and other evidence of acute systemic inflammation,

**FIGURE 1** A, Electrocardiogram of a patient with multiple myeloma presenting with acute pericarditis. Diffuse ST elevation in a non-coronary distribution is evident. B, Two hours later, the same patient showed diffuse PR depression (arrows) and partial resolution of the ST elevation.

**FIGURE 2** Parasternal long axis echocardiographic view showing a large pericardial tumor (arrows) in a patient with metastatic lung cancer compressing the left atrium.

such as C-reactive protein, erythrocyte sedimentation rate, and platelet count. Serum cardiac markers such as troponin can be mildly elevated, reflecting some degree of associated myocarditis.

Differential diagnosis of acute pericarditis includes, most importantly, acute myocardial ischemia. Cancer patients often have multiple risk factors for coronary artery disease, such as

advanced age, smoking history, chronic systemic inflammation, chest radiation, etc. Symptom characteristics, ECG abnormalities, and elevated cardiac markers can all mimic an acute myocardial infarction and lead to this misdiagnosis. Distinguishing ischemia from pericarditis in some cases can thus be difficult, especially in the acute setting. Correct diagnosis is crucial, however, as administration of thrombolytics to a cancer patient with pericarditis can have disastrous consequences, such as hemorrhagic tamponade or intracranial bleed. Features that favor the diagnosis of acute pericarditis include pleuritic chest pain, PR depression, generalized distribution of ECG changes, presence of pericardial effusion, and absence of wall motion abnormalities on echocardiography.

Pulmonary embolism is also an important consideration when a cancer patient presents with acute pleuritic chest pain. Given the obvious risk of thromboembolic disease in this population and its high overall incidence, a search for pulmonary embolism is mandatory unless specific findings of pericarditis (such as a pericardial rub) are present. Hypoxemia and obvious

lower-extremity, deep venous thrombosis are helpful when present, but pulmonary emboli often present without these features. Pneumonia, other lung diseases, and metastases to the ribs are also in the differential diagnosis of acute pericarditis, but are usually easily excluded after preliminary evaluation.

Management of nonmalignant acute pericarditis consists of a short course of a nonsteroidal anti-inflammatory drug such as aspirin, ibuprofen, or naproxen. Recent evidence suggests that colchicine may also be beneficial, especially in recurrent disease.<sup>55,56</sup> Corticosteroids may be needed for refractory cases but are generally avoided given their substantial side-effect profile and possible increased likelihood of recurrence. A follow-up echocardiogram is often obtained 1 to 2 weeks after symptoms resolve to rule out a late-forming pericardial effusion, even if effusion is absent initially.

Even in the cancer patient, acute pericarditis without effusion that responds rapidly and completely to therapy is unlikely to represent malignant disease, and an exhaustive search for pathologic evidence of pericardial invasion is not warranted. Features that make malignant pericarditis more likely include recurrent or refractory symptoms, large pericardial effusions, and evidence of widespread metastatic disease. Pericardial masses on echocardiography are highly suggestive of malignant involvement. As noted above, when radiation or chemotherapy are the likely causes of pericarditis, the physician can usually continue these treatments after initial symptoms have resolved with the administration of anti-inflammatory drugs; prophylaxis against recurrence with anti-inflammatory drugs has also been successfully employed. When infectious agents are identified as the etiology, appropriate antimicrobial therapy is indicated.

### Pericardial Effusion

Pathologic accumulation of fluid in the pericardial space is the most common manifestation of pericardial disease in cancer patients. Clinical presentation is widely variable, and possible etiologies are numerous. Unlike acute “dry” pericarditis, which is typically not related directly to malignancy, a pericardial effusion in a patient with cancer is always of concern, and often a poor prognostic sign. Because malignant invasion of the pericardium occurs frequently, all patients with pericardial effusion need to be carefully evaluated. It should be noted, however, that up to two-thirds of cancer patients who develop pericardial effusions do so through mechanisms other than malignant invasion of the pericardium.<sup>3</sup>

In the general population without preceding diagnosis of malignancy, large pericardial effusions are usually associated with an obvious

patients, between one-third and one half will have malignant pericardial disease.<sup>18</sup> Once diagnosed, the prognosis for patients with a malignant effusion is typically measured in months, and aggressive local and systemic cancer treatment is needed to provide palliation and prevent rapid demise. Since up to two-thirds of such patients will have a nonmalignant and easily treatable etiology, the correct diagnosis is of utmost importance.

The mainstay of pathologic diagnosis of malignant pericardial disease is cytology from pericardial fluid. The reported sensitivity ranges generally from 80 to 90% in the literature,<sup>1,11</sup> and the specificity is virtually 100%. The false-negatives that do occur have been attributed to either very low cell counts or large amounts of obscuring blood. Sensitivity of cytology is also lower for certain malignancies, namely leukemia and lymphoma.<sup>11</sup> One problem encountered in sensitivity analysis is that some studies used autopsy findings as the gold standard. Since there is usually a significant time delay between a diagnostic pericardiocentesis and death, there is the possibility that pathologic invasion of the pericardium occurred in the interim, and the presenting effusion may well have been nonmalignant at the time of pericardiocentesis.

In cases of malignant pericardial disease, diagnostic yield can be enhanced with biopsy. Percutaneous biopsy of the parietal pericardium or intrapericardial tumors has been shown to be feasible,<sup>59,60</sup> but surgery is the more usual route of obtaining tissue samples. Through a surgical approach, biopsy specimens from both the visceral and parietal pericardium can be obtained. These are often facilitated by pericardioscopy, which can directly visualize tumors protruding into the pericardial space and thus help direct biopsy. Without direct visualization, pericardial biopsy alone is less sensitive than cytology because of sampling errors.<sup>61</sup> When both cytology and pericardioscopy-guided biopsy are used, sensitivity is maximized. This approach, however, may not be feasible for certain patients or may not be available at certain institutions. Fluid analysis is usually adequate to make the diagnosis, but if the clinical suspicion for malignant effusion is high and cytology findings are benign, a more rigorous investigation is warranted.

