Patients with left ventricular hypertrophy (LVH) may be at increased risk of developing torsades de pointes related to early ventricular afterdepolarization.<sup>31</sup> Thus, a drug that does not prolong the QT interval is preferable as first-line therapy, and in the absence of CAD or marked LVH (LV wall thickness  $\geq 1.4$  cm), propafenone and flecainide are reasonable choices.<sup>24</sup> Proarrhythmia with one agent does not predict this type of response to another type of drug. For example, patients with LVH who develop torsades de pointes during treatment with a type III agent may tolerate a type IC agent uneventfully.<sup>24</sup> Amiodarone prolongs the QT interval but carries a very low risk of ventricular proarrhythmia; its extracardiac toxicity profile relegates it to second-line therapy in these individuals, but amiodarone becomes first-line therapy when marked LVH is present. When amiodarone and sotalol either fail or are inappropriate, disopyramide, quinidine, or procainamide may be used as alternatives.<sup>24</sup>

### Nonpharmacologic Correction of Atrial Fibrillation

In a selected group of patients, surgical ablation (Maze operation) or catheter ablation can be carried out. In one small study, 64% of patients who were in atrial fibrillation at the beginning of the procedure converted into sinus rhythm during ablation.<sup>36</sup>

Although these procedures have produced promising results, they have not yet been widely applied. Potential complications of catheter ablation for atrial fibrillation include systemic embolism, pulmonary vein stenosis, pericardial effusion, cardiac tamponade, and phrenic nerve paralysis.

### Drugs for Heart Rate Control during Atrial Fibrillation

The adequacy of rate control during atrial fibrillation may be judged from clinical symptoms and ECG recordings. The rate is generally considered controlled when the ventricular response ranges between 60 and 80 beats per minute at rest and between 90 and 115 beats per minute during moderate exercise.<sup>37,38</sup> Achieving a target ventricular rate of 90 beats per minute in patients with atrial fibrillation at rest would result in control with the least compromise of cardiac output.<sup>37</sup>

The following agents may be administered to achieve control of the ventricular response to atrial fibrillation in an emergency setting.

#### Digoxin

Although intravenous digoxin may effectively slow the ventricular rate at rest, there is a delay of at least 60 minutes before onset of a therapeutic effect in most patients, and a peak effect does not develop for up to 6 hours. Digoxin is no more effective than placebo in converting atrial fibrillation to sinus rhythm.<sup>39</sup> Intravenous digoxin offers no substantial advantage over placebo for conversion to sinus rhythm and also provides weak rate control.<sup>40</sup> Given the availability of more effective agents, digoxin is no longer first-line therapy for management of acute atrial fibrillation, except in patients with heart failure or left ventricular dysfunction.

#### Non-dihydropyridine Calcium Antagonists

The most commonly used calcium channel antagonist agents for treatment of atrial fibrillation are verapamil and diltiazem. Intravenously, each drug is effective in emergency settings, but the response is transient, and repeated doses or a continuous intravenous infusion may be required to maintain heart rate control. These agents, particularly verapamil, generally should not be used in patients with heart failure due to systolic dysfunction.

#### $\beta$ -Blockers

Intravenous  $\beta$ -blockade with propranolol, atenolol, metoprolol, or esmolol hydrochloride may help to control the rate of ventricular response to AF in specific settings.  $\beta$ -blockers may be particularly useful in states of high adrenergic tone (eg, postoperative atrial fibrillation). In the immediate postoperative period,  $\beta$ -blockers appear to provide a more rapid conversion to sinus rhythm compared to calcium channel blockers<sup>41</sup>.

#### Amiodarone

Amiodarone has both sympatholytic and calcium antagonistic properties, depresses AV conduction, and is effective in controlling the ventricular rate in patients with atrial fibrillation. Intravenous amiodarone is effective and well tolerated in critically ill patients, and amiodarone is considered a suitable alternative agent for heart rate control when conventional measures are ineffective.<sup>42</sup> It not only decreases heart rate but also significantly improves blood pressure and lowers pulmonary artery wedge pressure in this group of patients.<sup>42</sup> Unlike oral amiodarone, short-term dosing with intravenous amiodarone is not associated with any significant prolongation of action potential duration (QT interval) or use dependent sodium channel blockade,<sup>43</sup> and hence

may be particularly useful in the intensive care patients in cancer population, a lot of whom are on antifungals and other medications that prolong QT interval.

In the acute setting, in the absence of conduction over an accessory pathway, the current recommendation<sup>24</sup> is to administer intravenous  $\beta$ -blockers or calcium channel antagonists (verapamil, diltiazem) to slow the ventricular response to atrial fibrillation, exercising caution in patients with hypotension or heart failure. Immediate electrical cardioversion should be performed in patients with acute paroxysmal atrial fibrillation and a rapid ventricular response associated with acute myocardial infarction, symptomatic hypotension, angina, or cardiac failure that does not respond promptly to pharmacological measures.<sup>24</sup>

In patients with accessory pathway (Wolff-Parkinson-White [WPW] syndrome) and symptomatic atrial fibrillation, catheter ablation of the accessory pathway is the treatment of choice.<sup>24</sup>

In hemodynamically stable patients with atrial fibrillation and accessory pathway (WPW syndrome), intravenous quinidine, procainamide, disopyramide, ibutilide fumarate, or amiodarone can be used.<sup>24</sup> In such patients, it is critically important to avoid agents with the potential to increase the refractoriness of the AV node, which could encourage preferential conduction over the accessory pathway. Hence, administration of AV nodal blocking agents such as digoxin, diltiazem, or verapamil is contraindicated in patients with atrial fibrillation in association with WPW syndrome.<sup>24</sup>

Control of heart rate is important not only for prevention of tachycardia-induced cardiomyopathy, but it may also lead to improvement in left ventricular (LV) systolic function and ejection fraction.<sup>25</sup>

#### Anti-Coagulation in Atrial Fibrillation

In patients with persistent (also known as sustained, and including patients categorized as permanent in certain classification schemes) or paroxysmal (intermittent) atrial fibrillation at high risk of stroke (ie, having any of the following features: prior ischemic stroke, Transient Ischemic Attack (TIA) or systemic embolization, age >75 years, moderately or severely impaired left ventricular systolic function and/or congestive heart failure, history of hypertension or diabetes mellitus) the recommendation is for oral anticoagulation with warfarin (target International Normalized Ratio (INR) 2.5; range 2.0 to 3.0).<sup>44</sup>

In patients with persistent or paroxysmal atrial fibrillation at age 65 to 75 years, in the absence of other risk factors, anti-thrombotic therapy with either warfarin (target INR 2.5; range 2.0 to 3.0) or aspirin 325 mg daily are acceptable alternatives in this group of patients

who are at intermediate risk of stroke.<sup>44</sup> In patients with persistent or paroxysmal atrial fibrillation, who are < 65 years of age and with no additional risk factors, aspirin 325 mg daily is recommended.<sup>44</sup>

#### Atrial Flutter

Atrial flutter is due to a re-entry circuit in the atrium.<sup>45</sup> This produces atrial contractions at a rate of about 300 beats/min seen on the ECG as flutter (F) waves. These are broad and appear saw-toothed and are best seen in the inferior leads and in lead V1 without an isoelectric baseline between deflections. Atrial flutter may degenerate into atrial fibrillation, or vice versa, which may be reflected on the ECG. The ventricular rate depends on conduction through the atrioventricular node. Typically 2:1 block (atrial rate to ventricular rate) occurs, giving a ventricular rate of 150 beats/min. Identification of a regular tachycardia with this rate should prompt the diagnosis of atrial flutter. The non-conducting flutter waves are often mistaken for, or merged with, T waves and become apparent only if the block is increased. Maneuvers that induce transient atrioventricular block (such as carotid sinus massage or use of adenosine) will slow the conduction and help in identification of flutter waves.

Not all atrial contractions are propagated through to the ventricles due to a variable block within the junctional area (this is due to the refractory nature of the conduction pathway at the higher rate). When conduction through the ventricles does occur, the morphology is normal but the RR interval is irregular.

#### Cause

The causes of atrial flutter are similar to those of atrial fibrillation, although idiopathic atrial flutter is uncommon. It may convert into atrial fibrillation over time or, after administration of drugs such as digoxin.

The findings on examination are similar to those in patients with atrial fibrillation, except that the rhythm may be regular, and rapid venous oscillations may occasionally be visible in the jugular pulse.

#### Treatment

The treatment of atrial flutter is almost similar to atrial fibrillation, as these two conditions are frequently present together in the same patient. When rapid control of ventricular response rate to atrial flutter is desired, intravenous administration of a calcium channel blocker (eg, verapamil or diltiazem) or of a  $\beta$ -blocker is usually effective.<sup>45</sup> Sometimes, combination therapy using a calcium channel blocker and a  $\beta$ -blocker is needed for rate control. For ventricular rate control during atrial flutter, drugs should be

prescribed that prolong the refractory period of the AV node, such as  $\beta$ -blocking agents, calcium antagonists, digitalis, and amiodarone.<sup>45</sup> With Ibutilide, there is a 60% likelihood of converting atrial flutter to sinus rhythm,<sup>46</sup> and hence, this provides a valuable tool for treatment of atrial flutter.

For prevention of recurrence, class I drugs (flecainide, procainamide, quinidine),  $\beta$ -blockers, class III drugs, and amiodarone can be used.<sup>45</sup> When deciding on pharmacologic therapy, side effects and the possible dangers of drug administration (including arrhythmias and torsades de pointes) should be considered.<sup>47</sup>

### Nonpharmacologic Therapy

#### Electrical Cardioversion and Overdrive Pacing

External electrical cardioversion is safe and effective, terminating atrial flutter in > 90% of episodes.<sup>45</sup> Because external electrical cardioversion requires sedation and anesthesia, some doctors and patients prefer atrial overdrive pacing to terminate atrial flutter. This also has the advantage of being able to pace in the case of sick sinus syndrome after termination of atrial flutter. Implantable devices have become available, allowing both anti-tachycardia and burst pacing, as well as (when needed) internal cardioversion of atrial flutter.

**Catheter Ablation** Nowadays, catheter ablation of atrial flutter has become a safe, curative, and highly successful procedure.<sup>45</sup> In a selected group of patients with atrial flutter, the patients treated with catheter ablation reported a significant improvement in their quality of life and symptoms scores.<sup>48</sup> The indications for long-term anticoagulation and anti-thrombotic therapy is the same as for atrial fibrillation.<sup>44</sup>

**Anticoagulation for Elective Cardioversion of Atrial Fibrillation or Atrial Flutter** Patients For patients with atrial fibrillation of > 48 h or of unknown duration for whom pharmacologic or electrical cardioversion is planned, anticoagulation with warfarin (target INR, 2.5; range 2.0 to 3.0) is recommended for 3 weeks before elective cardioversion and for at least 4 weeks after successful cardioversion.<sup>44</sup>

For patients with atrial fibrillation of > 48 h or of unknown duration undergoing pharmacologic or electrical cardioversion, an alternative to the strategy outlined above is anticoagulation (immediate unfractionated intravenous (IV) heparin with target PTT of 60 seconds [range, 50 to 70 seconds], or at least 5 days of warfarin with a target INR of 2.5 [range, 2.0 to 3.0] at the time of cardioversion), and a screening multiplane TEE should be performed. If no thrombus is seen and cardioversion is successful, then anticoagulation (target INR, 2.5; range 2.0 to 3.0) is recommended for at least 4 weeks. If a thrombus

is seen on TEE, then cardioversion should be postponed and anticoagulation should be continued indefinitely. A TEE should be repeated before attempting later cardioversion.<sup>44</sup>

For patients with atrial fibrillation of known duration < 48 h, cardioversion can be performed without anticoagulation.<sup>44</sup> However, in patients without contraindications to anticoagulation, anticoagulation with IV heparin (target Activated Partial Thromboplastin Time (APTT), 60 seconds; range 50 to 70 seconds) or Low Molecular Weight Heparin (LMWH) (at full Deep Vein Thrombosis (DVT) treatment doses) should be started at presentation.<sup>44</sup>

For patients with risk factors for stroke, it is particularly important to be confident that the duration of AF is < 48 h. In such patients with risk factors, a TEE-guided approach is a reasonable alternative strategy. According to ACC/AHA guidelines,<sup>24</sup> cardioversion without TEE guidance during the first 48 hours after the onset of atrial fibrillation is a class IIb indication.

For emergency cardioversion where a TEE-guided approach is not possible, IV unfractionated heparin (target PTT, 60 seconds; range 50 to 70 seconds) be started as soon as possible, followed by 4 weeks of anticoagulation with warfarin (target INR, 2.5; range 2.0 to 3.0).<sup>44</sup> Following cardioversion, the continuation of anticoagulation beyond 4 weeks is based on whether the patient has experienced more than one episode of atrial fibrillation and on risk factor status. Patients experiencing more than one episode of atrial fibrillation should be considered as having paroxysmal atrial fibrillation.<sup>44</sup>

Anticoagulation increases the frequency and severity of major extracranial and intracranial hemorrhage and the issue of anticoagulation in the cancer population is complex, for most patients in clinical trials are carefully selected, and exclude those with a high risk of bleeding. Presence of thrombocytopenia prevents the use of warfarin in a number of patients with cancer and atrial fibrillation. There are no guidelines in existence regarding how to best manage these patients. Clinical judgment is needed and a decision about initiating anticoagulation, or even aspirin, should be made on an individual basis.

### Broad Complex Tachycardia

Broad complex tachycardias occur by various mechanisms and may be ventricular or supraventricular in origin.

Varieties of broad complex tachycardia include ventricular (regular, monomorphic ventricular tachycardia, irregular, torsades de pointes tachycardia, and polymorphic ventricular tachycardia), and supraventricular (bundle branch block with aberrant conduction, and atrial tachycardia with pre-excitation).

### Ventricular Tachycardia

Ventricular tachycardia (VT) is defined as three or more ventricular extrasystoles in succession at a rate of more than 100 beats/min. The tachycardia may be self-terminating but is described as “sustained” if it lasts longer than 30 seconds or results in hemodynamic collapse. Ventricular tachycardia is described as “monomorphic” when the QRS complexes have the same general appearance, and “polymorphic” if there is wide beat-to-beat variation in QRS morphology. Monomorphic ventricular tachycardia is the most common form of sustained ventricular tachycardia

### Mechanism of Ventricular Tachycardia

The mechanisms responsible for ventricular tachycardia include reentry or increased myocardial automaticity. Ventricular tachycardia in a patient with chronic ischemic heart disease and in post-myocardial infarction patients is caused by reentrant mechanism.<sup>49</sup> The reentry circuits that support ventricular tachycardia can be micro or macro in scale and often occur in the zone of ischemia or fibrosis surrounding damaged myocardium.

Triggered automaticity of a group of cells can result from congenital or acquired heart disease. Once initiated, these tachycardias tend to accelerate, but slow markedly before stopping. The mechanism of ventricular tachycardia in dilated cardiomyopathy is less well understood, but even in patients with nonischemic cardiomyopathy, reentry appears to play a role in the initiation of sustained monomorphic VT.<sup>50</sup>

Ventricular tachycardia may result from direct damage to the myocardium secondary to ischemia or cardiomyopathy, or from the effects of myocarditis or drugs—for example, class I antiarrhythmics (such as flecainide, quinidine, and disopyramide).

### Broad Complex Tachycardia of Supraventricular Origin

In the presence of aberrant conduction or ventricular pre-excitation, any supraventricular tachycardia may present as a broad complex tachycardia and mimic ventricular tachycardia.

### Atrial Tachycardia with Aberrant Conduction

Aberrant conduction is defined as conduction through the atrioventricular node with delay or block, resulting in a broader QRS complex. Aberrant conduction usually manifests as left or right bundle branch block, both of which have characteristic features. The bundle branch block may predate the tachycardia, or it may be a rate-related functional block, occurring when

atrial impulses arrive too rapidly for a bundle branch to conduct normally. When atrial fibrillation occurs with aberrant conduction and a rapid ventricular response, a totally irregular broad complex tachycardia is produced.

### Wolff-Parkinson-White Syndrome

Broad complex tachycardias may also occur in the Wolff-Parkinson-White syndrome, either as an antidromic atrioventricular reentrant tachycardia or in association with atrial flutter or fibrillation.

### Antidromic Atrioventricular Reentrant Tachycardia

In this relatively uncommon tachycardia, the impulse is conducted from the atria to the ventricles via the accessory pathway. The resulting tachycardia has broad, bizarre QRS complexes.

### Atrial Fibrillation

In patients without an accessory pathway, the atrioventricular node protects the ventricles from the rapid atrial activity that occurs during atrial fibrillation. In the Wolff-Parkinson-White syndrome, the atrial impulses are conducted down the accessory pathway, which may allow rapid conduction, and consequently, very fast ventricular rates.

Drugs that block the atrioventricular node—such as digoxin, verapamil, and adenosine—should be avoided as they can produce an extremely rapid ventricular response.

The impulses conducted via the accessory pathway produce broad QRS complexes. Occasionally, an impulse will be conducted via the atrioventricular node and produce a normal QRS complex or a fusion beat. The result is a completely irregular, and often rapid, broad complex tachycardia with a fairly constant QRS pattern, except for occasional normal complexes and fusion beats.

Differentiating Between Ventricular and Supraventricular Origin

### Clinical Features

The presentation and symptoms related to broad complex tachycardia are similar to other tachycardia and are largely dependent upon heart rate, underlying cardiac function, and hemodynamic consequences of the arrhythmia. Symptoms relate to the heart rate and the underlying cardiac reserve rather than to the origin of the arrhythmia. Rapid tachycardia in the presence of heart disease can lead to syncope and sudden death, whereas those with slower heart rate and normal heart may remain asymptomatic.

It is wrong to assume that a patient with ventricular tachycardia will inevitably be in a state of collapse; some patients look well but present

with dizziness, palpitations, syncope, chest pain, or heart failure. In contrast, a supraventricular tachycardia may cause collapse in a patient with underlying poor ventricular function.

A history of coronary artery disease, congestive heart failure, or age >35 years are 90% specific for ventricular tachycardia, but their absence does not establish the diagnosis of supraventricular tachycardia.<sup>51</sup>

### Physical Examination

Physical examination of a patient with ventricular tachycardia may reveal the clinical evidence of atrioventricular dissociation—that is, “cannon” waves in the jugular venous pulse or variable intensity of the first heart sound. However, these signs will be absent if there is 1:1 retrograde conduction, and absence of these findings does not exclude the diagnosis.

### ECG

Electrocardiographic diagnosis of monomorphic ventricular tachycardia is based on the following features:<sup>52,53</sup>

#### Duration and Morphology of QRS Complex

In ventricular tachycardia, the sequence of cardiac activation is altered, and the impulse no longer follows the normal intraventricular conduction pathway. As a consequence, the morphology of the QRS complex is bizarre, and the duration of the complex is prolonged (usually to 0.12 seconds or longer). The exception is fascicular ventricular tachycardia, which can have relatively narrow QRS complexes.<sup>52</sup>

As a general rule, the broader the QRS complex, the more likely the rhythm is to be ventricular in origin, especially if the complexes are greater than 0.16 seconds. Duration of the QRS complex may exceed 0.2 seconds, particularly if the patient has electrolyte abnormalities or severe myocardial disease or is taking antiarrhythmic drugs, such as flecainide.

The QRS complex in ventricular tachycardia often has right or left bundle branch morphology. In general, a tachycardia originating in the left ventricle produces a right bundle branch block pattern, whereas a tachycardia originating in the right ventricle results in a left bundle branch block pattern. The intraventricular septum is the focus of the arrhythmia in some patients with ischemic heart disease, and the resulting complexes have left bundle branch block morphology.

#### Rate and Rhythm

In ventricular tachycardia, the rate is normally 120 to 300 bpm. The rhythm is regular or almost regular (<0.04 seconds beat-to-beat variation), unless disturbed by the presence of capture or fusion beats. If a monomorphic broad complex

tachycardia has an obviously irregular rhythm, the most likely diagnosis is atrial fibrillation with either aberrant conduction or pre-excitation.

#### Frontal Plane Axis

In a normal electrocardiogram, the QRS axis in the mean frontal plane is between  $-30^\circ$  and  $+90^\circ$ , with the axis most commonly lying at around  $60^\circ$ . With the onset of ventricular tachycardia, the mean frontal plane axis changes from that seen in sinus rhythm and is often bizarre. A change in axis of more than  $40^\circ$  to the left or right is suggestive of ventricular tachycardia.

#### Direct Evidence of Independent Atrial Activity

In ventricular tachycardia, the sinus node continues to initiate atrial contraction. Since this atrial contraction is completely independent of ventricular activity, the resulting P waves are dissociated from the QRS complexes and are positive in leads I and II. The atrial rate is usually slower than the ventricular rate, though occasionally 1:1 conduction occurs. It is important to scrutinize the tracings from all 12 leads of the electrocardiogram, as P waves may be evident in some leads but not in others.

Although evidence of atrioventricular dissociation is diagnostic for ventricular tachycardia, a lack of direct evidence of independent P wave activity does not exclude the diagnosis. Artifacts that simulate P wave activity may complicate the situation.

However, beat to beat differences, especially of the ST segment, suggest the possibility of independent P wave activity, even though it may be impossible to pinpoint the independent P wave accurately.

#### Indirect Evidence of Independent Atrial Activity

##### Capture Beat

Occasionally an atrial impulse may cause ventricular depolarization via the normal conduction system. The resulting QRS complex occurs earlier than expected and is narrow. Such a beat shows that, even at rapid rates, the conduction system is able to conduct normally, thus making a diagnosis of supraventricular tachycardia with aberrancy unlikely.

Capture beats are uncommon, and although they confirm a diagnosis of ventricular tachycardia, their absence does not exclude the diagnosis.

##### Fusion Beats

A fusion beat occurs when a sinus beat conducts to the ventricles via the atrioventricular node and fuses with a beat arising in the ventricles. As the ventricles are depolarized, partly by the impulse conducted through the His-Purkinje system and partly by the impulse arising in the ventricle, the resulting QRS complex has an appearance intermediate between a normal beat and a tachycardia beat.

Like capture beats, fusion beats are uncommon, and although they support a diagnosis of ventricular tachycardia, their absence does not exclude the diagnosis.

#### QRS Concordance throughout the Chest Leads

Concordance exists when all the QRS complexes in the chest leads are either predominantly positive or predominantly negative. Concordance can be either positive or negative. The presence of concordance suggests that the tachycardia has a ventricular origin.

A previous electrocardiogram may give valuable information. Evidence of a myocardial infarction increases the likelihood of ventricular tachycardia, and a change in mean frontal plane axis during the tachycardia (especially if the change is  $>40^\circ$  to the left or right), points to a ventricular origin. Ventricular tachycardia and supraventricular tachycardia with bundle branch block may produce similar electrocardiograms. If a previous electrocardiogram shows a bundle branch block pattern during sinus rhythm that is similar to or identical with that during the tachycardia, the origin of the tachycardia is likely to be supraventricular. But if the QRS morphology or axis changes during the tachycardia, then a ventricular origin is suspected.

#### Maneuvers to Elicit the Underlying Rhythm

Vagal stimulation—for example, carotid sinus massage or Valsalva's maneuver—does not usually affect a ventricular tachycardia but may affect arrhythmias of supraventricular origin. Transiently slowing or blocking conduction through the atrioventricular node may terminate an atrioventricular nodal reentrant tachycardia or atrioventricular reentrant tachycardia. In atrial flutter transient block may reveal the underlying flutter waves

Adenosine can also be used to block conduction temporarily through the atrioventricular node to ascertain the origin of a broad complex tachycardia, but failure to stop the tachycardia does not necessarily indicate a ventricular origin. In one study of adenosine in broad complex tachycardia, adenosine terminated the arrhythmia or induced diagnostic atrioventricular block in 8 of 9 patients with broad complex Supraventricular tachycardia and all nine patients with narrow complex Supraventricular tachycardia.<sup>54</sup> However, adenosine terminated VT in only 1 of 17 patients.<sup>54</sup>

#### Danger of Misdiagnosis

The safest option is to regard a broad complex tachycardia of uncertain origin as ventricular tachycardia unless good evidence suggests a supraventricular origin.

If a ventricular tachycardia is wrongly treated as supraventricular tachycardia, the consequences may be extremely serious. Misdiagnosis of broad complex tachycardia and use of verapamil in patients who actually have VT, results in worsening of clinical condition in most of these patients, with poor outcome.<sup>55</sup>

#### Treatment of Ventricular Tachycardia

In any patient with ventricular tachycardia it is important to exclude coronary ischemia and structural heart disease, including dilated cardiomyopathy, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular dysplasia. Therapy for patients who present with ventricular tachycardia should be determined by the hemodynamic status, symptoms, and history. In unstable patients, electrical cardioversion should be carried out promptly.<sup>56</sup> Treatment of hemodynamically stable ventricular tachycardia depends on whether the VT is monomorphic or polymorphic and whether left ventricular systolic function is normal or impaired. Treatment of polymorphic VT depends on whether QT intervals are normal or prolonged (as in torsades de pointes, when QT is prolonged during sinus rhythm). When polymorphic VT develops in patients who have prolonged QT during sinus rhythm, treatment with magnesium is recommended.<sup>56</sup> Polymorphic VT in the absence of prolonged QT is treated the same as monomorphic VT. For stable monomorphic VT in patients with normal LV function, intravenous procainamide, lidocaine, or amiodarone can be used.<sup>56</sup> In patients with stable monomorphic VT and impaired LV function, use of amiodarone or lidocaine is preferred.<sup>56</sup> Ideally, clinicians should attempt to identify whether a broad complex tachycardia is supraventricular or ventricular and treat accordingly. However this is not always possible diagnostically, hence the wise thing is to assume that wide complex tachycardia is VT until proven otherwise. From a statistical point of view, such an assumption sounds like safe practice, since about 90% of wide complex tachycardia are VT.<sup>56</sup> Also, use of medications like verapamil can have disastrous consequences in such cases.<sup>55</sup> Unstable wide complex tachycardia should be treated with immediate cardioversion. For stable wide complex tachycardia of uncertain origin, amiodarone and procainamide are good choices since they are effective for treating both supraventricular tachycardia and ventricular tachycardia.<sup>56</sup> As a general rule, it is better to use just one antiarrhythmic agent in a given patient to avoid proarrhythmic effects. If one agent has not converted a tachycardia after an appropriate dose, then the next step should usually be DC cardioversion.<sup>56</sup> The long-term therapy for patients with sudden cardiac death is largely determined by the

presence of concomitant disease, each of which has specific risk stratification and treatment.<sup>57</sup> Ventricular tachycardia can degenerate into ventricular fibrillation, which should be treated with an unsynchronized electric shock using an initial energy of 200 joules (J). If this is unsuccessful, a second shock using 200 to 300 J and, if necessary, a third shock using 360 J is indicated.<sup>56</sup>

Ventricular fibrillation that is not easily converted by defibrillation may be treated with additional adjunctive measures. Epinephrine (1 mg intravenously) should be given and repeated every 3 to 5 minutes, or Vasopressin (40 units intravenously) as a single dose should be given.<sup>56</sup> For persistent and recurrent VF and ventricular tachycardia (VT), amiodarone in a dose of 300 mg intravenously can be given.<sup>56</sup>

#### Pacemakers

Pacemakers are increasingly being used in the United States. At our institution, we implanted 22 permanent pacemakers in the 19 months prior to this writing. Cancer patients, particularly in the elderly population who have underlying degenerative conduction system disease, are prone to the side effects of chemotherapeutic agents, a wide variety of which can cause bradycardia and heart block.<sup>1</sup> The treatment of asymptomatic and symptomatic bradycardia in cancer patients is generally the same as in other populations. Where a clear offending agent is considered to be the cause, the approach is to discontinue the medication and observe. In most cases, the bradycardia and heart block resolves over time. In patients who have persistent sinus symptomatic bradycardia and heart block, the indications for pacemakers are the same as those for the general population.<sup>58</sup> In some cancer populations, a particular group of patients (ie, those with ongoing infection) poses a dilemma: any permanent pacemaker implantation in the face of infection creates a potential for infection of the pacemaker pocket site. In these cases, a temporary pacemaker is left in place for few days until the infection is controlled. Although the indication for a pacemaker involves clinical judgment, in the cancer population, this is an overwhelming necessity, as the main objective in some cases is only comfort care.

#### Pacing Modes

The generic pacemaker code of the North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group is used to describe various pacing modes. The first letter denotes the chamber or chambers that are paced (A = atrial, V = ventricular, D = dual [atrial and ventricular]). The second letter describes which chambers detect (sense) electrical signals. The third letter represents the response to sensed

events (I=inhibition, T=triggering, D=dual [inhibition and triggering]). A fourth letter, R, denotes activation of rate-response features. The most commonly used pacing modes are: AAI(R) single-chamber atrial pacing without (or with) rate response, VVI(R) single-chamber ventricular pacing without (or with) rate response, and DDD(R) dual-chamber pacing without (or with) rate response. In the latest version of the code, a fifth position denotes the chamber or chambers in which multisite pacing is delivered.<sup>59</sup>

## Indications

The decision to implant a permanent pacemaker should involve the cardiologist, the primary physician, the patient and the family. Before embarking on a pacemaker insertion, the need for pacing should be clearly documented. To evaluate patients more uniformly, the Joint American College of Cardiology–American Heart Association Task Force established a classification system for the indications for pacemaker implantation.<sup>58</sup> Class I includes all conditions for which it is generally agreed that a permanent pacemaker should be implanted; class II, all conditions for which such pacemakers are frequently used but for which there is disagreement about the need for their use; and class III, all conditions for which it is generally agreed that permanent pacing is not required.

## Atrioventricular Block

Atrioventricular heart block can be classified as first-degree, second-degree, or third-degree (ie, complete) heart block. Generally, first-degree atrioventricular block is not considered an indication for pacing, but in some patients with severe first-degree block and who are symptomatic, a pacemaker may be helpful.

Second-degree atrioventricular block is divided into type I (in which there is progressive prolongation of the PR interval before a blocked beat), type II (in which there is no such progressive prolongation), or advanced (in which two or more consecutive P waves are blocked). Second-degree type I atrioventricular block usually occurs in the atrioventricular node, whereas type II and the advanced type usually occur in tissues below the node.<sup>58</sup> When every other beat is conducted (in what is known as 2:1 block), the distinction between types I and II often cannot be made with certainty, and the site of the block may be either at or below the atrioventricular node.<sup>58</sup> Type I second-degree AV block is usually due to delay in the AV node, irrespective of QRS width, and progression to advanced AV block in this situation is uncommon, hence pacing is usually not indicated unless the patient is symptomatic.<sup>58</sup>

Type II second-degree AV block and a wide QRS indicate diffuse conduction system disease and constitute an indication for pacing even in

the absence of symptoms<sup>58</sup> as progression to third-degree AV block is common in this condition. However, it is not always possible to determine the site of AV block without electrophysiologic evaluation; hence, if type I second-degree AV block with a narrow or wide QRS is found to be intra- or infra-His upon electrophysiologic study, pacing should be considered.<sup>58</sup> Any form of second-degree atrioventricular block, regardless of the site or type of block that is associated with symptomatic bradycardia, is a class I indication for pacing.<sup>58</sup>

Asymptomatic second-degree type II and advanced atrioventricular blocks are class II indications for pacing.<sup>58</sup> An asymptomatic patient with a second-degree type I atrioventricular block should not receive a permanent pacemaker. Asymptomatic patients who have second-degree atrioventricular block with 2:1 conduction and evidence of infranodal block (based on the results of electrophysiologic study or the presence of a bundle-branch block) are considered to have a class II indication for pacing.<sup>58</sup>

In third-degree atrioventricular block or advanced second degree AV block, class I indication for pacing is present if (1) bradycardia with symptoms are present, (2) arrhythmias or other medical conditions that require drugs result in symptomatic bradycardia, (3) if pauses in the QRS rhythm exceed three seconds in length, or if there are escape rates <40 beats per minute in awake, symptom-free patients.<sup>58</sup>

In general, the decision regarding implantation of a pacemaker must be considered with respect to whether or not AV block will be permanent. In conditions such as electrolyte abnormalities, medications, and conditions causing excessive vagal tone (where a clear precipitating factor is present), correction usually resolves the block. Similarly peri- and postoperative AV block, in which inflammation near the AV conduction system after surgery in this region plays a part, usually resolves over time. In systemic conditions like neuromuscular diseases, sarcoidosis, and amyloidosis, a pacemaker should be considered even if significant heart block is transient, since this may recur.

In patients with chronic bifascicular or trifascicular block, the presence of intermittent third-degree AV block, type II second degree AV block, and alternating bundle branch block is a class I indication for permanent pacing.<sup>58</sup>

In patients with sinus node dysfunction, symptomatic bradycardia (including frequent sinus pauses) that produces symptoms or symptomatic chronotropic incompetence is a class I indication for permanent pacing.<sup>58</sup>

In patients with tachyarrhythmias, like supraventricular tachycardia, in cases in which ablation and/or drugs fail to control arrhythmias, an anti-tachycardia pacing is considered.<sup>58</sup> Other conditions in which prevention of arrhythmias

by pacing is a reasonable choice is the Long QT syndrome (LQTS), in which pacing may be especially beneficial for patients with pause-dependent arrhythmias, and use of a pause prevention pacing algorithm for arrhythmia prevention in a young patient with congenital LQTS and documented pause-dependent torsades de pointes has been reported.<sup>60</sup>

## Syncope

Syncope in the absence of a clear cardiac cause like marked bradycardia or significant pause with carotid sinus hypersensitivity is, in general, not an indication for a pacemaker. Recurrent syncope caused by carotid-sinus hypersensitivity associated with pauses of more than three seconds in symptomatic patients is a class I indication for pacing.<sup>58</sup> For symptomatic and recurrent neurocardiogenic syncope associated with bradycardia documented spontaneously (or at the time of tilt table test) is a class II indication for pacing.<sup>58</sup> The two conditions where a pacemaker may be useful in cardiomyopathy are in patients with hypertrophic or dilated cardiomyopathy. In patients with moderate-to-severe heart failure, cardiac resynchronization therapy (CRT) produced significant improvement in Left Ventricle size and function, improved New York Heart Association functional class, exercise capacity, and quality of life.<sup>61</sup> In patients with hypertrophic obstructive cardiomyopathy (HOCM), those with significant LV outflow tract gradient may obtain symptomatic benefit from pacing,<sup>58</sup> although this may not result in improved survival.<sup>58</sup>

## Complications of Pacemakers

Complications related to venous access include hemothorax, air embolism, and pneumothorax. Lead-related complications include perforation, dislodgment, diaphragmatic stimulation, and malposition. Perforation can involve the great vessels, right atrium, or right ventricle. Cardiac tamponade, usually as a result of chamber perforation, is the most ominous implant complication and should be suspected whenever hypotension occurs. Any suspicion of tamponade can be confirmed by hemodynamics or an emergent echocardiogram and definitive treatment via emergent pericardiocentesis should not be delayed. Electrocardiogram during pacing normally should show a Left Bundle Branch Block pattern and any Right Bundle Branch Block pattern raises the questions of pacing lead being in the left ventricle, which is possible in cases of an atrial or ventricular septal defect. However, this configuration (RBBB pattern) is sometimes seen with properly placed right ventricular leads. In clinical practice, a chest radiograph and echocardiogram would usually resolve the issue, although following an algorithm to distinguish right versus left ventricular lead positions when

pacing produces a right bundle-branch block configuration by simple ECG is also possible.<sup>62</sup> Pocket-related complications include hematoma, wound pain, pocket erosion, and infection. In cancer patients, some of whom are severely immunosuppressed, every precaution should be taken to avoid pacemaker infection, because when any infection is strongly suspected, the entire system should be regarded as contaminated and the treatment of choice is complete system removal (pulse generator explant plus transvenous lead extraction), and antimicrobial therapy.<sup>63</sup>

Delayed complications of permanent pacing include venous thrombosis, exit block, insulation failure, and conductor fracture. Exit block manifests as increased pacing thresholds. Insulation failure results in decreased lead impedance. Conduction fracture manifests as increased lead impedance. Definitive treatment for these complications is lead replacement.

### Implantable Cardioverter Defibrillators

The modern implantable cardioverter defibrillator (ICD) is a transvenous system. The device is implanted either subcutaneously, as for a pacemaker, in the left or right deltopectoral area, or subpectorally in thin patients to prevent the device eroding the skin. The ventricular lead tip is positioned in the right ventricular apex, and a second lead can be positioned in the right atrial appendage to allow dual chamber pacing if required and discrimination between atrial and ventricular tachycardias. The ventricular defibrillator lead has either one or two shocking coils. Most new defibrillators have the ability to record intracardiac electrograms. This allows monitoring of each episode of anti-tachycardia pacing or defibrillation. If treatment has been inappropriate, then programming changes can be made with a programming unit placed over the defibrillator site. Current devices use anti-tachycardia pacing. Should anti-tachycardia pacing fail, then energy shocks are given to terminate the ventricular tachycardia.

### Complications

Complications include infection, perforation, displacement, fracture, or insulation breakdown of the leads; over-sensing or under-sensing of the arrhythmia; and inappropriate shocks for sinus tachycardia or supraventricular tachycardia. Psychological problems are common, and counseling plays an important role.

### Indications For ICD Implantation

#### Recommendations for ICD Therapy

The 2002 ACC guidelines<sup>58</sup> indicate that the following are class I indications (ie, conditions for

which there is evidence and/or general agreement that a given procedure or treatment is beneficial, useful, and effective) for insertion of ICD:

- Cardiac arrest due to VF or VT not due to a transient or reversible cause
- Spontaneous sustained VT in association with structural heart disease
- Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiologic study when drug therapy is ineffective, not tolerated, or not preferred
- Non-sustained VT in patients with coronary disease, prior MI, LV dysfunction, and inducible VF or sustained VT at electrophysiologic study that is not suppressible by a class I antiarrhythmic drug
- Spontaneous sustained VT in patients without structural heart disease not amenable to other treatments

Implantation is also appropriate for cardiac conditions with a high risk of sudden death—long QT syndrome, hypertrophic cardiomyopathy, Brugada syndrome, arrhythmogenic right ventricular dysplasia, and after repair of tetralogy of Fallot.<sup>64</sup>

A number of studies of primary and secondary prevention have shown benefit of ICD in patients with cardiomyopathy and depressed left ventricular ejection fraction.<sup>65</sup> In these trials compared with usual care (most commonly amiodarone), ICD significantly reduced mortality.<sup>65</sup> In most of these studies, the EF was <30%. In the Multicenter Automatic Defibrillator Implantation Trial 2 study,<sup>66</sup> patients with prior myocardial infarction and advanced left ventricular function (LVEF of 30% or less) benefited from prophylactic insertion of automatic implantable cardioverter defibrillators (AICD). In this study, compared with conventional medical therapy, defibrillation therapy was associated with a 31% reduction in the risk of death.<sup>66</sup> This has generated a lot of questions as to which patients with coronary artery disease and depressed LV function should receive a defibrillator and at what time in the course of their disease. Studies have included a heterogeneous group of patients, and, in MADIT 2, almost 88% of patients were enrolled at >6 months intervals after their myocardial infarction; patients with NYHA class 4 were also excluded.<sup>66</sup> In further analysis of this study,<sup>67</sup> it was shown that ICD provided a substantial reduction in mortality for patients with remote MI, but almost no survival benefit was found in patients with recent MI (<18 months).<sup>67</sup> In another recent study in which the average time from MI to randomization was 18 days,<sup>68</sup> use of prophylactic ICD implants in high risk patients who recently had an MI and who had low EF (35% or less), prophylactic insertion of ICD did not reduce overall mortality.