Carcinoembryonic antigen (CEA) has been found to be elevated in the pericardial fluid of patients with malignant effusions due to most cancers.<sup>62,63</sup> Although series have been small, results have been promising. Sensitivity and specificity are high, but both false-positive and false-negative results have been reported. One study found the sensitivity of CEA to be 86% for malignant effusion, and, when combined with cytology, the sensitivity was 100%.<sup>63</sup> Another more recent study derived an optimal cutoff for CEA

of 5 ng/mL and found that 14 of 15 patients with a malignant effusion but negative cytology had elevated CEA levels.<sup>62</sup> Given the ease of measurement once pericardial fluid has been obtained, CEA level should probably be routinely included in fluid analysis if malignancy is suspected. With cytology, it promises to increase sensitivity to nearly 100% if it is validated by larger studies.

Analysis of DNA ploidy by flow cytometry has been investigated as an additional means of diagnosing malignant pericardial effusion. In one small series, diploid DNA was associated with benign pathology, and aneuploid and tetraploid with positive cytology. In this series, findings other than diploidy had a sensitivity of 80% and a specificity of 100% for diagnosing malignant effusions.<sup>64</sup> Other studies have found similar results with DNA cytology on various different effusions, including from the pericardium.<sup>65,66</sup> Although not routinely performed in practice, DNA ploidy analysis has the potential to help detect malignancy when cytology is inconclusive. Immunocytochemistry has shown promise, not only in diagnosing malignancy, but also helping to distinguish among various forms. For example, staining with the monoclonal antibody Ber-EP4 was 95.4% sensitive for detecting metastatic carcinoma in effusions, but was not seen in any cases of mesothelioma or in benign effusions.<sup>67</sup> In the future, tumor-specific markers may be available for use in evaluating pericardial effusions of unclear origin in the cancer patient with very high sensitivity and specificity for detecting malignant disease.

Treatment of pericardial effusions in the cancer patient is aimed at the underlying cause. Acute inflammation, infection, hypothyroidism, heart failure, renal failure, etc., can all be managed appropriately, and favorable outcomes with regards to the pericardial disease can be expected. When chemotherapeutic medications or acute chest radiation are the culprit, conservative management is usually adequate, and these cancer treatments need not usually be interrupted. Malignant effusions are managed with a combination of local measures and systemic anti-tumor therapy if indicated. Chest radiation for pericardial metastases can help control aggressive disease as well. Pericardiocentesis, followed by several days of drainage, can often be adequate to prevent recurrences, as well as making the diagnosis. When this fails, a variety of percutaneous and minor surgical approaches can provide more definitive treatment.

Pericardiocentesis is the easiest and least risky of the drainage procedures. It can be done in a catheterization laboratory or at the bedside with echocardiographic guidance. The procedure is described in detail under the section on the emergent management of cardiac tamponade

below (see “Cardiac Tamponade”). Advantages include use of local anesthesia, percutaneous approach, and low complication rate with experienced operators. Fluid is available for analysis, and the catheter can be left in place for several days to allow continued drainage and prevent early recurrence of the effusion. Disadvantages include later recurrence of the effusion and lack of tissue for biopsy.

In some centers, intrapericardial administration of sclerosing agents or anti-tumor agents through the drainage catheter are used to help prevent reaccumulation of pericardial fluid. These interventions have not been the subject of controlled trials, but several small series have been published with encouraging results. Sclerosis with tetracycline analogues provides control of malignant pericardial disease in 90% of patients,<sup>68–70</sup> preventing recurrent effusion and alleviating symptoms. Significant side effects, including pain with administration, fever, and atrial arrhythmias, were more common with tetracycline than with newer agents such as minocycline. Intrapericardial chemotherapy has also shown promise for local control of malignant disease, regardless of primary tumor site. Pharmacokinetic study of intrapericardial cisplatin and 5-fluorouracil has shown much higher drug concentrations and greatly increased half-lives than can be obtained with systemic therapy.<sup>71</sup> Series with cisplatin have shown response rate of virtually 100% with minimal toxicity.<sup>61,72–74</sup> Results with mitoxantrone have been similarly encouraging,<sup>75,76</sup> but 5-fluorouracil appears to be less effective in controlling local pericardial disease.<sup>77</sup> Thiotepa, which has both sclerosing and antineoplastic properties, has recently been studied and showed excellent control of malignant pericardial disease with minimal toxicity.<sup>78</sup>

Subxiphoid pericardiotomy is a minimally-invasive surgical procedure that can be performed under local anesthesia at the bedside. It allows for direct visualization as well as thorascopic examination. A pleuropericardial window can also be created via the subxiphoid approach. Fluid and tissue specimens can be obtained for diagnostic purposes. Recurrences of the malignant effusion are possible, but less likely than with pericardiocentesis alone. Complication rates are low, making this the preferred treatment strategy for recurrent malignant effusions at many centers. Pericardioperitoneal shunt is an alternative drainage procedure that is likewise minimally invasive and can be done under local anesthesia. It is technically simpler than subxiphoid pericardiotomy and has been associated with shorter recovery times.<sup>79</sup> Catheter-based pericardiotomy, using a balloon across the pericardium that can be inflated to disrupt the pericardium and allow drainage, has been explored but is seldom undertaken, especially in view of the newer surgical techniques for subxiphoid pericardiotomy. The procedure is

especially uncomfortable for the patient, and has only been used in a number of centers.

More definitive surgical management of malignant pericardial disease requires partial or complete pericardiectomy. This requires general anesthesia for anterior thoracotomy or sternotomy, and is associated with significant morbidity and mortality. In most patients with malignant pericardial effusions, prognosis is limited, and less invasive strategies are preferred, but pericardiectomy can be considered in those with a relatively good prognosis in whom more definitive therapy is desired.

Patients who have undergone needle or catheter drainage should have a follow-up cardiac ultrasound examination one month following the procedure, or sooner in the event symptoms of recurrent pericardial tamponade appear. Patients who undergo pericardiectomy or creation of a pleuropericardial window should have a follow-up ultrasonography two months following the procedure; these guidelines are based on personal preference and prudence. There is no clear evidence, however, that discovering a recurrence by ultrasonography prior to the development of symptoms alters the course or improves the quality of life in these patients.

### Cardiac Tamponade

Cardiac tamponade is a condition that exists when the pericardial space contains fluid under sufficient pressure to interfere with cardiac filling, resulting in decreased cardiac output and the inability to sustain vital functions. Tamponade is not created merely by a certain quantity of fluid, but by the pressure created by that fluid in the pericardial sac. Life-threatening increases may be seen with relatively small quantities of fluid, as may occur following traumatic injury to the heart with hemorrhage into the pericardium. In the cancer patient, the fluid is more likely to accumulate at a slower rate allowing the pericardial space to expand gradually, and the quantity of fluid required to raise pressure sufficiently to impede cardiac filling is usually much larger. In some instances, the quantity of fluid is greater than two liters.

Malignant pericardial disease is the most frequent cause of cardiac tamponade in the general inpatient population. Furthermore, among the various pericardial syndromes, tamponade is the most likely to be associated with malignancy.<sup>1</sup> It is not rare that cardiac tamponade is the first indication of malignancy; in one clinical series of consecutive patients with tamponade and no prior diagnosis of cancer, 9 of 52 patients (17%) were ultimately diagnosed with malignant effusions.<sup>2</sup> It is more common, however, that a patient with known malignancy who is unaware of malignant spread to the heart experiences cardiac decompensation with cardiac tamponade as the

mechanism. Any malignancy that spreads to the pericardium is capable of causing pericardial tamponade, and the phenomenon is seen with some regularity in the face of metastatic breast cancer. Despite the close association between tamponade and malignant pericardial disease, any non-malignant etiology of pericardial disease is capable of causing tamponade—even in a patient with known malignancy. It is thus best to keep open a broad differential for pericardial disease, even in a patient with known malignancy.

Patients with tamponade may not experience the typical chest discomfort of acute pericarditis, and the first clinical manifestation may be increasing shortness of breath. Anxiety, cough, and severe weakness are other common symptoms. Overt tamponade can present as cardiogenic shock or pulseless electrical activity requiring immediate intervention. Physical examination characteristically demonstrates hypotension, tachycardia, and jugular venous distention that may be very pronounced; right atrial activity may be transmitted to the jugular veins with a prominent x descent. Cardiac auscultation may demonstrate distant heart sounds because the fluid separating the heart from the stethoscope may diminish the amplitude. Pericardial friction rubs and pericardial knocks are usually absent or distant on auscultation. The pulse is characteristically weak, and may show an exaggerated decrease during inspiration, known as the phenomenon of pulsus paradoxus. This finding is a manifestation of the interdependence of the right and left cardiac chambers; a preferential filling of the right ventricle during inspiration must be at the cost of left ventricular filling due to the external volume limitation imposed by the pressurized effusion. A paradoxical pulse is defined as a  $> 10$  mm Hg drop in systolic blood pressure with inspiration, and should be measured quantitatively in any patient suspected of having cardiac tamponade. It may also be appreciated by palpating the radial pulse, which can disappear during inspiration in frank tamponade.

Laboratory studies confirm the diagnosis of tamponade. The chest roentgenogram shows an enlarged cardiac silhouette with a sac-like configuration—a helpful, although nonspecific, finding. The electrocardiogram may show electrical alternans, a cyclical variation in QRS voltage occurring with a two-cycle period. Electrical alternans is caused by the heart moving towards and away from the exploring electrode as the heart rocks back and forth within the sac of fluid. Electrical alternans may be seen in some (but not all) electrocardiographic leads; its clear presence in any single lead is sufficient to establish electrical alternans, a very specific (although not especially sensitive) finding in patients with pericardial tamponade.

The most useful noninvasive test is cardiac ultrasonography. A complete transthoracic echocardiogram not only demonstrates the size and location of the pericardial effusion, but several hemodynamic findings suggestive of tamponade as well. One of the earliest findings is compression of the right atrium during systole (Figure 4A), as this chamber typically has the lowest pressures. As tamponade progresses, right ventricular compression during diastole may be evident (Figure 4B). In all patients with frank tamponade, the inferior vena cava is dilated and fails to collapse with inspiration. Doppler echocardiography reveals respiratory variation in ventricular filling velocities that corresponds to the pulsus paradoxus;  $> 25\%$  decrease in mitral inflow velocities or  $> 50\%$  decrease in tricuspid inflow velocities with respiration are suggestive of tamponade (Figure 4C). Real-time two-dimensional as well as M-mode echocardiograms may demonstrate the to-and-fro rocking motion of the heart that is responsible for electrical alternans. It should be noted that cardiac tamponade progresses along a continuum, and not all of the above echocardiographic findings may be present in individual patients. Furthermore, care must be taken not to attempt to predict the pace of progression based on echocardiography alone; it is impossible to tell the rate of fluid accumulation and the distensibility of the pericardium. Cardiac tamponade is ultimately a clinical diagnosis, and echocardiography serves a basically confirmatory role.