In all these studies, the LVEF was taken at one point in time, and in clinical practice, its application post-MI is somewhat difficult for it's known that, by day 90 post-MI, a substantial number of patients who have abnormal baseline ejection fraction and wall motion abnormalities recover their systolic function, with nearly 22% of these patients having complete recovery of function.<sup>69</sup>

### Special Considerations for Pacemakers And ICDs in Cancer Patients

Potential life-threatening malfunction of ICDs and pacemakers has been reported in cancer in patients undergoing radiation therapy.<sup>70,71</sup> The three different manufacturers (Medtronic, Guidant, and St Jude Medical) offer widely different guidelines during radiotherapy.<sup>71</sup> Previous recommendations regarding pacemaker and radiation therapy do not include guidelines for ICD.<sup>71</sup> After completion of radiotherapy full interrogation of pacemakers and ICDs should be carried out.<sup>71</sup>

The defibrillator affects the lives of patient and families<sup>72</sup> and, in terminally ill cancer patients, inappropriate triggering of a defibrillator can be an extremely distressing event for all concerned.<sup>73</sup> A deactivation of the ICD may be appropriate in such cases, but a recent review has suggested that clinicians rarely discuss deactivating ICDs, even in those who are perceived to be near death or those who have expressed a desire to limit life prolonging therapy.<sup>74</sup> For a family to see a loved one shocked from an ICD at the end of life can be very distressing.<sup>74</sup> In this survey of 100 patients who died with an ICD in place, the discussion about deactivation occurred in only 27 patients, of which three-quarters of these conversations occurred within the last few days of the patient's life.<sup>74</sup>

# Congestive Heart Failure

J. Christopher Champion, MD

To promote community awareness of the social impact of heart failure (HF), some have utilized a comparison with cancer outcomes (Table 1) to underscore the gravity of this public epidemic as noted in a recent article by Stewart.<sup>1</sup> He keenly observes that cancer, despite tremendous advances in treatment, persists as one of the most recognized but feared disease states. Recent statistics suggest that, in people younger than 85 years of age, cancer exceeds heart disease as the leading cause of death (Figure 1).<sup>2</sup> This approach to raising cancer awareness has energized the subsequent demand for aggressive screening, research, and treatment programs that have established the necessary support for earlier detection of cancer, as well as the development of more effective therapies. This process would appear to be an exemplary model for other disease states and raises an intriguing contrast to heart failure. Though a complex array of medical and device therapies are available for the management of cardiac disease, the prevalence of heart failure continues to rise as the direct and indirect costs of this disease swell at an alarming rate.<sup>3</sup> Yet, the comparisons between cancer and the heart do not end at the socioeconomic level.

The biologic principles underlying cell survival and apoptosis appear to be just as central to the onset of heart failure as in tumor progression, and pathways for cell proliferation and cardiac myocyte hypertrophy are highly conserved.<sup>4</sup> However, the burgeoning field of biologically targeted therapy seen with cancer has not been paralleled in heart failure research.<sup>5</sup> This is, in

## Death Rates from Cancer & Heart Disease in People <85.

**FIGURE 1** Death rates from cancer and heart disease in people younger than 85. Redrawn based on data from Jemal A et al.

part, due to the potentially exorbitant cost of randomized, multicenter trials, but there has also been a lack of effective, molecular surrogate end points in cardiovascular research that would make these trials meaningful. In the new era of heart failure research, lessons can be learned from the field of cancer biology whereby future drug development can be tailored to specific molecular targets in order to customize medical care for patients in order to maximize benefits and minimize side effects.

## Treatment-Related Cardiomyopathy

### Anthracycline Treatment

#### Background

Anthracyclines are well established as highly efficacious antineoplastic agents for various hemopoietic<sup>6</sup> and solid tumors.<sup>7</sup> However, the cardiotoxicity of these agents has been documented for more than 30 years<sup>8</sup> and remains a potential limitation for many patients with cancer.

#### Clinical Manifestation

Doxorubicin produces a cardiomyopathy clinically indistinguishable from other forms of congestive heart failure. Patients may be asymptomatic in the early stages and may exhibit only minimal signs of cardiac dysfunction. Among the first signs of cardiac abnormality are new-onset resting tachycardia and loss of normal heart variability due to impaired autonomic function.<sup>9</sup> Without intervention, the cardiac impairment may progress, thus leading to advanced symptomatology with rest dyspnea generally being a poor prognostic sign. Cardiac examination of a patient with decompensated cardiomyopathy often reveals jugular venous distension, an S3 gallop, lower extremity edema, and pulmonary rales. Not all of these physical signs may be present in every patient, but the constellation of findings is generally quite suggestive of acute heart failure.

Three discrete types of anthracycline-induced cardiotoxicity have been described in the literature. First, acute or subacute injury can occur soon after anthracycline exposure. This

**Table 1** Comparison of Heart Failure and Cancer Mortality

	Men	Women
Heart failure (Framingham data)	59	45
Breast cancer	—	14
Ovarian cancer	—	45
Colorectal cancer		40*
Lung Cancer		84*

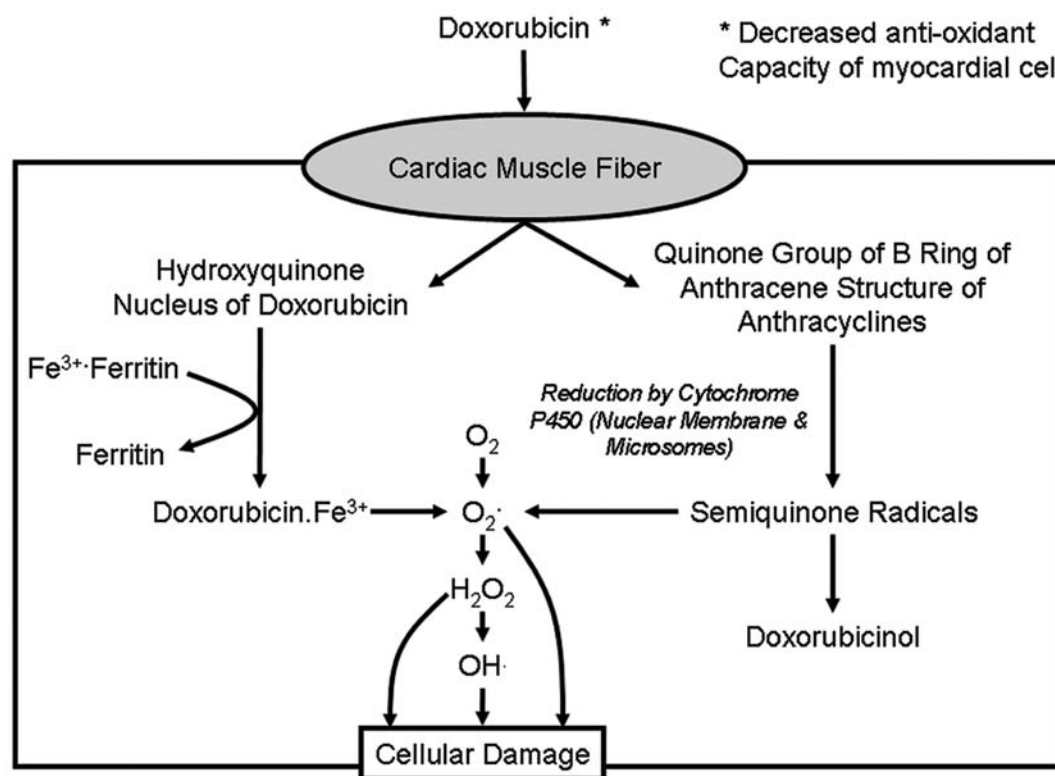

Adapted from Stewart S.<sup>1</sup>  
\*Gender-specific data is not available.

infrequent form of cardiotoxicity may manifest as transient arrhythmias,<sup>10</sup> a pericarditis-myocarditis syndrome, or acute failure of the left ventricle.<sup>11</sup> Second, anthracyclines can induce a chronic form of injury over the course of cumulative exposure that may eventually result in overt cardiomyopathy. This represents the most common type of damage and warrants careful long-term observation for appropriate diagnosis and treatment.<sup>12</sup> Finally, a delayed (or late-onset) anthracycline cardiotoxicity has been well described as a precipitator of left ventricular dysfunction<sup>13</sup> that may manifest years to decades after anthracycline treatment has been completed.<sup>14</sup> Further confounding this presentation is the observation that many individuals may actually have asymptomatic left ventricular dysfunction, thus representing a dormant, subclinical form of toxicity.<sup>15</sup>

Chronic anthracycline-induced cardiomyopathy characteristically presents within 1 year of treatment. Von Hoff describes a large series of patients who developed congestive heart failure secondary to anthracycline-induced chronic cardiomyopathy usually within 231 days after the completion of anthracycline therapy.<sup>16</sup> On the other hand, delayed anthracycline cardiotoxicity may not be apparent for many years. Unfortunately, the concurrent presence of other heart failure risk factors, such as occult hypertension and subclinical coronary artery disease, makes it difficult to precisely ascertain the singular contribution for anthracycline-mediated injury. Nevertheless, anthracyclines are clearly an important independent risk factor leading to both early and delayed congestive heart failure in survivors of cancer.

#### Pathophysiology

The use of doxorubicin, a highly effective anti-neoplastic agent of the anthracycline family, has been extensively studied and is associated with various types of cardiotoxicity. Doxorubicin intercalates into the deoxyribonucleic acid (DNA) and thus interferes with both DNA and ribonucleic acid polymerase activity. The exact mechanism of cardiac toxicity is not known; however, it may be related to the generation of highly reactive oxygen species.<sup>17</sup> These free radicals may lead to the production of superoxide anions and highly reactive metabolites, such as hydroxyl radicals and hydrogen peroxide, resulting in membrane lipid peroxidation and direct damage to the cardiac myocytes (Figure 2). This toxic effect may be amplified by the relatively poor antioxidant defense system of the heart.<sup>18</sup> Thus, there is evidence that free-radical scavengers, such as the bispiperazine dexrazoxane, might provide protection from this toxicity.<sup>15</sup> Doxorubicin may interfere with the sarcolemmic sodium-potassium pump, and may also hinder the mitochondrial electron-transport chain. This

**FIGURE 2** Proposed pathways for formation of reactive oxygen species in anthracycline-induced cardiac injury.

may explain the propensity for toxicity in the mitochondrial-rich myocardium. Doxorubicin might stimulate certain immune responses, and induce myocardial apoptosis.<sup>19</sup> Future research will be necessary to elucidate these mechanisms and clarify the underlying pathology that leads to long-term disease sequelae.

Cardiac function is generally preserved until a critical point of myocardial damage is achieved, at which time ventricular impairment progresses rapidly. This is clearly related to the total cumulative dose.<sup>20</sup> Clinically perceptible doxorubicin-induced cardiotoxicity is rarely observed below cumulative doses of 400 mg/m<sup>2</sup>, but becomes increasingly common with higher dosages (Figure 3).<sup>16</sup> However, subclinical toxicity is much more frequent and occurs at much lower cumulative dosages. This is demonstrated in the study by Bristow and colleagues of patients who had received doxorubicin and underwent evaluation with serial echocardiography, cardiac catheterization, and endomyocardial biopsy.<sup>21</sup> Twenty-seven of 29 patients who received greater than 272 mg/m<sup>2</sup> had endomyocardial biopsy evidence of myocyte damage, and one patient had histologic changes after only 45 mg/m<sup>2</sup>.

#### Evaluation

Noninvasive cardiac imaging cannot distinguish anthracycline-related cardiomyopathy from other causes of left ventricular dysfunction. Indeed,

the same studies used in the routine evaluation of congestive heart failure are generally employed for surveillance during and after anthracycline exposure to identify functional changes from baseline.

The experience with anthracycline chemotherapy has demonstrated that the early detection of cardiotoxicity in preclinical stages can reduce the development of symptomatic cardiac manifestations through modification of the dosing schedule. There is little consensus on which technique is best when monitoring for evidence of anthracycline-induced cardiotoxicity. Endomyocardial biopsy is considered to be the most sensitive and specific test for the detection of cellular injury; studies have shown the characteristic ultrastructural changes are present before cardiac dysfunction.<sup>21</sup> Unfortunately, the procedure is limited, not only by its invasive nature but by the expertise required in biopsy interpretation, making it less desirable in the routine evaluation of patients.

Cardiac imaging for the assessment of ventricular structure and function has long been the standard of care for routine follow-up of cancer patients receiving cardiotoxic chemotherapy, despite the lack of clearly established guidelines concerning type, frequency, and duration of testing. The most common method of monitoring for myocardial toxicity with anthracyclines has

**FIGURE 3** Effect of cumulative anthracycline dose on the development of heart failure.

been the assessment of left ventricular systolic function, either with radionuclide ventriculography or echocardiography. The measurement of fractional shortening and the calculation of left ventricular ejection fraction (LVEF) have been the most frequent measurements. These measurements, however, are preload- and afterload-dependent, thereby affecting their reliability as hallmarks of cardiotoxicity. Previous studies have suggested that diastolic dysfunction may actually be the earliest pathology detected by echocardiography in cardiac dysfunction associated with anthracycline toxicity, suggesting a role for diastolic assessment in the preclinical identification of cardiovascular disease.<sup>9</sup>

The echocardiographic evaluation of left ventricular (LV) diastolic filling patterns by Doppler has become widely available and better characterized in recent years, thereby yielding a reliable and noninvasive measure of diastolic performance. Newer methods involve the measurement of transmitral flow, pulmonary venous flow, and, more recently, tissue Doppler imaging.<sup>22</sup> Tissue Doppler imaging (TDI) is a newer ultrasound modality that records systolic and diastolic velocities within the myocardium at the corners of the mitral annulus. It provides information concerning intramyocardial velocity and, thus, LV mechanics during isovolumic contraction and relaxation.<sup>23</sup> Thus, TDI has been proposed as a reliable marker for early identification of myocardial disease before the overt development of LV systolic dysfunction.

Recently, interest has grown in the utilization of circulating markers that may allude to covert myocardial injury or impending decompensation. In the past decade, several studies have confirmed the usefulness of the measurement of

the B-type natriuretic peptide (BNP), a cardiac neurohormone, in the diagnosis and management of heart failure. Not only is BNP inversely correlated with ejection fraction, but it is also directly proportional to the degree of heart failure decompensation and left ventricular end diastolic pressure elevation.<sup>24</sup> Notably, elevated secretion of natriuretic peptides has been associated with both left ventricular systolic dysfunction<sup>25</sup> and diastolic filling abnormalities<sup>26</sup> in doxorubicin-treated patients. Transient increases in BNP are seen after administration of a single dose of anthracycline, but the patients with sustained elevation appear to have the greatest risk for developing cardiotoxicity.<sup>27</sup> BNP has also been shown to be elevated prior to the development of LV dysfunction in patients undergoing high-dose therapy and hematopoietic stem cell transplantation.<sup>28</sup> Other biomarkers for early doxorubicin cardiotoxicity, such as cardiac troponins I and T, have recently been shown to be elevated prior to changes in LVEF and before the appearance of cardiac symptoms.<sup>29,30</sup> Such testing is minimally invasive and inexpensive, yielding an excellent means for longitudinal monitoring if further research clearly establishes the utility.

#### Treatment

Patients who develop congestive heart failure are given standard treatment according to the guidelines of the American College of Cardiology/American Heart Association and the Heart Failure Society of America.<sup>31,32</sup> Our practice and formal recommendation is the use of angiotensin converting enzyme (ACE) inhibitors and  $\beta$ -blockers to treat most anthracycline-associated congestive heart failure. Specific drug regimens are dictated by disease severity, renal function,

and level of symptoms, but they may include a variety of oral and intravenous agents, including vasodilators, nesiritide, inotropes, and pressors as indicated. In patients with heart failure who are black or who have significant renal insufficiency, the combination of nitrates and hydralazine may be employed. Depending upon the prognosis from the patient's cancer, device therapy such as biventricular pacemakers and/or defibrillators may be appropriate. Consideration of cardiac transplantation is generally not warranted unless disease-free survival from cancer is at least five years.

Observational data from our institution supports the long-term continuation of ACE inhibitors and  $\beta$ -blockers is necessary for maintenance of cardiac compensation. Withdrawal of heart failure therapy for chemotherapy-induced cardiac dysfunction at our institution has been shown to commonly result in relapse of heart failure symptoms (New York Heart Association classification) as well as a recurrent decline in left ventricular ejection fraction (Figure 4).<sup>33</sup>

Cardioprotective agents have been developed; however, clinical practice guidelines do not recommend their routine use.<sup>34</sup> Dexrazoxane can be considered for use in breast cancer patients who are receiving more than 300 mg/m<sup>2</sup> of doxorubicin, but this has not been a habitual practice at our institution. Theoretically, if the cardiac complications resulting from anthracycline exposure could be reduced or prevented, higher and potentially more effective doses could be considered. Furthermore, avoidance of cardiotoxicity may preserve alternative therapeutic options should cancer recur in a patient. On a broader scale, such preventative strategies may have favorable economic implications given the annual cost of treating patients with chemotherapy-induced congestive heart failure.<sup>35</sup>

#### Summary

Certainly, the management of patients with anthracycline-induced cardiomyopathy can pose various dilemmas to oncologists and cardiologists alike. Nevertheless, irrespective of the stage at which it is recognized, the therapeutic tactic remains consistent; that is, to employ appropriate medical therapy that may stabilize the cardiac disease as soon as possible. By accomplishing this task effectively, patients may go on to receive further cancer treatment before disease progression negatively impacts their options and outcomes.

#### Trastuzumab

##### Background

Herceptin (Genentech, South San Francisco, CA) (trastuzumab) is a monoclonal antibody effective against breast cancers that overexpress the receptor Her-2/neu (*erb-B2*), a characteristic

Mean LVEF/NYHA in Response to Chemotherapy and ACE-I/Beta Blocker Therapy

FIGURE 4 Response to initiation and withdrawal of heart failure medication in chemotherapy-induced cardiac dysfunction.

present in about 27% of all breast cancers, through its inhibition of tyrosine kinase. Herceptin used in combination with first-line chemotherapy, including doxorubicin, has been associated with significantly longer time to disease progression, higher response rate, and overall significantly improved survival rates, representing a major advance in therapy for metastatic breast cancer. Importantly, this efficacy has been coupled with a good tolerability profile.

Herceptin alone is infrequently associated with significant cardiomyopathy. However, the incidence of cardiomyopathy has been reported to be as high as 28% in the Herceptin Pivotal Trial (Table 2) among patients who received the combination of Herceptin and anthracyclines.<sup>36</sup>

Clinical Manifestation

As with other cardiac complications of cancer therapy, the precise incidence of trastuzumab-related events is limited by the retrospective nature of their collection and the fact that there is a diminished tendency to report milder, non-specific symptoms. Furthermore, to be able to understand the true significance of trastuzumab-related events, it is important to determine the baseline incidence of systolic dysfunction as well as the influence of other clinical syndromes unrelated to trastuzumab cardiotoxicity, such as sepsis or pulmonary embolism.

Most reported trastuzumab-related cardiac events appear to be asymptomatic decreases in

left ventricular ejection fraction. However, when symptoms do occur, they initially tend to be milder in severity and include nonspecific dyspnea, tachycardia, and, occasionally, chest pain. Without appropriate recognition and intervention, symptoms may progress to more advanced stages of heart failure. The clinical findings are identical to those for other causes of cardiomyopathy and are detailed in the prior section for anthracycline-induced cardiomyopathy.

Pathophysiology

As with anthracyclines, the underlying mechanism for this observed cardiomyopathy has not been fully explained, but several hypotheses have been offered. One such theory proposes a “sequential stress” phenomenon that is produced by Herceptin exposure superimposed on the previous or concurrent damage of doxorubicin or other preexisting cardiac disease.<sup>37</sup> Such explanations offer a framework for understanding the concept of this process, but it is laboratory research that has yielded greater insight into a potential cellular basis for this theory. For instance, Chien and colleagues have shown that *ERBB2* knockout mice can develop a dilated cardiomyopathy with impaired systolic and diastolic function in response to hemodynamic stress.<sup>38</sup> Conversely, overexpression of BcL-xL can lead to rescue through the salvage pathway, suggesting that the *erb-B2* myocyte survival pathway may lead to a modifiable predisposition to heart failure.

Such research into the pathophysiology has yielded important findings that may also allude to the regulation of cardiac myocytes. The epidermal growth factor (EGF) signaling system appears to have a vital role in cardiac growth and development. EGF ligands, such as the neuregulins (NRG) seem to mediate interactions between the endothelial cell and the myocyte. The neuregulins promote stabilization of structural proteins and can lead to attenuation of myocyte death.<sup>39</sup> Furthermore, NRG-*erb-B2* signaling is important not only for cardiac function under normal conditions but also for attenuation of stress-induced myocyte apoptosis.<sup>40</sup> Therefore, trastuzumab, through its effect on *erb-B2*, may down-regulate this essential pathway and impair the counter-regulatory mechanism for preserving cardiac function (Figure 5).

Evaluation

The identification of trastuzumab -induced cardiotoxicity is similar to that used for the monitoring of anthracycline treatment by noninvasive cardiac imaging. Please see “Evaluation” above for further information.

Treatment

Herceptin has an FDA warning for cardiomyopathy and, historically, has not been administered to patients with preexisting LV systolic dysfunction. Traditionally, patients without prior cardiac dysfunction who developed overt heart failure or asymptomatic declines in LV systolic function were denied further trastuzumab treatment. Although congestive heart failure occurring in patients treated with trastuzumab may be moderate or severe, the majority of patients at our center who develop congestive heart failure tend to improve with standard treatment. In fact, the use of angiotensin converting enzyme-inhibitors and  $\beta$ -blockers appears to be quite important in reversing symptomatic and asymptomatic LV dysfunction related to trastuzumab therapy. Our experience has shown that withdrawal of such therapy may lead to recurrent left ventricular dysfunction and relapse of symptoms. Based on observational data from the M. D. Anderson Cancer Center, certain patients with metastatic breast cancer may be safely rechallenged with Herceptin after heart failure has been stabilized with the use of standard HF therapy, especially angiotensin converting enzyme-inhibitors and  $\beta$ -blockers. If clinical benefit from treatment with trastuzumab has been observed then reinitiation must be seriously considered after the risks and benefits of continued use of trastuzumab are thoroughly discussed with the patient. If trastuzumab has been discontinued because of cardiac dysfunction yet symptoms respond to treatment, then resumption of trastuzumab is acceptable with close observation for signs and

Table 2 Incidence of Cardiac Dysfunction according to Background Chemotherapy

symptoms of heart failure. Routine cardiac imaging and regular clinical assessment should also be performed.

## Ischemic Cardiomyopathy

### Background

Despite the proliferation of therapeutic interventions for numerous cardiovascular conditions, coronary heart disease continues to be the most common cause of death in the United States and remains the principal reason for heart failure. Ischemic heart disease is identified as the primary etiology for approximately two-thirds of the 5 million heart failure patients in this country. While cancer is observed in a much smaller subset of this group, coronary disease continues to be an exceedingly common comorbid condition that not only complicates therapy, but also often leads to death during the course of treatment for malignancy.

Thus, the effective management of the cancer patient requires careful attention to the signs and symptoms that may signal cardiac decompensation related to myocardial ischemia. The specific issues surrounding the diagnosis and treatment of chronic or acute ischemic syndromes are addressed in another chapter of this book. However, it is worth reiterating that there is a significantly elevated risk for coronary heart disease in cancer patients due to the preponderance of risk factors in this population and to the concurrent existence of conditions that can potentiate ischemia (such as anemia, hypoxia,

and increased myocardial demand). Additionally, several chemotherapeutic agents can actually induce coronary events through vasospasm, thrombosis or other less understood mechanisms. As in non-cancer patients, single or multiple ischemic insults can lead to left ventricular dysfunction requiring medical therapy and/or revascularization to restore compensation. However, many issues unique to cancer patients can complicate the clinical management decisions. These will be discussed in detail in this chapter.

### Clinical Manifestation

There is no set pattern for the presenting clinical syndrome of ischemic cardiomyopathy, and this appears to be particularly true of those patients who also have active neoplastic disease. Typical anginal symptoms may not necessarily be noticed prior to presentation with overt heart failure decompensation. Furthermore, misdiagnosis of heart disease may be promoted by the vague presenting complaints that are often attributed to coexisting medical conditions. For instance, general fatigue is a common symptom related to both the presence of cancer and to its treatment with chemotherapy. Similarly, dyspnea may be attributed to the anemia often seen with hematologic malignancies or with myelosuppression from cancer treatment. And many other comorbid conditions such as obstructive lung disease or severe cachexia can confound both the history and physical examination. It is not surprising that the earliest stages of heart failure may go unnoticed, even in experienced hands, and

diagnosis may be made “incidentally” when declines in left ventricular ejection fraction are revealed on screening imaging studies.

These things said, the greatest diagnostic yield may be obtained from a carefully performed evaluation that collects multiple elements of the classic constellation of signs and symptoms. Hallmarks of heart failure caused by ischemic myocardial dysfunction and recurrent ischemia/infarction can dominate the clinical picture, especially at advanced stages of presentation. Under such circumstances, suggestive symptoms include exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, fatigue, weight gain, lower extremity edema, and activity tolerance, as well as typical anginal chest pain with radiation and associated symptoms that are relieved with rest or nitroglycerin.

The differentiation of heart disease from other diseases is often made difficult by the frequency with which concurrent illnesses appear in cancer patients. Pulmonary embolism, pericardial disease and pneumonia can all present with varying degrees of dyspnea and chest pain, and each has a dramatically different therapeutic course compared to ischemic cardiomyopathy. Additionally, esophageal disease is not uncommonly observed and may be indistinguishable upon initial presentation.

### Pathophysiology

A detailed discussion of the progression of atherosclerotic disease to eventual cardiac dysfunction is beyond the scope of this chapter. Suffice it to say that the process has been well described in a number of animal and human studies. Nevertheless, there are several important points to be made about the coronary pathophysiology as it pertains to the cancer patient:

The underlying mechanism of disease is frequently identical to that seen in other patients with ischemic cardiomyopathy. That is, the disease may be initiated/propagated by a localized infarct with subsequent diffuse fibrosis, areas of dysfunctional ischemic myocardium, or a combination of these.

Several chemotherapeutic agents, such as the antimetabolite 5-fluorouracil, may elicit ischemic symptoms.<sup>41</sup> Usually, the ischemia is reversible with cessation of the agent and initiation of anti-anginal medical therapy. Underlying coronary artery disease (CAD) is not necessarily a prerequisite to the development of symptoms, but the incidence is higher in those with preexisting coronary disease (1.1% in those without CAD and 4.5% in patients with CAD).<sup>42</sup> Several mechanistic theories have suggested a metabolite that is directly toxic to the myocardium, an autoimmune process, thrombogenesis or inducible vasospastic coronary ischemia.

Radiation has a unique potential for the initiation of coronary vascular disease with an increased risk of death due to ischemic events in patients treated for Hodgkin's disease and breast cancer (see "Effects of Radiation Therapy" below).<sup>43</sup>

Cancer patients commonly exhibit a variety of triggers that may precipitate an acute coronary syndrome, such as anemia, hypoxia, hypotension, infection, up-regulated markers of inflammation, and the need for transfusion of blood products. If these factors are not addressed, recurrent ischemic insult and cardiac decompensation may result.

## Evaluation

The evaluation for ischemic disease in the cancer patient is performed using the same methods for non-cancer patients. The history and physical examination may help to identify the presence of suggestive features; however, as noted previously, atypical presentations with non-specific symptoms are quite common. Assessment of global function and regional wall motion by echocardiography or radionuclide ventriculography can allude to areas of anatomic coronary involvement. The decision to pursue further ischemic assessment by invasive or noninvasive imaging should be tempered by the clinical features of comorbid conditions, such as cancer prognosis or general state of illness. At our institution, the needs of the individual patient are taken into consideration and appropriate treatment options such as revascularization are discussed in the context of expected risk/benefit ratio. Factors, such as bleeding risk due to thrombocytopenia or to metastatic brain lesions, for example, are carefully weighed beforehand. A multidisciplinary discussion amongst healthcare providers is often performed to clarify such issues before proceeding with extensive evaluations. Under these circumstances, appropriate candidates will enter a workup that may ultimately culminate in coronary revascularization through percutaneous or surgical means. On occasion, myocardial perfusion imaging or stress echocardiography may be used as a risk assessment tool in the preoperative setting with deferment of cardiac catheterization unless large areas of ischemia are identified.

## Treatment

When possible, identification and treatment of a reversible etiology is important for the acute and long-term survival of these patients, as demand ischemia is a common problem throughout the course of cancer treatment. Importantly, the medical management of patients with large areas of hibernating myocardium remains suboptimal compared to revascularization strategies.<sup>44</sup> As with other cardiomyopathies treated at our

institution, patients are given standard therapy according to the guidelines of the American College of Cardiology/American Heart Association and the Heart Failure Society of America.<sup>31,32</sup> This generally includes not only angiotensin converting enzyme inhibitors and  $\beta$ -blockers, but also 3-hydroxy-3-methyl-glutaryl-Coenzyme A reductase (HMG-CoA) inhibitors, nitrates and diuretics as indicated. When permissible by bleeding risk and platelet count, aspirin and/or clopidogrel are used. Provided that longevity is expected beyond six months, device therapy with defibrillators or pacemakers is also considered.

## Valvular Heart Disease

### Specific Disease Entities

While there are several diseases listed below that may lead to valvular heart disease, these entities also may lead to heart failure through other mechanisms. These various syndromes are described in detail separately.

#### Carcinoid Heart Disease

**Pathophysiology** Carcinoid tumors are generally rare (1.2 to 2.1 per 100,000).<sup>45</sup> Cardiac involvement may occur in more than 50% of patients diagnosed with carcinoid syndrome, a constellation of symptoms that may include flushing, bronchospasm, and secretory diarrhea. Carcinoid tumors can lead to cardiac valvular disease through the action of peptides that induce the formation of fibromuscular plaques, thereby disrupting valvular integrity. The precise mechanism for plaque creation is somewhat uncertain but may involve several potential mediators of injury including serotonin, 5-hydroxytryptophan, histamine, prostaglandins, bradykinins and tachykinins. Observational data indicates that serotonin levels are higher among carcinoid patients who demonstrate cardiac involvement, compared to patients without cardiac involvement. Such an association implies causality, but does not exclude the role of other cytokines in the pathogenesis.<sup>46</sup>

Mediator release into the hepatic vein from metastatic liver disease predisposes patients to right-sided cardiac lesions. The margins and distal portions of the tricuspid leaflets are often thickened, and involvement of the chordae tendineae may also be seen. Similarly, the pulmonic valve shows thickening and retraction. However, when the primary or metastatic tumor is in the lung, mediators are then released directly into the pulmonary venous bed, thereby bypassing inactivation within the lung tissue and predisposing to left-sided valvular lesions.<sup>47</sup> While left-sided lesions are encountered less frequently than those on the right side, when they are present, they are more likely to result in hemodynamic compromise.

The ultrastructure of cardiac plaques has been studied extensively. These lesions are formed of smooth muscle cells embedded in a stroma of acid mucopolysaccharide and collagen, and they lack elastic fibers.<sup>48</sup> The most important consequence of carcinoid plaques is fibrosis of the valves with resultant distortion of the valvular apparatus and ring. Tricuspid regurgitation and pulmonic stenosis are typically seen, but in the case of progressive destruction, a rigid tricuspid valve may be encountered with characteristic hemodynamic abnormalities. Significant pulmonic regurgitation is rare. Stiffening of the right atrium may be noted and contributes to the neck-vein distention commonly seen with the carcinoid syndrome.

The diagnosis of carcinoid syndrome is usually suggested by the clinical features and established by elevation of 5-hydroxy indole acetic acid (5-HIAA), a product of serotonin metabolism. Urinary 5-HIAA provides a dependable biologic marker, not only for the activity of the tumor but also the response to treatment.<sup>49</sup>

**Evaluation** Echocardiography is the most useful noninvasive diagnostic tool for evaluating patients with carcinoid heart disease (Figure 6). Echocardiography not only identifies the valvular abnormality but, when coupled with Doppler ultrasonography studies, can also provide hemodynamic data for estimating the degree of valvular involvement.<sup>50</sup>

Concomitant with the thickening and loss of mobility of the tricuspid leaflets, there is increased flow velocity across the tricuspid valve during diastole. Likewise, a regurgitant jet can be seen in the right atrium during systole.<sup>51</sup> Furthermore, chamber enlargement may also be quantified, where both right atrial and right ventricular enlargement are characteristic.

**Treatment** During the past decade, progress in the management of malignant carcinoid tumors and carcinoid syndrome has resulted in better patient survival. Octreotide acetate (Sandostatin) (Novartis Incorp., New York, NY), the somatostatin analog, is a synthetic octapeptide that binds to subtypes of the somatostatin receptors and inhibits the secretion of bioactive substances that cause the carcinoid syndrome. Treatment with the somatostatin analog relieves symptoms in more than 70% of patients.<sup>52</sup>

Cardiac surgery is the only effective treatment for carcinoid heart disease and should be considered for symptomatic patients whose metastatic carcinoid disease and symptoms of carcinoid syndrome are well controlled. The timing of cardiac operation for carcinoid heart disease remains difficult. No definitive guidelines can be established from the published series to date. Cardiac surgery has been successful in

Carcinoid heart disease. *A*, Thickened, retracted tricuspid valve leaflets (arrow).  
*B*, Tricuspid regurgitation (arrow) shown by color flow Doppler imaging.

**FIGURE 6** Echocardiographic feature of carcinoid heart disease.

reducing or relieving the cardiac symptoms of many patients with carcinoid heart disease. However, review of a small surgical series from the Mayo Clinic suggests a high surgical mortality and incomplete symptom resolution among surgical survivors.<sup>53</sup> Despite the high surgical mortality, the survival among surgically treated patients was better than the survival among patients with similar symptoms related to carcinoid heart disease who were treated medically.

**Effects of Radiation Therapy** Radiation therapy is frequently utilized as an adjunct to chemotherapy or surgery in the treatment of various cancers. Radiation to the thorax can cause damage to the pericardium, myocardium, valves, and coronary vessels, with pericardium being most frequently involved.<sup>54</sup> The risk of radiation-induced cardiac disease is greater in patients who receive high doses of radiation or concurrent treatment with doxorubicin<sup>43,55</sup> as well as in those patients with cardiac risk factors or preexisting coronary artery disease.<sup>56</sup> Preemptive treatment strategies to minimize the effects of cardiac irradiation include subcarinal shielding techniques, lower total radiation doses, and avoidance of concurrent cardiotoxic agents.

The precise incidence of radiation-induced atherosclerosis is difficult to determine due to the high prevalence of preexisting coronary artery disease in the United States, but it has certainly been observed in a number of patients without the traditional risk factors for coronary heart disease,<sup>57</sup> including young adults. The exact mechanism responsible for vascular injury is not clearly delineated but is possibly related to triggered endothelial damage that leads to accelerated vascular fibrosis.<sup>58</sup>

Vascular injury due to radiotherapy may be silent, considering that half of asymptomatic

patients develop new myocardial perfusion defects, possibly due to damage at the microvascular level.<sup>59</sup> Clinically, most symptomatic patients present with angina, dyspnea, or heart failure,<sup>57</sup> though reports of sudden cardiac death have been noted. The mean time interval from radiation treatment to development of coronary heart disease is approximately 82 months according to one study.<sup>54</sup> The management of radiation-induced atherosclerosis is identical to that for atherosclerotic disease due to traditional causes. Both percutaneous intervention and coronary artery bypass graft have been used, though thoracic surgery may pose a particular challenge in these patients due to mediastinal fibrosis and a concomitantly elevated incidence of complications.<sup>57</sup>

Radiation-induced myocardial fibrosis resulting from deposition of fibrous tissues in all three layers of the ventricular wall has also been observed.<sup>54</sup> There is marked alteration in collagen synthesis with increases in collagen as well as increases in the ratio of type I versus type III production.<sup>60</sup>

Similarly, valvular heart disease is commonly seen following radiation treatment due fibrous thickening of cardiac valves with a predilection for left-sided valvular involvement being noted.<sup>58</sup> Only rarely do these patients with radiation-induced valvular disease have clinically moderate or severe dysfunction, with the mean time from radiation to onset of symptoms being approximately 98 months in one observational study.<sup>54</sup> The treatment of valvular disease related to radiotherapy is the same as in the general population.

Radiotherapy may cause fibrous thickening of the pericardium,<sup>58</sup> pericardial effusion, or pericarditis with or without constriction.<sup>54</sup> Pericardial

disease is described in greater detail in another chapter of this book (see Chapter 52, “The Pericardium in the Cancer Patient”).

# Vascular Disease

Daniel J. Lenihan, MD  
Atiar M. Rahman, MD, PhD

The manifestations of vascular disease in patients with cancer can affect any organ and may have a profound influence on overall outcomes. In the general population, arterial and venous thromboembolic disease portends a worse prognosis and is associated with important morbidity, but these complications are even more important in a patient with cancer.<sup>1</sup> Frequently, these patients already have other comorbidities,<sup>2</sup> including immunosuppression and hematologic manifestations, placing them at higher risk of major complications. Thus, optimal therapy for thromboembolic disease, including prevention, is of paramount importance in this particular group of patients. This chapter focuses on a discussion of vascular disease manifested by aortic aneurysms, arterial thromboembolism, and venous thrombosis. The emphasis is on the clinical manifestations, pathophysiologic mechanisms (if known), diagnostic approaches, and optimal treatment in the cancer patient. Additionally, anticipated developments that may further improve the care of these patients are highlighted. The goal of this chapter is to provide a basis for improved understanding of vascular disease in the patient with cancer, which, it is hoped, will lead to development of improved evidence-based treatment and subsequent outcomes.

## Aortic Aneurysm

The development of aneurysmal vascular diseases is intimately associated with atherosclerosis, which is typically of a diffuse nature. The common feature involves weakened elastin or collagen that leads to poor arterial tensile strength that results in aneurysmal dilatation.<sup>3</sup> In special populations, such as patients with Ehler-Danlos or Marfan syndrome, the defect may be specifically with elastin or collagen. However, in the cancer patient, there is likely a combination of atherosclerosis, owing to the aging population, and other complications of cancer or cancer therapy that predisposes a patient to the development of aortic aneurysms. Radiation therapy, a known contributor to atherosclerosis,<sup>4-7</sup> and disseminated fungal infections leading to mycotic aneurysms are examples of such conditions.

## Clinical Manifestations

The large majority of aneurysms, particularly abdominal aortic aneurysms (AAAs), are asymptomatic and frequently detected at physical examination or during radiologic or ultrasound evaluation. This may occur in up to 75% of patients.<sup>8</sup> The minority of patients will develop abdominal, flank, or back pain if an AAA is present and may have early satiety, occasionally nausea and vomiting, or, uncommonly, ureteral obstruction owing to local compression. However, since these are also manifestations of intra-abdominal malignancy, an unwary physician might miss them. Acute rupture, an immediate life-threatening condition, may occur in up to 20% of cases and results in death more than 50% of the time.<sup>9,10</sup> This may initially manifest clinically with retroperitoneal bleeding and resultant physical findings (psoas sign), which demand immediate recognition. Additionally, thrombus or atheromatous material may embolize distally and patients may develop livido reticularis, renal insufficiency, or blue toe syndrome as a result. Because cancer patients may have mycotic aneurysms in a variety of locations, other manifestations of embolic phenomenon may be evident in the tissues subtended by the aneurysmal segment. Thus, a high degree of suspicion is necessary to detect these serious conditions by both physical examination and radiologic examination (Table 1).