Advanced pericardial tamponade with hemodynamic collapse constitutes a medical emergency of the first order, and any temporizing in establishing the diagnosis or delay in drainage may prove fatal. Prompt drainage often provides very dramatic symptomatic improvement. When tamponade is hemodynamically compromising, emergent needle drainage is the most expedient.

The most direct technique for needle drainage for patients with pericardial tamponade involves inserting the exploring needle just to the left of the xiphoid process in the angle formed by the xiphoid and the ribs. With the patient lying as flat as can be tolerated, the 18-gauge needle attached to a syringe containing 1% lidocaine is advanced in the direction of the acromial process of the left shoulder until fluid is aspirated. A small aliquot of agitated saline may be injected and visualized under echocardiographic guidance to confirm entry into the pericardial space (Figure 5); echocardiographic visualization has made obsolete the use of the electrocardiographic confirmation of an electrical current of injury as the exploring needle serving as an electrode touches the myocardium.

Once the pericardial space has been entered and the location confirmed, a guide wire is

**FIGURE 4** Echocardiographic features of pericardial tamponade. A, Non-traditional four-chamber view showing a large pericardial effusion and notching of the right atrium during systole (arrow), one of the early hemodynamic alterations of pericardial tamponade. B, Further hemodynamic embarrassment results in compression of the right ventricle (arrow), seen in this parasternal long axis view. C, Pulse-wave Doppler of the mitral valve showing marked respiratory variation of the mitral inflow velocities consistent with tamponade.

**FIGURE 5** Echocardiography-guided pericardiocentesis (apical four-chamber views). A, Large effusion is present with systolic notching of the right atrium (arrow). B, Agitated saline (arrow) has been injected into the pericardial space to confirm proper location of the pericardiocentesis needle. C, After drainage, the effusion is no longer evident and all four cardiac chambers have re-expanded.

advanced through the needle, a dilator is advanced over the wire, and a catheter introducer is inserted into the pericardial space. A catheter may then be inserted and fluid drained through the catheter. In most instances, the fluid is drained in a single sitting using a vacuum bottle. The catheter may remain in place for several days so that additional drainage can be undertaken without reinserting a new catheter. We usually drain each day until the daily aliquot fluid that can be removed is less than 50 mL, the catheter has been in place for five days, or the amount of fluid remains constant at greater than 50 mL for more than two days; while these guidelines have not been scrutinized by clinical trials, they represent a reasonable compromise in that the risk of infection is maintained at safe levels, and the return of fluid is less than would be the case if the catheter were removed immediately following initial drainage.

In cases of cardiac tamponade where hemodynamic collapse does not appear imminent, consideration can be given to some of the other methods of pericardial drainage discussed above. Recurrent pericardial effusion and tamponade may warrant a more definitive procedure, for example. Any therapeutic strategy for tamponade must be instituted without delay, however, as small increases in pericardial fluid volume are

associated with large increases in intrapericardial pressure; rapid progression can occur without warning and may be fatal.

### Pericardial Constriction

Pericardial constriction occurs when a thick and inflexible shell of pericardium compresses the heart and interferes with normal chamber filling. It causes a syndrome seemingly similar to congestive heart failure, but systolic function of the right and left ventricles are preserved, and important differences exist in the pathophysiology. Constriction is usually seen as a fibrous or calcific response to chronic pericardial inflammation, but can also be caused by direct tumor infiltration.<sup>80</sup> Carcinoid syndrome has also been found to lead to constrictive pericarditis without evidence of pericardial invasion by tumor.<sup>81</sup> In the general population, most causes of pericardial constriction are unknown or follow cases of pericarditis, which are themselves idiopathic.<sup>20</sup> Of the known causes, infection, post-cardiac surgery, and chest radiation are the most commonly implicated. Tuberculous pericarditis was formerly the most common etiology of constriction, but its incidence has decreased in industrialized nations. Any cause of acute or chronic pericardial

disease, however, can lead to subsequent constriction.

One surgical pathology series from the Mayo Clinic looked at specimens from 143 consecutive cases of constrictive pericarditis.<sup>20</sup> Etiology was idiopathic in 49%, post-pericardiotomy in 30%, and post-irradiation in 11%. Interestingly, although malignant pericardial disease is a well-established, if uncommon, cause for constrictive pericarditis, no cases were reported, which is likely a reflection of the fact that surgical resection is not feasible in this group.

In the cancer patient exposed to previous chest radiation, this is by far the most likely etiology of constrictive disease. Other possible causes include any pericardial disease that results in a hemorrhagic effusion, as blood typically produces a brisk inflammatory response. Malignant pericardial disease (especially from breast or lung cancer) can lead to constriction, but this is not a common entity, likely because malignant effusions are not especially inflammatory and because the prognosis is so poor in these patients that constriction has not yet had the chance to develop. Complete encasement of the heart by solid tumor in the pericardium can also be clinically indistinguishable from constriction. Mesothelioma has rarely presented as pericardial constriction.<sup>4</sup>

Pericardial constriction can result from pathologic changes to the parietal pericardium, visceral pericardium, or both. These changes primarily include fibrotic thickening and chronic lymphocytic inflammation, with gross calcification present in less than one-third of cases.<sup>20</sup> Pericardial thickening is usually symmetric and completely encases the heart, but other patterns are possible, including loculated or band-like pathology. At its maximum thickness, the parietal pericardium ranged from 1 to 17 mm, with a mean of 4 mm in the Mayo Clinic series of patients with constriction.<sup>20</sup> Interestingly, 4% of cases were categorized as having normal pericardial thickness.