## Pathophysiologic Mechanisms

The etiology of aneurysmal disease in general is multifactorial, with genetic predisposition and atherosclerosis, as well as other vascular risk factors (such as hypertension or hyperlipidemia) being most commonly associated. In the patient with cancer, other factors may predominate. Radiation therapy enhances the atherosclerotic process in cancer patients, and this is an important risk factor.<sup>5</sup> For instance, in patients with lymphoma who receive mantle radiation to great vessels, the incidence of significant vascular disease appears to be increased.<sup>4</sup> Additionally, patients with breast cancer have an increased incidence of atherosclerosis and a higher than

expected mortality.<sup>11</sup> Likewise, immunosuppression from chemotherapy increases the risk of disseminated fungal infections in cancer patients. Certain fungal infections, such as aspergillosis and mucormycosis, are angioinvasive and can result in aneurysmal changes in any vessel in the body (Figures 1 and 2).<sup>12</sup> The final common pathway for development of aneurysmal disease is insufficient elastin, collagen, or both that results in a weakened vessel wall. Once this process produces dilatation and resultant increased wall tension it will continue to progress. Ultimately, rupture is the end result if uncontrolled.

## Diagnostic Approaches and Optimal Treatment

The increasing age of the population in general and specifically those being diagnosed with cancer has led to the more common occurrence of multiorgan disease. AAAs are more common in the elderly, and the concomitant occurrence of these two potentially lethal diseases always presents a therapeutic dilemma regarding the priority

**FIGURE 1** Two computed tomographic images of a ruptured mycotic aortic aneurysm in a patient with underlying atherosclerosis and hematologic malignancy. The *top image* indicates the area of rupture (*white arrow*), and the *bottom image* indicates the resultant pseudoaneurysm (*hatched white arrow*).

**FIGURE 2** Two computed tomographic images indicating a right pulmonary artery mycotic aneurysm that developed in a patient with a prolonged fungal illness. The *arrows* indicate the aneurysm.

of treatment. Intra-abdominal or thoracic malignancy may be discovered unexpectedly at laparotomy for elective treatment of an AAA and vice versa. The incidence of coexistence ranges from as low as 0.5% to as high as 22% depending on the patient population. Of note, in one study, 22% of patients were found to have abdominal malignancy at the time of AAA repair.<sup>13,14</sup>

Although it is generally agreed that both lesions should be treated to achieve optimal life expectancy, significant uncertainty revolves around whether to treat them simultaneously or as staged procedures. A risk of postoperative rupture of the aneurysm exists when the malignancy is resected first. On the other hand, contamination by gastrointestinal or urinary tract contents may infect the prosthetic graft during simultaneous surgery. Additionally, delaying necessary cancer surgery for approximately 2 months to allow recovery after aneurysmectomy may result in a poorer cancer outcome.

The general principles of surgical approaches for concomitant AAA and intra-abdominal cancer depend on (1) the urgency of the operation, (2) the site and staging of the malignant lesion, (3) the size and location of the aortic aneurysm, and (4) the projected long-term survival of the patient. Aneurysms over 6 cm in diameter pose a greater threat for rupture to the patient and should be treated, initially or simultaneously, in view of the high risk of rupture. This may include a percutaneous repair with a stent graft placement (Figure 3). In many situations, this may be an ideal choice owing to comorbidities.<sup>15</sup> On the other hand, aneurysms of less than 5 cm are usually not life-threatening, and unnecessary reparative surgery may significantly delay the treatment of cancer. For AAAs between 5 and 6 cm in diameter, a multidisciplinary approach to address relative risks would be recommended to determine a strategy. Simultaneous resection, by way of segregated approaches, is useful in some patients with early intra-abdominal cancer. However, eventually both lesions must be resected for improvement of the long-term survival.<sup>16</sup> When both lesions are complicated, a case for simultaneous treatment may be appropriate.<sup>17</sup> Many authors

**FIGURE 3** A, An abdominal aortogram showing the AneuRx (Medtronic Vascular, Santa Rosa, CA) stent graft with the cephalic portion deployed just below renal arteries (*white arrow*) and the caudal end anchored in the common iliac arteries. Proximal stenosis of the left internal iliac artery is noted. B, A cartoon depiction of the AneuRx stent graft.

believe that simultaneous AAA repair and resection of an associated, unexpected abdominal neoplasm can be safely performed in most of the patients, sparing the need for a second procedure, except for malignancies requiring major surgical resections.<sup>18</sup>

In patients who are considered too ill for an open AAA repair, endovascular grafting may be a valuable tool in simplifying simultaneous treatment or in staging the procedures with a very short delay.<sup>19</sup> Since the approval of endoluminal grafts for treatment of AAA, endoluminal aortic repair has gained increasing popularity as an alternative to traditional open surgery in the setting of associated malignancy and multiple comorbid conditions. However, despite well-documented, good, early results and the benefits of endoluminal stent graft repair of AAA,<sup>20</sup> the role of endovascular stent grafting in patients with challenging medical and anatomic problems remains a developing area. Some concern has been expressed regarding technical failure and the durability of endovascular grafts, although, overall, the reports are promising.

Many patients with AAA may also have aneurysms at multiple sites within the aorta, for example, thoracoabdominal (TAA) and aortoiliac aneurysms.<sup>3,21</sup> Repair of TAA presents additional challenges secondary to oblige intraoperative visceral, renal, and spinal cord ischemia. Various novel operative techniques for sequential revascularization and reconstruction have been attempted.<sup>22</sup> Others have reported success with endovascular treatment of TAA combined with a simultaneous open AAA repair. In general, patients with at least one of the following categories are considered to be at high risk: age more than 80 years, renal insufficiency (creatinine > 2.0 mg/dl), multivessel coronary artery disease, poor left ventricular function, poor pulmonary reserve, reoperative aortic procedure, a “hostile” abdomen, or an emergent operation.<sup>23</sup> In the case of patients with an aortoiliac aneurysm and a concurrent gastrointestinal tumor, not an infrequent occurrence, there is less of a therapeutic challenge; these patients can be managed as discussed previously, and a multidisciplinary approach is encouraged. With appropriate care to identify high-risk patients, it is feasible to do synchronous conventional resection or use endoluminal techniques.

In summary, the concurrent presence of aortic aneurysmal disease and cancer is a not infrequent occurrence and presents a therapeutic challenge. The open repair of AAA continues to evolve with incorporation of less invasive methods for surgical exposure. Endovascular treatment presents an appealing alternative and will likely continue to develop as a preferred treatment for this condition. In cancer patients, as in the general population, the therapeutic decision

remains an individualized approach with a multidisciplinary input recommended to explore the best therapy for the patient.

### Arterial Thromboembolism

The incidence of de novo arterial thromboembolic phenomenon is much lower than that of thrombotic events in the venous system; however, the risk is several-fold higher in cancer patients compared with the general population.<sup>24</sup> This high incidence may be attributable to the general inflammatory condition associated with cancer<sup>25,26</sup> or may be the result of cancer therapy. Atherosclerosis is again the principal culprit when arterial insufficiency is noted; however, in the present and future of cancer therapy, in which antiangiogenesis is a focus, the risk of arterial insufficiency or thrombosis is likely to be increased.<sup>27</sup> An increased awareness and attention to arterial thrombotic events are therefore necessary. There is no better example to illustrate this point than the issues related to rofecoxib and celecoxib, which revealed increased serious arterial thrombotic events in cancer prevention trials.<sup>28–30</sup>

### Clinical Manifestations

The complications related to arterial thromboembolism differ significantly from those related to venous thrombosis, mostly owing to the organs supplied by the respective tissues. This could include unstable angina, acute myocardial infarction, stroke, arterial insufficiency, ischemic colitis, and progressive renal insufficiency in specific clinical situations (Table 2). Disseminated intravascular coagulation and marantic endocarditis (Figure 4) are late-stage manifestations of these processes in cancer patients.<sup>31</sup>

### Pathophysiologic Mechanisms

In contrast to altered blood flow that may result in venous stasis, arterial thrombosis typically stems from endothelial injury and platelet activation, especially in the presence of atherosclerosis.<sup>32</sup> Platelet activation, rather than inherited hypercoagulability, plays a dominant role in arterial thromboembolism. This may explain the increase in arterial thrombosis in patients with cancer since disorders of platelet number and function

**Table 2** Manifestations of Arterial Thromboembolism in Cancer Patients

**FIGURE 4** Echocardiography indicating marantic endocarditis (white arrow), with the left ventricle (LV), mitral valve (MV), right ventricle (RV), and left atrium (LA) indicated in a patient with multiple embolic phenomena or events.

are common in these patients. Arterial thrombosis tends to occur more commonly in hypertensive patients at sites of turbulent blood flow, primarily owing to endothelial injury associated with shearing forces at points of narrowing and branching in the arterial tree. Other pathogenetic mechanisms for arterial thrombosis and thromboembolism include nonbacterial endocarditis,<sup>33</sup> autoimmune vasculitis, aortic aneurysms, the presence of mechanical prosthetic valves, sustained spasm of arteries, precipitation of cryoglobulins or other abnormal proteins in small arteries, direct tumor invasion of arteries, fragmentation and embolization of intracardiac or intra-arterial metastases, and spontaneous arterial thrombosis owing to hypercoagulability.<sup>34,35</sup> Growth factor administration may stimulate atherosclerosis<sup>36</sup> or a hypercoagulable state.<sup>37</sup> It should be noted that hyperhomocysteinemia and the antiphospholipid syndromes are risk factors for both arterial and venous thrombosis (Table 3).

### Diagnostic Approaches and Optimal Treatment

Diagnostic approaches to arterial embolic phenomenon in the cancer patient require a high level of suspicion. At times, the ischemic tissue is plainly evident and diagnostic strategies are

**Table 3** Pathophysiologic Mechanisms for Arterial Thromboembolism in Cancer Patients

obvious. Common locations for arterial thrombi include the cerebral vasculature (stroke), coronary arteries (myocardial infarction or unstable angina), mesenteric arteries (ischemic bowel), and renal arteries (renal insufficiency with casts). These conditions are discussed in greater detail in other sections of this text. In many other clinical situations, the diagnosis of arterial embolism may not be as obvious and frequently eludes diagnosis until there is marked deterioration. For instance, worsening hypertension or proteinuria may be an early indicator of arterial embolic disease to the renal arteries. Livido reticularis, a characteristic rash usually apparent on the lower extremities, may be a harbinger of ischemic vascular injury. Typical risk factors for vascular disease, which are commonly present in those who develop embolic phenomenon, likely contribute in a significant manner.

Various methods of diagnosis and treatment of these conditions have been discussed elsewhere in this text (see Chapter 5). Therapeutic approaches should therefore include aggressive vascular risk factor modification with lipid reduction therapy (particularly statins), control of diabetes and hypertension, and an exercise program. Acetylsalicylic acid and clopidogrel are the mainstays of therapy to prevent recurrence. In selected patients, warfarin-based therapy may be chosen; however, there is an associated increased bleeding risk to consider. In patients with critical limb ischemia, revascularization may be necessary by the usual surgical or percutaneous techniques, and, in general, these approaches are effective. The key for success in management involves prevention of these end-organ manifestations.

It is being recognized that cancer therapy-induced arterial thrombosis may be a separate entity to consider. For example, the results from randomized controlled studies show that patients with colorectal cancer receiving bevacizumab (Avastin) in addition to 5-fluorouracil infusional therapy had a twofold higher risk of serious arterial thromboembolic events, including cerebrovascular accident (stroke), myocardial infarction, transient ischemic attack, and angina, with an estimated overall risk of 5%. Risk factors causing higher rates of arterial thrombosis include age 65 years and older and a history of arterial thromboembolism prior to bevacizumab therapy.<sup>38</sup> The overall effect of this medication is beneficial in selected cancer patients,<sup>39,40</sup> understanding that the increased risk of thrombosis and developing a strategy for minimizing these complications may lead to an even greater beneficial outcome for patients.

### Venous Thromboembolism in Cancer Patients

Cancer is inextricably intertwined with thromboembolic phenomenon. Thrombi are solid masses

composed of platelets, insoluble fibrin, and entrapped red blood cells that form on flow disturbed endovascular surfaces. By definition, a thrombus is attached to vascular endothelium or to endocardium and a thromboembolus is a detached fragment of a thrombus that is carried forward to occlude a smaller vessel. This association of cancer and thromboembolism was noted 140 years ago by Armand Trousseau. He described phlegmasia alba dolens or migratory thrombophlebitis as a sign of internal malignancy.<sup>41</sup> Recurrent thromboembolism in cancer patients frequently interferes with the management of cancer and the patients' quality of life and may be massive, resulting in death despite early and aggressive treatment. Cancer is usually associated with other known risk factors for thromboembolism, such as old age, extensive surgery, and decreased mobility, all of which increase the risk of thromboembolic disease in these patients. It has been noted, for example, that the incidence of thromboembolism is up to 5 to 7% in breast cancer patients compared with approximately 0.1% in the general population.<sup>42</sup> Furthermore, patients with cancer represent 15 to 20% of all patients with thrombosis; additionally, 10% of patients with venous thromboembolism (VTE) are diagnosed with malignancy in a 2-year period.<sup>43,44</sup> Hence, approximately one-quarter of all VTE are related to malignancy.

### Clinical Manifestations

The symptoms and signs of VTE are caused by obstruction to venous flow, vascular inflammation, or embolization. The most common presentation of venous thromboembolic disease in cancer patients is unilateral leg edema. This is usually associated with redness and warmth in the affected extremity. Many patients with cancer, however, do not complain of pain and calf tenderness. A confounding, or perhaps coexistent, condition is cellulitis, and cancer patients with profound immunosuppression are certainly at higher risk of developing this condition. It is not uncommon that patients may develop bilateral lower extremity edema as a manifestation of VTE, but other conditions, such as congestive heart failure, should be considered in that instance. Additionally, thrombosis may be evident in unusual locations, such as the upper extremity,<sup>45</sup> right atrium (Figure 5), or even the internal jugular veins (Figure 6). The most common clinical manifestation of a pulmonary embolus is sudden onset of shortness of breathing and tachypnea. This may be accompanied by pleuritic chest pain, cough, and possibly hemoptysis. Occlusion of small pulmonary arterioles leading to segmental pulmonary infarction may go unnoticed. On the other hand, obstruction of the main pulmonary

**FIGURE 5** A transesophageal echocardiogram with a thrombus evident (white arrow) attached to the right atrium (RA). Ao = aorta; LA = left atrium. , RV = right ventricle.

artery by a large thromboembolus can cause acute right ventricular failure, cardiogenic shock, and death (Figure 7). Other clinical consequences of venous thrombosis and thromboembolism include pulmonary hypertension, postphlebotic syndrome, and peripheral venous insufficiency (Table 4).

### Pathophysiology of the Coagulation Abnormalities in Cancer

The pathophysiology of thromboembolism in cancer is not clearly understood. It is known that several changes in the coagulation cascade may contribute to this complex phenomenon, resulting in hypercoagulability. In general, the mechanisms involved in thrombus formation include endothelial injury, alterations in blood flow, or hypercoagulability. Normal hemostasis is a balance between opposing coagulative and fibrinolytic mechanisms within intact blood vessels. Intact vascular endothelium produces coagulation inhibitors such as prostacyclin and endothelium-derived nitric oxide, which inhibit intravascular platelet aggregation. Heparin-like molecules on the endothelial surface combine with the plasma antithrombin III to inactivate thrombin, factors Xa and IXa, and most other

**FIGURE 6** A carotid sonogram showing the right internal jugular vein (Right I J) with a thrombus present (white arrow).

Death

coagulation factors. Another cell surface molecule, thrombomodulin, binds to thrombin. This complex prevents the conversion of fibrinogen to fibrin and activates two other naturally occurring anticoagulants, protein C and protein S, which degrade activated factors V and VIII. Additionally, laminar blood flow without turbulence maintains the platelets in the center and away from the vessel wall, which prevents activation on contact with the endothelium.

Once formed, a thrombus may progress in a variety of stages: (1) the fibrinolytic system may completely degrade the clot, allowing normal blood flow to return, that is, resolution; (2) the thrombus may accumulate more fibrin and platelets and grow along the course of the vessel, that is, propagation (an example is a calf vein thrombus that propagates into the thigh and pelvis becoming high risk of embolism); (3) the thrombus may become incorporated into the vessel wall by the process of fibrosis, that is, organization (an example of this process is postphlebotic syndrome or chronic venous insufficiency); and (4) the thrombus may be partially resorbed despite occlusion of the vessel, resulting in restoration of blood flow, that is, recanalization.<sup>46</sup>

In the specific instance of cancer, neoplastic cells may activate platelets and coagulation proteases by secreting adenosine diphosphate-like activating substances and expressing tissue factor on exposed membrane surfaces.<sup>47</sup> Many cancers generate procoagulants such as tissue factor or enzymes that activate plasma coagulation factors. Levels of protein C and antithrombin III, which are natural anticoagulants, are decreased in malignancy.<sup>48</sup> Tumor necrosis factor and other substances secreted by malignancies induce the release of intracellular tissue thromboplastin into the bloodstream,<sup>42</sup> which promotes thrombin formation. There may be increased turnover of clotting factors such as fibrinogen and factors V, VIII, IX, and XI in patients with malignancy.<sup>49,50</sup> Mucin and the proteases secreted by malignant cells may activate factor X.<sup>51</sup> Thrombocytosis and megakaryocyte hyperplasia are known to be associated with lung, breast, gastric, and ovarian

cancers and in Hodgkin's disease.<sup>52</sup> Furthermore, some substances secreted by various human tumors can directly stimulate the aggregation of platelets.<sup>53</sup> The treatment of cancer may also induce abnormalities in the levels of endogenous anticoagulant factors. Levels of protein C and S may be decreased in breast cancer patients treated with cyclophosphamide, methotrexate, and 5-fluorouracil.<sup>54</sup> Similarly, tamoxifen decreases antithrombin III.<sup>55</sup> Corticosteroids are not only known to decrease the platelet count and the levels of clotting factor VIII–von Willebrand factor complex; they may also inhibit blood fibrinolytic activity<sup>56</sup> and decrease the clearance rate of activated clotting factors by reticuloendothelial blockade.<sup>57</sup> The use of estrogen and progesterone agents promotes thrombosis in patients by decreasing coagulation inhibitors antithrombin III, protein C, and protein S. Furthermore, advanced metastatic disease may induce disseminated intravascular coagulation by unknown causes (Table 5).

As a result of these complex interactions, it is clear that thrombus formation is a multifactorial process, but its predisposition is clinically identifiable. In general, well-known risk factors for the development of VTE include prolonged immobilization (bed rest, stroke, prolonged travel), surgical and nonsurgical traumas (including burns), congestive heart failure, pregnancy, estrogen therapy, age over 50 years, malignancy, a history of previous deep venous thrombosis (DVT), acute infectious disease, and immunologic or inherited disorders, such as protein S, protein C, and antithrombin III deficiency.<sup>58,59</sup>

### Increased Risk of Venous Thrombosis Unique to Cancer Patients

The presence of cancer itself increases the risk of recurrent thromboembolic disease threefold,<sup>60</sup> more so with metastasis.<sup>61</sup> For example, patients with liver and massive retroperitoneal metastases have more thromboembolic events than those without them. In patients with metastatic liver disease, a predisposing factor for the development of thromboembolism may be the impaired

clearance of activated coagulation factors and the decreased synthesis of anticoagulants in the liver.<sup>62</sup> Large retroperitoneal metastases, on the other hand, may increase the risk of thrombosis by mechanical obstruction of the femoral and abdominal vessels.

Similarly, the treatment of cancer may increase the risk of both arterial and venous thromboembolism through a variety of mechanisms,<sup>24</sup> including administration of prothrombotic medications, the placement of long-term venous catheters, and residual mechanical effects resulting from the underlying cancer, as well as the treatment or complications therein.<sup>35</sup>

### Prothrombotic Medications in Cancer Patients

In terms of medications with prothrombotic effects, several are known from clinical experience, although there are likely to be many others in which the association is either not established or not suspected at present. Tamoxifen, for example, widely used in the treatment of estrogen receptor–positive breast cancer, is known to be associated with a several-fold increase in thromboembolism.<sup>63–67</sup> The risk of venous and arterial thromboembolism is even higher in patients receiving tamoxifen in combination with chemotherapy compared with those receiving tamoxifen or chemotherapy alone.<sup>64</sup> This increased incidence of venous and arterial thromboembolic complications is more prevalent in premenopausal patients receiving combination therapy. In addition, postmenopausal women also have a higher incidence of venous thromboembolic complications when receiving tamoxifen and chemotherapy compared with those receiving tamoxifen alone.<sup>64</sup> These data, taken together, may suggest that tamoxifen may be dangerous; however, the recurrence rate of breast cancer is markedly reduced with tamoxifen, and, when taken in context, the benefit from cancer reduction outweighs the risk of thrombosis.<sup>68</sup> Furthermore, newer agents, such as raloxifene, may be superior to tamoxifen regarding thrombosis while still reducing the cancer risk.<sup>69</sup> Similarly, a higher incidence of arterial thrombosis has also been reported with multiagent chemotherapy in patients with breast cancer,<sup>63</sup> but it is still unclear if this is due to the medication or the disease itself. Other medications associated with a higher than expected rate of thrombosis include the use of cytokines and hematopoietic growth factors.<sup>36,37,48,70</sup> Furthermore, the use of high-dose corticosteroids and administration of intravenous contrast medium are recognized risk factors for the development of both arterial and venous thrombosis and thromboembolic events in cancer patients.<sup>71–73</sup> Corticosteroids, especially dexamethasone at a dosage of 80 mg or higher per cycle of chemotherapy, increase thromboembolic

complications.<sup>71–74</sup> Thalidomide, a medication used to treat multiple myeloma, is known to significantly increase the rate of venous thrombosis, and current practice includes prophylactic anticoagulation to prevent this complication.<sup>75–77</sup> A burgeoning area of cancer therapy includes antiangiogenic medications intended to decrease the blood supply to specific tumors. It stands to reason that this therapeutic aim will likely have an important impact on vasculature throughout the body. In fact, early studies have confirmed this suspicion. Bevacizumab has been associated with increased thrombotic events and substantial hypertension, although it appears to be effective in reducing cancer recurrence.<sup>78,79</sup> New chemotherapy agents or combinations of established medications should continue to be monitored for an increased risk of thromboembolism.

### Catheter-Related Venous Thrombosis

The placement of indwelling long-term central venous catheters is common in cancer patients to aid in administration of chemotherapy, antibiotics, or other drugs. However, an indwelling central venous catheter substantially increases the risk of thromboembolism. The reported incidence of symptomatic catheter-related DVT in adult patients varies from 0.3 to 28.3%.<sup>80,81</sup> These patients are prone to two kinds of catheter-related thromboembolism: sleeve thrombi that build around the indwelling catheters<sup>82</sup> and intraluminal thrombi that build inside the lumen of the catheter.<sup>83</sup> Potential risk factors include the size of the catheter, the position of the catheter, and the site of insertion.<sup>84</sup> The type of chemotherapy appears to influence the rate of catheter-associated thrombosis. Infusion of sclerosing chemotherapy through the catheter increases the risk of thrombosis compared with those patients treated with nonsclerosing chemotherapy.<sup>85</sup> Catheter-associated venous thrombi may partially or completely occlude the blood vessel. In symptomatic patients, swelling or pain of the arm or neck, erythema and numbness of the extremity, jaw pain, and headache may be the presenting symptoms. The prevalence of pulmonary embolism in patients with an upper extremity venous thrombosis is high, and it is close to that observed in cohorts of patients with lower extremity DVT.<sup>86</sup>

### Mechanical Effects of Cancer Resulting in Thrombosis

There are many potential examples of how mechanical impingement or obstruction may result in venous thrombosis. Certainly, a large pelvic tumor can physically compress the iliac veins, resulting in lower extremity DVT. Any other location in which a tumor results in compression has the potential for a similar thrombotic complication. These include splenic or hepatic

**Table 5** Altered Factors in Malignancy Promoting Thrombosis

<i>Reduced Anticoagulants</i>	<i>Increased Thrombotic Factors</i>

	Reduced reticuloendothelial system
	Thrombin production
	Factor VIII and fibrinogen

vein thrombosis. An extraordinary example of this concept is a superior vena cava (SVC) thrombosis or SVC syndrome, which is an emergent condition. It is caused by direct invasion and/or compression of the SVC, typically from an intrathoracic malignancy (> 90% of cases). Although any cancer involving the intrathoracic lymph nodes may result in compression of the SVC, the most common cause (67%) is related to advanced lung cancer (particularly right upper lobe tumors or those with paratracheal adenopathy), lymphomas (20%), and metastatic solid malignancy (5%).<sup>87</sup> Some patients may present with an SVC syndrome as their first indication of cancer. Rarely, thrombosis related to a central venous catheter may contribute to an SVC syndrome.

The clinical features of SVC syndrome include swelling of the face, neck, and upper arm; cyanosis; and papilledema and may be associated with shortness of breath and cough. It may very rapidly progress to obstruct the airway, necessitating assisted ventilation. Typically, a complete history and physical examination often reveals the diagnosis of SVC syndrome in a patient with known intrathoracic malignancy; however, additional confirmatory tests are performed, including radiography (a widened mediastinum or a mass in the right side of the chest), computed tomography (CT), or magnetic resonance imaging (MRI) of the chest. CT has replaced invasive contrast venography and may guide attempts at biopsy by mediastinoscopy, bronchoscopy, or percutaneous fine-needle aspiration. It should be kept in mind that biopsy presents an increased risk of bleeding in patients with SVC syndrome secondary to elevated central venous pressure. Sputum cytology and biopsy of a palpable supraclavicular node may give diagnostic information in more than two-thirds of patients.

SVC syndrome may progress rapidly in cancer patients and requires prompt workup and treatment.<sup>88,89</sup> Intravenous steroids and local external beam radiation therapy may give rapid relief by reducing the obstructing mass. Chemotherapy and surgery may also be used in appropriate situations as primary management of SVC syndrome.<sup>90–92</sup> Palliative bypasses may be considered for symptoms that do not respond to medical therapy.<sup>93</sup> Survival in patients with SVC syndrome is related to the course of the underlying malignancy, and patients with untreated malignant SVC syndrome survive, on average, less than 30 days.<sup>94</sup>

Inferior vena cava (IVC) syndrome is a poorly characterized complication of intra-abdominal cancer. It has neither been commonly recognized nor adequately described. This syndrome results from occlusion of the IVC, either by external tumor compression (malignant hepatic enlargement, either secondary or primary), intraluminal tumor invasion (hypernephroma, hepatoma, and

adrenal carcinoma), or propagation of thrombotic tumorous material in cancer patients.<sup>95</sup> Clinically, IVC syndrome is characterized by abrupt onset of ascites, bilateral lower extremity edema, and unusual patterns of dilated abdominal wall collateral veins. Up to one-third of patients have thromboembolic complications, but fatal pulmonary embolism is rarely reported. A high index of suspicion must accompany the evaluation of a patient at risk of IVC syndrome. Duplex ultrasonography, CT, or MRI usually yields the diagnosis, and venocavography is rarely needed. Patients with primary or secondary tumoral occlusion of the IVC are difficult to manage with safety and success. When IVC syndrome is identified, prophylactic anticoagulation is recommended. Although patient survival is generally short, life expectancy and treatment depend on the type of accompanying tumor. Nevertheless, their survival may be prolonged by an aggressive surgical approach, chemotherapy, or radiation. Intravascular stenting<sup>96–98</sup> is a rapidly expanding and useful palliative procedural option and will, at least partially, relieve the IVC pressure gradient in these unfortunate patients and provide symptomatic relief by improving lower extremity edema and ascites.

### Diagnostic Approaches and Optimal Treatment

VTE is a common disorder associated with significant morbidity and mortality. In the case of patients with cancer, the concurrent mortality associated with DVT or pulmonary embolism is substantially higher than in those without cancer.<sup>1,99</sup> As a result, accurate diagnosis and treatment are crucial. Physical examination is often inadequate for establishing the diagnosis of VTE,<sup>100</sup> and, in most cases, noninvasive testing is needed as an adjunct to clinical assessment.<sup>101</sup> Venography is the diagnostic reference standard<sup>102</sup>; however, because of its invasive nature and technical difficulty, venography is rarely used for routine clinical evaluation of suspected DVT owing to sophisticated and reliable ultrasound techniques. Color flow venous duplex scanning of the proximal and distal veins performed by skilled operators provides the most practical and cost-effective method for assessing DVT of the proximal and distal lower extremity veins. Current ultrasound technology is able to image calf veins in the large majority of patients. Overall, venous duplex scanning has a very high sensitivity and specificity for the diagnosis of symptomatic proximal DVT (above 90%). This allows initiation or withholding anticoagulation treatment without further confirmatory tests. However, a normal bilateral proximal venous sonogram may not exclude a pelvic source of thrombosis. Even in the presence of objective evidence of pulmonary embolism, compression ultrasonography may

detect DVT of the proximal lower extremity veins only in approximately 50% of patients.<sup>46</sup> Other less commonly used procedures to diagnose DVT include impedance plethysmography (IPG), CT, and MRI. IPG has a sensitivity for proximal DVT of approximately 65%<sup>103</sup> and was used as the initial noninvasive test for patients with suspected lower extremity DVT before the widespread use of venous duplex scanning.<sup>104</sup> The limitations of IPG include its failure to detect nonocclusive proximal DVT and those isolated to the calf veins or occlusive proximal DVT present in parallel venous systems.<sup>105</sup> Less commonly, a thrombus is noted in the cardiac chambers on echocardiography either related to a catheter or other pathology. Ventilation-perfusion scanning is still being used but is certainly being supplanted by CT angiography. Ultrasonography for extremity swelling has excellent sensitivity and specificity, whereas CT for pulmonary emboli and other organ thromboses is well established as the diagnostic procedure of choice.<sup>68,101</sup> The use of magnetic resonance angiography is also increasing but is limited to tertiary care centers.<sup>106–108</sup> Serologic testing with the measurement of D-dimer is very useful in the general population as a screen for thrombus, but the lack of specificity of the D-dimer assay for VTE in cancer patients warrants interpreting positive assay results with caution.<sup>109</sup>

The diagnostic approaches to venous thrombosis in cancer patients are no different from those for patients without cancer. The level of suspicion must be higher, but the techniques are similar. The diagnosis of catheter-associated DVT may be difficult, and Doppler ultrasonography has a lower accuracy in this setting than it does in symptomatic lower extremity venous thrombosis.<sup>110</sup> Therefore, when the suspicion for catheter-associated thrombosis is high, it should be objectively followed by venography or be treated empirically on clinical suspicion. Catheter-associated DVT (intraluminal) can be lysed in most situations (80–95%) with fibrinolytic agents such as urokinase, streptokinase, and tissue plasminogen activator,<sup>111–114</sup> but if there is a complicating line infection, this catheter will likely have to be removed.

Initiating antithrombotic therapy in cancer patients frequently presents a clinical dilemma. A variety of factors may contribute. These include: difficult venous access, increased risk of bleeding associated with warfarin, hepatic and renal dysfunction, thrombocytopenia, and other comorbid conditions are only a portion of the considerations that often complicate therapeutic decisions in patients with cancer. In general, antithrombotic therapy involves the use of thrombolytics, anticoagulants, and antiplatelet medications. Thrombolytic therapy removes an established thrombus, whereas anticoagulants and antiplatelet drugs are mostly used to prevent or limit the propagation of a thrombus. The

treatment of thromboembolism varies significantly depending on which portion of the circulatory system (venous or arterial) is involved; the size and location of the thrombus; the risks of extension, embolization, or recurrence; and the benefits of therapy while balancing the risks of hemorrhage.

Guidelines for antithrombotic therapy for VTE have been published by the Seventh American College of Chest Physicians.<sup>115</sup> Standard treatment for acute VTE traditionally uses low-molecular-weight heparin, unfractionated intravenous heparin, or adjusted-dose subcutaneous heparin, followed by long-term therapy with an oral anticoagulant.<sup>116</sup> The use of unfractionated heparin has been replaced by low-molecular-weight heparin as the first-line treatment in the majority of cancer patients with VTE and cancer, in the hospital or as an outpatient. Long-term oral anticoagulation with warfarin may be complicated by several factors, including drug-drug interactions, malnutrition, nausea and vomiting during chemotherapy, and thrombocytopenia. Additionally, hepatic dysfunction coexisting in cancer patients either from a primary tumor or secondary to chemotherapy may lead to unpredictable levels of anticoagulation, resulting in increased bleeding complications. Recent studies suggest that low-molecular-weight heparin may be more efficient when compared with oral anticoagulant therapy with coumarin for the prevention of recurrent

VTE in patients with cancer who had acute, symptomatic, proximal DVT, pulmonary embolism, or both.<sup>44</sup> Furthermore, low-molecular-weight heparin allows easy dose adjustment, has predictable pharmacokinetic properties, does not require routine laboratory monitoring, and has fewer drug interactions compared with oral anticoagulants. There have also been reports that heparins have antiproliferative, antiangiogenic, antimetastatic effects and that low-molecular-weight heparin may increase the response to chemotherapy and prolong the survival of cancer patients.<sup>117</sup> Thus, secondary prophylaxis with low-molecular-weight heparin may be a more effective and feasible alternative to oral anticoagulant therapy,<sup>44</sup> although the risk of bleeding is not different between the two groups. Very recently, in patients with polycythemia vera, low-dose acetylsalicylic acid has been safely used to prevent thrombotic complications<sup>118</sup> and has been suggested as an alternative option in patients with cancer presenting with paraneoplastic thrombocytosis, who have no contraindications to such treatment.

Recent data suggest that certain anticoagulants might also improve cancer survival rates independently of their effect on thromboembolism.<sup>119,120</sup> New antithrombotic agents, such as oral direct thrombin or long-acting synthetic factor Xa inhibitor, may be useful in cancer patients.<sup>121,122</sup> Furthermore, mechanical treatments, such as compression stockings, used to prevent post-thrombotic syndrome,<sup>123</sup> have value, as well as selected surgical techniques to treat venous ulceration to improve outcomes.<sup>124</sup> In patients with recurrent DVT or in whom the risk of serious bleeding is high, vena cava filters may be employed instead of anticoagulation.<sup>125</sup> It is known that vena cava filters have inherent risks<sup>126</sup> and should be limited to patients with specific contraindications to anticoagulation. Other factors to consider include the life expectancy and quality of life of a cancer patient and the patient's preferences for therapy.

## Conclusion

Vascular disease in a cancer patient represents a unique and special entity. Pathogenesis of various vascular and thromboembolic mechanisms may be a feature of the primary malignancy, related to the growth and metastasis of cancer. Patients undergoing chemotherapy or radiation therapy for cancer also mandate a high index of suspicion for thromboembolic complications, and therapy may need to be carefully considered when compared with the general population.

# Hematologic Complications in Patients with Malignancy

Graeme A.M. Fraser, MD, MSc, FRCPC

Donald M. Arnold, MD, MSc, FRCPC

Agnes Y.Y. Lee, MD, MSc, FRCPC

Hematologic complications are common in patients with cancer and can also complicate and potentially compromise cancer treatment. Furthermore, the morbidity of febrile neutropenic episodes, the risk of hemorrhagic and thrombotic events, and the potential hazards associated with blood product transfusions can further compromise the patients' quality of life. Although some of these clinical problems are due to the malignancy, many are iatrogenic and secondary to treatments for the cancer. Over the past decade, significant advances and technologies have emerged to help guide clinical practice in some of these areas. This chapter provides physicians who care for these patients with a broad overview of the management of secondary hematologic problems in patients with cancer. The topics are organized according to clinical problems that are encountered in daily practice.

## Anemia

Anemia is the most common hematologic problem complicating the management of patients diagnosed with cancer. It is associated with increased morbidity, decreased quality of life, and reduced survival compared with similar patients without anemia. A systematic approach to the evaluation of anemia in this patient population is critical because the differential diagnosis is broad and because multiple causes may be occurring simultaneously. Only after an accurate diagnosis is made can appropriate therapies be administered.

The World Health Organization has defined anemia as a hemoglobin concentration below 130 g/L for men and 120 g/L for women.<sup>1</sup> The prevalence of anemia in cancer patients varies across individual studies, depending on the definition used and the patient population evaluated. Data from a recent meta-analysis found that moderate anemia (hemoglobin 80–110 g/L) occurred in 30 to 90% of patients, most frequently

in those with an underlying hematologic malignancy or a solid tumor at an advanced stage.<sup>2</sup> In addition, anemic patients had poorer overall survival compared with nonanemic patients in 18 of 19 studies included in this analysis. Whether this represents a causal relationship or simply reflects differences in the population studied is not clear. To date, definitive evidence that correcting anemia improves disease-free or overall survival is lacking.

A comprehensive clinical assessment is important when evaluating a patient with anemia. However, laboratory parameters are often more useful when formulating a diagnostic approach. Historically, the two most common approaches have classified anemia according to either the underlying pathophysiologic mechanism (decreased erythropoiesis, increased red blood cell [RBC] destruction, blood loss) or changes in the RBC mean cell volume (MCV) and reticulocyte count (Table 1).<sup>3</sup> Although the

differential diagnosis for anemia is broad, the etiology in cancer patients is usually due to one or more of a few common causes that are associated with the underlying malignancy or its treatment. Cancer-related anemia is a general term used to describe anemia that is due to the underlying malignancy (malignant bone marrow infiltration and anemia of chronic inflammation) and the myelosuppressive effects of cancer therapy (chemotherapy-associated anemia).

## Anemia of Chronic Inflammation

Anemia of chronic inflammation (ACI), also called anemia of chronic disease, is one of the most common causes of anemia in cancer patients.<sup>4</sup> It is characterized by normocytic or slightly microcytic anemia (80–110 g/L), low serum iron, normal or elevated serum ferritin, and preserved bone marrow iron stores; however, about 20% of patients may present with severe anemia (<80 g/L).<sup>5</sup> Clinically, it is often difficult

**Table 1** Common Causes of Anemia

<i>Microcytic Anemia</i> (MCV < 80 fL)	<i>Normocytic Anemia (MCV 80–100 fl)</i>		<i>Macrocytic Anemia</i> (MCV > 100 fl)
	<i>Increased Reticulocyte Count</i>	<i>Decreased Reticulocyte Count</i>	
Iron deficiency* Thalassemia ACD* Sideroblastic anemia	Blood loss Hemolysis Immune hemolysis <sup>†</sup> Nonimmune Intrinsic RBC abnormalities Membranopathies Enzymopathies Hemoglobinopathies Microangiopathy* HUS-TTP	ACD* Renal insufficiency Bone marrow failure* Malignant infiltration Aplastic anemia Pure red cell aplasia MDS Drugs/toxins (including chemotherapy-associated anemia)	Vitamin B <sub>12</sub> deficiency* Folate deficiency* Clonal bone marrow disorders MDS* Hypothyroidism Liver disease Reticulocytosis Alcohol Drugs (hydroxyurea, methotrexate, AZT)

ACD = anemia of chronic disease; AZT = azathioprine; HUS = hemolytic-uremic syndrome; MCV = mean cell volume; MDS = myelodysplasia; RBC = red blood cell; TTP = thrombotic thrombocytopenic purpura.

\*Diseases associated with an underlying malignancy or its treatment.

<sup>†</sup>See Table 4 for classification of immune hemolysis.

to differentiate ACI from iron deficiency anemia. Furthermore, concomitant ACI and iron deficiency are not uncommon in cancer patients, particularly those with gastrointestinal malignancies. The diagnostic approach should emphasize the use of serum ferritin and bone marrow aspirate because serum iron, transferrin, and iron saturation may be reduced in both ACI and iron deficiency and, thus, are generally not helpful. A reduced serum ferritin level confirms iron deficiency and should prompt a search for its cause. In the setting of a normal or increased ferritin, bone marrow aspirate may be required to establish a diagnosis of ACI and/or iron deficiency. In ACI, iron staining is classically normal or increased in bone marrow macrophages and absent in erythroid precursors.