Effusive-constrictive disease is a variation on this theme, which includes features of constriction as well as a significant effusion. It can be seen with malignant pericardial invasion or post-irradiation. Most typically, presentation is consistent with tamponade, and the features of constriction become apparent after pericardiocentesis. Not surprisingly, these cases usually involve constriction by the visceral pericardium.

The pathophysiology of pericardial constriction involves impaired right and left ventricular filling and ventricular interdependence, which is caused by the externally imposed volume limit. Any increased filling in the right heart must be at the expense of left-sided filling, and vice versa. Diastolic pressures in all four cardiac chambers are nearly equalized as well as significantly elevated. Hemodynamic findings with respiratory variation are a key diagnostic feature of constriction; both the right and left atria become insulated from the normal intrathoracic pressure changes, which leads to characteristic patterns during catheterization and echocardiography that are unique to constriction.

Symptoms of constriction arise from elevation of either left- or right-sided filling pressures. Gradually worsening weakness, fatigue, and dyspnea on exertion are prominent, but highly non-specific in the cancer patient. Lower extremity edema, abdominal congestion, and ascites are common, and are often confused with heart failure or tamponade.

Physical examination can be helpful in pericardial constriction. Tachycardia or an irregular heart rate from atrial fibrillation may be present. Pulsus paradoxus may be present, but is less of a phenomenon than it is in the presence of tamponade; it is nearly always under 15 mm Hg. Jugular venous pressure is elevated, and pulsations reveal prominent *x* and *y* descents. Kussmaul's sign is a failure of the central venous pressure to decrease with inspiration, owing to high right atrial pressure and the physiologic isolation of the right atrium from changes in intrathoracic pressure. If the central venous pressure is high enough, pulsations of the jugular

vein may be absent and erroneously suggest normal or low pressures. A loud S3, also referred to as a pericardial knock, is due to rapid ventricular filling. Hepatomegaly (sometimes pulsatile), ascites, and lower extremity edema can be present.

Chest radiographs may reveal cardiomegaly, pericardial calcification, an enlarged azygous vein, and pleural effusions. MRI and CT can define pericardial anatomy fairly well and are both more accurate at determining pericardial thickness than echocardiography. They can also show dilation of the superior and inferior vena cavae. ECG findings in constriction are nonspecific. Diagnosis of constriction, however, really requires the hemodynamic data available from echocardiography and catheterization.

Echocardiography can reveal several aspects of pericardial constriction, but the findings can be subtle, and the interpreting cardiologist must have a reasonable index of suspicion to make the diagnosis. Pericardial anatomy can be visible, but image quality is often limited by the high echogenicity of the pericardium, especially when calcification is present. Increased pericardial thickness can sometimes be measured (Figure 6), but this is not a consistent finding and is better evaluated by CT or MRI. The inferior vena cava is dilated and fails to compress with respiration. The interventricular septum can show a characteristic "bounce" corresponding to the rapid ventricular filling in early diastole. An M-mode through the posterior wall of the left ventricle sometimes shows separate densities corresponding to parietal and visceral pericardium that are adherent to the posterior wall and move with the myocardium, a phenomenon known as "tram-tracking" (Figure 7).

Doppler examination of mitral inflow reveals a restrictive filling pattern of severe diastolic dysfunction, including E wave  $\gg$  A wave velocities and very rapid deceleration time. Unlike restrictive cardiomyopathy, however, tissue Doppler measurements of the mitral annulus can remain

**FIGURE 6** Parasternal short axis echocardiographic view through the left ventricle in a patient with constrictive pericarditis. The posterior pericardium (arrows) is markedly thickened and echogenic.

**FIGURE 7** M-mode echocardiogram with slice taken through the left ventricle in a patient with constrictive pericarditis. The pericardium is thickened (bracket) and echogenic, and the adherent parietal pericardium (arrow) moves in concert with the contracting ventricle, a finding known as "tram-tracking."

normal. Ventricular interdependence is probably the most specific finding, and is demonstrated by mitral inflow velocities that decrease with inspiration and increase with expiration, and tricuspid velocities that conversely increase with inspiration and decrease with expiration.

Hemodynamic measurements during cardiac catheterization play a confirmatory role. Elevation and equalization of diastolic pressures is seen. Left and right ventricles both show a characteristic diastolic pressure tracing—"dip and plateau"—which reflects rapid early filling followed by abrupt cessation of filling due to a rigid unexpandable heart. This is also affectionately known as the "square-root sign" for obvious reasons (Figure 8). Right atrial pressure tracings demonstrate the prominent *x* and *y* descents (Figure 9) and Kussmaul's sign. Simultaneous right atrial and pulmonary capillary wedge tracings can demonstrate the equivalent of ventricular interdependence, with one rising while the other falls.

In practice, diagnosis of pericardial constriction is not straightforward, as many of the above findings can also be seen with tamponade, restrictive cardiomyopathy, or right ventricular failure. The findings that are most specific for constriction are often the hardest to measure. Furthermore, combinations of these entities exist, such as in effusive-constrictive disease or the combined restriction and constriction that frequently occurs after chest irradiation. Sometimes endomyocardial biopsy is used to help rule out a myopathic process if surgical intervention for constriction is being considered. Diagnosis requires a high index of suspicion, an appropriate clinical setting, and radiology, catheterization, and echocardiography findings that help support the diagnosis of pericardial constriction.

Treatment of pericardial constriction is surgical, and complete pericardiectomy is required, usually through a median sternotomy approach.

**FIGURE 8** Simultaneous pressure tracings from the right and left ventricles demonstrating elevation and equalization of the diastolic pressures as well as the characteristic dip-and-plateau, or “square-root sign”, consistent with pericardial constriction.