The reduction in bone marrow erythropoiesis in ACI is due to impaired iron regulation, trapping of iron in tissue macrophages, decreased erythropoietin production, and poor erythropoietin responsiveness.<sup>6,7</sup> Although the precise mechanisms have not been fully elucidated, recent evidence suggests a central role for the iron regulatory hormone called hepcidin.<sup>8–10</sup> This 25–amino acid protein is a key regulator of intestinal iron absorption and iron release from tissue macrophages. It is synthesized by hepatocytes and induced by infection or inflammation primarily via cytokine-mediated up-regulation (interleukin-6).<sup>8,11</sup>

### Treatment

The management of patients with ACI or cancer-related anemia is directed at treating associated diseases, excluding other causes of anemia (see Table 1), and maintaining an adequate hemoglobin in patients with symptomatic anemia. Historically, the administration of allogeneic RBC transfusions was the only option for cancer patients with symptomatic anemia; indeed, they remain an important treatment modality today. Newer strategies include administration of recombinant human erythropoietin (rhEPO) and, possibly in the future, infusion of synthetic oxygen-carrying products.

**RBC Transfusions** The indications for RBC transfusion depend on the presence of bleeding or anemia-related symptoms in addition to the absolute hemoglobin concentration prior to transfusion. Since the therapeutic goals are to maintain hemodynamic stability, limit anemia-related symptoms, and prevent ischemic events, the need for transfusion will vary from patient to patient. Setting absolute hemoglobin concentration triggers below which RBC transfusions are indicated are appealing; however, a patient-specific transfusion strategy may be more appropriate than universal RBC transfusion triggers.<sup>12,13</sup> In the absence of randomized clinical trials in

cancer patients, a hemoglobin concentration of 80 g/L is often used as a trigger for RBC transfusions for clinically stable, nonbleeding patients with anemia owing to myelotoxic chemotherapy.<sup>14–16</sup> A review of published clinical practice guidelines for RBC transfusions found that only 1 of 13 guidelines recommended a specific hemoglobin trigger for RBC transfusions and that most others advocated either a range of hemoglobin values based on clinical judgment or clinical judgment alone.<sup>17</sup> One randomized controlled trial in critically ill adult patients admitted to the intensive care unit showed that a restrictive RBC transfusion strategy (transfusion trigger of 70 g/L) was as safe as a liberal transfusion strategy (trigger of 100 g/L).<sup>18</sup> Further studies are needed to determine whether these results can be applied to patients with cancer-associated anemia.

**Erythropoiesis-Stimulating Agents (ESAs)** More recently, recombinant erythropoiesis-stimulating agents (ESAs) have been accepted as a standard alternative to RBC transfusion for the treatment of chemotherapy-associated anemia; the best studied of these agents are epoetin alpha and darbepoetin alpha. Tested in large randomized controlled trials that have been summarized in several meta-analyses, the use of ESAs have been outlined in practice guideline recommendations in both North America and Europe.<sup>19–22</sup> Overall, the administration of an ESA has consistently demonstrated a significant reduction in the need for RBC transfusion (approximately 20–55%) and an increase in the hemoglobin concentration from baseline. Evidence for a positive impact on quality of life is more difficult to demonstrate because studies are generally of poorer quality and show conflicting results.<sup>20–22</sup> No clear benefit has been observed in terms of overall survival, tumor response rate, and response duration. Erythropoiesis-stimulating agents are generally well tolerated; however, an increased incidence of thromboembolic events (both venous and arterial) and hypertension has been reported in some clinical trials (Singh AK, Szczch L, Tang KL, Barnhart H, Sapp S et al. Correction of Anemia with Epoetin Alfa in Chronic Kidney Disease. *N Engl J Med* 2007;355:2085–2098). In a recent meta-analysis of 12 randomized controlled trials evaluating 1,738 cancer patients, treatment with an ESA, increased the relative risk of thromboembolic events (1.58, 95% confidence interval 0.94–2.66), and hypertension (1.19, 95% confidence interval 0.96–1.49) compared with placebo.<sup>23</sup> A recently completed randomized, double-blind, placebo controlled trial evaluated whether the use of epoetin alpha titrated to maintain a hemoglobin level between 120–140 g/L improved quality of life in non-small cell lung cancer patients not receiving chemotherapy (unpublished data). Overall survival was significantly reduced (median 68 days vs. 131 days,  $p=0.040$ ) in patients

randomized to receive epoetin alpha compared with placebo; in addition, no beneficial effect was observed on quality of life in patients treated with epoetin alpha. These findings have resulted in a black box warning issued by the FDA. Until additional data become available, it remains prudent to inform patients of these potential risks prior to initiating therapy. Acquired pure red cell aplasia (PRCA) owing to antierythropoietin antibodies has not been reported in patients treated for cancer-associated anemia.

The use of ESAs in cancer patients should be limited to patients that are receiving chemotherapy. The smallest dose required to achieve a hemoglobin level sufficient to maintain transfusion independence (approximately 100–120 g/L) should be administered as per manufacturer instructions.

**RBC Substitutes** RBC substitutes are an attractive alternative to allogeneic RBC transfusions because they avoid alloimmunity and minimize the risk of transfusion-transmissible disease. Three types of RBC substitutes have been tested in human clinical trials: perfluorocarbons, hemoglobin-based oxygen carriers, and liposomes containing hemoglobin.<sup>24</sup> Perfluorocarbons are chemically and biologically inert substances prepared as emulsions for intravenous administration that are capable of dissolving large volumes of oxygen. In clinical studies, these agents have shown promise in the treatment of perioperative anemia but were associated with toxicities attributed to the emulsifying agent.<sup>25,26</sup> Hemoglobin solutions, derived from outdated human RBCs, bovine RBCs, or recombinant technology, have oxygen-carrying capacity and oxygen delivery properties that are similar to those of endogenous hemoglobin. So far, clinical benefit derived from hemoglobin solutions has been offset by safety concerns.<sup>27,28</sup> Liposomes of bilamellar spheres of phosphatidylcholine loaded with hemoglobin solution can also act as oxygen transporters and may have a role as substitutes for RBC transfusions. These agents have a long half-life in circulation, but they are technically difficult to prepare and currently remain in preclinical stages of investigation only.<sup>29</sup>

### Therapy-Related Acute Myeloid Leukemia–Myelodysplastic Syndrome

In rare instances, anemia in patients with a history of cancer may be caused by a secondary hematologic malignancy. Patients treated with radiation therapy or certain chemotherapeutic agents subsequently have an increased risk of developing clonal bone marrow cytogenetic abnormalities, myelodysplasia (MDS), and acute myeloid leukemia (AML). Therapy-related AML-MDS is a devastating late complication of cancer therapy and is associated with specific cytogenetic abnormalities that portend a poor prognosis. Two

distinct syndromes have been identified: one is characterized by a prolonged latency period (5–7 years) and an antecedent period of MDS following treatment with alkylating agents; the other has a shorter latency period (1–3 years) and often transforms to AML without an antecedent myelodysplastic phase following treatment with topoisomerase II inhibitors (Table 2).<sup>30</sup> The cumulative incidence of therapy-related AML-MDS varies between 1.5 and 10% and peaks approximately 5 to 9 years after treatment exposure.<sup>31–33</sup> Combined-modality therapy with radio- and chemotherapy results in a synergistic increase in the frequency of therapy-related AML-MDS, thus creating a treatment paradox that can complicate management decisions: improved disease control with combined-modality therapy may be offset by increased morbidity and mortality from delayed therapy-related cancers. Host factors that predispose patients to the development of therapy-related AML-MDS have not been clearly identified; therefore, prevention has focused on reducing the exposure to offending agents where possible.

**Treatment**

In general, the treatment of therapy-related AML-MDS has been disappointing.<sup>30</sup> Treatment decisions must be individualized. Younger patients with adequate organ function may be candidates for aggressive induction chemotherapy and allogeneic hematopoietic stem cell transplantation (HSCT) with curative intent.<sup>34–36</sup> In contrast, elderly patients may be candidates only for low-dose chemotherapy and palliative, supportive measures.

**Acquired PRCA** Acquired PRCA is a rare condition characterized by profound anemia, marked reticulocytopenia, and absent bone marrow erythroid precursors in the setting of normal white blood cell and platelet lineages. Malignancy, thymoma, and lymphoproliferative disorders in particular are well-known causes of PRCA (Table 3).<sup>37–39</sup> Several unique mechanisms, occurring alone or in combination, have been

**Table 3** Causes of Acquired Pure Red Cell Aplasia

HIV = human immunodeficiency virus.	

implicated in the pathophysiology of acquired PRCA, including (1) T cell–mediated inhibition of erythropoiesis (thymoma, T-cell lymphoproliferative diseases); (2) development of antibodies with selective cytotoxicity for bone marrow erythroid progenitors; (3) direct infection and lysis of erythroid progenitor cells (parvovirus B19); (4) intrinsic stem cell defects (MDS); and (5) antierythropoietin antibodies (rhEPOs, connective tissue diseases).<sup>37</sup> Diagnostic hallmarks of PRCA include peripheral blood reticulocytopenia (usually < 1%) and absent erythroblasts in a normocellular bone marrow. The presence of giant proerythroblasts in the bone marrow is virtually pathognomonic for parvovirus B19 infection.

The incidence of antibody-associated PRCA in patients treated with rhEPO increased dramatically after 1998, peaked by approximately 2002,

and has now sharply declined. This observation was limited almost exclusively to patients treated for anemia owing to end-stage renal disease. This association has been linked to a variety of factors that appear to influence the immunogenicity of the recombinant product, including the route of administration (subcutaneous injection may be more immunogenic compared with intravenous administration) and differences in manufacturing, processing, and storage (formulations stabilized in human serum albumin appear to be less immunogenic than products using polysorbate-based vehicles).<sup>40,41</sup> To date, no cases of rhEPO-induced PRCA have been reported in cancer patients treated for chemotherapy-associated anemia.

**Treatment** Management of PRCA should focus on transfusional support in patients with symptomatic anemia and on treatment of any associated conditions, including removal of offending medications. Patients with PRCA owing to infection with parvovirus B19 often respond to therapy with intravenous immunoglobulin (IVIG).<sup>42</sup> Otherwise, first-line therapy for patients with idiopathic PRCA usually consists of immunosuppression based on the assumption that immune mechanisms play an important role in the pathophysiology of PRCA. Owing to a lack of well-designed clinical trials to determine the optimal immunosuppressive regimen, treatment decisions are often empiric. Prednisone, administered at a dose of 1 mg/kg, is a standard first-line agent. In refractory cases, cyclophosphamide, cyclosporine, rituximab (anti-CD20 monoclonal antibody), alemtuzumab (anti-CD52 monoclonal antibody), antithymocyte globulin, and IVIG have been used, with variable success.<sup>43–52</sup>

**Autoimmune Hemolytic Anemia**

Autoimmune hemolytic anemia (AIHA) represents a group of diseases characterized by the development of autoantibodies with specificity to one or more RBC antigens (Table 4). Subsequent RBC destruction follows owing to (1) intravascular hemolysis if the autoantibody can sufficiently activate complement on RBC membranes and/or (2) extravascular hemolysis owing to Fc and/or complement receptor-mediated destruction by phagocytic cells of the reticuloendothelial system. Among patients with secondary immune hemolysis owing to an underlying malignancy, warm AIHA accounts for greater than 80% of cases and is associated most often with lymphoproliferative diseases or their treatment (fludarabine therapy) and less frequently with solid tumors. Cold agglutinin disease (CAD) accounts for most of the remaining cases of immune-mediated hemolysis and is associated with a similar spectrum of malignancies.

**Table 2** Clinical Characteristics of Therapy-Related Acute Myeloid Leukemia–Myelodysplastic Syndrome

Therapy	Latency Period (yr)	Clinical Presentation	Cytogenetic Abnormalities	Median Survival (mo)
Alkylating agents or radiation (cyclophosphamide, procarbazine, nitrogen mustard, vinblastine)	5–7	Insidious onset Preceding myelodysplastic phase	Deletions involving chromosomes 5 and 7 Complex ( $\geq 3$ ) cytogenetic abnormalities	6–8
Topoisomerase II inhibitors (etoposide, tenoposide, doxorubicin)	2–3	AML without a preceding myelodysplastic phase	Translocations involving the <i>MLL</i> gene (chromosome 11q23)	6–8

AML = acute myeloid leukemia.

Table 4 Classification of Autoimmune Hemolytic Anemias

	Warm Autoantibodies		Cold Autoantibodies		
	Primary AIHA	Secondary AIHA	Primary CAD	Secondary CAD	PCH
Etiology	Idiopathic	Lymphoproliferative disorders (CLL, LGL, NHL, MM) Drugs (fludarabine, penicillin, methyl dopa, quinidine) Autoimmune disorders (SLE) Infections (viral)	Idiopathic	Lymphoproliferative disorders (NHL, CLL, MM, LGL) Infections (EBV, <i>Mycoplasma pneumoniae</i> )	Syphilis Viral infections
Immunoglobulin Clonality	Polyclonal	Polyclonal	Monoclonal	Monoclonal (malignancy) Polyclonal (infection)	Polyclonal
DAT	IgG	IgG	C3	C3	C3
RBC antigen specificity	Panagglutinin	Panagglutinin	I	I/i	P

AIHA = autoimmune hemolytic anemia; CAD = cold agglutinin disease; DAT = direct antiglobulin test; EBV = Epstein-Barr virus; Ig = immunoglobulin; PCH = paroxysmal cold hemoglobinuria; MM = multiple myeloma; NHL = non-Hodgkin's lymphoma; RBC = red blood cell; SLE = systemic lupus erythematosus.

### Warm AIHA

Warm AIHA is usually due to polyclonal immunoglobulin (Ig)G autoantibodies that react more strongly with RBC antigens at core body temperature than at lower temperatures—hence the term “warm.” Warm autoantibodies are usually panagglutinins, that is, they react with all cells in a panel of RBC antigens, but occasionally will show specificity, most often to Rh blood group antigens. Definitive diagnosis relies on demonstrating the presence of autoantibody (IgG) or complement (C3) on the RBC surface (positive direct antiglobulin test [DAT]) and laboratory evidence of extravascular hemolysis (reticulocytosis, elevated unconjugated bilirubin and lactate dehydrogenase, decreased or absent haptoglobin, and peripheral blood spherocytosis and polychromasia). Greater than 95% of patients will have a positive DAT owing to IgG and/or C3 coating the RBC surface; the small percentage of DAT-negative patients likely represents IgG autoantibodies below the detectable threshold of the DAT, IgA autoantibodies, or IgM autoantibodies that do not fix and activate complement.<sup>53,54</sup> Delayed hemolytic transfusion reaction, characterized by a positive DAT, the detection of a new alloantibody, and laboratory evidence of extravascular hemolysis 2 to 14 days following transfusion, should be excluded in those patients who have been recently transfused.

Treatment of malignancy-associated warm AIHA should focus on limiting hemolysis by treating the underlying malignancy and the use of immunosuppressive therapy, generally prednisone 1 mg/kg/d. Splenectomy and additional

immunosuppressive agents, such as cyclophosphamide, rituximab, cyclosporine, and IVIG, may be beneficial in refractory cases.<sup>55–57</sup> The indications for RBC transfusion are the same as for anemic patients without warm AIHA; however, the presence of panagglutinating autoantibodies usually renders all RBC units cross-match “incompatible.” Nevertheless, in the absence of an occult alloantibody, the life span of the transfused RBCs should be similar to that of the patient's own RBCs. Consultation with the transfusion medicine laboratory is often required to exclude occult hemolytic alloantibodies.<sup>58</sup>

### Cold Agglutinin Disease

CAD is usually caused by IgM autoantibodies that react optimally between 0 and 4°C, often with specificity to I/i and Pr blood group antigens. The thermal range of the antibody and the titer are important determinants in the degree of hemolysis. Clinically, symptoms relate to the presence of anemia and/or agglutination of RBCs in the distal extremities (acral discoloration, pain, skin ulceration, and necrosis, especially on exposure to a cold environment). A marked spurious increase in the MCV, the presence of RBC agglutination on examination of a peripheral blood smear, and laboratory evidence of hemolysis are clues to the presence of a clinically significant cold agglutinin. IgM antibodies can efficiently fix and activate complement; therefore, the DAT is usually positive with anti-C3 but negative with anti-IgG antibodies.

Treatment of CAD should focus on three issues: (1) keeping patients warm (avoidance of

cold environments to reduce hemolytic exacerbations); (2) reducing the antibody titer with systemic chemotherapy for underlying malignancies, additional immunosuppressive therapies, and plasmapheresis, when necessary; and (3) RBC transfusions in symptomatic patients using warmed blood products administered slowly. In contrast to warm AIHA, glucocorticoid therapy and splenectomy are generally not effective therapies for CAD. Cyclophosphamide, rituximab, and plasmapheresis used alone or in combination may be able to reduce autoantibody titer and control hemolysis more effectively.<sup>59–61</sup>

### Thrombocytopenia

Thrombocytopenia is defined as a platelet count of less than  $150 \times 10^9/L$ . Clinically significant bleeding rarely develops until the platelet count falls below  $50 \times 10^9/L$  unless there is an accompanying platelet function defect or coagulopathy. Once the platelet count drops below 10 to  $20 \times 10^9/L$ , patients have a higher risk of spontaneous bleeding, ecchymoses, mucosal bleeding (gums, epistaxis, gastrointestinal tract), and intracranial hemorrhage.

A common diagnostic approach divides the causes of thrombocytopenia into disorders associated with increased peripheral platelet destruction, impaired bone marrow platelet production, or splenic sequestration (hypersplenism) (Table 5). Careful examination of the peripheral blood smear is critically important when evaluating thrombocytopenia and should be performed for several reasons: (1) to exclude “pseudothrombocytopenia” owing to ethylenediaminetetraacetic acid–induced platelet clumping; (2) to look for

Table 5 Common Causes of Thrombocytopenia in Cancer Patients

Decreased platelet production
Myelosuppressive chemotherapy/radiation
Bone marrow infiltration by malignancy
Myelodysplastic syndrome
Vitamin B <sub>12</sub> or folate deficiency
Increased platelet destruction
Immune mechanisms:
Immune thrombocytopenic purpura (often associated with lymphoproliferative diseases)
Post-transfusion purpura
Heparin-induced thrombocytopenia
Nonimmune mechanisms:
DIC
HUS-TTP
Hypersplenism
Splenomegaly (lymphoproliferative diseases, other)
DIC = disseminated intravascular coagulation; HUS = hemolytic-uremic syndrome; TTP = thrombotic thrombocytopenic purpura.

RBC fragments suggestive of a microangiopathic process, such as disseminated intravascular coagulation (DIC), hemolytic-uremic syndrome (HUS), or thrombotic thrombocytopenic purpura (TTP); and (3) to examine for evidence of decreased platelet production (eg, circulating blast cells suggestive of acute leukemia, macrocytosis and hypersegmented neutrophils suggestive of vitamin B<sub>12</sub> or folate deficiency). Drug-induced causes of thrombocytopenia are common and should always be considered. In particular, physicians should have a high index of suspicion for heparin-induced thrombocytopenia (HIT) in hospitalized patients because of its paradoxical and potentially life-threatening thrombotic complications, and commonly used antibiotics such as Vancomycin must be considered as a cause of severe thrombocytopenia and bleeding (REF Annette Von Drygalski, NEJM 2007). A bone marrow aspirate and biopsy may be required to determine the cause of thrombocytopenia in selected patients, especially when a malignant infiltrate or myelodysplastic syndrome is suspected. Peripheral consumption of platelets is suggested when increased numbers of morphologically normal megakaryocytes are observed in the bone marrow concurrently with peripheral blood thrombocytopenia and megathrombocytes.

### Cancer-Related Thrombocytopenia

Thrombocytopenia is common in cancer patients and is most often due to reduced thrombopoiesis from the myelosuppressive effects of radiation or chemotherapy or from bone marrow infiltration by tumor cells. Chemotherapy-induced thrombocytopenia is temporally and predictably related to cancer treatment; bone marrow examination is generally required to diagnose a myelophthisic syndrome.

#### Treatment

**Recombinant Thrombopoietin** The discovery of thrombopoietin (TPO), the principal megakaryopoietic growth factor, garnered initial enthusiasm as a potential therapeutic alternative to platelet transfusions for the treatment of chemotherapy-associated thrombocytopenia. Two forms of recombinant human thrombopoietin (rhTPO) have undergone clinical drug development: (1) a full-length molecule (rhTPO) and (2) a truncated molecule called pegylated recombinant human megakaryocyte growth and development factor (PEG-rHuMGDF). Production of PEG-rHuMGDF has now been suspended owing to the development of neutralizing anti-TPO antibodies and clinically significant thrombocytopenia in some patients. rhTPOs have been evaluated in patients with chemotherapy-associated thrombocytopenia, but the results have generally been disappointing thus far. In a series

of randomized controlled trials evaluating patients being treated for acute leukemia, the concomitant administration of rhTPO did not reduce the duration of severe thrombocytopenia or platelet transfusion requirements.<sup>62–64</sup> It is now recognized that the effects of rhTPO are delayed compared with those of other cytokines (ie, granulocyte colony-stimulating factor [G-CSF]). Therefore, ongoing clinical trials have been developed to test alternative dosing regimens in a variety of disease states.

#### TPO agonists

A new class of molecules that is currently undergoing clinical trials are TPO agonists. These are small molecules that activate the TPO receptor and stimulate platelet production, but are sufficiently different from endogenous TPO that they do not induce anti-TPO antibodies. Results of phase II trials in immune mediate thrombocytopenia have been encouraging (REF Bussel J, Kuter D, George J, NEJM 2006); testing in cancer related thrombocytopenia is ongoing.

#### Indications for Platelet Transfusions

Platelet transfusions are generally indicated for the treatment or prevention of bleeding in patients with thrombocytopenia. Given that the risk of bleeding increases as the platelet count decreases,<sup>65</sup> the absolute platelet count often dictates when platelet transfusions are administered. However, the decision to transfuse platelets should not be influenced only by the platelet count but also by the presence of bleeding or bleeding risk factors, including concurrent coagulopathies or the presence of underlying comorbid illness.<sup>66</sup> Platelet transfusions should generally be avoided in thrombocytopenic patients with TTP<sup>67,68</sup> or HIT<sup>69,70</sup> as platelet transfusions can worsen the outcome of these disease processes.

In clinically stable, nonbleeding thrombocytopenic patients with hematologic malignancies, prophylactic platelet transfusions are recommended for patients with platelet counts below  $10 \times 10^9/L$ . A recent meta-analysis, which included three randomized controlled trials enrolling 492 patients, concluded that bleeding complications were not different using a platelet transfusion trigger of  $10 \times 10^9/L$  or  $20 \times 10^9/L$ . The studies were insufficiently powered to claim that a trigger of  $10 \times 10^9/L$  is as safe as (or not inferior to)  $20 \times 10^9/L$ . However, platelet transfusion triggers even lower than  $10 \times 10^9/L$  appear to be safe in certain circumstances.<sup>72</sup> Although there is less evidence to guide platelet transfusion practice for patients with solid tumors, a platelet trigger of  $10 \times 10^9/L$  is generally recommended, with the exceptions of patients receiving aggressive therapy for bladder tumors and patients with necrotic tumors (of any type), who may benefit from a more liberal platelet transfusion strategy (trigger of  $20 \times 10^9/L$ ) owing to the increased risk of

bleeding from these sites.<sup>73</sup> Additional randomized trials are needed to determine safe triggers for prophylactic platelet transfusions in anticipation of invasive procedures and in thrombocytopenic disorders other than myelotoxic chemotherapy that commonly affect patients with cancer, such as DIC and sepsis. Recommended platelet transfusion triggers for various clinical indications are summarized in Table 6.<sup>73–76</sup>

#### Platelet Transfusion Alternatives

Novel platelet products are being developed to improve on the safety and quality of allogeneic platelet transfusions.<sup>77</sup> Frozen platelets, lyophilized platelets, and hemostatically intact platelet membrane microparticles are currently under investigation. Red cells with surface-bound fibrinogen or RGD (Arg-Gly-Asp) ligand, the fibrinogen peptide that binds to platelet integrin on glycoprotein GpIIb/IIIa, fibrinogen-coated albumin microcapsules or microspheres, and liposome-based hemostatic agents also hold promise as substitutes to platelet transfusions. In addition, recombinant activated factor VII and adequate correction of concomitant anemia may be important adjuncts in the treatment of bleeding owing to thrombocytopenia.<sup>78,79</sup>

### Leukopenia

Leukopenia refers to a decrease in the peripheral blood white blood cell count and can be due to lymphopenia, granulocytopenia, or both. Although numerous causes for leukopenia exist, when it occurs in patients with an underlying malignancy, it is usually due to either malignant infiltration of the bone marrow or the myelosuppressive effects of chemo- or radiotherapy. The term *neutropenia* is generally used interchangeably with *granulocytopenia*. Neutropenic fever is one of the most serious complications of cancer therapy and a harbinger of potentially life-threatening infection.

### Neutropenia

Neutropenia is defined by an absolute neutrophil count (ANC) of less than  $1.5 \times 10^9/L$  and is further classified as mild (ANC  $1.0–1.5 \times 10^9/L$ ), moderate (ANC  $0.5–1.0 \times 10^9/L$ ), or severe (defined as ANC  $0.5 \times 10^9/L$  or less or  $0.1 \times 10^9/L$  or less). The risk of infection is determined by both the degree and duration of neutropenia. This relationship was demonstrated in a study that evaluated the frequency of infections in 52 patients with acute leukemia and neutropenia of variable duration and severity; 80% of patients with severe neutropenia lasting 2 weeks (ANC  $<0.1 \times 10^9/L$ ) developed an identifiable infection, and 100% of patients with severe neutropenia lasting 3 weeks or more developed an infection.<sup>80</sup> Clinically, the risk of infection begins to increase once the ANC falls below  $1.0 \times 10^9/L$ . Most infections that occur in the setting of

**Table 6** Recommended Platelet Transfusion Triggers according to Indications

Indication for Platelet Transfusion	Platelet Count Trigger
Patients with acute leukemia or HSCT and bone marrow failure owing to disease or its therapy, in the absence of additional risk factors such as bleeding, sepsis, or the concomitant use of drugs	$10 \times 10^9/L$
Chemotherapy-induced thrombocytopenia for the treatment of solid tumors	$10 \times 10^9/L$ $20 \times 10^9/L$ for bladder tumors or necrotic tumors
Chronic, stable, severe thrombocytopenia in the absence of bleeding	Observation only
Bone marrow aspiration and biopsy	Generally not recommended
Lumbar puncture and epidural anesthesia	$50 \times 10^9/L$
Gastroscopy and biopsy	$50 \times 10^9/L$
Insertion of indwelling endovascular catheters	$50 \times 10^9/L$
Transbronchial biopsy	$50 \times 10^9/L$
Liver biopsy	$50 \times 10^9/L$
Laparotomy	$50 \times 10^9/L$
Operation in critical sites including brain and eyes	$100 \times 10^9/L$
Massive transfusion (transfusion of a volume of red cell concentrates equivalent to two blood volumes)	$50 \times 10^9/L$
Multiple trauma or CNS injury	$100 \times 10^9/L$
Acute disseminated intravascular coagulation	$50 \times 10^9/L$
Autoimmune thrombocytopenia	Platelet transfusion should be reserved for life-threatening bleeding

CNS = central nervous system; HSCT = hematopoietic stem cell transplantation.

moderate to severe neutropenia are due to endogenous pyogenic bacteria (both gram positive and gram negative) and certain fungal pathogens. Prolonged neutropenia, therapy with broad-spectrum antibiotics, and treatment with corticosteroids predispose patients to systemic fungal infections.

Patients receiving systemic chemotherapy who become neutropenic are consequently at risk of infection-related morbidity and mortality, cancer treatment delays, and chemotherapy dose reductions. The degree and duration of neutropenia are determined predominantly by the specific chemotherapeutic regimen, but host-related factors are also important. Predictors for the development of chemotherapy-induced neutropenia include advanced patient age, poor functional status, and the presence of underlying comorbid illnesses (eg, renal disease, cardiovascular disease).<sup>81,82</sup> Attempts to limit the degree and duration of neutropenia are accomplished by either chemotherapy dose reduction or myeloid growth factor support. Granulocyte transfusions are no longer routinely used.

#### Treatment

The prophylactic administration of myeloid growth factors (G-CSF, granulocyte-macrophage colony-stimulating factor) following chemotherapy has been evaluated in randomized controlled trials.<sup>83-86</sup> In general, prophylactic administration of myeloid growth factors results

in a higher ANC nadir, shortened duration of severe neutropenia, and fewer episodes of febrile neutropenia compared with placebo. However, no improvement in overall survival, tumor response rates, or progression-free survival has been shown. Furthermore, economic analyses suggest that the incidence of febrile neutropenia associated with a specific chemotherapeutic regimen must be 40% or higher before prophylaxis with myeloid growth factors is cost-effective.<sup>87,88</sup> With the exception of treatments for advanced germ cell tumors and small cell lung cancer, chemotherapeutic regimens for most common malignant diseases are associated with rates of febrile neutropenia that are substantially below 40%.

Based on the most recent update of the practice guidelines developed by the American Society of Clinical Oncology in 2000, primary prophylaxis with myeloid growth factors is not recommended for most patients because there is no evidence of improved overall or progression-free survival and therapy is not cost-effective. In patients with an expected risk of febrile neutropenia of at least 40%, primary growth factor support is recommended. Therapy in these patients reduces the risk of febrile neutropenia by approximately 50% but does not change response rates or progression-free or overall survival. Also, there may be special circumstances, such as advanced patient age, poor functional status, and poor bone marrow reserve owing to previous chemotherapy

or cytopenias prior to therapy, that may influence the decision to administer primary prophylaxis, but the evidence for a positive impact on clinical outcomes is not strong. Recommendations are similar for secondary prevention of infections in patients with a previous episode of febrile neutropenia. Chemotherapy dose reduction rather than growth factor administration is recommended for most patients. Secondary prophylaxis may be appropriate for a subset of patients undergoing chemotherapy for potentially curable malignancies (eg, germ cell tumors, non-Hodgkin's lymphoma) to maintain dose intensity. There is little evidence to support the routine use of myeloid growth factors for patients with severe neutropenia.

### Hemorrhagic Complications

Bleeding is one of the most common hematologic problems encountered in patients with cancer. This is usually directly related to the malignancy, but it may also be due to thrombocytopenia, invasive procedures, and other acquired hemorrhagic syndromes. The two most serious coagulopathies are DIC and acquired inhibition of coagulation factors.

### Disseminated Intravascular Coagulation

DIC is common in malignancy. It is a syndrome characterized by widespread fibrin deposition in the vasculature owing to systemic intravascular activation of coagulation. It can be chronic and clinically silent or present acutely with symptomatic thrombosis, mild to catastrophic hemorrhage, or end-organ damage.<sup>89,90</sup> Diagnosis of DIC requires laboratory evidence of microangiopathy, thrombin generation, fibrinolytic activation, and consumption of platelets and pro- and anticoagulant factors in a clinical setting associated with a hypercoagulable state, such as malignancy and sepsis.<sup>91,92</sup> The exact pathogenesis of DIC is not understood, but excessive activation of coagulation via the tissue factor-factor VIIa pathway is considered to be the initiating event. Propagation of this process occurs because there is concomitant suppression of the natural inhibitory pathways, impairment of fibrinolysis, and an inflammatory cytokine response to the initial insult.<sup>93</sup> The most common malignancies that are associated with DIC are acute myelogenous leukemias, particularly M3 and M5, and cancer of the prostate, ovary, or lung.<sup>89,90</sup> Tumor expression of procoagulant molecules is likely involved in the activation of coagulation.

#### Management

Clinical studies are lacking to guide therapy in patients with DIC. Treatment is usually directed at supporting the patient with blood products if

bleeding is the major manifestation and with heparin therapy if symptomatic thromboembolism is present. Intervention is not recommended if the patient is asymptomatic and only laboratory parameters are abnormal. Treatment of the underlying disease is necessary to terminate the ongoing stimulus for activation of coagulation. The role of restoring acquired deficiencies in physiologic anticoagulants such as antithrombin and tissue factor pathway inhibitor has not been evaluated in patients with DIC related to cancer, but these products have had disappointing results in patients with DIC and sepsis.<sup>94,95</sup> Recently, infusion of activated protein C concentrate was shown to improve survival in patients with sepsis; however, patients treated with this product had a higher incidence of bleeding.<sup>96</sup> Whether activated protein C will be beneficial to patients with fulminant DIC and malignancy has not been tested.

### Acquired Inhibitors of Coagulation Factors

The development of an acquired inhibitor of a coagulation factor protein represents a rare but potentially life-threatening cause of bleeding in cancer patients.<sup>97</sup> Although the pathophysiology resulting in their formation is not clearly understood, inhibitors are usually IgG autoantibodies that bind to specific epitopes on coagulation factors and interfere with their normal function. Most cases are idiopathic, but approximately 10% are associated with an underlying solid tumor or hematologic malignancy, the presence of which imparts an adverse prognosis.<sup>98</sup> Patients typically present with a bleeding diathesis that can range from mild bruising to catastrophic, life-threatening hemorrhage. The most frequent sites of bleeding include soft tissues, retroperitoneal structures, skin, mucosal surfaces, and the gastrointestinal tract; in contrast to patients with congenital hemophilia A, hemarthroses occur infrequently. An acquired inhibitor should be suspected when a prolonged activated partial thromboplastin time (aPTT), international normalized ratio (INR), or both either fail to correct when patient plasma is mixed in a 1:1 ratio with normal plasma or correct with excess phospholipid, suggesting the presence of an anti-phospholipid antibody. Specific coagulation factor assays (guided by whether the aPTT, INR, or both are prolonged) allow subsequent inhibitor identification. The vast majority of acquired inhibitors are directed against factor VIII. The inhibitor titer can be estimated using the Bethesda assay, which measures residual coagulation factor activity after incubation of patient plasma with normal plasma for 2 hours at 37°C.

#### Treatment

The management of patients with an acquired inhibitor is difficult owing to potentially

life-threatening bleeding episodes and a lack of well-designed, prospective clinical trials to help guide treatment decisions. Specific therapeutic recommendations are beyond the scope of this chapter, and referral to a specialist with expertise in disorders of hemostasis and coagulation is recommended. Two main therapeutic goals exist for the treatment of acquired inhibitors: termination of active bleeding and eradication of the inhibitor to prevent future episodes of bleeding. Strategies to control active bleeding include intravenous infusions of specific factor concentrates or factor-bypassing agents such as activated prothrombin complex concentrates, factor VIII inhibitor bypassing activity, or activated factor VII (niastase).<sup>98,99</sup> Initial treatment decisions should be dictated by the severity of the bleeding symptoms and the inhibitor titer. The mainstay of inhibitor eradication has focused on immunosuppressive therapies, most commonly prednisone alone or in combination with cyclophosphamide. Treatment directed toward the underlying malignancy may contribute to inhibitor regression, particularly in patients with hematologic cancers<sup>100</sup>; the relationship in patients with solid tumors is less certain.

### Thrombotic Complications

Thrombotic complications in cancer patients may occur spontaneously or secondary to additional risk factors, such as surgery and central venous catheterization. Although the vast majority of the events are venous, arterial thrombosis can also develop. Paradoxically, the two most fulminant thrombotic complications are HIT and TTP, both of which are characterized by an acute onset of severe thrombocytopenia.

### Venous Thromboembolism

Active malignancy, with or without chemotherapy, increases the risk of venous thromboembolism (VTE) by four- to sixfold.<sup>101</sup> Cancer is also an independent risk factor for death within 7 days after a thrombotic event, with up to an eightfold increased risk of death in patients receiving chemotherapy.<sup>102</sup> Moreover, cancer patients with VTE have worse survival than cancer patients free of this complication. In a population-based study, the 1-year survival rate of patients diagnosed with cancer and VTE at the same time was 12%, compared with 36% in cancer patients without VTE, who were matched for gender, age at the time of the diagnosis of cancer, and year of cancer diagnosis.<sup>103</sup> The poor prognosis may indicate that patients are dying prematurely of VTE, that VTE is a harbinger of aggressive malignancies, or that activation of coagulation promotes tumor progression. VTE often presents late in the course of malignancy, but it can also be the first

manifestation of occult cancer. Approximately 10% of patients with unprovoked or idiopathic VTE are diagnosed with cancer within the first year after their diagnosis of VTE.<sup>104</sup> Although extensive screening for underlying cancer in such patients allows earlier detection of the malignancy, a positive impact on survival has not been demonstrated.<sup>105</sup>

Although the risk of VTE by tumor type remains uncertain for the majority of cancers, the risk appears to be highest for patients with malignant brain tumors and cancer of the ovary, pancreas, and lung.<sup>106</sup> On the other hand, the most common tumor types found in patients with VTE are cancers of the lung, colon, breast, and prostate, which largely reflect the prevalence of these cancers in the general population. The risk of thrombosis is increased with the use of chemotherapy, hormonal therapy, and indwelling central venous catheters.<sup>104</sup> Recent clinical trials also report a high incidence of VTE associated with the use of antiangiogenic agents, such as thalidomide and inhibitors of the vascular endothelial growth factor/receptor pathway.

Venous thrombotic complications in cancer patients can occur in any venous bed, although the most common manifestations are deep venous thrombosis (DVT) of the legs and pulmonary embolism (PE). Most of the clinical studies to date have focused on the prevention and treatment of VTE at these two sites.

#### Prophylaxis of VTE in Surgical Patients

Anticoagulant prophylaxis is recommended for patients undergoing major surgery because the risk of postoperative thrombosis is substantial.<sup>107</sup> After surgery, cancer patients have twice the risk of DVT and over three times the risk of fatal PE compared with patients free of cancer.<sup>107</sup> Low-molecular-weight heparin (LMWH) or unfractionated heparin (UFH) can reduce the risk by approximately 70%, and these agents are comparable in efficacy and safety for the prevention of postoperative thromboembolism.<sup>108,109</sup> The major advantages of LMWH over UFH are the lower risk of HIT and the requirement for only once-daily injection. Newer and more selective anticoagulants, such as fondaparinux, are also effective for prophylaxis but do not appear to be better than the heparins.<sup>110</sup> More recently, it was shown that extending prophylaxis with LMWH for 3 weeks after hospital discharge in cancer patients can reduce the risk of venographic and proximal VTE by 60%.<sup>111,112</sup> This benefit was achieved without an increase in bleeding. Therefore, cancer patients undergoing surgery should receive pharmacologic prophylaxis with either LMWH or UFH while in hospital. Continuing prophylaxis after hospitalization is reasonable and should be considered in those patients with additional risk factors.

### Prophylaxis of VTE in Medical Oncology Patients

The indications for primary prophylaxis in medical oncology patients remain undefined. To date, only one publication has addressed the efficacy and safety of thromboprophylaxis in medical oncology outpatients. In a placebo-controlled trial, it was demonstrated that low-dose warfarin is effective and safe in reducing the incidence of symptomatic thromboembolic events during chemotherapy.<sup>113</sup> However, standard practice does not include routine prophylaxis of ambulatory medical oncology patients because of concerns for anticoagulant-related bleeding and the need for laboratory monitoring. Recent reports of a relatively low incidence of symptomatic VTE (3%) in ambulatory patients with advanced or metastatic malignancies also argue against routine prophylaxis.<sup>114</sup> For hospitalized patients, there is indirect evidence that cancer patients would benefit from thromboprophylaxis with LMWH.<sup>115,116</sup> The risk of bleeding is likely low, but, currently, there are no reliable data about bleeding associated with anticoagulant prophylaxis specifically in cancer patients.<sup>117</sup> In summary, it is reasonable to use LMWH for primary prophylaxis in cancer patients when they are admitted to hospital with an acute illness, but evidence is lacking to support routine prophylaxis in patients in an outpatient setting.

### Treatment of VTE

To date, multiple randomized trials and meta-analyses of these trials have confirmed that for initial therapy, LMWHs are at least as efficacious as UFH in reducing recurrent thrombosis and are associated with a lower risk of major bleeding.<sup>118–121</sup> Furthermore, LMWH can be given safely in an outpatient setting without the need for laboratory monitoring and has a lower risk of HIT.<sup>122,123</sup> However, whether LMWHs and UFH perform comparably in patients with cancer and acute VTE has not been formally investigated.