**FIGURE 9** Right atrial pressure tracing in constrictive pericarditis, showing elevated mean right atrial pressure (19mmHg) and prominent X and Y descents (labeled).

The surgery is long and technically challenging due to adherent fibrotic debris, and can be complicated by severe bleeding, myocardial damage, arrhythmias, and hypotension. Overall operative mortality is 6 to 12%, and is even higher (21%) in the case of radiation disease.<sup>3</sup> If myocardial fibrosis or atrophy is present, the results after pericardiectomy are dismal. Good outcomes rely on careful patient selection, and it is the rare patient with metastatic cancer who is able to tolerate such a procedure.

# Treatment-Induced Arrhythmia, Pacemakers, and Automatic Implantable Cardioverter Defibrillators

S. Wamique Yusuf, MD, FACC

Arrhythmias in cancer patients may be due to a condition related to the primary malignancy (eg, pericarditis and pericardial effusion) or related to the treatment of the disease. Various chemotherapeutic agents can lead to a wide variety of cardiovascular problems, including ischemia, prolongation of QT interval and arrhythmias<sup>1</sup>. Atrial fibrillation (AF) and supraventricular tachycardia are probably the most common arrhythmias encountered in the cancer population and have been reported with the use of chemotherapeutic agents,<sup>1-4</sup> following lung surgery<sup>5,6</sup> and bone marrow transplant.<sup>7,8</sup>

## Atrial Fibrillation

This is the most common sustained arrhythmia in both the general population and the cancer population.<sup>4-8</sup> The prevalence of atrial fibrillation increases with age and is about 0.5% for patients aged 50 to 59 years and 8.8% for those aged 80 to 89 years.<sup>9</sup> It may become a major drain on health care resources as it is estimated that the lifetime risks for development of atrial fibrillation are 1 in 4 for men and women 40 years of age.<sup>10</sup> It is associated with increased mortality and, in subjects from the original cohort of the Framingham Heart Study, atrial fibrillation was associated with a mortality risk 1.5 to 1.9 times higher after adjustment for the preexisting cardiovascular conditions with which atrial fibrillation was related.<sup>11</sup>

## Mechanism of Atrial Fibrillation

Two theories for mechanism of atrial fibrillation have been advanced; enhanced automaticity involving one or more foci firing rapidly or reentry involving one or more circuits.<sup>12,13</sup> The most widely accepted is the multiple wavelet reentry theory.<sup>12</sup> This hypothesis envisions multiple reentrant impulses of variable sizes wandering through the atria creating continuous

electrical activity that creates daughter wavelets. The number of wavelets present at any time depends on the refractory period, mass, and the conduction velocity in different parts of the atria.

## Risk Factors

The clinical risk factors for atrial fibrillation include advancing age, diabetes, hypertension, congestive heart failure, rheumatic and non-rheumatic valve disease, and myocardial infarction.<sup>14</sup> The echocardiographic risk factors for non-rheumatic atrial fibrillation include left atrial enlargement, increased left ventricular wall thickness, and reduced left ventricular fractional shortening.<sup>15</sup>

## Causes and Associated Conditions

Atrial fibrillation is usually precipitated by underlying cardiac or noncardiac disease. The resultant atrial abnormality (frequently inflammation or fibrosis) acts as a substrate for the development of the arrhythmia.<sup>16</sup> In addition, the onset of atrial fibrillation usually requires a trigger. Triggers that may initiate the arrhythmia include alterations in autonomic tone<sup>17</sup> and acute or chronic changes in atrial wall tension.<sup>18</sup> Lung surgery is a potent trigger of atrial fibrillation.<sup>6</sup>

Atrial fibrillation is also the most common arrhythmia after hematopoietic stem cell transplantation, affecting about 4% of patients after transplant, with a relapse rate of 49%.<sup>8</sup> In the vast majority of these patients, multiple antiarrhythmics are needed for rate control.<sup>8</sup>

Various chemotherapeutic agents cause heart failure,<sup>1</sup> and a history of heart failure is significantly more common in patients with chronic atrial fibrillation compared to other forms of atrial fibrillation.<sup>19</sup> Patients with chronic atrial fibrillation also have significantly lower left ventricular ejection fraction compared to patients

with paroxysmal or recent atrial fibrillation.<sup>19</sup> The increased propensity for atrial arrhythmias in patients with heart failure results from structural heart disease secondary to congenital, valvular, or ischemic etiologies. These patients have underlying substrate that predisposes them to develop electrically irritable foci, functional or fixed conduction block, and consequently, recurrent tachyarrhythmias. For example, atrial enlargement and hypertrophy predisposes to atrial arrhythmias by decreasing conduction velocity and myocardial refractoriness, while low cardiac output increases sympathetic tone, thereby accelerating the frequency and prolonging the duration of such arrhythmias.

Recently inflammation has been linked to atrial fibrillation,<sup>20</sup> with an elevated C-reactive protein (CRP) level in patients with atrial fibrillation. In the same study, cancer was significantly associated with atrial arrhythmias, with 18.3% of patients with atrial arrhythmias having a history of cancer.<sup>21</sup> Cancer was also significantly associated with elevated CRP levels,<sup>21</sup> although multivariate analysis did not identify cancer as an independent predictor of atrial arrhythmias, leading the authors to suggest that inflammation may be the casual intermediary link between cancer and atrial fibrillation. In another study,<sup>22</sup> patients with colorectal cancer were twice as likely to have atrial fibrillation. At our institution, atrial fibrillation is a common postoperative arrhythmia after lung surgery, with an incidence of about 12%,<sup>6</sup> although others have reported a higher rate of postoperative atrial fibrillation affecting about 26% patients after non-cardiac chest surgery.<sup>23</sup> Male sex, history of arrhythmia, peripheral vascular disease, congestive heart failure, type of procedure performed, and the use of intraoperative transfusion are predictors of postoperative atrial fibrillation.<sup>6</sup> Postoperative atrial fibrillation is usually self-limiting, but in most instances, it

is associated with increased duration of hospitalization and higher mortality.<sup>6,23</sup>