Although vitamin K antagonists are the mainstay of long-term anticoagulant treatment for VTE because they are highly effective in reducing recurrent thrombosis in the general population, treatment failures, serious bleeding, and difficulties with maintaining the INR within the therapeutic range are common problems in patients with cancer. A prospective cohort study reported that the 12-month cumulative incidence of recurrent VTE in cancer patients was 20.7%, versus 6.8% in patients without cancer, whereas the corresponding estimate for major bleeding was 12.4% versus 4.9%, respectively.<sup>124</sup> Patients with cancer also experience recurrent VTE despite having therapeutic INR levels and suffer serious bleeding complications without receiving excessive anticoagulation.<sup>125</sup> Cases of warfarin-induced limb gangrene owing to protein C depletion have also been reported in patients with cancer.<sup>126,127</sup>

Recent evidence from randomized trials shows that LMWH should be the first-line treatment for long-term anticoagulation in cancer patients with VTE.<sup>128,129</sup> In the CLOT trial, LMWH dalteparin was found to reduce the risk of recurrent VTE by 52% ( $p = .002$ ), from 17 to 9% at 6 months, compared with warfarin therapy.<sup>128</sup> Patients in the dalteparin group received therapeutic doses at 200 U/kg once daily for the first month and then 75 to 80% of the full dose for the next 5 months. Overall, there were no differences in bleeding between the groups. Other trials have suggested that LMWHs may be safer than warfarin therapy for long-term treatment of VTE in cancer patients.<sup>129,130</sup> In addition, LMWHs have few drug interactions, do not require laboratory monitoring, and can readily accommodate thrombocytopenia and invasive procedures. Improvement in overall survival may also be associated with LMWH use in patients with a better prognosis, but further studies are needed to confirm this observation.<sup>114,131,132</sup>

### Thrombosis Associated with Central Venous Catheters

Recent studies show that the incidence of catheter-related thrombosis (CRT) is much lower than what was previously reported in historical studies. According to randomized trials and prospective cohort studies, approximately 15% of patients develop CRT that is detectable with venography, but only 4% of patients have symptomatic CRT.<sup>133–135</sup> Furthermore, recent placebo-controlled trials showed that prophylaxis with low-dose warfarin or low-dose LMWH is not effective in reducing symptomatic thrombotic events.<sup>133,134</sup> In addition, low-dose warfarin can produce suprathreshold anticoagulant levels in one-third of patients receiving fluorouracil-based chemotherapy and therefore should not be given without laboratory monitoring.<sup>136</sup> Therefore, contradictory to previous guideline recommendations, routine prophylaxis for CRT is not warranted.<sup>107</sup>

**Treatment** The lack of prospective data on the natural history and treatment of CRT precludes any evidence-based recommendation for therapy. In general, patients with symptomatic CRT are treated with anticoagulant therapy, using the same regimens as those for VTE. Some clinicians advocate removal of the involved central line, but this has not been proven to improve short-term morbidity or reduce long-term sequelae. Anticoagulant therapy should be continued for a minimum of 3 months and perhaps until the catheter is no longer needed and is removed.

### Arterial Thrombotic Events

Patients with cancer receiving active cancer treatment have an increased risk of arterial thrombotic

events. The true incidence is not well defined, but approximately 20% of all thrombotic complications in cancer patients are arterial thrombotic events.<sup>90</sup> These include myocardial infarction, cerebrovascular accidents, nonbacterial thrombotic endocarditis, and peripheral arterial thromboembolism.<sup>90,137–140</sup> The pathogenic mechanisms are unknown, but these events may be due to treatment-related injury to the endothelium.<sup>141–143</sup> In reviews of studies evaluating adjuvant therapy for breast cancer, the risk of arterial thrombosis was approximately 1%.<sup>144,145</sup> Estimates in other types of cancer are not available. In general, standard antithrombotic therapies appropriate for the clinical situation are recommended.

### Heparin-Induced Thrombocytopenia

HIT is an immune-mediated drug reaction to heparin caused by the development of antibodies directed against an antigenic target formed by heparin bound to platelet factor 4. Binding of the resultant immune complex to the Fc $\gamma$ RII receptors on circulating platelets induces platelet activation and aggregation and ultimately leads to thrombin generation.<sup>146</sup> A definitive diagnosis of HIT requires confirmation of the presence of functional HIT antibodies, but treatment should not be withheld until the laboratory result is available. Currently, commercially available assays for HIT antibodies are not completely satisfactory and are not standardized. Enzyme-linked immunosorbent assays are designed to detect the presence of HIT antibodies, whereas functional <sup>14</sup>C-serotonin release assays detect antibodies with the ability to induce platelet activation.<sup>147,148</sup> The most common presentation of HIT is new or extension of existing venous or arterial thrombosis in a patient who has received heparin as recently as 5 days previously (or longer) and who has a platelet count of less than  $150 \times 10^9/L$  or a platelet count that has dropped by more than 50% below baseline values. HIT should also be considered in cases of rapid onset thrombocytopenia (less than 5 days after heparin exposure) in patients who have previously received heparin in the past 120 days.<sup>147,149</sup>

Generally, HIT with thrombosis is most commonly described in patients who have inflammatory processes that lower the threshold for platelet activation, for example, surgery. Theoretically, the incidence of HIT may be lower in patients with cancer because of their immunosuppression, but a small retrospective study suggested that cancer patients with HIT are more likely to develop thrombosis than noncancer patients with HIT.<sup>150</sup> In addition, HIT is more difficult to diagnose in this population because thrombocytopenic disorders are relatively common. Therefore, it is important to maintain a high index of suspicion and investigate for HIT in patients presenting with

unexplained thrombocytopenia following exposure to heparin.

#### Treatment

In patients with a confirmed diagnosis of HIT or in whom there is a high clinical suspicion for HIT, alternative anticoagulants are now available for prophylaxis and treatment.<sup>147,149,151</sup> Argatroban and lepirudin are direct thrombin inhibitors that are given intravenously and must be monitored according to the aPTT.<sup>152,153</sup> Argatroban is preferred in patients with renal insufficiency because it is primarily metabolized by the liver, whereas lepirudin is cleared by the kidneys. Danaparoid sodium is a low-molecular-weight heparinoid that can be given as fixed-dose subcutaneous injections, and its anticoagulant effect can be monitored by antifactor Xa activity.<sup>154</sup> In patients with acute thrombosis with HIT, all heparins should be stopped immediately and treatment with one of these alternative anticoagulants should be instituted and continued for a minimum of 5 days. Warfarin should be avoided until thrombocytopenia has resolved. Heparin should also be discontinued in patients with HIT who have isolated thrombocytopenia even without evidence of thrombosis. These patients may benefit from the prophylaxis using an alternate anticoagulant because they have a higher risk of developing thrombosis.<sup>155</sup>

### Thrombotic Thrombocytopenic Purpura

TTP is a microangiopathic hemolytic anemia characterized by platelet-rich microvascular thrombosis. The clinical syndrome is characterized by the pentad of thrombocytopenia, microangiopathic hemolytic anemia (schistocytic anemia), neurologic complications, renal impairment, and fever; however, it is uncommon for all five elements to occur concomitantly. A large prospective study of TTP patients found that 100% of patients had schistocytic anemia and thrombocytopenia, 71% had neurologic complications, 59% had renal impairment, and 24% had fever.<sup>156</sup> Significant overlap exists between TTP and HUS, another thrombotic microangiopathy. However, HUS generally affects children, is marked by renal impairment, and, in its classic form, follows a diarrheal illness triggered by an infection with *Escherichia coli* O157:H7.

Excess ultralarge-molecular-weight multimers of von Willebrand's factor (vWF) have been demonstrated in the plasma of patients with TTP and facilitate the formation of microvascular thrombosis, the hallmark of this disease.<sup>157</sup> Recently, using a genome-wide linkage analysis in four pedigrees of affected patients, mutations in the *ADAMTS13* gene (a disintegrin metalloproteinase and thrombospondin-like domain) have been identified as the cause of congenital

TTP.<sup>158</sup> Mutations in this gene result in decreased vWF protease activity and high levels of plasma ultralarge-molecular-weight VWF. The underlying mechanism of acquired TTP, the more common form of the disease, may also be a mutation of *ADAMTS13*; however, vWF protease activity has been shown to be reduced not only in TTP but also in other thrombocytopenic disorders.<sup>159,160</sup>

TTP is a recognized complication of cancer and occurs most commonly in one of three clinical settings: metastatic disease, treatment with chemotherapy, and HSCT. The tumors most commonly associated with TTP are metastatic adenocarcinomas of the stomach, breast, and lung.<sup>161,162</sup> Certain chemotherapeutic agents have been implicated in TTP, in particular, mitomycin C. Up to 10% of patients who receive a cumulative dose of 60 mg or more of mitomycin C have been reported to develop this complication.<sup>163</sup> Chemotherapy-induced TTP portends a poor prognosis with a mortality rate of over 50% within 2 months despite adequate therapeutic plasma exchange (TPE), the mainstay of treatment.<sup>163</sup> For HPCT-associated TTP, a recent systematic review reported that the frequency of diagnosis of TTP-HUS following allogeneic HSCT varied from 0.5 to 63.6%.<sup>164</sup> TTP may mimic other HSCT-related complications, such as sepsis and graft-versus-host disease, which should be excluded prior to initiating therapy with TPE.<sup>165</sup> Risk factors for the development of TTP in the setting of HSCT include total-body irradiation,<sup>166</sup> the use of cyclosporine,<sup>167,168</sup> and graft-versus-host disease.<sup>167</sup> Cyclosporine, a common medication used in the post-HSCT setting, is the most common cause of drug-associated TTP.<sup>169</sup> In general, the prognosis of cancer-associated TTP is worse than sporadic or hereditary TTP and responds poorly to TPE.<sup>170</sup>

#### Management

The mainstay of treatment for TTP is TPE. Prior to the use of plasma exchange, 90% of patients with TTP died<sup>171</sup>; with current therapies, the mortality from TTP is close to 20%. Patients who respond poorly to once-daily plasma exchange (generally defined as patients with persistence or recurrence of severe thrombocytopenia and hemolysis or patients with new neurologic abnormalities while on TPE) may benefit from increased frequency or increased volume of TPE or the addition of corticosteroids.<sup>172</sup> Other ancillary treatments include vincristine, splenectomy, IVIG, immunosuppressive therapy, or antiplatelet agents.

### Transfusion Medicine Issues in Cancer Patients

Blood transfusion is an important component of the care of cancer patients. Roughly half of all RBC transfusions are administered to medical

patients, and patients with hematologic disorders account for approximately 15% of overall RBC use on medical wards.<sup>173–175</sup> In the mid-1980s, blood transfusion was plagued by a high rate of viral disease transmission; however, since then, refined donor testing and better methods of virus inactivation have rendered the current risk of transfusion transmission of known viruses extremely low. Currently, bacterial contamination has become recognized as the most important infectious disease threat to the safety of the blood supply. New and emerging pathogens are a constant threat, and thus, general methods of pathogen inactivation, including the addition of alkylating agents or photosensitive agents such as riboflavin or psoralens, are currently being developed.<sup>176</sup>

Apart from infectious risks, blood transfusion can be associated with important clinical complications that require prompt recognition and treatment. Knowledge of infectious and noninfectious transfusion-associated complications is essential so that these complications can be managed appropriately and prevented when possible and patient requiring blood transfusions can be adequately informed.<sup>177</sup>

### Infectious Complications of Blood Transfusion

#### Virus and Prion Transmission

The risks of transfusion transmission of known viruses are summarized in Table 7. With current nucleic acid-amplification testing (NAT) of blood donors, the residual risk of human immunodeficiency virus (HIV) and hepatitis C virus transmission is approximately 1 in 2 million blood units.<sup>178</sup> The rate of transmission of cytomegalovirus and human T-lymphotrophic virus I and II is effectively reduced by the removal of white blood cells from the donor unit,<sup>179,180</sup> a

Table 7 Infectious risks of blood Transfusion

Infection	Risk per unit transfused
HIV	1: 2–1:4 million
Hepatitis C	1: 2–1:3 million
Hepatitis B	1:30,000–1:500,000
Hepatitis A	Extremely low risk
HTLV I/II	1:2 million; lower rate with leukoreduction
Cytomegalovirus	Up to 1–2% in high-risk patients
Syphilis	Extremely low risk
West Nile virus	Risk unknown
Variant Creutzfeld-Jacob disease	2 cases reported in the United Kingdom

Adapted from Dodd RY et al, Kleinman S et al, and Chiavetta JA et al.<sup>233–235</sup>  
HIV = human immunodeficiency virus; HTLV = human T-lymphotrophic virus.

practice that has become routine in many centers. Screening of blood donors for West Nile virus by minipool (six sample) NAT testing was implemented in the United States in June 2003, ever since transfusion-transmission of West Nile virus infection became recognized following the 2002 US epidemic. Seven cases of transfusion transmitted West Nile virus disease have been reported in the United States since testing was implemented, prompting the implementation of more sensitive, single-donor NAT testing.<sup>181,182</sup>

Two cases of transfusion transmission of the prion protein associated with variant Creutzfeldt-Jacob disease have been reported in the recent literature.<sup>183,184</sup> Currently, no effective donor screening test is available; however, many blood collection agencies defer donors who resided in areas where bovine spongiform encephalopathy was prevalent.<sup>185</sup>

#### Bacterial Contamination

Bacteria are currently the greatest infectious disease risk of blood transfusion<sup>186</sup> and the second most common cause of transfusion-related deaths reported to the US Food and Drug Administration (FDA) after transfusion-related acute lung injury.<sup>187</sup> Platelet products are especially prone to bacterial contamination as they are stored for up to 5 days at room temperature, thus providing an ideal growth medium for bacteria. It is estimated that 1 in 1,000 to 1 in 3,000 platelet concentrates is contaminated with bacteria.<sup>188,189</sup> The incidence is approximately fivefold higher for a typical transfusion of random donor platelets (transfused as a pool of five whole blood-derived platelet concentrates).<sup>190</sup> The prevalence of transfusion-associated sepsis is estimated to occur following one-sixth of contaminated transfusions,<sup>191</sup> and one study estimated a fatality rate of 1 in 500,000 platelet units transfused.<sup>192</sup> The organisms most commonly implicated in bacteria-contaminated platelets are *Staphylococcus aureus*, coagulase-negative staphylococci, *Corynebacterium*, *Propionibacterium*, and *Streptococcus* species. These organisms form part of the normal skin flora that can contaminate the blood unit at the time of donation.

Bacterial contamination of RBCs is much less common; however, RBC-associated sepsis is more often fatal.<sup>193</sup> The most common organisms implicated in septic RBC transfusion reactions are *Yersinia enterocolitica*, *Serratia*, and *Pseudomonas* species. These gram-negative organisms can cause endotoxic shock and are not inactivated during cold storage.

The clinical presentation of septic reactions to platelet transfusions varies from fever and chills to hypotension and shock. Generally, these reactions occur shortly after the transfusion. A body temperature elevation of at least 2°C is invariably present. RBC-associated sepsis tends to be more severe, with shock and DIC often occurring

even before the transfusion is completed. Blood products are often overlooked as the source of sepsis, especially in patients with malignancy, who may acquire infections from multiple other sources. However, vigilance in recognizing and preventing septic transfusion reactions is especially important in cancer patients, who may be at increased risk of infection owing to underlying immunosuppression.

**Treatment** In cases of new fever and/or hypotension associated with a blood transfusion, the transfusion should be immediately stopped, blood cultures should be drawn from the recipient and from all implicated blood components, and the transfusion medicine service should be notified so that co-components can be recalled if necessary. Hemolytic transfusion reactions should be excluded. Empiric therapy with antibiotics and hemodynamic support are often required even before an organism can be isolated.

To prevent septic reactions owing to bacterial contamination, the American Association of Blood Banks implemented a new safety standard in March 2004 requiring blood banks to implement strategies to limit and detect bacterial contamination of all platelet products.<sup>194</sup> Such strategies may include ensuring proper donor skin antisepsis and initial aliquot diversion from blood collections, bacterial detection of platelets by culture or indirect methods (ie, measurement of oxygen tension or pH), and the use of apheresis platelets instead of pooled random donor platelets.<sup>190</sup> Ensuring the appropriate use of blood products for all patients is another important principle that should be upheld.

#### Non-infectious Transfusion Complications

Noninfectious complications of blood transfusion are common (Table 8). Discussed in the following section are the clinical emergencies: transfusion-related acute lung injury (TRALI), hemolytic transfusion reactions, anaphylactic transfusion reactions, and post-transfusion

purpura (PTP); and the most common transfusion reaction, febrile nonhemolytic transfusion reaction (FNHTR).

#### Transfusion-Related Acute Lung Injury

TRALI is a rare complication of blood transfusion characterized by the rapid development of acute lung injury occurring within 6 hours of the transfusion. The clinical presentation is indistinguishable from adult respiratory distress syndrome, with hypoxemia, bilateral pulmonary infiltrates on chest radiograph, and preservation of cardiac function (noncardiogenic pulmonary edema). Other features include fever and hypotension that is generally refractory to fluid resuscitation, the need for intubation and mechanical ventilation, and, in most cases, a rapid recovery within 48 to 96 hours.<sup>195</sup> However, TRALI is fatal in approximately 5 to 10% of cases and was the most common cause of transfusion-related deaths reported to the FDA from 2001 to 2003.<sup>187</sup>

Both immune and nonimmune mechanisms have been proposed in the pathophysiology of TRALI. Antileukocyte antibodies, usually with specificity for human leukocyte, granulocyte, or monocyte antigens, have been detected in patients with TRALI or in implicated donors.<sup>187,196,197</sup> These antibodies are thought to react with recipient leukocytes, causing leukosequestration and activation of monocytes and complement, endothelial damage, and a capillary leak syndrome in the lungs.<sup>197</sup> Antileukocyte antibodies may also form immune complexes, causing neutrophil activation.<sup>198</sup> Some authors report a low rate of antibody detection, suggesting that other, nonimmune mechanisms may be important in the pathophysiology of TRALI,<sup>199</sup> such as the accumulation of neutrophil-priming lipids in stored blood products that cause neutrophil activation and lung injury.<sup>200,201</sup> Patients with hematologic malignancy and cardiac disease seem to be at greatest risk of TRALI.<sup>199</sup> It has been hypothesized that two events are required for TRALI to occur: the first is a predisposing clinical condition such as surgery, trauma, or severe infection that results in activation of the pulmonary endothelium and the second is the transfusion of cytokines, biologically active lipids, or leukoagglutinating antibodies that results in neutrophil activation and acute lung injury.<sup>202</sup>

Treatment for TRALI is largely supportive, and patients often require a brief period of intubation and mechanical ventilation. Diuretics are generally ineffective, and the benefit of corticosteroids, prostaglandins, nonsteroidal anti-inflammatory medications, and antibody-based therapies remains unproven.<sup>195,203</sup>

#### Hemolytic Transfusion Reactions

Acute hemolytic transfusion reaction (AHTR) is the accelerated destruction of donor and/or

**Table 8** Non-infectious risks of blood transfusion

Transfusion Reaction	Risk per unit transfused
Transfusion-related acute lung injury	1:5,000–1:100,000
Acute hemolytic	1:20,000
Anaphylactic	1:1,500–1:23,000
Allergic	1:33–1:300
Delayed hemolytic	1:10,000
Febrile nonhemolytic	1:500 RBC transfusions 1:14 platelet transfusions
Transfusion-associated circulatory overload	1:100

Adapted from Kleinman S et al.<sup>234</sup>  
RBC = red blood cell.

recipient RBCs immediately following or within 24 hours of a transfusion.<sup>204</sup> These reactions most often occur when preexisting antibodies in the recipient's circulation react with RBC antigens on donor cells (ie, group A or red cells transfused to a group O recipient); however, AHTRs may also occur as a result of the passive transfer of hemolytic antibodies in plasma-containing blood products.<sup>205–208</sup> Clerical errors (ie, inadvertently transfusing the wrong units of blood) accounted for 86% of fatal AHTRs reported to the FDA between 1976 and 1985.<sup>209</sup> The consequence is intravascular hemolysis, and the clinical presentation includes fever, pain, hemoglobinemia, and hemoglobinuria. In severe cases, hypotension, DIC, and acute renal failure ensue as a result of cytokine release,<sup>210–212</sup> endothelial tissue factor overexpression,<sup>213</sup> and the nephrotoxic effects of free hemoglobin.<sup>214,215</sup>

The severity of AHTR is directly related to the volume of incompatible blood transfused. Therefore, the transfusion must be stopped as soon as hemolysis is suspected. Vigorous fluid resuscitation and vasopressor agents are often required in cases of hemodynamic compromise. Exchange transfusion with antigen-negative blood should be considered in patients who respond poorly to supportive measures and who have been exposed to large volumes of incompatible blood.

Delayed hemolytic transfusion reaction occurs when the transfusion of RBCs induces an anamnestic antibody response and hemolysis of the transfused cells 2 days to 3 weeks following the transfusion. Patients generally have an alloantibody to RBC antigens that is of sufficiently low titer to elude detection at pretransfusion testing; however, on secondary exposure to the offending antigen, the alloantibody titer rapidly rises and causes hemolysis. Extravascular hemolysis is the main feature of a delayed hemolytic transfusion reaction, which is characterized clinically by an unexplained post-transfusion drop in hematocrit, a positive DAT with IgG or complement coating the cells, and laboratory evidence of hemolysis. Treatment is supportive and, if required, additional transfusions must be antigen negative.<sup>216</sup>

### Anaphylactic Transfusion Reactions

Anaphylactic transfusion reactions are characterized by skin rash, respiratory compromise, upper airway obstruction, bronchospasm, cardiovascular collapse, nausea, vomiting, and abdominal pain occurring rapidly within 1 to 45 minutes following the start of the transfusion. The absence of fever and the presence of cutaneous signs distinguished anaphylactic reactions from septic or severe hemolytic reactions. Less severe allergic reactions, generally manifested by cutaneous reactions only, are far more common,

complicating up to 2 to 3% of transfusions.<sup>217</sup> The mechanisms of anaphylactic transfusion reactions include IgE-mediated mast cell activation from allergens in the transfused product; the passive transfer of exogenous anaphylatoxins such as IgE, C3a, C5a, and histamine; and IgG antigen-antibody interactions resulting in endogenous anaphylatoxins. Preformed (IgG) anti-IgA antibodies causing anaphylactic transfusion reactions was first described in 1968 by Vyas and colleagues.<sup>218</sup> However, most anaphylactic reactions are likely not due to anti-IgA<sup>219</sup> but to other mechanisms or perhaps other preformed IgG antibodies in the recipient (eg, antihaptoglobin antibodies).<sup>220</sup>

Anaphylaxis following blood transfusion is a medical emergency and should be managed in the same manner as anaphylaxis to other allergens. The offending agent must be removed immediately by stopping the transfusion, epinephrine should be administered subcutaneously or intravenously depending on the severity of the reaction, and cardiovascular support must be initiated with fluids, inotropes, oxygen therapy, and endotracheal intubation when necessary. Antihistamines may be given for the treatment of urticaria. For mild allergic reactions (itching and hives), administration of antihistamines alone may suffice and the transfusion may be slowly restarted once the reaction abates. Washed RBCs and platelets should be used for patients with repeated anaphylactic or anaphylactoid reactions who required additional transfusions and who do not have anti-IgA antibodies. Patients with undetectable IgA levels in whom anti-IgA antibodies are detected following an anaphylactic transfusion reaction should receive subsequent transfusions from IgA-deficient donors only.<sup>221</sup>

### Post-Transfusion Purpura

PTP is characterized by the sudden onset of severe thrombocytopenia 5 to 10 days following blood transfusion in a patient sensitized by previous pregnancies or transfusions.<sup>222</sup> Platelet counts usually fall below  $10 \times 10^9/L$ , and mucocutaneous bleeding, including wet purpura, epistaxis, and gastrointestinal or urinary tract hemorrhage, is common. In fact, PTP is associated with a 7% risk of death owing to intracranial hemorrhage.<sup>223,224</sup> Although other platelet antigens have been implicated in this syndrome, most patients with PTP are homozygous for the human platelet antigen 1b (HPA-1b, formerly PL<sup>A2</sup>) and have formed alloantibodies against HPA-1a in response to previous exposure. Blood transfusions containing platelet antigens, including whole blood, RBCs, platelets, and plasma transfusions, invoke a brisk antibody response, which destroys not only transfused antigen-positive platelets but also autologous antigen-negative platelets. The proposed mechanisms for autologous platelet destruction include immune complex formation

and platelet Fc receptor binding,<sup>225</sup> platelet auto-antibody formation in response to exogenous platelet antigen,<sup>226</sup> and adsorption of soluble platelet antigen onto autologous platelets.<sup>227</sup> Platelets from patients with PTP should be phenotyped for common platelet antigens using serologic or deoxyribonucleic acid (DNA)-based assays.

PTP is a rare syndrome; only 3% of Caucasians in North America do not express HPA-1a in their platelets, and less than one-third of them would be expected to mount the required immune response.<sup>228</sup> In addition, patients invariably have a history of pregnancies or transfusions. With these figures, 8,000 to 9,000 cases of HPA-1a-negative PTP would be expected per year in the United States; however, approximately 300 cases have been reported in the literature.<sup>223</sup>

IVIg (0.5 g/kg on each of 2 consecutive days) is considered first-line therapy for PTP.<sup>229</sup> Other therapies that have been used include high-dose corticosteroids and therapeutic plasma exchange. Platelet transfusions are generally ineffective; however, in patients with severe bleeding complications, a trial of antigen-negative platelet transfusions should be attempted.<sup>230</sup>

### Febrile Nonhemolytic Transfusion Reactions

FNHTRs are characterized by a rise in temperature of at least 1°C that cannot be explained by the patient's clinical condition, often accompanied by chills, rigors, and a feeling of discomfort. The frequency of FNHTR following RBC transfusion ranges from 1 to 12% and following platelet transfusion from 11.4 to 37.5%.<sup>231</sup> Product storage time, leukocyte content, and cytokines present in the transfusion have been associated with FNHTR; thus, leukocyte depletion of platelets, especially prior to storage, use of fresh platelets, and plasma removal of platelets are effective methods of preventing FNHTRs.<sup>232</sup>

FNHTR should be managed according to the severity of the reaction; mild reactions can usually be managed with antipyretics and a brief interruption of the transfusion; for moderate and severe reactions that include hypotension and dyspnea, the transfusion should be stopped and hemolytic or septic reactions should be excluded.<sup>232</sup>

# Rheumatologic Paraneoplastic Syndromes

Megan C. MacNeil, MD  
Frank C. Arnett, MD

Neoplastic diseases often present with manifestations in the musculoskeletal system or as mimics of systemic rheumatic diseases. Recognition of these paraneoplastic syndromes and their associated malignancies can lead to earlier cancer diagnosis and treatment. Often treatment of the cancer causes resolution or, at least, stabilization of the rheumatologic disease. At times, however, the paraneoplastic disease can be as morbid as the underlying cancer and require treatment in addition to primary oncologic care. This chapter reviews the most common paraneoplastic rheumatic syndromes and suggestions for their diagnosis and treatment.

## Hypertrophic Osteoarthropathy

Hypertrophic osteoarthropathy (HO), also known as Marie-Bamberger syndrome, is characterized by chronic proliferative periostitis of the long bones, clubbing of the fingers and toes, and oligoarticular or polyarticular synovitis.<sup>1</sup> It may be primary or secondary. Primary hypertrophic osteoarthropathy, or pachydermoperiostosis, is usually hereditary, but idiopathic cases have been reported. Secondary causes include malignancy, infectious diseases, especially of the lung, chronic liver disease, inflammatory bowel disease, hyperthyroidism, and cyanotic or congenital heart disease. When HO begins acutely and other causes are not apparent, it almost always indicates an underlying malignancy, usually bronchogenic carcinoma. It also may be seen in a multitude of other malignancies, including carcinoma of the esophagus, colon, liver, and intrathoracic lymphomas.<sup>2-5</sup> More recently, it has been reported in liver rhabdomyosarcoma and nasopharyngeal carcinoma.<sup>6,7</sup>

## Clinical Manifestations

Early recognition of HO, especially of rapid onset, should prompt an evaluation for an underlying

cancer. HO may precede the symptoms of a malignant diagnosis by as many as 18 months or follow the diagnosis of malignancy by months to years.<sup>1,3</sup>

Clubbing is characterized by<sup>1,8</sup>

1. Softening of the nail bed
2. A loss of the normal 15° angle between the nail and the soft tissue
3. Increased convexity of the nail
4. A shiny appearance of the nail and adjacent skin
5. Local warmth and swelling.

It is usually asymptomatic but may present with dysesthesias and stiffness of the fingers (Figure 1).

Periostitis is inflammation of the fibrous membrane that covers the bones. It may be asymptomatic or may lead to a burning, deep-seated pain, usually located in the distal extremities. The pain is exacerbated when the limb is in a dependent position and is alleviated by elevation.

**FIGURE 1** Acute clubbing and polyarthritis in a patient subsequently found to have bronchogenic carcinoma (courtesy of the American College of Rheumatology).

Arthritis, with pain, stiffness, and swelling, may involve both the large and small joints; typically, it affects the metacarpophalangeal, wrist, elbow, and knee joints. On physical examination, there may be joint effusions, decreased range of motion, and tenderness of both joints and intervening bony structures. Arthrocentesis typically reveals a noninflammatory fluid, with a synovial white blood cell count usually less than total WBC 1,000 count/min.<sup>9</sup>

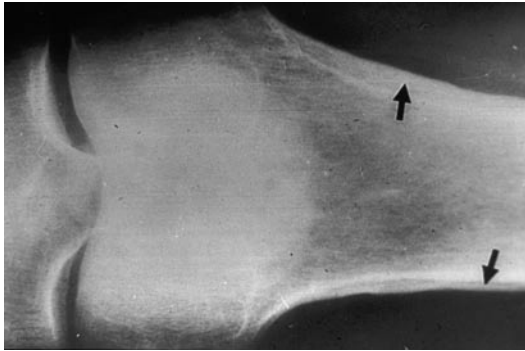

## Pathophysiology

Clubbing is the result of edema and accumulation of collagen deposition in the nail bed. The etiology of this process is unclear, but it is hypothesized that a growth factor from the tumor enters the systemic circulation and induces endothelial cell activation with vascular and periosteal hyperplasia.<sup>9</sup> Patients with lung cancer have elevated levels of vascular endothelial growth factor, which may play a role in the pathogenesis of HO.<sup>10</sup>

## Investigations

There are no definitive laboratory studies of the blood that diagnose HO. Inflammatory parameters such as a sedimentation rate and C-reactive protein may be elevated but more likely reflect the underlying malignancy. Plain radiographs of the involved bones usually reveal the diagnosis. The most consistent finding is periosteal thickening (Figures 2 and 3) and, at times, seeming detachment along the shafts of the long bones.<sup>11</sup> Mild periostosis typically involves only a few bones (usually the tibia and fibula), but severe periostosis may involve all tubular bones. Acro-osteolysis (extensive bone remodeling) may be present in long-standing clubbing. Bone scans also are useful, especially in early disease. Tracer is observed in a pericortical line adjacent to the long bones and occasionally at the digits (referred to as a “string of lights”).<sup>12</sup> Once the diagnosis is established, evaluation for age-appropriate malignancy

**FIGURE 2** Typical periosteal thickening and separation along the femur in a patient with HO (courtesy of the American College of Rheumatology).

**FIGURE 3** Typical periosteal thickening and separation along the phalanges and metatarsal bones in a patient with HO.

should begin, with the lung the focus of the initial evaluation, especially in patients who have smoked tobacco or been occupationally exposed to inhaled carcinogens.

### Treatment

Treatment of the underlying malignancy usually results in improvement in symptoms of periostosis. If the malignancy is surgically resectable, improvement may occur rapidly over the course of hours to days.<sup>13</sup> Interim treatment involves nonsteroidal anti-inflammatory drugs (NSAIDs) and other analgesics, or, if needed, low-dose corticosteroids may be helpful in controlling pain.<sup>13</sup> For those cases that are refractory to treatment, thoracic vagotomy should be considered.

### Carcinoma Polyarthrititis

Polyarthrititis may be the initial complaint in a patient with an underlying malignancy. Carcinomatous polyarthrititis is well described in both solid tumors and hematologic malignancies.<sup>11</sup> However, 80% of cases in women are reported to be associated with breast carcinoma.<sup>14</sup>

### Clinical Manifestations

The clinical presentation is most commonly confused with rheumatoid arthritis, although

adult-onset Still's disease is a diagnostic consideration when a patient presents with fever.<sup>15</sup> There are clinical features that suggest carcinoma polyarthrititis rather than rheumatoid arthritis or Still's disease. These include<sup>16</sup>

1. A close temporal relationship (10 months) between the onset of arthritis and malignancy
2. Late age at onset of inflammatory arthritis
3. Asymmetric joint involvement
4. Explosive onset
5. Lower extremity involvement with sparing of the wrists and small joints of the hands
6. Absence of rheumatoid nodules
7. Absence of rheumatoid factor
8. Absence of family history of rheumatic disease
9. Nonspecific biopsy findings of the synovial lining

### Pathophysiology

The pathophysiology of carcinoma polyarthrititis is poorly understood. Many theories have been proposed, including antigenic cross-reactivity between the synovium and the tumor, abnormalities in cell-mediated immunity, and circulating immune complex deposition.<sup>11</sup> A study on synovial fluid from a patient with carcinoma polyarthrititis failed to reveal any evidence of immune complex deposition, thus calling into question this last theory.<sup>17</sup> Most recently, Schultz and colleagues suggested that tumor-specific T lymphocytes might induce chronic synovitis by cross-reacting with synovial tissue components.<sup>18</sup>

### Investigations

Serologic studies in patients with carcinoma polyarthrititis are generally unrevealing, although some patients are reported to have positive antinuclear antibodies (ANAs) and rheumatoid factor.<sup>11,19</sup> The sedimentation rate and C-reactive protein also may be elevated. Synovial fluid analyses depict a mildly inflammatory pattern, although studies on synovial fluid are few.<sup>11,20,21</sup> No specific radiographic findings have been reported.

### Treatment

The most convincing evidence that carcinoma polyarthrititis is a paraneoplastic syndrome is the resolution of symptoms following successful treatment of the malignancy.<sup>11,14</sup> Recurrence of arthritis may indicate a relapse of the primary malignancy.<sup>11,14</sup> Patients also may respond to NSAIDs and intra-articular corticosteroids.<sup>20</sup>

### Dermatomyositis and Polymyositis

#### Clinical Features

Dermatomyositis and polymyositis are inflammatory muscle disorders characterized clinically by progressive, symmetric, proximal muscle

weakness. Legs and then arms are most commonly affected, but if the disease is not treated early, pharyngeal muscles may become involved, resulting in dysphagia, aspiration into the lungs, and dysphonia. Eventually, distal, truncal, and extraocular muscles become weak. Dermatomyositis includes cutaneous features such as a heliotrope rash, a violaceous rash that characteristically occurs over the eyelids (Figure 4). Other cutaneous features include erythema over the neck and shoulders (the shawl sign), erythema over the anterior neck and chest (the V sign) (Figure 5), and periungual telangiectasias. Gottron's papules are violaceous or pink plaques located over the interphalangeal joints, elbows, or knees that are diagnostic for dermatomyositis (Figure 6). There may be an associated inflammatory arthritis that typically affects the knees, elbows, wrists, ankles, metacarpophalangeal (MCPs), and proximal interphalangeal (PIP) joints, and, occasionally, symptoms of Raynaud's phenomenon are reported.

A multitude of malignancies have been described in association with dermatomyositis and polymyositis. Most commonly, these are carcinomas, which are age and gender appropriate to the patient. Virtually all types of tumors have

**FIGURE 4** Typical heliotrope or lilac discoloration around the eyes of a patient with dermatomyositis.

**FIGURE 5** Typical "V" sign in a patient with dermatomyositis. Note also lilac discoloration of face, hands and arms.

**FIGURE 6** Typical Gottron's papules with hypopigmentation over the knuckles and hyperpigmentation around the nailbeds in a patient with dermatomyositis.

been reported. There is much controversy in the literature regarding the incidence of associated malignancy. This stems, at least in part, from the various inclusion and diagnostic criteria applied in previous studies. However, since 1975, most studies have used the Bohan and Peter diagnostic criteria.<sup>11,22</sup> A recent review from Mastaglia and Phillips suggested that the frequency of malignancy varies from 4 to 42%.<sup>23</sup> The association between dermatomyositis and malignancy is stronger than for polymyositis.<sup>23</sup> The incidence of malignancy increases with age<sup>24</sup> and decreases as the duration of the disease course increases.<sup>25</sup> The diagnosis of malignancy may occur prior to, concurrent with, or subsequent to the diagnosis of an inflammatory myopathy.<sup>23</sup>

### Pathogenesis

The pathogenesis of malignancy-associated myositis, like that of other inflammatory myopathies, is not entirely understood, but various mechanisms have been proposed. These include environmental triggers, immune complex formation between tumor antigens and muscle and skin antigens, and a tumor myotoxin-inducing inflammation in muscle and skin.<sup>20</sup>

### Investigations

An elevated creatinine kinase, aspartate aminotransferase, or transaminase level supports the diagnosis of an inflammatory myopathy, but these laboratory results are not elevated in all cases. Muscle biopsies show different and characteristic histopathologic changes for both dermatomyositis and polymyositis, but neither provides clues to the presence of the underlying malignancy. There are no myositis-specific autoantibodies, such as anti-Jo1 or Mi2, that suggest a malignancy-associated myositis. In fact, the presence of any of these autoantibodies makes malignancy less likely. A positive or negative ANA is not at all discriminating. The search for a malignancy should be guided by a thorough history and physical examination.

Baseline laboratory studies should include a complete blood count, chemistries, liver function tests, urinalysis, stool examination for occult blood, and serum protein electrophoresis.<sup>20</sup> Imaging studies should include a chest radiograph and mammograms, but further studies should be pursued based on the findings in the clinical evaluation.<sup>20</sup> The highest risk of malignancy occurs within the first 3 years,<sup>23</sup> but screening for malignancy every 2 to 3 years is recommended by some authors.<sup>20</sup>

### Treatment

Myositis associated with malignancy may or may not respond to standard treatment with moderate- to high-dose corticosteroids. Patients who are resistant to standard treatment should raise the clinician's suspicion for malignancy.<sup>11</sup> Treatment of the primary malignancy will occasionally, but not always, improve symptoms.<sup>11,20</sup>

### Vasculitis

Vasculitis is characterized by inflammation of blood vessels, which subsequently results in a variety of clinical presentations in many different organ systems. Paraneoplastic vasculitis may involve small- or medium-sized vessels and is chiefly associated with lymphoproliferative disorders, myelodysplastic syndromes, and, occasionally, solid tumors.<sup>11,20,26</sup> It most commonly presents as a leukocytoclastic vasculitis (small vessel) appearing clinically as palpable purpura but may also present as a medium vessel vasculitis mimicking polyarteritis nodosa, which has a well-known association with hairy cell leukemia. Vasculitis may precede the diagnosis of the underlying malignancy, present after the diagnosis, or occur during tumor recurrence or escape from treatment.<sup>26</sup>

### Clinical Manifestations

Paraneoplastic vasculitis has various clinical presentations, but it most commonly presents as palpable purpura with or without arthritis.<sup>27</sup> Other cutaneous forms of small vessel vasculitis include urticaria or maculopapular eruptions.<sup>20</sup> Vasculitis of the intestine<sup>26</sup> and nerve and muscles<sup>28</sup> has been reported but is much less frequent.

Hairy cell leukemia deserves special note and has been associated with vasculitis in multiple reports. Hughes and colleagues first noted the association between hairy cell leukemia and polyarteritis nodosa in 1976.<sup>29</sup> There are three general classifications<sup>30</sup>:

1. Leukocytoclastic vasculitis
2. Polyarteritis nodosa-like disease
3. Direct invasion of the vessel wall by hairy cells

Polyarteritis nodosa generally occurs after the diagnosis of hairy cell leukemia and splenectomy and was frequently preceded by infection.<sup>30</sup> Clinical characteristics are variable and may include arthritis, fever, cutaneous vasculitis, digital infarctions, an acute abdomen, mononeuritis multiplex, and/or coronary arteritis.<sup>20</sup>

### Pathogenesis

Various mechanisms have been proposed in paraneoplastic vasculitis, including

1. Immune complexes of tumor with associated antigen and antibodies, which may explain most leukocytoclastic vasculitides<sup>26,31</sup>
2. Antibodies directed toward the endothelial cell wall that cross-react with antigens on leukemic cells
3. Leukemic cells that directly affect the vascular wall<sup>26,32,33</sup>

### Treatment

*Corticosteroids, cyclophosphamide, and treatment of the underlying malignancy may result in improvement in or resolution of the vasculitis. Corticosteroid treatment alone is associated with frequent relapses, and the addition of cyclophosphamide is usually necessary, especially in patients with a polyarteritis-like picture. Prognosis is dependent on the stage and primary malignancy.*

### Palmar Fasciitis and Polyarthritides Syndrome

Medsger and colleagues first described the palmar fasciitis and polyarthritides syndrome in 1982.<sup>34</sup> The initial case reports included six patients with ovarian cancer. Since that time, a multitude of other malignancies have been reported. The list includes but is not limited to breast,<sup>35</sup> lung, pancreatic,<sup>36</sup> stomach,<sup>37</sup> prostate,<sup>38</sup> uterine,<sup>39</sup> and endometrial<sup>40</sup> cancers. Although palmar fasciitis and polyarthritides syndrome usually indicates an underlying malignancy, the same syndrome may occur in patients on long-term therapy with barbiturates<sup>41</sup> or antituberculous drugs.<sup>42</sup>

### Clinical Features

Palmar fasciitis and polyarthritides syndrome is marked by dramatic nodular thickening of the palmar and, at times, plantar fascia (Figure 7). It may extend from the flexor retinaculum to the flexor tendons of the hand, resulting in contractures of fingers owing to palmar fasciitis and "claw hands" (Figure 8).<sup>36</sup> In many ways, it resembles an accelerated and more extensive form of Dupuytren's contracture. Paresthesias of the second and third fingers may lead to a diagnosis of carpal tunnel syndrome and may be relieved by carpal tunnel release procedures. The shoulder is commonly affected by an adhesive capsulitis (frozen shoulder), leading to diagnostic confusion with

**FIGURE 7** Thickening of the palmar fascia with tethering of overlying skin.

**FIGURE 8** Flexure contractures of the fingers resulting in a claw hand.

hand-shoulder syndrome. Hand-shoulder syndrome is a variant of reflex sympathetic dystrophy that is characterized by pain, swelling, and vasomotor changes of the skin over the hand and shoulder. Distinguishing features of palmar fasciitis and polyarthritis syndrome include a more aggressive disease course, bilateral involvement, and a more inflammatory arthritis.<sup>36</sup> In addition, patients commonly complain of morning stiffness and may develop lower extremity involvement and plantar fasciitis. Symptoms may present 1 to 23 months prior to the diagnosis of a malignancy, and, frequently, patients are misdiagnosed as having scleroderma.<sup>34,36</sup>

### Investigations

The diagnosis of palmar fasciitis is based on the typical clinical findings; however, biopsies of the fascia will show marked fibrosis with “whorls” of fibroblasts and connective tissue separated by fibrous septae.<sup>36</sup> Immunofluorescence studies have shown immune deposits, suggesting an immunologic pathogenesis.<sup>43–45</sup> Plain hand radiographs may show flexion contractures of the fingers and demineralization but are usually

unremarkable.<sup>36,40</sup> Bone scans have revealed increased uptake of tracer in the involved joints.<sup>40</sup>

### Treatment

Treatment of palmar fasciitis is directed toward identification and treatment of the primary malignancy, which may be quite small. In women, attention should be especially directed toward the ovaries. Responses to treatment of the underlying cancer are variable, with some patients improving and others progressing. This may be due to the late stage of presentation in some cases; patients presenting with extensive metastatic disease usually have an overall poor prognosis.<sup>45</sup> Treatment with corticosteroids and anti-inflammatory medications has resulted in variable clinical responses, with appreciable improvement in some patients but not in others.

### Panniculitis

Panniculitis is characterized by subcutaneous fat necrosis associated with pancreatitis or pancreatic cancer. Lesions resembling erythema nodosum usually appear over the distal extremities. When they occur in joints or bones, synovitis results from the periarticular fat necrosis.<sup>11</sup> The lesions are generally small and erythematous and range between 1 and 2 cm. Nodules may ulcerate and secrete an oily substance.<sup>46</sup> In addition to the skin and joints, fat necrosis may involve the omentum and peritoneum.<sup>47</sup> A massive release of pancreatic enzymes, including lipase, amylase, and trypsin, results in focal areas of fat necrosis.

Further investigation should be pursued in patients presenting with an unexplained mono- or polyarthritis with subcutaneous nodules. Studies should include a complete blood count; serum levels of lipase, amylase, and trypsin<sup>48</sup>; and a biopsy of the nodule. Eosinophilia is more commonly associated with pancreatic cancer than pancreatitis.<sup>11</sup> If the lipase, amylase, or trypsin level is elevated, the pancreas should be further evaluated with an imaging study. Biopsies of nodules reveal steatonecrosis and “ghost-like cells.” These cells have thick cell walls and no nucleus and are pathognomonic for this condition.<sup>11,49</sup> Areas of necrosis are surrounded by inflammatory cells, including neutrophils, lymphocytes, histiocytes, foamy cells, and foreign body giant cells. Basophilic calcium granules are also found in the area of necrosis.

Treatment of panniculitis should be directed at the underlying malignancy.<sup>50</sup> Octreotide has been used with variable results; however, some case reports have shown that the lesions did not progress and new lesions did not develop.<sup>51</sup> Treatment with corticosteroids and anti-inflammatory drugs is generally ineffective.<sup>11</sup> Although subcutaneous fat necrosis tends to occur late in the

disease course of a pancreatic malignancy, its early recognition may prevent long delays in diagnosis and treatment.

### Erythema Nodosum

Erythema nodosum is characterized by subcutaneous, firm, red, and tender nodules that may occur anywhere on the body but are most commonly located on the extensor surfaces of the lower extremities (Figure 9). A painful periartthritis and soft tissue swelling that occurs around the ankles and lower legs may be an accompanying feature. Erythema nodosum is often associated with fever, arthralgias, myalgias, abdominal pain, and headaches. Most cases of erythema nodosum usually remit spontaneously after 2 to 3 weeks,<sup>52</sup> but in cases associated with malignancy, the nodules may last longer than 6 months.<sup>43</sup> The female to male ratio is approximately 3 to 6:1.<sup>52</sup> Erythema nodosum has been associated with a number of malignancies but most commonly Hodgkin’s and non-Hodgkin’s lymphoma and leukemia.<sup>20</sup> Taylor described the first case of erythema nodosum associated with Hodgkin’s lymphoma in 1906.<sup>53</sup>

Symptoms may precede the diagnosis of malignancy by up to 24 months or may occur after the diagnosis or with a recurrence.<sup>52</sup> The pathogenesis is not understood but may result from immune complex deposition in the vessels in the dermis and subcutaneous fat.<sup>54</sup> Biopsies of skin lesions show septal panniculitis that is initially characterized by a neutrophilic infiltrate but will eventually progress to lymphocytic and histiocytic infiltration.<sup>55,56</sup> As the lesion matures, a granulomatous lesion develops and there is fibrosis of the septal tissue.<sup>56</sup>

The more common causes of erythema nodosum include infections (streptococcal, mycobacterial, and fungal), medications, and granulomatous diseases, such as sarcoidosis and Crohn’s disease. Malignancy should be considered when unexplained lesions last longer than 6 months and respond poorly to conventional treatments.<sup>43,52</sup> Erythema nodosum may respond to NSAIDs or low doses of corticosteroids, but

**FIGURE 9** Raised tender nodules on the shin, typical of erythema nodosum.

treatment of the underlying malignancy usually leads to resolution of the lesions without recurrence.

## Raynaud's Phenomenon and Digital Ischemia

### Clinical Manifestations

Raynaud's phenomenon is characterized by intermittent vasospasm, resulting in pallor, cyanosis, and hyperemia of any body part but most commonly the fingers. It is associated with numbness or pain of the fingertips and is precipitated by cold or, less commonly, emotional upsets. It may progress to digital ischemia and ulcers (Figure 10).

The association of digital ischemia and malignancy was first reported in 1884.<sup>57</sup> Reports of malignancy and Raynaud's phenomenon were noted in the early 1900s. It has been reported with solid tumors, including breast, stomach, pancreatic, small bowel, kidney, lung, and ovarian cancer, as well as with lymphoma, leukemia, and myeloma.<sup>20,58-61</sup> It may precede the diagnosis of malignancy by several years.<sup>61</sup> Features that suggest an underlying malignancy include<sup>20,43,58</sup>

1. An older age at onset (over 50 years)
2. An asymmetric presentation (found in 30% of cases)
3. An acute presentation as opposed to a more common insidious one
4. A rapid progression to digital ulcers and gangrene.

### Pathogenesis

The pathogenesis is unknown but may be related to circulating immune complexes, paraproteins, cryoglobulins, cryofibrinogens, cold agglutinins, and/or cytokines.<sup>20,58</sup> Inflammatory parameters, such as a sedimentation rate or C-reactive protein, may be elevated but are more likely to be related to the underlying malignancy.

**FIGURE 10** Typical findings of dry gangrene.

### Prognosis and Treatment

Paraneoplastic Raynaud's syndrome will progress to digital gangrene in 80% of cases. It was previously associated with a dismal prognosis, but treatment of the primary malignancy has led to resolution of symptoms in some cases.<sup>43</sup>

### Erythromelalgia

Erythromelalgia is a rare disorder that is characterized by redness, warmth, and pain in the skin of any body part but is most commonly described in the extremities. It was originally described by Mitchell in the 1870s, using the Greek words *erythros* (red), *melos* (extremities), and *algos* (pain).<sup>62</sup> It is generally classified into primary erythromelalgia (an idiopathic form) or secondary erythromelalgia, which is associated with an underlying disease process. In one study, 41% of patients were diagnosed with secondary erythromelalgia and 20% of these patients had a myeloproliferative disorder.<sup>63</sup> The majority of these patients have polycythemia vera (59%) or essential thrombocythemia (38%).<sup>63</sup> Secondary erythromelalgia has also been reported in agnogenic myeloid metaplasia, chronic myelogenous leukemia, and colon cancer.<sup>64,65</sup>

### Clinical Manifestations

The median age at onset of myeloproliferation-associated erythromelalgia is 59 years, and it is rarely reported under the age of 30 years.<sup>64</sup> Of note, primary erythromelalgia occurs most commonly in patients younger than 30 years. A 3:2 male to female ratio has been reported in myeloproliferation-associated erythromelalgia; however, this ratio has not been observed in patients with primary forms.<sup>64</sup>

Patients describe a pruritic or prickling sensation that eventually progresses to a burning or throbbing pain. Episodes may last minutes to days. During an episode, there is redness and warmth of the involved area. Limb dependency, exercise, and warm temperatures are common triggers. The patient often describes immersing the hands and feet in ice water to obtain relief. The physical examination is unremarkable when the patient is not having an episode, and this commonly leads to a delay in diagnosis. During an episode, there is erythema and increased temperature of the skin. The patient may have normal or bounding peripheral pulses. Local congestion may develop, leading to acrocyanosis and, rarely, gangrene, requiring amputation. Episodes may result in ischemic ulcers that can become secondarily infected. A few cases of concomitant and alternating episodes of Raynaud's phenomenon have been recorded.

Up to 85% of patients have reported symptoms before the diagnosis of a myeloproliferative disorder was established.<sup>64</sup> The average time

between onset of symptoms and diagnosis of a myeloproliferative disorder is 2.5 years, but symptoms may precede the diagnosis by as many as 16 years.<sup>64,66</sup>

### Pathophysiology

The pathophysiology in erythromelalgia associated with myeloproliferative disorders, although not entirely understood, appears to be related to platelet hyperaggregability and arteriolar fibrosis.<sup>66,67</sup> Skin biopsies show arteriolar inflammation, fibromuscular intima proliferation, and thrombotic occlusion.<sup>66</sup> Symptoms often improve with treatment with low-dose aspirin or other NSAIDs, suggesting an important role for cyclooxygenase and prostaglandins.<sup>66</sup>

### Investigations

Laboratory studies may be useful in identifying a myeloproliferative disorder. All patients should be evaluated with routine complete blood counts. Elevations in hemoglobin, leukocytes or subsets thereof, and platelets should be further evaluated with bone marrow biopsies.

No specific findings are present on plain radiographs of hands or feet, but bone scans may be useful in excluding other differential diagnoses, such as reflex sympathetic dystrophy. Thermography is rarely necessary but typically shows temperatures between 31°C and 36°C, and differences up to 9°C have been observed.<sup>64</sup>

Skin biopsies will often show arteriolar lesions with swollen endothelial cells, intimal proliferation, and thrombosis, with sparing of the venules, capillaries, and nerves.<sup>66</sup>

### Treatment

Local measures, such as elevating or cooling the involved extremity, may be helpful. Aspirin, in a single dose of 650 mg, will often relieve symptoms within hours and last for up to 4 days. Indomethacin and other NSAIDs are also helpful but do not provide long-lasting relief. Sodium-salicylate, dipyridamole, sulfipyrazone, ticlopidine, and dazoxiben have no significant effect on symptoms.<sup>66</sup>

Treatment of the underlying disease leads to variable responses. Phlebotomy in polycythemia vera and normalization of platelet counts in patients with thrombocytosis have led to improvement in symptoms in many but not all patients.

### Lupus-Like Syndrome

A lupus-like syndrome has been associated with a variety of malignancies, including breast carcinoma, hairy cell leukemia, and Hodgkin's and non-Hodgkin's lymphoma.<sup>20,68-70</sup> The syndrome resembles systemic lupus erythematosus and is

classically described as a nondeforming polyarthritides, pleuritis, or pneumonitis with a positive ANA.<sup>11,69</sup> The ANA is positive in 70% of cases and anti-double-stranded deoxyribonucleic acid (DNA) positive in 50% of cases.<sup>71</sup> Although a majority of patients will have positive antinuclear antibodies (ANAs), they tend to lack specific antibodies to Smith (Sm), ribonuclear protein (RNP), SS-A (Ro), and SS-B (La).<sup>68</sup> The differential diagnosis includes metastases or radiation-induced injury, but the diagnosis of a lupus-like syndrome should be considered in a patient with these systemic symptoms because they are responsive to treatment with corticosteroids.<sup>11,20</sup>

### Multicentric Reticulohistiocytosis

Multicentric reticulohistiocytosis (MRH) is a systemic disease characterized by an insidious onset of papules or nodules in the skin, mucosa, subcutaneous tissue, synovium, periosteum, and bones that may result in a destructive arthritis (Figure 11).<sup>72</sup> The cause of MRH is unknown but is likely related to the proliferation of histiocytes in the nodules. The histiocytes are considered reactive and not malignant cells.<sup>73</sup> Approximately one-third of patients have an underlying malignancy, which is detected after the diagnosis of MRH in 73% of reported cases.<sup>72</sup> It has been associated with a multitude of malignancies; however, there is no association with a predominant type of cancer.<sup>73</sup>

### Clinical Manifestations

The mean age at onset of MRH is 50 years, and it is associated with a slight female to male preponderance (1.85:1).<sup>72,74</sup> Eighty-eight percent of cases are reported in Caucasians, which may reflect more reports from developed countries.<sup>74</sup>

The skin lesions are described as reddish brown, pink, or gray papules or nodules that range from a few millimeters to 2 cm in circumference. They typically affect the hands, followed by the face, arms, trunk, legs, ears, mucosa, and

**FIGURE 11** Polyarthritides affecting distal and proximal interphalangeal joints and cutaneous nodules over the metacarpal and interphalangeal joints in a patient multicentric reticulohistiocytosis.

neck.<sup>74</sup> They may be clustered around the nail, forming a “string of coral beads,” which is a pathognomonic sign for MRH. Other typical findings may be palpebral xanthelasmas, found in 17% of cases, and vermicular lesions bordering the nostrils in 15% of cases.<sup>74</sup>

The arthritis is typically symmetric and commonly affects the hands and interphalangeal (especially distal) joints (75% cases). However, MRH also may affect the wrists (46%), shoulders (36%), elbows (31%), ankles and hips (9%), feet (6%), and neck and spine (2%).<sup>72,74</sup> It is an erosive arthritis that may progress to arthritis mutilans in as many as 45% of cases.<sup>72</sup> The clinical course is typically relapsing and remitting, and, eventually, most cases will remit spontaneously after 7 to 8 years.<sup>73</sup>

### Investigations

Although there is no specific serum laboratory test that is diagnostic for MRH, some patients may have an elevated sedimentation rate or anemia.<sup>72</sup> The skin biopsy contains histiocytic multinucleated giant cells with an eosinophilic, finely granulated, ground-glass cytoplasm.<sup>72</sup> These cells are considered the structural hallmark for MRH. Radiographs of the affected joints reveal periarticular “punched-out” erosions and reabsorption of the juxta-articular zone.<sup>74</sup>

### Treatment

There is no therapy that consistently improves MRH. It usually does not follow the same clinical course as the underlying malignancy; however, there have been case reports of regression with successful treatment of the cancer.<sup>75</sup> The patient may be treated symptomatically with NSAIDs and corticosteroids. There have been case reports of successful treatment of MRH with cyclophosphamide<sup>76–79</sup> and methotrexate.<sup>80,81</sup> Treatment regimens with other alkylating agents also have occasionally shown good results,<sup>74,82,83</sup> and, more recently, there have been promising case reports with tumor necrosis factor inhibitors, such as etanercept.<sup>84,85</sup>

# Rheumatologic Issues in Cancer Patients

Firas Alkassab, MD  
Frank C. Arnett, MD

As discussed in the preceding chapter, certain rheumatologic disorders typically or frequently present as paraneoplastic syndromes, thus alerting the physician to a high likelihood of an underlying malignancy. As is presented in this chapter, there are a number of rheumatic and autoimmune diseases that themselves predispose patients to neoplasia, often after many years. Moreover, certain antirheumatic therapeutic agents may augment the risk of these same cancers or predispose patients *de novo* to others. Similarly, a number of oncologic therapies may induce true rheumatic or autoimmune syndromes, or mimics of them. The implications of these interrelationships are highly clinically significant in both diagnosis and management and require recognition by both primary care physicians and specialists alike. Moreover, they even carry over into the care of patients who happen to suffer from both cancer and a rheumatic disease.<sup>1-3</sup>

## Rheumatic and Autoimmune Diseases Predisposing Individuals to Cancer

Associations between rheumatic autoimmune diseases and cancer are increasingly being recognized,<sup>4,5</sup> although the pathogenetic mechanisms underlying these predispositions are not well understood. It is difficult to demonstrate a causal nature of such relationships owing to the rarity of the co-occurrence of these conditions and the difficulties associated with designing large studies that would answer such questions with certainty.

It has been shown that certain rheumatic or autoimmune conditions carry an increased risk of certain types of malignancies; among these are rheumatoid arthritis (RA), Sjögren's syndrome (SS), dermatomyositis (DM), and systemic sclerosis.<sup>4</sup> Moreover, there is an increased incidence of autoimmune phenomena developing after initiating cancer therapy, as well as an increased malignant potential associated with administration of immunomodulating drugs. This observation makes it even harder to ascertain a causal relationship between rheumatic diseases, cancer and their treatments.

Table 1 displays the suggested associations between the rheumatic diseases and certain

malignancies. A brief discussion of the most common diseases and their associations follows.

### Rheumatoid Arthritis

The association between (RA) and lymphoproliferative disorders is suggested from epidemiologic data derived primarily from two population-based studies from Sweden<sup>6</sup> and Finland<sup>7</sup> that found an approximately twofold overall increased risk of lymphomas in the RA population. Consistent with these data, in a recent prospective US study, the overall standardized incidence ratio (SIR) for development of lymphoma was reported to be 1.9, which was increased further with the

use of antirheumatic drugs,<sup>8</sup> as is discussed later. A nested-control study based on the Swedish data found that rheumatoid disease activity is an independent risk factor conferring up to a 25-fold increase in lymphoma risk in severe arthritis with a high inflammatory state.<sup>9,10</sup> Most of the lymphomas appear to be of the non-Hodgkin's disease type, particularly the diffuse large B-cell form.<sup>11</sup>

### Sjögren's Syndrome

Many studies have reported an increased incidence of lymphomas ranging from 2 to 9% in patients with primary Sjögren's Syndrome (SS),<sup>12-14</sup> exceeding the frequency of lymphoma in the general population by up to 44-fold.<sup>13</sup> There is, however, a long latency period between the onset of SS, which is often subtle, and the diagnosis of lymphoma ranging from 1.5 to 12 years.<sup>15</sup> There also is an increased incidence of malignant lymphoma with time (2.6% at 5 years compared with 3.9% at 10 years in one study).<sup>16</sup> Similar to RA, most of the lymphomas are of the non-Hodgkin's B-cell type,<sup>12</sup> and some are of the MALT (mucosa-associated lymphoid tissue) type.<sup>17</sup> Hyperstimulation of B cells, an inherent characteristic of SS that has been termed *pseudolymphoma*, appears to be the main pathogenic mechanism that precedes and predisposes patients to the malignant transformation, in conjunction with other suggested mechanisms still under investigation.<sup>18</sup> In patients with primary SS, one in five deaths is attributable to lymphoma.<sup>16</sup>

### Dermatomyositis/Polymyositis

The association between Dermatomyositis (DM) and malignancy has long been noted and found to be stronger than polymyositis (PM). An Australian population-based study estimated the SIR for cancer in DM at 6.2 and in PM at 2.0.<sup>19</sup> The incidence was found to be highest within 2 years of the diagnosis of myositis and to fall significantly after that.<sup>19,20</sup> Solid tumors, such as breast, ovarian, lung, pancreatic, gastric, and colorectal cancers, as well as lymphoproliferative malignancies, are overrepresented in the myositis population.<sup>21</sup>

Table 1 Rheumatic Diseases' Associations with Malignancies

Rheumatic Disease	Associated Neoplasms
Rheumatoid arthritis	Lymphoproliferative diseases (non-Hodgkin's lymphoma, Hodgkin's disease)
Sjögren's syndrome	Paraproteinemia and multiple myeloma <sup>89,90</sup> Lymphoproliferative diseases (non-Hodgkin's lymphoma, Hodgkin's disease) Monoclonal gammopathies, <sup>17,91</sup> angiimmunoblastic lymphadenopathy <sup>92</sup>
Dermatomyositis/polymyositis	Solid tumors (breast, ovarian, lung, pancreatic, gastric, and colorectal cancers)
Systemic sclerosis	Lymphoma at the end after; lung, breast, ovarian, skin, esophageal, and liver cancers; Lymphoma
Systemic lupus erythematosus	? Non-Hodgkin's lymphoma; lung, liver, and vulvar cancers
Giant cell arteritis (temporal arteritis)	? Lymphoid malignancies
Behçet's disease	T-cell lymphoma <sup>93</sup>

There is no consensus on cancer screening in DM/PM patients, but most authorities advocate routine screening based on the patient's age group, with special attention to those with more risk factors (age 40 years and older, weight loss, previous malignancy, a positive family history of cancer).<sup>22</sup>

Screening should include a thorough history and physical examination along with complete blood counts, serum chemistries that include liver and renal function tests, urinalysis, and a chest radiograph. Thorough pelvic and breast examinations, including PAP smears and mammograms, should be performed in women and digital rectal/prostate examinations in men.<sup>22</sup> Colonoscopy also should be strongly considered.

Myositis may improve with successful treatment of the cancer and return with cancer relapse. Careful follow-up is emphasized. In most cases, however, the myositis requires urgent treatment on its own beginning with high doses of corticosteroids (prednisone 60–80 mg daily) and continuing at those levels (or higher if necessary) until serum levels of creatine kinase (CK) have normalized. Thereafter, corticosteroids should be tapered slowly with close follow-up of the patient's weakness and rash and especially CK levels.<sup>22–25</sup> It should be noted that approximately 5% of myositis patients will never have elevated CK or other muscle enzyme levels despite proximal muscle weakness and positive electromyography and/or muscle biopsy. In such cases, frequent assessment of muscle strength as corticosteroids are tapered is essential.<sup>26,27</sup>

It also is important to note that some DM patients with or without underlying malignancy will have the typical rash but never develop clinically evident myositis (amyopathic DM).<sup>28</sup> Treatment of the rash again usually requires systemic corticosteroids.

### Systemic Sclerosis

Associations between Systemic Sclerosis (SSc) and cancer have been studied in two population-based studies from Sweden and South Australia, which reported a 1.5- to 2- fold overall increased risk of malignancy,<sup>29–31</sup> with a high incidence of lung cancer (SIR 5–6) among others. Typically, bronchogenic carcinoma may occur in patients with long-standing pulmonary fibrosis.

Ovarian, liver, breast, and nonmelanoma skin cancers, as well as Lymphoma were overrepresented, and Barrett's esophagus occurs more frequently owing to esophageal dysmotility and gastroesophageal reflux. A subset of patients has been reported in which the onsets of scleroderma and breast cancer occurred contemporaneously.<sup>31</sup>

### Systemic Lupus Erythematosus

There are conflicting data regarding the overall risk of cancer in systemic lupus erythematosus

(SLE) patients. Non-Hodgkin's lymphoma, in particular, was found to occur four to five times more often in SLE patients than in the general population in two large studies from Denmark and Canada.<sup>32,33</sup> Other malignancies with a suggested increased risk include cancers of the lung, liver, and vagina.

### Polymyalgia Rheumatica and Giant Cell Arteritis

Conflicting data exist regarding any association between polymyalgia rheumatica (PMR) or giant cell arteritis (GCA) and malignancy. A prospective study from Norway found no overall increased risk of cancer in patients with PMR or GCA,<sup>34</sup> nor did another Canadian population-based study.<sup>35</sup> There was at least a 2.3-fold increased risk of cancer in patients with biopsy-proven GCA, however, in the Norwegian study, whereas the Canadian study found no such association. Malignancies were reported to be of the lymphoid type in general. Of note, PMR has been reported as a secondary paraneoplastic syndrome associated with renal cell carcinoma.<sup>36</sup> The symptoms of PMR also can be mimicked by multiple myeloma and primary amyloidosis.

### Spondyloarthropathies

Spondyloarthropathies per se are not associated with an increased risk of malignancy.<sup>37</sup> Ankylosing spondylitis patients previously treated with spinal irradiation therapy, however, have been found to have an increased risk of developing leukemia and colon cancer.<sup>38</sup>

## Cancer and Its Treatment: Implications for Rheumatic Diseases

### Acute Monoarthritis

Cancer and its treatment can lead to an acute or chronic monoarthritis, especially in the hospital setting. The possible causes are multiple, and prompt diagnosis is critical to effective treatment (Table 2).

**Table 2 Common Causes of Acute and Chronic Monoarthritis in the Causes patient**

Acute
Septic arthritis (bacterial)
Gout
Pseudogout
Hemarthrosis
Occult trauma/fracture
Chronic
Septic arthritis (mycobacterial and fungal)
Avascular necrosis (usually from steroids)
Metastases

Needle aspiration and laboratory examination of synovial fluid should be performed immediately in patients who develop acute swelling, severe pain, erythema, and warmth in one or more joints or bursae (Table 3).

### Bacterial Arthritis

Bacterial arthritis, usually spread hematogenously from another site of infection, is common and life-threatening. Predisposing factors in cancer patients include impaired host defenses by virtue of the malignancy itself or the drugs used to treat it, along with indwelling venous catheters and hospital reservoirs of nosocomial pathogens. It also should be emphasized that patients with preexisting joint diseases, such as RA or osteoarthritis, are more liable to infection in already damaged joints.<sup>39</sup> Patients with prosthetic joints also are at high risk of bacterial seeding during bouts of sepsis, including those occurring during diagnostic and therapeutic manipulations of the oral cavity and respiratory tract, lower gastrointestinal (colonoscopy, surgery) tract, and genitourinary (cystoscopy, catheterization, and surgery) tract.<sup>40</sup>

The most common organism to infect joints is *Staphylococcus aureus*, often methicillin-resistant, originating from cutaneous wounds, cellulitis, decubitus ulcers, or even simple

**Table 3 Synovial Fluid Findings in Various Causes of Monoarthritis**

Finding	Implication
Appearance	
Clear	Noninflammatory*
Cloudy	Inflammatory
Bloody (does not clot)	Hemarthrosis (bleeding disorder, trauma, tumor)
White blood cell count	
< 2,000/mm <sup>3</sup>	Noninflammatory
> 2,000/mm <sup>3</sup>	Inflammatory
Neutrophilic	Bacterial or crystalline
Lymphocytic	Mycobacterial, fungal, tumor
Glucose	
Low (< 25% of serum level)	Infection
Gram stains and cultures	Diagnostic for bacteria
Mycobacterial and fungal stains and cultures	Diagnostic for mycobacteria and fungi
Wet preparation viewed with polarizing microscope	Diagnostic for MSU and CPPD crystals
Fat bodies viewed with polarizing microscope	Fat bodies imply bony fractures

CPPD = calcium pyrophosphate dihydrate;  
MSU = monosodium urate.

abrasions, as well as infected venous lines.<sup>41,42</sup> Virtually any bacterial type, gram positive or negative, may cause an infectious arthritis in debilitated and immunocompromised patients. Therefore, bacteriologic identification is imperative from aspirated synovial fluid and/or blood cultures, which should be obtained prior to empiric antibiotic therapy.

Mycobacterial and fungal joint infections tend to be more indolent and chronic. Synovial fluid cultures and stains are less likely to reveal the organisms. Synovial tissue biopsy performed by special needles or arthroscopically with special histopathologic stains and cultures are more likely to yield a correct identification.<sup>42</sup>

Infectious arthritis can rarely be cured with antibiotics alone. Joint drainage is essential in nearly all instances, either arthroscopically or by surgical opening of the joint.<sup>42</sup>

### Gouty Arthritis

Gouty arthritis is common in patients with malignancy by virtue of overproduction of uric acid. Proliferating tumor cells, their destruction by chemotherapy or radiation, and cachexia all result in increased cell breakdown and metabolism of purines to uric acid, which may deposit as monosodium urate (MSU) crystals in cartilaginous joint structures, renal interstitium, or both.<sup>43</sup> Renal underexcretion of uric acid may compound hyperuricemia when there is renal insufficiency or medications such as diuretics reduce renal output.<sup>44</sup>

Acute attacks of crystalline arthritis are triggered by sudden changes in serum uric acid levels, either up or down, induced by changes in tumor bulk, drugs and radiocontrast agents, acidosis, or joint trauma. Thus, attacks occurring in the hospital are not unusual. The most commonly affected joints include the first metatarsal phalangeal (podagra), instep and/or dorsal foot, ankle, knee, wrist, or elbow. Gout often mimics cellulitis, thus prompting ineffectual antibiotic coverage. Joint involvement is distinguishable by the exquisite pain elicited by attempts to actively or passively move the adjacent joint. Diagnosis is established by finding the typical intracellular MSU crystals in synovial fluid (see Table 3). It should be noted that even neutropenic patients may have gouty attacks because synovial macrophages can ingest MSU crystals and initiate an inflammatory response.<sup>44</sup>

Treatment of the acute attack must be complete before attempts to lower serum uric acid levels; otherwise, the inflammatory phase may be perpetuated and prolonged. Low-dose colchicine 0.6 mg daily or twice daily may be sufficient in an early or mild episode. Most patients require an additional short-acting non-steroidal anti-inflammatory drug (NSAID), such as indomethacin 50 mg twice or three times daily,

tolmetin 600 mg three times daily, or naproxen 500 mg twice daily. Patients with any degree of renal impairment or a history of peptic ulcer disease should not receive NSAIDs. Instead, prednisone (or another corticosteroid) 30 to 40 mg daily for 2 to 3 days followed by tapering off over the next week is an effective and far safer option. Another option is injection of a repository corticosteroid into the affected joint.<sup>44</sup>

Once the pain and inflammatory signs are resolved, low-dose colchicine should be continued as prophylaxis against another attack. If there is renal impairment, only a very low dose of colchicine 0.6 mg every 3 to 4 days should be continued so that colchicine-induced neuromyopathy does not occur.<sup>45</sup> The xanthine oxidase inhibitor allopurinol then should be started slowly, beginning at 100 mg daily. The dose should be gradually adjusted upward over the next several weeks, aiming to achieve serum uric acid levels of 6 mg/dL or less. For patients allergic to allopurinol, recombinant uricase therapy may be an option.<sup>46</sup>

### Calcium Pyrophosphate Deposition Disease

Calcium pyrophosphate dihydrate (CPPD) deposition disease occurs in approximately 20% of elderly people, as evidenced by the radiographic appearance of stippled calcifications of articular and meniscal cartilage (chondrocalcinosis) in knees, wrists, symphysis pubis, or other joints. The majority of such people remain asymptomatic unless admitted to hospitals for a medical illness or surgery. Similar to uric acid, changes in circulating levels of serum calcium may result in release of CPPD crystals into a joint, causing an acute inflammatory arthritis termed *pseudogout*.

The most commonly affected joints are the knee and wrist. Podagra is exceedingly rare in pseudogout and almost always indicates gout.

CPPD in most patients is likely to be caused by as yet unknown genetic factors. Several metabolic disorders associated with CPPD and acute attacks of pseudogout should be considered and, when found, corrected (Table 4).

Treatment of an acute attack of pseudogout is similar to that described above for gout. Low-dose colchicine may be useful as prophylaxis but is not as effective as in gout.<sup>47</sup>

### Acute Polyarthritis

Abrupt onset of acute polyarthritis in a cancer patient should lead to several major considerations. Although usually monoarticular, infections, gout, and pseudogout may present in a polyarticular fashion. The same principles of diagnosis and treatment as discussed above for monoarthritis should apply.

Serum sickness-like reactions (including polyarthritis) owing to drugs, such as sulfonamides, penicillin, and cephalosporins, are not uncommon.

An acute viral infection, especially parvovirus B19, may present in adults in a rheumatoid-like pattern, often with a transient, truncal, maculopapular rash. Such patients have typically been exposed to young children with erythema infectiosum, or fifth disease. This form of arthritis is typically short-lived (weeks to months) and responds to NSAIDs or low-dose prednisone 5 to 10 mg daily. A more serious aplastic anemia may occur in patients whose bone marrows have been compromised by virtue of malignancy or chemotherapy.<sup>48</sup>

Several cancer chemotherapeutic agents also may cause arthritis and are discussed below.

Finally, a paraneoplastic syndrome, such as hypertrophic osteoarthropathy, palmar fasciitis with polyarthritis syndrome, or carcinomatous polyarthritis, may be emerging (see Chapter 59).

### Rheumatic and Autoimmune Diseases Complicating Cancer Therapy

A multitude of rheumatic and autoimmune phenomena have been observed in cancer patients, both before and after initiating certain treatment modalities. Many of these less frequent conditions are based on case reports or small series at best, making the evidence for a true association very weak. Those supported by the most consistent and compelling evidence are summarized in Table 5; a brief discussion of the most relevant associations follows:

Bleomycin, a chemotherapeutic agent used to treat breast cancer, among others, has been linked to pulmonary fibrosis, which resembles that of scleroderma,<sup>49,50</sup> as well as Raynaud's phenomenon and fingertip necrosis. Even local use of bleomycin to treat verrucous skin lesions can induce Raynaud's phenomenon in digits so treated.<sup>51</sup>

Interferon- $\alpha$ , used primarily for the treatment of chronic viral hepatitis but also for malignant lymphoma and carcinoid tumors, has been associated with induction of autoimmune diseases, including RA, PM, SLE, and Hashimoto's thyroiditis.<sup>52,53</sup> Of these, SLE occurred at an incidence of 0.1 to 0.7%. There is increasing evidence that idiopathic SLE and other autoimmune

**Table 4** Common Metabolic Causes of Calcium Pyrophosphate Dihydrate and Attacks of Pseudogout

Hypercalcemia (from primary or secondary hyperparathyroidism, metastatic bone disease)
Hypomagnesemia
Hypothyroidism
Hemochromatosis

Table 5 Rheumatic and Autoimmune Syndromes Associated with Cancer Treatments

Cancer Treatment	Associated Rheumatic and Autoimmune Conditions	Comments
Bleomycin	Scleroderma-like pulmonary fibrosis Raynaud's phenomenon	See text
Interferon- $\alpha$	Rheumatoid arthritis Polymyositis Systemic lupus erythematosus -Hashimoto's thyroiditis	See text
GVHD (after hematopoietic cell transplantation)	Localized and generalized scleroderma (morphea) Cutaneous lupus Sjögren's syndrome Polymyositis	See text
Autologous stem cell transplantation	Spondyloarthropathy Reactive arthritis	See text
BCG immunotherapy	Reactive arthritis Sjögren's syndrome RS3PE syndrome	See text
Radiation therapy	Postradiation morphea	See text
Gemcitabine	Vasculitis (in the form of necrotizing enterocolitis) <sup>94,95</sup>	Used for bladder cancer
Goserelin	Relapsing polychondritis <sup>96</sup>	Used for prostate cancer
Interleukin-2	Rheumatoid-like seronegative polyarthritis <sup>97</sup>	Used to treat melanoma
Uracil-tegafur	Localized and generalized scleroderma (morphea) <sup>98-100</sup>	Symmetric polyarthritis and seronegative for both RF and ANAs Cutaneous scleroderma without systemic or vascular manifestations
Melphalan Paclitaxel		

ANA = antinuclear antibody; BCG = bacille Calmette-Guérin; GVHD = graft-versus-host disease; RF = rheumatoid factor; RS3PE = remitting seronegative symmetric synovitis with pitting edema.

diseases are driven by interferon-dependent pathways<sup>54</sup>; therefore, this agent should be avoided in such patients because it may exacerbate their autoimmune disease.

Chronic graft-versus-host disease, a known complication after hematopoietic cell transplantation, can cause rheumatic-like syndromes resembling localized and generalized scleroderma (morphea), cutaneous lupus, SS, and PM.<sup>55-57</sup>

Autologous stem cell transplantation, used for lymphoid malignancies, has been linked to the development of spondyloarthropathy in human leukocyte antigen B27-positive patients.<sup>58</sup> Patients who have a history of reactive arthritis (Reiter's syndrome) have been noted to have exacerbations after immunosuppressing chemotherapy, similar to patients with human immunodeficiency virus (HIV) infections<sup>59</sup> (F.C.A., personal observations, 1988).

Bacille Calmette-Guérin immunotherapy, used as an adjunctive treatment for superficial bladder carcinoma, can cause a reactive arthritis (formerly termed Reiter's syndrome), SS, and remitting seronegative symmetric synovitis with pitting edema (RS3PE syndrome).<sup>60-63</sup>

Radiation therapy has been associated with scleroderma skin changes over the irradiated areas (postradiation morphea), especially in patients with preexisting scleroderma.<sup>64-66</sup> In fact, many authorities consider scleroderma a relative contraindication for the use of radiation therapy. A risk-benefit evaluation should be performed in these circumstances.

### Rheumatic Disease Treatment: Implications for Cancer Patients

Many agents used to treat rheumatic diseases carry a small but significantly increased risk of the future development of neoplastic diseases.

It has been demonstrated that the increased risk of malignancy associated with certain rheumatic diseases, as discussed above, is independent of drug treatments. This inherent disease association risk, however, is increased even further by the use of these agents.<sup>67</sup> Drugs such as cyclophosphamide, methotrexate, chlorambucil, azathioprine, and possibly tumor necrosis factor (TNF)- $\alpha$  antagonists have been reported to predispose patients to certain types of malignancies.