Atrial fibrillation may be paroxysmal, persistent, or permanent<sup>24,25</sup>:

- Paroxysmal—self-terminating episodes of atrial fibrillation
- Persistent—atrial fibrillation does not terminate spontaneously, but reverts to sinus rhythm with electrical or pharmacological cardioversion
- Permanent—return of sinus rhythm is not feasible

The term “lone atrial fibrillation” describes atrial fibrillation in the absence of demonstrable underlying cardiac disease or a history of hypertension. Although by definition there is an absence of any demonstrable cardiac disease, it has been found that localized atrial myocarditis frequently (up to 66 %) exists in these patients.<sup>26</sup> It has been estimated that lone atrial fibrillation occurs in approximately 30% of patients with atrial fibrillation.<sup>19</sup>

Conditions associated with atrial fibrillation include:

- Ischemic heart disease/myocardial infarction
- Hypertensive heart disease
- Rheumatic heart disease
- Cardiomyopathy (dilated or hypertrophic)
- Thyrotoxicosis
- Alcohol
- Chronic pulmonary disease
- Post cardiac or other surgery
- Idiopathic
- Sick sinus syndrome.
- Congenital heart disease (eg ASD and Ebstein anomaly)
- Pericarditis
- Tumor
- Catheter in the right atrium

Compared to pre-infarct atrial fibrillation or sinus rhythm, atrial fibrillation that develops in the setting of an acute myocardial infarction is associated with an adverse prognosis.<sup>27</sup>

## Clinical Manifestations

Clinical symptoms depends upon the ventricular rate, underlying functional status, presence of any coronary artery disease, obstructive valvular disease, or heart failure.

In an individual, the symptoms vary from the patient being asymptomatic to syncope and congestive heart failure. The dysrhythmia may present for the first time with an embolic complication or exacerbation of heart failure, but most patients with atrial fibrillation complain of palpitations, chest pain, dyspnea, fatigue, lightheadedness, or syncope.<sup>19</sup> Atrial fibrillation associated

with a fast ventricular response, may lead to tachycardia-mediated cardiomyopathy,<sup>25</sup> and dilated cardiomyopathy may be the initial presentation, especially in patients who are unaware of the tachycardia. Syncope is an uncommon but serious complication that is usually associated with sinus node dysfunction or hemodynamic obstruction, such as valvular aortic stenosis, obstructive cardiomyopathy, or an accessory atrio-ventricular (AV) pathway.

## Clinical History and Physical Examination

The initial evaluation of a patient with suspected or proven atrial fibrillation includes characterizing the pattern of the arrhythmia as paroxysmal or persistent, determining its cause, and defining associated cardiac and extracardiac factors.

Precipitating factors should be specifically enquired for; commonly mentioned triggers include alcohol, sleep deprivation, caffeine, exercise, and emotional stress, but vagally mediated AF episodes may occur during sleep or after a large meal and are more likely to arise during a period of rest after a period of stress. Vagally mediated atrial fibrillation is also suggested when a  $\beta$ -blocker or digitalis has increased the tendency towards atrial fibrillation.<sup>28</sup>

The clinician should determine whether the onset and termination of palpitations is abrupt or gradual; the former favors atrial fibrillation or another supraventricular tachyarrhythmia, whereas the latter suggests a mechanism other than atrial fibrillation, including sinus tachycardia. Are there associated symptoms? Dyspnea may indicate underlying heart disease, whereas angina pectoris points toward coronary artery disease (CAD).

The physical examination may suggest atrial fibrillation on the basis of irregular pulse, irregular jugular venous pulsations, and variation in the loudness of the first heart sound. Examination may also disclose associated valvular heart disease like mitral stenosis or heart failure.

The findings on examination are similar in patients with atrial flutter, except that the rhythm may be regular, and rapid venous oscillations may occasionally be visible in the jugular pulse.

## Investigations

Hemoglobin, electrolytes, and thyroid function should be checked. Thyrotoxicosis is important to consider if the heart rate remains uncontrolled, despite therapy.

## Electrocardiogram

Normally during atrial fibrillation, the underlying atrial rate is greater than 300 per minute,<sup>25</sup>

resulting in small (or “fine”), irregular f (fibrillation) waves. The amplitude of these waves varies and may be especially prominent (or “coarse”) in lead V1. As only occasional impulses penetrate the atrioventricular node, a totally irregular ventricular rhythm results, which is the characteristic of this arrhythmia.

In most cases, this is a narrow complex tachycardia, but occasionally, a broad complex tachycardia can be seen in atrial fibrillation. Broad complex tachycardia with atrial fibrillation can occur in the following settings:

- Atrial fibrillation with conduction over an accessory pathway
- Atrial fibrillation with underlying bundle-branch block
- Atrial fibrillation with aberrant ventricular conduction

A review of a previous electrocardiogram (ECG) may show pre-excitation or bundle branch block.

A rapid, irregular, wide-QRS-complex tachycardia strongly suggests atrial fibrillation with conduction over an accessory pathway or atrial fibrillation with underlying bundle-branch block. Extremely rapid rates (over 200 beats per minute [bpm]) suggest the presence of an accessory pathway.

Aberrant ventricular conduction results in wide QRS complexes. In these circumstances, it is important to differentiate atrial fibrillation with aberrant ventricular conduction tachycardia from ventricular tachycardia. This can be done by careful analysis of the rhythm strip.