Little is known about the applications of these antirheumatic drugs in patients with an established diagnosis of cancer. Their concomitant use should be based on expert opinions on a case-by-case basis.

### Alkalyting Agents

Cyclophosphamide has been clearly shown to increase the risk of cancer (relative risk 1.5), particularly bladder cancer.<sup>4,67</sup> The duration and dosing of therapy play important roles.<sup>68</sup> Some cases of malignancy, however, have been reported to occur as long as 15 years following drug discontinuance.<sup>67</sup> The incidence was estimated to be approximately 5% in a study of patients with Wegener's granulomatosis, a disease in which cyclophosphamide has proven to be lifesaving.<sup>67,69</sup> The bladder cancer is usually aggressive in nature,<sup>70</sup> justifying a close surveillance program for patients so treated, including periodic examination of the urine for the presence of hematuria and, when indicated, cystoscopy.<sup>69</sup> Finally, monthly intravenous cyclophosphamide pulse therapy rather than daily oral dosing has been found to decrease the malignant potential by reducing the cumulative dose and the total time of exposure to the carcinogenic metabolite acrolein, and it is widely preferred over continuous daily therapy nowadays.<sup>71</sup> Cyclophosphamide also may increase the risk of cutaneous squamous cell carcinomas and lymphoproliferative malignancies, especially B-cell lymphoma, which may present in the brain.<sup>72</sup>

Chlorambucil behaves similarly to cyclophosphamide but has a greater hematotoxic effect and a higher risk of inducing leukemia (1-7%).<sup>73,74</sup>

### Antimetabolites

Azathioprine use carries a malignant potential that is smaller in size in patients with RA (1 case of lymphoma per 1,000 patient-years) compared with renal transplant recipients who are receiving the drug,<sup>75</sup> and this risk increases by increasing the cumulative duration of exposure.<sup>68</sup> The most common cancers are squamous cell carcinoma of the skin, B-cell lymphomas, Hodgkin's disease, Kaposi's sarcoma, and carcinoma of the uterine cervix.<sup>76</sup>

Methotrexate increases the risk of lymphoproliferative diseases, generally after long-term use.<sup>77</sup> It has been suggested, albeit still controversially, that Epstein-Barr virus latent infection might play a role in this neoplastic transformation.<sup>78</sup> A French national prospective study found the incidence of Hodgkin's disease to be no higher in RA patients receiving methotrexate than in the general population, a scenario that was not true for non-Hodgkin's lymphoma.<sup>79</sup> These B-cell lymphomas tend to be nonaggressive, and many experts recommend a period of observation off

the drug before starting anticancer treatment since spontaneous regression does occur in many cases within a few weeks.<sup>77,80,81</sup> This approach, however, should be coupled with a very careful surveillance program in such patients because recurrence of the lymphoma is a definite possibility.<sup>82</sup> Some of these lymphomas, in complicated cases, can be refractory to conventional chemotherapy but may ultimately respond to newer therapies, such as rituximab.<sup>83</sup>

## Anticytokines

Anti-TNF- $\alpha$  agents such as infliximab, adalimumab, and etanercept, used for treatment of moderate to severe RA, psoriasis and psoriatic arthritis, ankylosing spondylitis, and Crohn's disease, have been linked in postmarketing surveillance reports to the development of lymphoproliferative malignancies with SIRs of 2.6 to 3.8.<sup>84</sup> The majority of cases have been non-Hodgkin's lymphomas with a median 8-week latency period after starting therapy.<sup>84</sup> Spontaneous regression of the tumor was described in some cases. This association is still controversial, and additional data are needed.

NSAIDs, including aspirin, used to treat many rheumatic diseases, may actually decrease the risk of colon cancer (SIR of 0.6–0.7).<sup>6</sup> This finding could be related to the presumed chemoprotective effect that these drugs have against colon neoplasms. Further clinical trials are necessary.

In conclusion, the treatments of both rheumatic and neoplastic diseases in patients who happen to have both interrelate substantially, factoring in all of the associations presented above. Some treatment modalities beneficial for one disease may prove to also be effective,<sup>85–87</sup> or detrimental,<sup>49,66,88</sup> for the other condition. Therapeutic approaches should be decided on an individual basis and after weighing the potential risks and benefits for each intervention.

# Cancer Rehabilitation

Rajesh Yadav, MD

Ki Y. Shin, MD

Ying Guo, MD

Benedict Konzen, MD

Cancer is associated with significant mortality, morbidity, and disability. With improvements in the ability to detect and treat cancer, people are living longer with it.<sup>1</sup> The goal of cancer rehabilitation is to add to quality of life by improving self-reliance and decreasing the burden of care for their caregivers.

Lehman and colleagues first studied this issue of functional deficits in the cancer setting in 1978 with support from the National Cancer Institute.<sup>2</sup> Multiple barriers were also identified, which limited the delivery of cancer rehabilitation care. Many of the remediable cancer rehabilitation problems and barriers remain the same (Table 1).

## General Rehabilitation Concepts

One of the differentiating factors in a rehabilitation evaluation is a clear picture of how an illness affects a patient's life and how such an illness precludes what is meaningful to him or her. To describe such changes, the terminology of impairments, disabilities, and handicaps is used but often misunderstood.

Impairment is any loss or abnormality of psychological, physiologic, or anatomic structure or function.<sup>3</sup> Impairment refers to a problem at

the organ level. For example, in a postoperative patient with a pathologic fracture of the left hip, impairment would be left lower extremity dysfunction with decreased range of motion about the left hip and decreased weight-bearing status.

Disability is any restriction or lack resulting from an impairment of ability to perform an activity in the manner or within the range considered normal for a human being.<sup>3</sup> Disability refers to a problem at the person level. With the above example, disability would be not being able to perform the activity of getting out of bed on one's own or to ambulate independently.

Handicap is a disadvantage for a given individual resulting from an impairment or a disability that limits or prevents the fulfillment of a role that is normal for that individual. Handicap refers to a problem at the society level. With the above example, if the patient were a postal employee and had to deliver mail, he would be disabled for that job since he is unable to ambulate and fulfill that role. However, if the employment required answering the telephone, then that patient would not be considered handicapped.

A thorough functional history and social support system are also key components of a rehabilitation evaluation.

## Types of Cancer Rehabilitation

In the cancer setting, rehabilitation has been described as being preventive, restorative, supportive, and palliative.<sup>4</sup> Preventive interventions are started before or soon after a treatment to prevent functional loss and disability. Restorative interventions include comprehensive restoration of function in a disabled patient with cured or stable disease. Supportive rehabilitation is geared toward patients with progressive disease and disability. Palliative rehabilitation interventions are focused on maintaining comfort and function in terminal phase (Table 2).

## Settings for Cancer Rehabilitation

Delivery of rehabilitation can be provided in various settings, including acute inpatient rehabilitation, consultative care, outpatient care (including home care), and even a hospice. Acute inpatient cancer rehabilitation can directly follow cancer treatments such as surgery and/or chemotherapy. After such interventions, patients may be unable to perform basic activities of daily living, such as transfers and ambulation. The goals of acute inpatient rehabilitation include improving mobility and self-care activities to allow for safe discharge. Marciniak and colleagues described functional improvements after acute inpatient rehabilitation in such patients.<sup>5</sup> Some common inpatient rehabilitation diagnoses include

**Table 1** Remediable Rehabilitation Problems and Barriers to Delivery of Rehabilitation Care

<i>Remediable Rehabilitation Problems</i>		<i>Barriers to Delivery of Rehabilitation Care</i>
Psychological/psychiatric impairments	Lymphedema management	Lack of identification of patient problems
Generalized weakness	Musculoskeletal difficulties	Lack of appropriate referral by physicians unfamiliar with the concept of rehabilitation
Impairments in activities of daily living	Swallowing dysfunction	Patient too ill to participate
Pain	Impaired communication	Patient denies need
Impaired gait/ambulation	Skin management	Cancer prognosis too limited
Disposition/housing issues	Vocational assessments	Rehabilitation unavailable
Neurologic impairments	Impaired nutrition	No financial resources

**Table 2** Benefits of Rehabilitation

Training to maximize functional independence
Facilitation of psychosocial coping and adaptation by patient and family
Improved quality of life through community reintegration: includes resumption of prior home, family, recreational, and vocational activities
Recognition, management, and prevention of comorbid illnesses that limit or impede function

significant asthenia, hemiparesis, severe gait abnormality, dyspnea with exertion, spinal cord injury, and neurogenic bowel and bladder. Significant pain with activity is quite common in patients with musculoskeletal deficits.

Rehabilitation consultation interventions have been linked to functional improvements during acute hospital stay. Outpatient rehabilitation can be prescribed for patients who do not require hospitalization and following acute inpatient rehabilitation to further improve function. Concepts and techniques taught during acute inpatient rehabilitation may also be reinforced during this phase. Common outpatient rehabilitation diagnoses include lymphedema, myofascial pain, rotator cuff dysfunction, peripheral neuropathy, and low back pain.

For terminally ill patients who are declining rapidly, issues of family training, comfort care, and appropriate adaptive equipment(s) may be addressed by the rehabilitation team. These patients may also have limited energy to pursue daily activities. Thus, therapy interventions and exercise may lead to early fatigue and prevent patients from spending quality time toward doing desired activities.

## Rehabilitation Team

Rehabilitation is a comprehensive effort and requires an interdisciplinary team of health care professionals, including rehabilitation physicians, rehabilitation nurses, physical therapists, occupational therapists, speech therapists, dietitians, pharmacists, chaplains, social workers, and case managers. Each member of the team is indispensable owing to specific expertise in assisting the patient with a care plan to maximize medical stability, function, financial resources, and caregiver involvement for a meaningful and safe discharge. Medical care is closely coordinated with primary cancer physicians and various consultants. Rehabilitation professionals can give feedback on the patient's functional issues to treating oncologists. Alteration in functional capacity may change the course of medical treatment.

## Concept of Safe Discharge

A frequent reason for cancer rehabilitation consultation is to assess the patient's functional status for safe discharge. Important variables here are the patient's physical capacity, cognition, family or caregiver support available, and financial resources. A safe discharge usually requires some combination of these factors. Many of the patients admitted to an acute inpatient rehabilitation unit require some degree of supervision and assistance on discharge owing to physical and cognition dysfunction. Patients usually lose some of their autonomy in exchange for personal safety. More time and financial resources are required

for their care. Often abnormal family dynamics come to the surface at the time of discharge, when the resources of family time and physical and financial assistance are needed. Attention is also directed toward community resources and local support, including church and friends, to fill in the gaps.

## Functional Assessment Tools

There are various tools for measuring performance in the cancer setting. The most commonly used scale is the Karnofsky Performance Scale (KPS). In the absence of any medical treatment, the KPS was found to be the best determinant of ultimate patient survival in a national hospice study. With a score of 40, patients lived, on average, less than 50 days; with a score of 20, they lived only 10 to 20 days (Table 3).<sup>6</sup> Another commonly used tool is the Eastern Cooperative Oncology Group (ECOG) scale for performance status (Table 4).

KPS does not address cognitive function or quality of life. Additional limitations of this scale that limit its use as a functional outcomes measure are its inability to objectively quantify the amount of assistance needed and its linkage of physical function with medical status. These criteria fail to accommodate severely disabled but otherwise healthy patients. Its linkage of medical status with work status is often heavily influenced by completely nonmedical factors, such as insurance, family support, and type of work done. These criticisms are also valid for ECOG and similar performance status scales.

**Table 4** Eastern Cooperative Oncology Group (ECOG) Scale Performance Status

Grade	Definition
0	Fully active, able to carry on all predisease performance without restriction
1	Restricted in physically strenuous activity; ambulatory; able to perform light or sedentary work
2	Capable of all self-care; ambulatory; unable to perform work activities; up and about more than 50% of waking hours
3	Only capable of limited self-care; confined to bed more than 50% of waking hours
4	Completely disabled; cannot carry out any self-care activity; totally confined to bed or chair

Among rehabilitation professions, one of the most commonly used scales has been the Functional Independence Measure (FIM) (Figure 1). This numeric scale is divided into various categories, from self-care to social cognition. In each of these categories, various tasks and patients are assigned a score of 1 through 7 depending on their ability to complete them. Higher scores denote that a lesser amount of assistance is required with a particular task. For example, with a score of 6 with the self-care task of toileting, patients are able to complete the task on their own but require adaptive equipment, such as an elevated commode seat. With the same task, a

**Table 3** Karnofsky Performance Status Scale

Activity Level	Scale (%)	Criteria
Able to carry on normal activity and to work; no special care needed	100	Normal: no complaints; no evidence of disease
	90	Able to carry on normal activity; minor signs or symptoms of disease
	80	Normal activity with effort: some signs or symptoms of disease
Unable to work: able to live at home and care for most personal needs; varying amount of assistance needed	70	Able to care for self; unable to carry on normal activity or to do active work
	60	Requires occasional assistance but is able to care for most of own needs
	50	Requires considerable assistance and frequent medical care
Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly	40	Disabled; requires special care and assistance
	30	Severely disabled; hospitalization indicated, although death is not imminent
	20	Very sick; hospitalization is necessary; active supportive treatment is necessary
	10	Moribund; fatal process progressing rapidly
	0	Dead

**FIGURE 1** Functional Independence Measure (FIM) instrument.

score of 4 denotes that minimum assistance is needed. This score implies that patients need somewhere between 1 and 25% assistance and patients are able to perform somewhere between 75 and 99% of the task on their own.

This tool may also be inadequate to assess cancer patients who have fewer persisting motor and communication disorders than patients with neurologic disorders, such as stroke.<sup>7</sup> This scale is also inadequate to assess patients who are clearly able to perform various tasks, but such a performance takes a long amount of time and leaves them fatigued.

Bell and colleagues found that a population of tumor patients admitted to inpatient rehabilitation units had a generally poorer functional prognosis than did noncancer patients.<sup>8</sup>

### Quality of Life

General quality of life questionnaires for patients with cancer are listed in Table 5. Quality of life status may be more strongly predictive of survival than performance status.<sup>9-12</sup> Factors associated with a better quality of life include absence of depression, good social involvement, greater

energy, and fewer symptoms. Age has not been demonstrated to be a significant factor.<sup>8,13-15</sup>

Having to motivate and push patients toward functional improvement often brings members of the cancer rehabilitation team closer to the patient. Thus, functional declines owing to advancing disease can be frustrating and disappointing. In a sense, many of the patients may have ever-changing rehabilitation targets. Such a change is not the case in traditional noncancer rehabilitation, in which there is recurrence and relapse. The morbidity and mortality associated with cancer are quite challenging to the cancer rehabilitation process. However, the patient and family's new appreciation and comfort level with everyday activities make the process worthwhile for the patient and team. An important aspect of cancer rehabilitation is alleviation of fear in patients and caregivers, which can decrease the patient's concern about being a burden.<sup>16</sup>

### Specific Topics and Rehabilitation

After delineation of basic foundations and principles of cancer rehabilitation, specific topics are presented.

#### Central Nervous System Tumors

Neurologic tumors can involve the central nervous system (CNS) with either the brain or spinal cord and are either primary or metastatic. Owing to direct injury of neural structures, patients may have motor, sensory, cognitive, and speech deficits. Functional deficits decline further owing to the indirect effects of chemotherapy and radiation treatments. More than 15,000 new cases of primary brain tumor and 4,000 new spinal tumors are diagnosed each year.<sup>17</sup> Metastatic lesions from various sites account for 20 to 40% of brain tumors,<sup>17</sup> occur in approximately 15% of cancer patients,<sup>18</sup> and produce neurologic symptoms in 85,000 patients per year. The lung and breast are the most frequent primary sources of metastatic CNS tumors. Most spinal tumors are extradural and are predominantly metastatic carcinomas, lymphomas, or sarcomas.<sup>19</sup> Spinal cord compression can occur in 5 to 10% of the cancer cases,<sup>20</sup> and resultant functional consequences can include pain, sensory deficits, motor deficits, neurogenic bowel and bladder, and sexual dysfunction (Table 6).

Even a small low-grade malignant tumor in the brain may cause significant functional deficits if present in a critical location, particularly if present close to the brainstem. The location of tumors can determine respectability (Table 7).

Changes in behavior, appetite, memory, and endocrine function may be seen following radiation treatment.<sup>18</sup> Hyponatremia, as seen with syndrome of inappropriate diuretic hormone (SIADH), may lead to mental status changes.<sup>21</sup> Fatigue may be an issue with radiation

treatment. Steroid psychosis may complicate the rehabilitation course also.

With prolonged bed immobility, supportive care is important. Measures should be taken to prevent pressure ulcers and deep venous thrombosis. Range of motion (ROM) of all joints should be done with daily exercises. Passive ROM may

be needed in patients who are paralyzed or have altered mentation. Sensory stimulation in addition to socialization should be provided. With steroid treatment initiation, strengthening therapies and programs should be instituted. Orthotic devices that support a limb or joint and assistive devices, such as walkers, may be needed. In patients with significant weakness and balance deficits, use of a wheelchair may be necessary even for household distance mobility. Physical and occupational therapists should be consulted early for evaluation and teaching of activities of daily living (ADL), ambulation, and strengthening and stretching exercises. Speech therapists can assess cognitive, linguistic, and communication deficits. They can also determine swallowing deficits and recommend appropriate dietary modifications, compensatory maneuvers, and therapeutic exercises. Hydrocephalus and seizures are complications of brain tumors and most often negatively impact rehabilitation through declining functional status. Hydrocephalus has been classically described as a triad of subcortical dementia, incontinence, and gait abnormality. It should be suspected when mental status changes occur, when a patient fails to make expected functional gains, or when spasticity, seizures, and emotional problems are present. When training patients with visual deficits, an ophthalmology consultation should be included to quantify the extent of visual field loss. Visual deficits typically affect independent living adversely and must be considered in discharge planning. Patients should be trained to use compensatory techniques such as scanning to improve visuospatial awareness. Patients with double vision can be treated with alternating-eye patching. Before discharge, driving recommendations should be given, with plans for further evaluation as vision improves. Facial and eyelid paralysis may require plastic surgery consultation for corneal protection or cosmesis. For hearing deficits, audiology and speech therapy evaluations are necessary. Vestibular disturbances are typically treated with habituation, which leads to decreased sensitivity of the vestibular response. The goals of rehabilitation are to resolve reversible deficits and to learn

compensatory and adaptive techniques for irreversible deficits, thereby improving safety and increasing independence. Spontaneous resolution is possible and is often related to the severity of the initial insult and the possible plasticity of the CNS.

Cognitive deficits are most often seen in areas involving memory, attention, initiation, and psychomotor retardation. Interventions for memory deficits include memory aids and use of visual imagery. Cognitive remediation programs teach patients adaptive strategies and compensatory techniques. Psychostimulants, such as methylphenidate, have been reported to be helpful with psychomotor retardation, depression, and opioid-induced drowsiness.<sup>15,22</sup> Dopamine agonists and stimulating antidepressants improve attention deficits in higher-level patients.<sup>23</sup> Bromocriptine can be effective for motor aphasia and neglect in some patients.<sup>24</sup>

A lack of cortical influence can lead to uninhibited bladder in these patients. Frequent prompting for urination during daytime (every 2 hours) and before sleep is very helpful. Behavioral training may be helpful in patients with unimpaired cognition. This process involves progressively increasing the time between voiding, often by 10 to 15 minutes every 2 to 5 days, until a reasonable interval between voiding is obtained. Drugs to inhibit bladder evacuations, such as anticholinergic and antispasmodic agents for the bladder, should be judiciously used. External catheters can be an option in male patients. A used diaper should be changed soon to protect against skin breakdown. Immobile or sedentary patients may become constipated easily and may require a bowel program with higher fluid intake, stool softeners, and digital stimulation. In patients with stool impaction, a thorough evacuation is needed with an oral laxative, suppositories, and enemas prior to the more conservative measures outlined above.

## Myelopathy

Myelopathy may occur owing to tumor involvement, irradiation, and intrathecal chemotherapy. Spinal cord compression eventually occurs in 5% of cancer patients.<sup>25</sup> In addition to myelopathy, radiculopathy is also possible at any level (Table 8).<sup>26,27</sup>

**Table 7** Brain Tumor Type and Possible Deficits

Type of Brain Tumor	Possible Deficits
Temporal lobe	Dysnomia, difficulty with comprehension, defective hearing and memory
Parietal lobe	Loss of vision, spatial disorientation, memory loss, dressing apraxia, proprioceptive agnosia
Frontal lobe	Personality changes, libido changes, impulsive behavior, labile emotions, excessive jocularity
Pituitary gland	Headaches, bilateral visual loss, hormonal abnormalities
Acoustic neuromas	Hearing loss, vertigo, facial palsy and numbness, dysphagia, hydrocephalus
Craniopharyngioma (adult)	Visual loss, sexual dysfunction
Craniopharyngioma (children)	Growth failure

**Table 8** Symptoms of Myelopathy

Weakness
Sensory deficits
Autonomic disturbance
Pain: spinal or radicular
Incontinence: bowel or bladder
Gait abnormality
Spinal instability

Imaging studies and neurosurgical consultation should be obtained early in patients suspected of having spinal involvement and thus prevent spinal cord damage. In patients with myelopathy, large-dose corticosteroids should be instituted emergently. Spinal stabilization and spinal cord decompression followed by radiation treatment usually provide the best outcome. When spinal surgery is not possible, patients still may be candidates for radiation treatment (Tables 9 and 10).

### Radiation-Related Myelopathy

The detrimental effects of radiation are multifactorial and cannot be entirely attributed to dosage, site, or technique. Usually, myelopathy is either transient or delayed. Transient myelopathy is reversible and has a peak onset at 4 to 6 months after radiation.<sup>28</sup> Symmetric paresthesia or shock-like sensation in a nondermatomal pattern is seen from the spine to the extremities.<sup>29</sup> Unfortunately, delayed myelopathy is irreversible and has a latency period of 9 to 18 months. Symptoms typically begin with lower extremity paresthesias and are followed by sphincter incontinence. Central pain can occur in 20% of patients and is characterized by midback pain and dysesthetic pain in the lower extremities. Such pain is treated in a manner similar to that for neuropathic pain.

### Rehabilitation

Physical and occupational therapists should be consulted early to address deficits with ADLs and mobility so that appropriate exercises and adaptive equipment may be provided. Spinal immobility may be helpful in patients with pain from forward flexion of the spine. With any new pain or neurologic deficits, additional spinal or spinal cord involvement should be entertained. Adequate pain control is essential and is required for effective rehabilitation outcomes.

**Table 9** Findings Associated with a Better Prognosis for Functional Recovery Following Cord Compression

<p>Sphincter incontinence          Complete paraplegia          Rapid evolution of symptoms (&lt; 72 h)</p>
---

Patients with myelopathy can develop detrusor-sphincter dyssynergia, a condition in which the bladder contracts but the bladder outlet (sphincters) fails to relax in a timely manner, leading to impaired emptying and increased bladder pressure. Although patients may void on their own, any such attempts should be followed by a postvoid residual volume check on multiple occasions, preferably with a catheter. With residual volumes in excess of 100 to 150 cc, an intermittent catheterization program should be performed every 4 to 6 hours. The goal is to keep urine volumes in the bladder at no more than 350 to 400 cc at any time to prevent overdistention, detrusor muscle injury, and retrograde flow of urine back into the kidneys. More frequent catheterizations may be required with increased fluid intake. Such a program should be taught to patients and their caretakers. In patients who are unwilling to learn such programs, for whom wound care may be an issue, an indwelling Foley catheter should be considered. Patients with injuries at C7 or below should be able to perform such a program on their own. In male patients who have a hyperactive bladder without bladder dyssynergia or those who have normal bladder function but with incontinence owing to impaired cognition or mobility, condom catheters may be used.

Patients with spinal cord injury usually have an upper motoneuron bowel, in which there is difficulty with evacuation. Prior to institution of a regular bowel program, bowel evacuation may be necessary on more than one occasion to rid the patient of hard stool and impaction. Once such cleansing occurs, a program consisting of adequate fluid intake, fiber, stool softeners, and digital stimulation on a daily basis should be started. Warm fluids after meals supplement gastrocolic reflex.

### Autonomic Dysreflexia

This medical emergency occurs with a massive sympathetic discharge in response to a noxious stimulus in a spinal cord–injured patient with an injury at T6 or above. The clinical presentation is that of an anxious patient with paroxysmal hypertension, nasal congestion, sweating above the level of the lesion, facial flushing, piloerection, and reflex bradycardia. The most common etiology is a distended bladder, followed by a distended bowel. Other causes include enemas, tight clothing, infection, deep venous thrombosis, and bladder catheterizations. Treatment should focus on finding the underlying cause. Lidocaine jelly should be allowed to sit for some time prior to checking the rectal vault for hard stool or evacuating a distended bladder or bowel. If a cause cannot be found, then treatment with an antihypertensive should be initiated.

### Spasticity

In patients with an upper motoneuron lesion (ie, brain or spinal cord injury), spasticity may occur. This motor disorder is characterized by a velocity-dependent increase in resistance to movement across a joint. In addition, there is an increase in tendon reflexes and muscle tone. This tone is the resistance felt by the examiner as passive ROM is tested. Examples of lesions include CNS tumors and myelopathy. Treatment should be initiated with daily ROM exercises, proper positioning, and removal of noxious stimuli. Short-term benefits are obtained with cold modality. In patients in whom spasticity interferes with ADL and mobility, systemic treatment with oral spasmolytic medications should be initiated (ie, baclofen, diazepam, dantrolene, tizanidine). For more severe spasticity, chemical neurolysis, such as phenol block, epidural infusion of medications, and botulinum toxin via an implantable pump should be considered. For patients with deficits with ROM across joints, casting and splinting techniques are helpful.

### Peripheral Neuropathy

Peripheral neuropathy symptoms include numbness, paresthesias, weakness, and, occasionally, severe neuropathic pain. Consideration should be given to nonpharmacologic means of pain management, including transcutaneous electrical nerve stimulation and various physical modalities, such as heat and physical therapy. Adaptive strategies such as energy conservation, orthotics, and adaptive equipment can be prescribed. With sensory loss in the lower extremity, preventive measures such as those used for management of diabetic neuropathy and neuropathic ulcers should be considered. Education, nonconstricting footwear, and daily inspection of feet are important.

In patients with lower motoneuron injuries, such as cauda equina syndrome or pudendal nerve injuries, areflexic bowel and a hypotonic external sphincter are present. These patients have difficulty with retaining stool and are more difficult to manage than upper motoneuron bowel patients. Since these patients have bowel accidents, excessive stool softeners, suppositories, and digital stimulation should be avoided. Oral fiber intake with a reduced amount of fluids usually helps.

### Leptomeningeal Disease

These patients have a very poor prognosis. Both central and peripheral nervous system involvement may occur, along with cerebrospinal fluid flow obstruction leading to hydrocephalus. Symptoms can include mental status changes, polyradiculopathy with radicular pain, and cauda

equina syndrome. Rehabilitation goals are primarily supportive, and management is similar to that outlined earlier depending on the deficits.

## Metastatic Bony Disease

Metastatic bony disease is quite common. It is the third most common site of metastases and usually is the most symptomatic. The more commonly involved tumors include breast, lung, kidney, and prostate cancer and multiple myeloma. The axial skeleton is the most common site, with involvement of the spine, ribs, pelvis, skull, proximal femur, and humerus. Osteolytic and osteoblastic activity leads to lytic and sclerotic types of bony lesions, both of which are susceptible to fractures. At the time of diagnosis of an osseous lesion, usually more than one lesion is present. Over two-thirds of the lesions can be painless, and when pain is present with activity, it often heralds fracture. With spinal involvement, the patient may present with new-onset back pain, particularly when recumbent. Consider ruling out a metastatic lesion in a cancer patient with new pain onset.

Treatment consists of primary disease management, radiation, surgical intervention including vertebroplasty, symptom management, and rehabilitation. With mean survival times after fixation of pathologic fractures at roughly 19 months,<sup>30</sup> it is important to maximize quality of life and manage symptoms.

Rehabilitation interventions require comprehensive assessment. Manual muscle testing of the involved limb is contraindicated. Only active movement limited by pain is assessed in the affected limb. Interventions are focused on keeping patients from becoming bedbound, training patients to use residual function or to develop compensatory techniques, use of compensatory techniques, and patient and family education. Prior to chest physical therapy, rib metastases should be ruled out. Resistive exercises are contraindicated.

Although pathologic fractures may occur during rehabilitation, it is uncommon to see them clearly during rehabilitation intervention.<sup>31</sup> Indeed, the fractures may occur even when lying in bed and without any activity in patients with erosive and progressive disease. Alternatives to rehabilitation include bed rest and, if so, then for how long? Complications of bedrest include disuse atrophy, orthostatic hypotension, lower quality of life with more assistance required for ADL, pressure ulcers, and increased risk of deep venous thrombosis.

The majority of nonambulatory patients admitted to a rehabilitation unit after surgical stabilization ambulate with or without assistive device(s).<sup>32</sup> Weight bearing of the affected extremity is usually affected depending on the surgical intervention. With methylmethacrylate

cementation, weight bearing as tolerated may be permitted. Such cementation also does not interfere with radiation treatment. With more complicated surgery, touch down or no weight bearing may be allowed. ROM is most often limited during this acute phase. Patients may also have an orthosis in place to limit the joint ROM. Such restrictions may continue for several weeks to months, depending on the surgeon's discretion. A straight-point cane may be used in patients with smaller, painful lesions. With forearm crutches, 40 to 50% weight-bearing reduction may be possible.<sup>33,34</sup> Axillary crutches and walkers allow non-weight bearing in the lower extremities. A rolling walker may be used in patients who are afraid of losing balance while lifting a standard walker.

The hip is a common site of fracture, and patients require partial or total hip arthroplasty. Even nonambulatory patients may be candidates to decrease pain and a low for basic nursing care. Standard hip precautions include hip flexion < 90° and avoidance of adduction and internal rotation for a period of up to 3 months. Early mobilization is crucial. Weight bearing is typically tolerated on postoperative day 1. Patients are generally ambulating independently with assistive devices in a few days at least at a household-level distance (roughly 150 feet). If the trochanters and attached musculature are sacrificed, then an unstable hip is present; thus, a hip abduction brace is required and a more conservative rehabilitation program is instituted. In one study, 28 patients underwent proximal femur surgical resection for metastatic disease and had cementation.<sup>35</sup> Preoperatively, 71% had intractable pain; postoperatively, 81% had no need for analgesics. Over 50% of the patients had good to excellent results with hip ROM and walking ability, and 46% were alive at 12 months.

In patients undergoing pelvis reconstruction for metastatic disease, the mean survival time is of 14.5 months. All of these patients were initially nonambulatory, and with rehabilitation, over 88% were independent with ambulation at 1 month.<sup>36</sup>

Conservative treatment with metastatic lesions to upper extremity consists of bracing and radiation treatment. Surgical treatment options include an intramedullary rod for larger lesions and a compression plate for smaller lesions. Cemented prosthesis may be used with a humeral head and neck metastases. Consideration may be given for prophylactic fixation of a nonfractured upper extremity lesion in patients requiring an assistive device for ambulation. During rehabilitation, active ROM of the affected joint(s) is typically delayed compared with a lower extremity lesion (typically postoperative day 3 or 4). With extensive disease in the upper extremity and lower extremity involvement, a wheelchair may be necessary (Table 11).

**Table 11** Effects of Prolonged Immobility

Loss of muscle strength
Joint contractures
Disuse osteoporosis
Cardiac effects: resting tachycardia, orthostatic hypotension, ↓ cardiac output
Venous thrombosis
Pressure ulcers

## General Severe Asthenia

Generalized weakness and deconditioning are commonly seen in cancer patients, particularly after various treatments and in advanced disease. Although multifactorial in nature, prolonged bed immobility is a major factor leading to such a state. Rehabilitation interventions are focused on restoring a patient's function through exercises and mitigating decline through compensatory strategies, including environmental modification. Typically, both of these strategies are concurrently applied.

In the muscles of patients with prolonged immobility, declines of 1 to 1.5% of the initial strength have been noted on a daily basis. Such declines correspond to roughly 10 to 20% strength loss per week.<sup>37</sup> Larger muscles are disproportionately affected more severely. A daily stretching program retards muscle atrophy.<sup>38</sup> In addition, isometric exercises on a daily basis can help maintain muscle strength.<sup>37</sup> Generally, it takes two or more times the period of immobilization to recover muscle strength.<sup>39</sup>

Disuse osteoporosis most commonly affects weight-bearing bones with bed immobility. Such a complication is best treated with preventive measures such as active weight-bearing exercises and active muscle contraction. Exercises in bed are not as effective.<sup>40</sup>

Resting heart rate can increase by a half-beat per minute per day for the first 3 to 4 weeks of bed immobilization.<sup>41</sup> Decreased diastolic filling time, myocardial perfusion, stroke volume (with exercise), and cardiac output are all associated with deleterious hemodynamic and orthostatic changes.<sup>40</sup> Such a decline can be reversed by a progressive exercise program and resumption of upright activities. Sudden changes should be avoided with orthostasis. In patients who have been immobilized for a week or more, a tilt table may be needed for an even slower resumption of upright posture. Standing and ambulation may begin when the patient is able to tolerate a 70° angle for 30 minutes.

Although lower-rated (< 20 mm Hg) elastic garments may be effective against deep venous thrombosis, higher ratings (20–30 mm Hg) are helpful with venous insufficiency and orthostasis. Such nonpharmacologic treatments should be supplemented with abdominal binders and medications such as ephedrine and fludrocortisone.

Measures such as frequent turning (preferably every 2 hours) should be taken to prevent pressure ulcers in patients who are totally bed-bound. Irreversible changes can occur with lying in one position for as little as 5 hours. Sitting upright as tolerated should be encouraged.

## Breast Cancer and Rehabilitation

The extent of the surgical and usual postoperative radiation treatments typically determines the complications. In lumpectomy, only the tumor and a margin of the breast tissue are removed. With a modified radical mastectomy, all breast tissue with the exception of the pectoralis minor is removed and axillary lymph nodes are sampled (Table 12).

In patients undergoing immediate reconstruction with a transverse rectus abdominis myocutaneous (TRAM) flap, functional gains with ROM are similar to those of non-TRAM patients.<sup>42</sup> Shoulder passive ROM exercise should be started carefully and until tolerance, only earlier. Active movement may be started at the earliest after day 4. More complications are encountered with more aggressive mobilization through range earlier.<sup>43,44</sup> Restrictions with functional activities should be lifted after removal of sutures, typically at 2 weeks.

## Lymphedema

The incidence of lymphedema has been variable and reported at up to 37%.<sup>45-47</sup> A median time of 39 months has been noted between treatment and presentation (Table 13).<sup>46</sup>

The patient and involved caretakers should be educated about lymphedema. Skin integrity is crucial. Insect repellents and long-sleeved clothing are typically recommended. Needlesticks

and blood pressure measurements should be avoided in the affected extremity. At the earliest sign of skin tenderness and erythema, antibiotics should be considered. Avoidance of heat exposure is helpful.

Exercises should include improvement in ROM for shoulders bilaterally and the neck and improvement in chest wall tightness with stretching of the pectoralis musculature and trapezius. Although a great deal of activity can precipitate lymphedema, no clear data exist in terms of limitation of activity. Heavy lifting should be avoided, typically less than 15 to 20 pounds. Retrograde massage techniques to improve and aid in lymphatic circulation are helpful and should be done daily.

Lymphedema may be acute and chronic in nature. In addition to a difference in limb size and "heaviness," patients note "joint tightness" and decreased ROM in the affected joints. Measurements of the affected limb are typically done with circumferential measurements at various points across the affected limb and with volume displacement techniques.

During an earlier stage, spontaneous resolution of lymphedema may occur. More chronic condition requires a daily long-term regimen and commitment. Exacerbations are treated with early referral to a physical therapist specializing in its management. Compression bandaging with a short stretch bandage for the majority of the day is most useful. At least once a day, this garment should be removed for a short period of time and rewrapped. Once limb volume stabilizes or plateaus with such treatment, a compression garment with a rating of up to 40 mm Hg should be ordered. These garments, when used regularly, should be changed every few months. Consider their use also when traveling via airplane to prevent exacerbation.

Attempts at treatment of chronic lymphedema using benopyrones, which stimulate macrophage-induced protein breakdown, were felt to be promising<sup>48</sup>; however, a recent study did not reveal such benefits.<sup>49</sup>

A rare but serious complication of chronic lymphedema is lymphangiosarcoma. This tumor has a poor prognosis despite aggressive intervention of forequarter amputation in candidates suitable for such surgery.

## Head and Neck Cancers

Such cancers and treatments frequently result in deficits with swallowing, communication, nutrition, and musculoskeletal issues. Radical neck dissection is often performed and involves removal of the sternocleidomastoid muscle, spinal accessory nerve (cranial nerve XI), internal and external jugular veins, and submandibular gland. A modified radical neck dissection spares the spinal accessory nerve.

Trapezius impairment leads to shoulder pathology with depression and protraction. Patients have a painful shoulder with decreased ROM, and abduction is typically less than 90°. Rehabilitation focuses on neck ROM, emphasizing flexion and rotation, after suture removal. Active ROM is usually delayed by a few weeks. Transient worsening of dyspnea in patients using the accessory muscle for respiration may be noted. ROM exercises should be continued throughout radiation treatment to combat soft tissue fibrosis and contractures. Scapular stabilizers such as the serratus anterior, rhomboids, and levator scapula should be strengthened.<sup>50</sup> Heavy lifting with the affected side should be avoided.<sup>51</sup> Speech pathology consultation should be obtained early to address communication and swallowing deficits. A dietitian should follow these patients closely also. Use of artificial saliva and good oral care are necessary after radiation treatment for head and neck cancers. ROM with the jaw, tongue, and masticatory muscles and other oral exercises may be needed.

## Hematologic Malignancies

Such malignancies include those involving bone marrow and the lymphatics. These malignancies and associated treatments result in fatigue and localized disabling effects. Neurologic deficits, lymphedema owing to local obstruction, pain, and malnutrition may be present.

Walking is very helpful and should be continued to maintain endurance. ROM exercises should be continued and advanced as tolerated. Transfusions are quite common during rehabilitation, especially with bone marrow suppression. Exercise in thrombocytopenic patients is controversial. A major concern in these patients is development of intracranial hemorrhage. In one study, fatal intracranial hemorrhage was found in only 1 of 92 patients receiving chemotherapy.<sup>52</sup> Clinicians should use their judgment when prescribing exercises in this group of patients. However, it may be reasonable to allow nonresistive exercise with platelet counts between 5,000 and 10,000/mm<sup>3</sup> and light resistive exercises with counts above 10,000/mm<sup>3</sup>. Ambulation may be allowed with platelet counts above 5,000/mm<sup>3</sup> with fall precautions.

## Conclusions

Successful rehabilitation of patients with cancer requires understanding of the behavior of tumor pathology, flexibility in determining the functional goals and a timeline for achievement of these goals, and awareness of the complications of cancer and its treatments, which negatively impact patient function. The ultimate goals of rehabilitation interventions are to maximize function, promote adaptive and compensatory

# Skin Neoplasms Related to Internal Malignancy

Major Michael Murphy, MC, USA, MD  
Tri H. Nguyen, MD

The skin is an accessible window through which internal conditions may manifest. Readily seen, touched, and sampled, lesions on the skin may provide valuable clues to internal conditions, especially malignancies. This chapter, therefore, focuses on the myriad of cutaneous clues that may alert one to investigate further for malignant processes. The information in this chapter is organized by an internal body system for ease of use by its intended audience. Some conditions may be associated with multiple malignancies, and these associations are discussed in the order of greatest incidence. Where there is no predominant association, conditions are discussed separately.