Factors favoring aberrant ventricular conduction includes long–short cycle length sequence, typical right bundle branch block, relatively rapid ventricular rate, lack of compensatory pause, absence of bundle branch block with shorter cycle length without preceding pause, and normalization of QRS complexes with minimal change in cycle length.<sup>25</sup>

## Holter and Event Recorder

If episodes are frequent, then a 24-hour Holter monitor can be used. If episodes are infrequent, then an event recorder, which allows the patient to transmit the ECG to a recording facility when the arrhythmia occurs, may be more useful.

## Imaging

A chest radiograph may detect enlargement of the cardiac chambers and heart failure.

Two-dimensional transthoracic echocardiography should be acquired to determine chamber dimensions, function, and to exclude occult valvular, pericardial disease, cardiomyopathy, and pulmonary hypertension. Thrombus should be sought in the left atrium but is seldom detected

without a transesophageal echocardiogram (TEE), which is the most sensitive and specific technique to detect sources and potential mechanisms for cardiogenic embolism.<sup>29</sup>

### Electrophysiologic Study

An electrophysiologic study is rarely needed to establish the diagnosis of atrial fibrillation but may be useful for other reasons. In patients with paroxysmal atrial fibrillation, an electrophysiologic study may help define the mechanism of atrial fibrillation, which is especially important when curative catheter ablation is considered for selected patients.

### Treatment

The major issues in management of patients with atrial fibrillation are related to the arrhythmia itself and to prevention of thromboembolism.

In patients with recurrent, persistent, atrial fibrillation, rate control is an acceptable alternative to rhythm control, and two strategies are associated with a similar number of major cardiovascular events.<sup>30</sup>

### General Approach to Antiarrhythmic Drug Therapy

Before any antiarrhythmic agent is administered, reversible cardiovascular and non-cardiovascular precipitants of atrial fibrillation should be addressed. Most of these relate to CAD, valvular heart disease, hypertension, pericardial disease, and heart failure. Those who develop atrial fibrillation in association with alcohol intake should practice abstinence. Prophylactic drug treatment is not usually indicated in case of a first-detected episode of atrial fibrillation. Antiarrhythmic drugs may also be avoided in patients with infrequent and well-tolerated paroxysmal atrial fibrillation. In patients who develop atrial fibrillation only during exercise, administration of a  $\beta$ -blocker may be effective. Selection of an appropriate agent is based first on safety and is tailored to any underlying heart disease that may be present, as well as the number and pattern of previous episodes of atrial fibrillation.<sup>31</sup>

### Combination Therapy

When treatment with a single agent fails, combinations of antiarrhythmic drugs may be tried, keeping in mind that combination therapy may cause bradycardia and side effects, some of which may be related to the proarrhythmic effects and prolongation of QT interval. Extra care should be taken in older populations who already have an element of degenerative conduction system disease. Drug interaction should be kept in mind; concurrent administration of amiodarone and propafenone with digoxin may result in a rise in serum digoxin level. Careful follow-up is needed,

as a drug that is initially safe may become proarrhythmic when the patient develops CAD or heart failure or starts other medication that, in combination, may be arrhythmogenic. Thus, the patient should be alerted to the potential significance of such symptoms as syncope, angina pectoris, or dyspnea, and warned about the use of noncardiac drugs that can prolong the QT interval.

Plasma, potassium, and magnesium levels, and renal function should be checked periodically during follow-up because renal insufficiency leads to drug accumulation and predisposes to proarrhythmia.

### Drugs for Pharmacologic Cardioversion

Drugs that have proven efficacy for pharmacologic conversion include amiodarone, dofetilide, flecainide, ibutilide fumarate, propafenone, and quinidine.<sup>24</sup>

Digoxin and sotalol are not recommended for pharmacologic conversion and, in fact, has been labeled as class 111 (conditions in which there is evidence and/or general agreement that the procedure or treatment is not useful/effective and, in some cases, may be harmful) in recent ACC guidelines.<sup>24</sup>

Drugs used to maintain sinus rhythm in patients with atrial fibrillation include amiodarone, disopyramide, dofetilide, flecainide, propafenone, quinidine, sotalol.<sup>24</sup>

Like other type IC drugs, propafenone should not be used in patients with ischemic heart disease or LV dysfunction.

There is no evidence to support the antiarrhythmic efficacy of calcium channel antagonist drugs in patients with paroxysmal atrial fibrillation, but they reduce heart rate during an attack.<sup>24</sup>

### Medications Used in Special Subgroup of Patients

#### Heart Failure

Patients with congestive heart failure are particularly prone to the ventricular proarrhythmic effects of antiarrhythmic drugs related to underlying myocardial dysfunction and electrolyte disturbances. Randomized trials have demonstrated the safety of amiodarone and dofetilide (given separately) in patients with heart failure<sup>32,33</sup> and these are the recommended drugs for maintenance of sinus rhythm.

#### Coronary Artery Disease

In stable patients with CAD,  $\beta$ -blockers may be considered first, as in one study in which more than 50% of patients had hypertension, 26% had CAD, and 26% had CHF, and in which use of metoprolol XL was effective in preventing relapse into atrial flutter or fibrillation.<sup>34</sup> Other  $\beta$ -blockers that reduce the duration and episodes of

paroxysmal atrial fibrillation are sotalol and atenolol.<sup>35</sup> In this study, about 32% of patients had ischemic heart disease.<sup>35</sup> Sotalol has substantial  $\beta$ -blocking activity and may therefore be chosen as the initial antiarrhythmic agent in atrial fibrillation patients with ischemic heart disease because it is associated with less long-term toxicity than amiodarone.

### Hypertensive Heart Disease