When examining the association of the skin to internal malignancy, Curth wrote, "Certain postulates must be fulfilled if the association of benign dermatoses with malignant internal tumors can be considered causal."<sup>1</sup> Those postulates are the following:

1. The dermatosis and malignant internal disease start at the same time or there is only a short interval between the onsets of each.
2. The internal malignant process and the dermatosis run a parallel course.
3. The type of the neoplasm associated with the dermatosis may be uniform or distinctive, i.e., its mechanical, toxic, or biochemical action has specific effects on the skin.
4. The dermatosis is not common.
5. If the association between the dermatosis and malignant disease is based on a genetic relationship, the internal disorder and the dermatosis develop independently of each other and postulates 1 and 2 will not be fulfilled.
6. The incidence of association between dermatosis and malignant disease is statistically important. Such a syndrome will, if one searches further, either fulfill the first four criteria or show a genetic background as postulated in #5.<sup>1</sup>

This chapter delves into many conditions that fulfill Curth's fifth postulate. Many of these conditions are genetic and do not fulfill the definition of a paraneoplastic syndrome as described by McLean, who felt that paraneoplastic manifestations of malignant tumors must fulfill two essential criteria: (1) "The dermatosis must develop after the development of a malignant tumor" and (2) "Both the dermatosis and the malignant tumor must follow a parallel course."<sup>2</sup> This chapter broadens the scope by examining instances that may not fulfill the paraneoplastic definition. Such described neoplasms are markers for syndromes with a higher risk of known internal malignancies. Most importantly, these skin markers of internal malignancy are reliable, recognizable, and relevant.

## Skin Neoplasms Related to Malignancies of the Gastrointestinal System

### Muir-Torre Syndrome

*Skin neoplasm:* Sebaceous adenoma, sebaceous epithelioma, and sebaceous carcinoma

*Internal malignancy:* Colorectal cancer predominantly; less commonly transitional cell cancer of the renal tract, endometrial cancer, ovarian cancer, breast cancer, upper gastrointestinal (GI) tract cancer, laryngeal cancer, and sarcomas

*Genetics:* Gene: *MSH2* on chromosome 2p and *MLH1* on chromosome 3p

*Online Mendelian Inheritance in Man (OMIM):* 158320

*Inheritance:* Autosomal dominant

Muir-Torre syndrome consists of multiple sebaceous neoplasms, keratoacanthomas, and GI, gynecologic, and urologic malignancies in the absence of other predisposing factors. Because of the risk of multiple internal malignancies, early recognition of this syndrome is essential. Twenty-eight percent of skin lesions appear before, 12% appear concurrently with, and 59% occur after the diagnosis of the first internal malignancy.<sup>3</sup>

The skin lesions in Muir-Torre syndrome consist of sebaceous neoplasms and keratoacanthomas. Sebaceous adenomas are slowly growing yellow to skin-colored papules usually found on the head or neck. They are the most sensitive skin marker for Muir-Torre syndrome. Sebaceous epitheliomas are yellowish papules and nodules often resembling a basal cell carcinoma. They are the most specific skin marker for Muir-Torre syndrome.<sup>4</sup> Sebaceous carcinoma can be found at its characteristic location on the eyelid presenting as a painless nodule on the inner eyelid surface or in extraocular locations. Although solitary, sebaceous tumors may occur, multiple lesions are more often the norm. Even though multiple lesions are more typical, the discovery of even one characteristic sebaceous neoplasm should prompt an evaluation for Muir-Torre syndrome. Sebaceous hyperplasia and nevus sebaceous are not associated with Muir-Torre syndrome.

Keratoacanthomas present as rapidly growing crateriform nodules on sun-exposed areas and can be difficult to differentiate from squamous cell carcinoma clinically and histologically. Of 139 patients with Muir-Torre syndrome, 22% had at least one keratoacanthoma.<sup>4</sup> Keratoacanthomas in Muir-Torre syndrome can also be multiple or present with sebaceous differentiation histologically.

Muir-Torre syndrome is associated with multiple internal malignancies. In one study of 139 patients, 282 primary internal malignancies were found. Sixty-one percent of cases have a family history of internal malignancy.<sup>4</sup> Colorectal carcinoma is the most common internal malignancy, accounting for about half of all malignancies in Muir-Torre syndrome. The second most common cancer type is genitourinary, at 24% of primary cancers. Other cancers that have been involved in the syndrome include lymphoma, leukemia, and cancer of the breast, parotid gland, inner ear, tongue, larynx, lung, and cartilage.<sup>4,5</sup>

Colorectal carcinoma in Muir-Torre syndrome has some unique features. First, about 58% of all colorectal carcinoma are found

proximal to the splenic flexure in this syndrome. It is usually detected about 10 years earlier than the general population. Despite these features, colorectal carcinoma tends to be less aggressive in Muir-Torre syndrome and tends to have a favorable prognosis. One hundred twenty people with Muir-Torre syndrome had a mean survival of 12 years after first diagnosis of malignancy.<sup>5</sup>

Once Muir-Torre syndrome is recognized and diagnosed, preventive screening should be initiated. The initial workup should also include a complete history, a physical examination, laboratory tests (carcinoembryonic antigen, complete blood cell count, erythrocyte sedimentation rate, chemistry, UA, urine cytology), chest radiography, a Pap smear, mammography, endometrial biopsy, and, especially, screening of the colon. Because of the location of colorectal cancer in this syndrome, colonoscopy and barium enema are favored over sigmoidoscopy. Other tests that can be considered include cystoscopy, intravenous pyelography, and computed tomography (CT) of the abdomen and pelvis.<sup>3</sup> All family members should be screened initially and regularly for the skin neoplasms and internal malignancies associated with Muir-Torre syndrome.

### Gardner's Syndrome

*Skin neoplasm:* Epidermal inclusion cysts, desmoid tumors, and fibrous tumors

*Internal malignancy:* GI carcinoma, thyroid carcinoma

*Genetics:* Gene: *APC* (adenomatous polyposis coli); Chromosome: 5q21-22

*OMIM:* 175100

*Inheritance:* Autosomal dominant

Gardner's syndrome consists of epidermal inclusion cysts, desmoid tumors, fibroid tumors, osteomas, congenital hyperpigmentation of the retinal epithelium, and other less common neoplasms coupled with GI and thyroid malignancies. The diagnostic criteria for Gardner's syndrome are outlined in Table 1.<sup>6</sup> One hundred percent of Gardner's syndrome patients develop GI carcinoma by age 20 to 30 years. Because of this, early recognition and prophylactic treatment are paramount.

**Table 1** Diagnostic Criteria for Gardner's Syndrome

1. Presence of all three diagnostic criteria
  - a. colonic polyps
  - b. soft tissue tumors
  - c. osteomas
2. Presence of any one usual finding in an individual, PLUS a family history that individually or collectively has all the criteria outlined in #1.

All based on reference 3.d.5

Epidermal inclusion cysts are the most common skin neoplasms associated with Gardner's syndrome and are found in 35% of patients with Gardner's syndrome. The cysts may even present at birth. Typically, they are firm, mobile, subcutaneous nodules that may aggregate into large masses, usually on the head and neck. Multiple epidermal inclusion cysts should prompt further inquiry for other signs of Gardner's syndrome.<sup>7,8</sup> Desmoid tumors occur in 3 to 17% of cases, with a female predominance (80%). These tumors may occur spontaneously or at sites of surgical incisions. They are nonmetastasizing but may be locally aggressive, causing usual or intestinal obstruction. Desmoid tumors in the retroperitoneum may have a poor prognosis.<sup>8</sup> Fibromas may also be found in the skin, subcutaneous tissue, mesentery, or retroperitoneum.

Osteomas are the most common benign neoplasm found in Gardner's syndrome, being present in 80% of cases. They are most commonly located in the mandible or maxilla as thickenings or masses. Congenital hyperpigmentation of the retinal epithelium (CHRPE) is found in 63% of Gardner's syndrome patients. Dental anomalies, including multiple supernumerary or impacted permanent teeth, are seen in 18% of patients. Other reported neoplasms include lipoma and leiomyomas.<sup>6,8-10</sup>

GI carcinoma is the most common type of malignancy in Gardner's syndrome. Adenomatous polyps develop predominantly in the colon but can also be seen in the small intestine and stomach. Polyps are rarely seen before age 10 years. Early presenting signs of polyposis include bleeding or obstruction. By 20 years of age, 50% of patients with Gardner's syndrome develop polyps. Carcinomatous degeneration occurs in 100% of patients, usually by the second to third decade.<sup>8</sup> The incidence of periampullary cancer increases 100 to 200 times in patients with Gardner's syndrome and also presents a decade earlier (average age of 48 years) than in the general population.<sup>6,8</sup> Treatment consists of early prophylactic total colectomy when polyp formation is detected.

Another malignancy associated with Gardner's syndrome is thyroid carcinoma. It is characterized by an early onset (78% < age 30 years), female predominance (89%), papillary histology (88%), and multicentricity (70%).<sup>9</sup> In 30% of patients, thyroid carcinoma can precede the diagnosis of Gardner's syndrome by as much as 12 years. Because the malignancy is often multicentric, treatment consists of total thyroidectomy.

Caring for patients with Gardner's syndrome should involve gastroenterologists for annual colonoscopy, ophthalmologists (CHRPE), dentists, and regular examinations of the thyroid (neck ultrasonography, physical examination), especially in young women.

### Peutz-Jeghers Syndrome

*Skin neoplasm:* Multiple lentigines

*Internal malignancy:* GI carcinoma, pancreatic carcinoma, bilateral breast carcinoma, cervical and testicular cancer

*Genetics:* Gene *STK11* (serine threonine kinase); Chromosome: 19p13.3

*OMIM:* 175200

*Inheritance:* Autosomal dominant

Peutz-Jeghers syndrome consists of multiple lentigines predominantly on the face and oral mucosa associated with hamartomatous GI polyps with a small potential for malignant transformation. This syndrome has also been associated with multiple other internal malignancies, many of which can be fatal. The most common GI complaints are abdominal pain, GI bleeding, anemia, vomiting, and rectal prolapse.<sup>8</sup> Clinical signs of the syndrome present at an early age. Early recognition and preventive screenings, therefore, facilitate timely detection and treatment of malignancies.

The skin neoplasms consist of 1 to 5 mm brown/black macules that are predominantly distributed on the central face, lips, and oral mucosa but can be seen on other body areas. These lesions may be present at birth or arise during infancy. Fifty to 60% of patients show clinical manifestations of the syndrome before age 20 years. The lentigines on the mucosa tend to persist throughout life.<sup>8</sup>

The predominant GI manifestations of Peutz-Jeghers syndrome are hamartomatous polyps found throughout the GI tract but most commonly in the ileum and jejunum. A small proportion of these polyps can undergo malignant transformation. The frequency of GI malignancy in Peutz-Jeghers syndrome has been estimated at 2 to 3%.<sup>11</sup> The most common site of malignancy was the large bowel, followed by the duodenum, jejunum, and stomach in a study of 104 patients.<sup>11</sup> The relative risk of death from GI cancer and from all forms of cancer is 13 and 9, respectively. There is a 48% chance of dying of cancer by age 57.<sup>12</sup>

Other malignancies have also been reported in Peutz-Jeghers syndrome. In one study, 36% of patients with Peutz-Jeghers syndrome with a diagnosis of cancer had pancreatic cancer.<sup>13</sup> Several case reports have shown an association between this syndrome and bilateral breast cancer, with a mean age at onset at 42 years.<sup>14</sup> Other reported cancers include ovarian sex cord tumors, adenoma malignum (rare form of cervical cancer), and Sertoli cell testicular tumors in prepubertal boys.<sup>12</sup>

Prophylactic screening in Peutz-Jeghers syndrome should include examination for occult blood, colonoscopy, and upper GI tract endoscopy. Some advocate removal of large or symptomatic colon polyps, whereas others feel

that all colon polyps should be removed.<sup>12</sup> Initial screening should be followed by periodic (6–12 months) upper endoscopy and colonoscopy with a small bowel follow-through. Given the risk of bilateral breast cancer, a baseline mammography at age 25 with annual examinations starting at age 40 is recommended. Further, an annual pelvic sonogram and cervical smears are also advisable.<sup>12</sup>

## Skin Neoplasms Related to Renal Malignancies

### Birt-Hogg-Dubé Syndrome

*Skin neoplasm:* Fibrofolliculomas, trichodiscomas, acrochordons

*Internal malignancy:* Renal cancer

*Genetics:* Gene: Folliculin; Chromosome: 17p11.2

*OMIM:* 135150

*Inheritance:* Autosomal dominant

Birt-Hogg Dubé syndrome consists of multiple fibrofolliculomas, trichodiscomas, other skin neoplasms such as lipomas, and collagenomas associated with pulmonary cysts and renal cancer. Pulmonary findings usually precede skin manifestations, which usually occur in the third to fourth decade of life. Renal disease usually presents after skin manifestations.<sup>15</sup>

The skin manifestations of Birt-Hogg-Dubé syndrome include most commonly fibrofolliculomas, trichodiscomas, and acrochordons. Clinically, these lesions can have a similar appearance as 2 to 4 mm smooth, dome-shaped, skin-colored to gray-white papules on the face, neck, and upper trunk that are asymptomatic. There is some contention that, histologically, all of these lesions represent fibrofolliculomas.<sup>16</sup> Other more rarely described skin lesions include deforming lipomas and collagenomas.<sup>15,17,18</sup> Other manifestations of the syndrome include oral papules and pulmonary cysts.

The most common internal neoplasms associated with Birt-Hogg-Dubé syndrome are renal tumors. In one study that included 13 patients with Birt-Hogg-Dubé syndrome, 7 had renal neoplasms.<sup>19</sup> The histologic spectrum of renal tumors in Birt-Hogg-Dubé syndrome is unique (Table 2). The original affected family reported by Birt and colleagues also had hereditary medullary thyroid carcinoma.<sup>15</sup>

**Table 2** Histologic Spectrum of Renal Tumors in Birt-Hogg-Dubé (BHD) syndrome

Histologic type	BHD	All renal cancers
chromophobe	34%	5%
oncocytoma	5%	5%
chromophobe/ oncocytic hybrid	50%	NA
clear cell	9%	75%
papillary	2%	15%

Prophylactic screening for patients and family members of patients with Birt-Hogg-Dubé syndrome should include chest radiography, abdominal and chest CT, and renal ultrasonography.<sup>16,20</sup>

### Tuberous Sclerosis

*Skin neoplasm:* Hypomelanotic macules, facial angiofibromas, periungual fibromas, connective tissue nevi

*Internal malignancy:* Renal cell carcinoma

*Genetics:* Genes: *TSC1* and *TSC2*; Chromosomes: 9q34 and 16p13

*OMIM:* 191100

*Inheritance:* Autosomal dominant with a spontaneous mutation rate as high as 75%

Tuberous sclerosis is a syndrome consisting of several skin findings coupled with tumors of the brain, heart, retinas, kidneys, and lungs, with frequent mental deficiency and epilepsy. The initial skin findings in this syndrome are hypomelanotic macules, which may be present at birth or perinatally. These macules are usually oval- to lance-ovate- (ash leaf) shaped, and their presence is more easily appreciated on Wood's lamp examination. Facial angiofibromas begin to develop next, usually within the first 2 years of life, with full expression by adolescence. These are 1 to 3 mm yellow to pink waxy dome-shaped papules distributed over the nose, cheeks, and forehead. Up to 50% of patients can develop a connective tissue nevus also known as the shagreen patch. These develop in the first decade of life and are usually 1 to 10 cm patches of knobby skin usually found on the lumbrosacral area. At puberty, about 50% of patients develop periungual papules known as Koenen's tumors. These present as firm, digitate, pink, protruding papules that histologically are angiofibromas.

The majority of tumors associated with tuberous sclerosis are benign. The most common renal tumor is an angiomyolipoma. However, renal cell cancer may occasionally develop, with 16 cases having been reported with tuberous sclerosis (bilateral renal cancer in seven patients). The median age at cancer presentation is 28 years, with clear cell carcinoma being the most common histologic subtype.<sup>21</sup> Enlarging renal lesions with intratumoral calcifications that have no fatty tissue as seen by ultrasonography, CT, or MRI are more suspicious. Diagnosis should be confirmed by fine-needle aspiration or surgical exploration. Because renal cancer in tuberous sclerosis is often bilateral, renal-sparing surgery should be performed when possible.<sup>22</sup>

### Hereditary Leiomyomatosis and Renal Cell Cancer

*Skin neoplasm:* Leiomyomas

*Internal malignancy:* Papillary renal cell carcinoma

*Genetics:* Gene: *HLRCC*; Chromosome: 1q42.1

*OMIM:* 605839

*Inheritance:* Autosomal dominant

Hereditary leiomyomatosis with renal cell cancer is a familial syndrome with a predisposition to skin leiomyomas, uterine leiomyomas, and papillary renal cell carcinoma. In one study, four unilateral renal cancer cases occurred in females aged 33 to 48 showing papillary histology and all were metastatic at the time of diagnosis.<sup>23</sup> Seven of 11 family members had cutaneous nodules, two of which were confirmed as leiomyomas.

Cutaneous leiomyomas present as erythematous firm nodules that can be painful to the touch. They are rare benign skin tumors thought to arise from the arrector pilorum muscle. Patients and family members with hereditary leiomyomatosis and renal cell cancer should undergo renal ultrasonography. Female patients should also have transvaginal ultrasonography of the uterus because of uterine leiomyosarcomas, which have been reported with this syndrome.

## Skin Neoplasms Related to Breast Cancer

### Cowden Syndrome

*Skin neoplasms:* Tricholemmomas, acral keratoses, oral papillomas, sclerotic fibromas, lipomas, angioliomas, hemangiomas, and multiple acrochordons

*Internal malignancy:* Breast carcinoma, thyroid carcinoma, rare colon adenocarcinoma

*Genetics:* Gene: *PTEN*; Chromosome: 10q22-23

*OMIM:* 158350

*Inheritance:* Autosomal dominant with variable expressivity and female predominance

Cowden syndrome consists of multiple skin neoplasms; increased propensity of breast, thyroid, and colon carcinoma; and other features, which can include a high arched palate, bird-like facies, GI polyps, female genital tract neoplasms, an enlarged tongue, and diabetes mellitus.<sup>24</sup> Skin lesions frequently appear before internal manifestations and therefore serve as an important marker for this syndrome.

The mucocutaneous lesions characteristically appear in the second to third decades. Tricholemmomas are a specific cutaneous marker for Cowden syndrome. They usually present as multiple yellow to skin-colored verrucous papules, especially on the face, with a predilection for the ears and periorificial areas. Multiple sclerotic fibromas are another skin marker for the disease. These appear as translucent to skin-colored waxy nodules with a characteristic histology of whorled collagen with significant clefting.<sup>8,25</sup> More than 50% of patients have punctate palmpoplantar keratoses. Oral lesions

consist of 1 to 3 mm papules that create a cobblestone appearance and can involve the entire oral mucosa and the tongue.

Twenty-five to 36% of female patients with Cowden disease develop breast cancer. Seventy-five percent of female patients have fibrocystic breast disease and fibroadenomas.<sup>26</sup> Breast cancer usually develops around the age of 40 and is a ductal adenocarcinoma that has often metastasized before the diagnosis has been confirmed.<sup>27</sup>

Seven percent of patients with Cowden disease develop thyroid adenocarcinoma. Two-thirds of Cowden disease patients develop some form of thyroid disease, including goiter, adenomas, and thyroglossal duct cysts. Hamartomatous polyps of the GI tract can also develop, and they have a small potential for malignant transformation.<sup>26</sup>

Prophylactic screening for Cowden syndrome should include monthly breast self-examination and periodic mammograms. Some also recommend consideration of bilateral prophylactic mastectomies in women with breast lesions in the third decade of life.<sup>26</sup> Screening should also include a thyroid examination, thyroid function tests, and ultrasonography of the thyroid gland. If nodules are noted on examination, fine-needle aspiration or surgical biopsy is recommended.

## Skin Neoplasms Related to Cancer of the Genitourinary System

### Extramammary Paget's Disease

*Skin neoplasm:* Intraepidermal neoplasm consisting of cells with glandular differentiation

*Internal malignancy:* Bladder, urethra, prostate, endometrial, endocervical, vaginal, colorectal, and breast carcinoma

The current theory is that extramammary Paget's disease arises as a primary intraepidermal neoplasm in most cases. Tumor cells are thought to arise from apocrine gland cells or pluripotent keratinocytes.<sup>28</sup> Approximately 25% of cases are thought to have associated neoplastic disease in adnexal structures or in internal organs with a contiguous epithelial lining. However, an increased incidence of noncontiguous malignancies has also been reported.

Clinically, extramammary Paget's disease presents as an erythematous, edematous, weeping, crusted, and nonhealing plaque with irregular borders. The most common anatomic sites of involvement include the vulva and the perianal area. Patients are usually between 50 and 80 years of age. The normal female to male ratio is 4:1.<sup>29</sup>

Vulvar extramammary Paget's disease usually originates in the epidermis but has been described in association with endometrial,

endocervical, vaginal, vulval, urethral, and bladder neoplasia. Breast cancer is the malignancy that occurs most often in conjunction with vulvar extramammary Paget's disease.<sup>30</sup> Perianal extramammary Paget's disease is rarer and is strongly associated with adenocarcinoma of the colon and rectum. In 70 to 80% of cases, perianal disease arises secondary to invasive malignancy of the anus, rectum, and colon.<sup>28</sup> Disease involving the male genitalia is more commonly associated with internal malignancy (urethra, bladder, and testicles) than vulval disease.

The prognosis for extramammary Paget's disease contained to the epidermis is excellent. When lymphovascular invasion occurs, the prognosis diminishes considerably. The 5-year survival rate with inguinal node metastases is 0%.<sup>28</sup> Treatment for disease in the skin includes wide local excision versus Mohs' micrographic surgery, which provides a higher cure rate with fewer recurrences.

Long-term follow-up is recommended for patients with extramammary Paget's disease to monitor for local skin recurrence and development of an associated cancer. In perianal disease, proctosigmoidoscopy and colonoscopy are recommended at 2- to 3-year intervals.<sup>29</sup> Disease involving the male or female genitalia should prompt examination of the appropriate internal organs looking for associated malignancy.

## Skin Neoplasms Related to Cancer of the Endocrine System

### Multiple Endocrine Neoplasia Type IIB

*Skin neoplasm:* Multiple mucosal neuromas

*Internal malignancy:* Medullary thyroid carcinoma

*Genetics:* Gene: *RET*; Chromosome: 10q11.2

*OMIM:* 162300

*Inheritance:* Autosomal dominant

Multiple endocrine neoplasia type IIB is a syndrome consisting of multiple neuromas, pheochromocytoma, and medullary thyroid carcinoma with a marfanoid body habitus. The skin findings in this syndrome are predominantly neuromas, which present as pedunculated nodules on the eyelid margins, lips, and tongue. Other features include enlarged nerves in the GI tract with megacolon and the eye, leading to corneal nerve thickening.<sup>31-33</sup>

Medullary thyroid cancer occurs in virtually all patients with this syndrome. Surgery is the preferred treatment since this tumor is generally resistant to radiation and chemotherapy. Children as young as 6 months old have been diagnosed with medullary thyroid cancer in this syndrome. Therefore, prophylactic total thyroidectomy within the first 6 months of life is the recommended treatment for patients with

multiple endocrine neoplasia type IIB. Early thyroidectomy is essential for survival. Once medullary thyroid cancer invades the lymph nodes or soft tissue, survival drops to 40% over 7.5 years of follow-up.<sup>31,33,34</sup>

## Carney's Syndrome

*Skin neoplasm:* Myxomas, blue nevi, lentigines, psammomatous melanotic schwannoma

*Internal malignancy:* Thyroid carcinoma, malignant psammomatous melanotic schwannoma

*Genetics:* Gene: *PRKARIA*; Chromosome: 17q23-q24

*OMIM:* 160980

*Inheritance:* Autosomal dominant

Carney's syndrome is a complex of myxomas (cardiac, cutaneous, mammary), spotty pigmentation of the skin and mucous membranes, and endocrine gland overactivity (Cushing's syndrome, sexual precocity, and acromegaly) described by Carney in 1985.<sup>35</sup> Patients often have tumors of two or more endocrine glands, including pigmented nodular adrenocortical disease, growth hormone- and prolactin-producing pituitary adenoma, testicular tumors, thyroid adenoma and carcinoma, and ovarian cysts.<sup>36</sup> Detection of this syndrome occurs at a median age of 20 years.

The earliest manifestations of Carney's syndrome are cutaneous. Lesions consist of pigmented brown/black macules and blue/black dome-shaped nodules (lentigines and blue nevi). These lesions are occasionally congenital but usually reach a more characteristic density in the prepubertal years. The typical distribution involves the face, lips, eyelids, ears, trunk, neck, conjunctiva, sclera, vulva, limbs, and back of the hands. Cutaneous myxoma present as sessile papules or subcutaneous nodules, usually less than 10 mm in diameter, some of which are cystic. The most common locations are the eyelid, external ear, and nipple.<sup>35,36</sup>

Malignancy is rare in Carney's syndrome. Up to 75% of patients have thyroid nodules, which usually develop in the first 10 years of life. Five thyroid carcinomas were detected in one series, three of the papillary type and two of the follicular type.<sup>36</sup> Thyroid ultrasonography is an effective method for screening for thyroid involvement in pediatric and young adult patients. Psammomatous melanotic schwannoma is a very rare peripheral nerve sheath tumor found in Carney's syndrome, about 10% of which are malignant and fatal. Screening is difficult because this condition can occur in many anatomic locations, including the esophagus, stomach, and parasplanchnic sympathetic chain. Fifty-seven percent of deaths in Carney's syndrome are caused by heart-related disease (cardiac myxomas). Cardiac screening should begin at age 5 years in known cases of Carney's syndrome.<sup>36</sup>

## Skin Neoplasms Related to the Neural System

### Gorlin's Syndrome or Nevoid Basal Cell Carcinoma Syndrome

*Skin neoplasm:* Multiple basal cell carcinoma, facial milia, epidermoid cysts, palmar/plantar pits

*Internal malignancy:* Medulloblastomas, fibrosarcoma, ovarian fibromas

*Genetics:* Gene: *PTCH*; Chromosome: 9q22.3-q31

*Inheritance:* Autosomal dominant

Gorlin's syndrome consists of multiple basal cell carcinomas that develop at a young age, odontogenic keratocysts, palmar pits, macrocephaly, frontal bossing, calcified falx cerebri, agenesis of the corpus callosum, bifid ribs, spina bifida occulta, calcified diaphragma sellae, and a high arched palate. This syndrome is important to recognize not only for these manifestations but also for the occasional association with medulloblastoma, which occurs at a very young age. The diagnostic criteria for Gorlin's syndrome are outlined in Table 3.

The skin findings in Gorlin's syndrome include basal cell carcinoma, which is found in 76% of affected patients.<sup>37</sup> Basal cell carcinoma has been reported as early as age 2 years, but it more commonly appears in the teenage years and proliferates between puberty and age 35. Basal cell carcinomas number from a few to the hundreds and usually affect the face, back, and

chest. A small proportion of Gorlin's syndrome patients have no basal cell carcinomas.

Other findings include odontogenic keratocysts, which are present in 80% of patients over 20 years old. Palmar pits are found in 60% of patients and present as 2 to 3 mm depressions that develop usually in the second decade of life.<sup>37</sup> Other associated anomalies include macrocephaly, frontal bossing, calcified falx cerebri, rib anomalies, spina bifida occulta, calcified diaphragma sellae, and a high arched palate.

Three to 5% of patients with Gorlin's syndrome develop medulloblastoma. Medulloblastoma in Gorlin's syndrome is unique in that it usually occurs in the first 2 years of life compared with the general population, in which incidence peaks at age 3 to 5 years. Medulloblastoma is a highly invasive embryonal neuroepithelial tumor that arises in the cerebellum and has a tendency to disseminate throughout the central nervous system early in its course. Infants at risk of developing medulloblastoma should be screened by annual MRI until age 8 years.<sup>37</sup> Radiation therapy is contraindicated in patients with Gorlin's syndrome as innumerable basal cell carcinomas later develop within previously irradiated skin. Other rare and possibly coincidental malignancies reported with Gorlin's syndrome include astrocytoma, malignant meningioma, ovarian fibrosarcoma, rhabdomyosarcoma, Hodgkin's lymphoma, leiomyosarcoma, and adenocarcinoma of the rectum.<sup>38-43</sup>

### Neurofibromatosis Type 1

*Skin neoplasm:* Neurofibromas, café au lait macules

*Internal malignancy:* Malignant peripheral nerve sheath tumors, optic glioma, malignant astrocytoma, ependymoma, meningioma, rhabdomyosarcoma, juvenile chronic myelogenous leukemia, Wilms' tumor, and neuroblastoma<sup>44-57</sup>

*Genetics:* Gene: *NF1*; Chromosome: 17q11.2

*OMIM:* 162200

*Inheritance:* Autosomal dominant

Neurofibromatosis type 1 is an inherited syndrome consisting of cutaneous, ocular, and osseous lesions coupled with malignancies involving the peripheral nerve sheath and central nervous system. The diagnostic criteria for neurofibromatosis are outlined in Table 4. Some of the tumors associated with neurofibromatosis are histologically benign but lethal nonetheless owing to the location.<sup>52</sup> Early detection and management of this syndrome and its associated tumors are essential for the survival of patients with neurofibromatosis.

The cutaneous neoplasms associated with neurofibromatosis include neurofibromas and café au lait macules. Neurofibromas present as pink to tan polypoid or pedunculated rubbery nodules measuring from a few millimeters to

**Table 4** Diagnostic Criteria for Neurofibromatosis Type I

- Neurofibromatosis Type 1 diagnostic criteria  
Must have 2 or more of the following criteria:
1. Six or more café au lait macules. >0.5cm prepuberty; >1.5cm postpuberty
  2. Two or more neurofibromas or one plexiform neurofibroma
  3. Axillary or inguinal freckling
  4. Optic gliomas
  5. Osseous lesions – pseudoarthrosis, sphenoid wing dysplasia
  6. First degree relative with NF1 by the above criteria

Reference 8.b.13

several centimeters. They invaginate into the skin easily on fingertip pressure, the so-called “buttonhole” sign. Plexiform neurofibromas are firm and tender masses in the subcutaneous tissue that may invade deeper structures. Café au lait macules are tan to brown uniformly pigmented macules with sharp demarcation.

Progression of plexiform neurofibroma to a malignant peripheral nerve sheath tumor occurs in 1 to 5% of patients with neurofibromatosis.<sup>53-56</sup> The relative risk of developing a malignant peripheral nerve sheath tumor in neurofibromatosis versus the general population is 113.<sup>53</sup> The mean age at development of these tumors has been estimated at 26 to 32 years of age.<sup>54,55</sup> Malignant peripheral nerve sheath tumors are often metastatic on presentation or refractory to therapy; therefore, early detection and treatment are paramount. The median survival was 18 months overall. Patients with malignant peripheral nerve sheath tumors on the limbs tend to survive longer (53 months) than those with a nonlimb location (21 months).<sup>55</sup> Pain associated with an enlarging mass is the strongest suggestion that a malignant peripheral nerve sheath tumor has developed. Imaging and biopsy of any painful or enlarging nodular or plexiform neurofibroma should be performed to assess for malignancy.

There is a 30 to 40 times higher than expected rate of association of neurofibromatosis type 1, juvenile chronic myelogenous leukemia, and juvenile xanthogranuloma. The risk of juvenile chronic myelogenous leukemia in children with neurofibromatosis type 1 is 20 to 30 times higher if juvenile xanthogranulomas are present.<sup>56</sup> Juvenile xanthogranulomas present as firm, rubbery, round, pink papules with a yellow tinge found on the head and neck, upper trunk, and upper extremities.

## Skin Neoplasms Related to Cancer of the Bone and Cartilage

### Maffucci's Syndrome

*Skin neoplasm:* Subcutaneous hemangiomas

*Internal malignancy:* Chondrosarcoma, astrocytoma, ovarian carcinoma, pancreatic carcinoma

**Table 3** Diagnostic Criteria for Gorlin's Syndrome

1. 2 major features
2. 1 major feature and an affected 1st degree relative
3. 2 minor features and an affected 1st degree relative
4. Multiple basal cell carcinomas in childhood

MAJOR FEATURES	MINOR FEATURES
1. Multiple BCC's or one prior to age 20	1. Congenital skeletal anomaly (bifid ribs vertebral anomaly)
2. Histologically confirmed odontogenic keratocysts	2. Macrocephaly >97th percentile with frontal bossing
3. >3 palmar or plantar pits	3. Cardiac or ovarian fibroma
4. Bilamellar calcification of the falx cerebri	4. Medulloblastoma
	5. Lymphomesenteric cysts
	6. Congenital malformations (cleft lip/palate, polydactyly, eye anomalies)

All based on reference 8.a.7

**Genetics:** Gene: *PTH/PTHrP* type 1 receptor; Chromosome: 3p22-p21.1

**OMIM:** 166000

**Inheritance:** Not genetically inherited in a simple mendelian manner

Maffucci's syndrome consists of multiple enchondromas associated with subcutaneous hemangiomas. The symptoms of this syndrome are congenital in 25% of cases but usually begin on average at age 4 to 5 years.<sup>58</sup> The hemangiomas present as soft, compressible, blue-red, and occasionally tender subcutaneous nodules usually located on the hands and feet. Enchondromas occur primarily along the long bones during a time of rapid skeletal growth. Enchondromas represent abnormal cartilage development. Islands of immature cells fail to ossify and later proliferate to form expanding cartilaginous tumors.

Chondrosarcoma develops in 22 to 30% of patients with Maffucci's syndrome.<sup>58</sup> The average age at development of chondrosarcoma is 40 years. They usually present as an enlarging mass that was previously quiescent without a history of preceding trauma. The affected area can be painful and feel heavy. Suspicious lesions should be imaged. Radiologic features that support malignancy include endosteal cortical erosion, cortical destruction with expanding soft tissue mass, or a zone of lucency in a previously mineralized region.<sup>59</sup> Lesions suspicious for malignancy should be biopsied, either by needle aspiration or with open techniques.

A wide variety of noncartilaginous tumors, including astrocytomas, ovarian cancer, and pancreatic cancer, have been reported with Maffucci's syndrome. Periodic assessment and imaging for other tumors involving the brain, abdominal organs, and endocrine glands should be performed.<sup>59</sup>

## Skin Neoplasms Associated with Multiple Internal Tumor Types

### Multicentric Reticulohistiocytosis

**Skin neoplasm:** Reticulohistiocytomas

**Internal malignancies:** Breast, cervix, colon, lung, bronchial, and ovarian carcinoma; lymphoma, leukemia, sarcoma, melanoma<sup>60</sup>

Multicentric reticulohistiocytosis is a noninherited disorder that usually begins around age 40 to 50 years. Eighty-five percent of affected patients are Caucasian.<sup>60</sup> Skin nodules are present in 90% of individuals at the time of diagnosis and present as round, symmetric, pink to brown papules ranging from a few millimeters to 2 cm. They are usually distributed on the face, arms, trunk, mucosa, and neck. In 27% of cases, the "coral bead" sign is present, manifested as papules aligned along the periungual region. Thirty

percent of patients have mucosal involvement, most frequently the buccal mucosa, nasal mucosa, and tongue. Arthritis may precede skin changes by months to years. The arthritis is usually a symmetric polyarthritis involving the hands, knees, wrists, shoulders, elbows, ankles, hips, feet, neck, and spine, in decreasing frequency. Twelve to 45% of patients progress to arthritis mutilans.<sup>61,62</sup> Involvement of the interphalangeal joints can result in "opera glass deformity" owing to telescoping and shortening of the digits.

Malignancy has been reported in association with multicentric reticulohistiocytosis in 20 to 31% of cases.<sup>61,62</sup> No specific type of cancer predominates. In cases associated with malignancy, multicentric reticulohistiocytosis preceded the development of cancer in 73% of cases.<sup>60</sup> Malignancy workup should be guided by a clinician's suspicions after a careful review of systems and physical examination. Various therapeutic regimens have been tried for multicentric reticulohistiocytosis, with variable benefit. These include nonsteroidal anti-inflammatory drugs, methotrexate alone or in combination with other immunosuppressive drugs, hydroxychloroquine, corticosteroids, cyclophosphamide, chlorambucil, and alendronate.<sup>60-66</sup> The disease tends to spontaneously remit after approximately 8 years. Many patients are significantly disabled owing to joint destruction.

# Graft-versus-Host Skin Disease

Sharon R. Hymes, MD  
Daniel R. Couriel, MD

Hematopoietic stem cell transplantation (HSCT) using peripheral blood, cord blood, or bone marrow is used to treat a wide variety of genetic and immunologic disorders, as well as advanced malignancies. Since the first bone marrow transplantations, significant advances in technology and immunology have improved the prognosis, rate of engraftment, and quality of life for many stem cell recipients. It is estimated that at least 8,000 HSCTs are performed annually in the United States and more than 15,000 procedures worldwide for a wide variety of indications (Table 1).<sup>1</sup> Graft-versus-host disease (GVHD) is one of the major problems encountered post-transplantation and remains a significant cause of morbidity and mortality. Conversely, in some patients, GVHD is desirable because of a beneficial graft-versus-tumor effect. To take advantage of this, graft manipulation is sometimes employed in an attempt to produce mild GVHD and thereby prevent or treat tumor relapse.<sup>2-4</sup>

Traditionally, two types of cutaneous GVHD are described; the acute form occurs less than 100 days after transplantation, and the chronic form occurs after 100 days. These rigid time-related criteria should serve only as a guide since both acute (aGVHD) and chronic (cGVHD) GVHD are more accurately diagnosed by clinical and, in some cases, histopathologic features. With the advent of new, less intense preparative regimens and the development of other transplantation techniques, such as donor lymphocyte infusions to treat relapsed malignancies following transplantation, the clinical characteristics of GVHD are changing. Now we frequently see delayed or late manifestations of aGVHD or overlapping aGVHD and cGVHD in the same patient.<sup>5,6</sup>

The skin plays a pivotal role in these complex immunologic reactions and manifests changes that are easily accessible for examination and biopsy. Cutaneous GVHD also shares clinical, histopathologic, and immunologic features with other autoimmune disorders, making it a useful model for study. This chapter reviews the pathogenesis, clinical presentation, and diagnostic and treatment dilemmas associated with cutaneous GVHD.

**Table 1 Diseases Treatable by Stem Cell Transplantation**

Acute leukemias
Acute lymphoblastic leukemia
Acute myelogenous leukemia
Acute biphenotypic leukemia
Chronic leukemias
Chronic myelogenous leukemia
Chronic lymphocytic leukemia
Juvenile chronic myelogenous leukemia
Juvenile myelomonocytic leukemia
Myelodysplastic syndromes
Stem cell disorders
Aplastic anemia
Fanconi's anemia
Paroxysmal nocturnal hemoglobinuria
Pure red cell aplasia
Myeloproliferative disorders
Acute myelofibrosis
Agnogenic myeloid metaplasia (myelofibrosis)
Polycythemia vera
Essential thrombocythemia
Lymphoproliferative disorders
Non-Hodgkin's lymphoma
Hodgkin's disease
Phagocyte disorders
Inherited metabolic disorders
Histiocytic disorders
Inherited erythrocyte abnormalities
β-Thalassemia major
Sickle cell disease
Inherited immune system disorders
Ataxia-telangiectasia
Kostmann's syndrome
Leukocyte adhesion deficiency
Other inherited disorders
Lesch-Nyhan syndrome
Glanzmann's thrombasthenia
Inherited platelet abnormalities
Amegakaryocytosis/congenital thrombocytopenia
Plasma cell disorders
Other malignancies
Breast cancer, Ewing's sarcoma, neuroblastoma
Renal cell carcinoma

## GVHD Risk Factors

Human leukocyte antigen (HLA) disparity is the major factor predisposing individuals to aGVHD.<sup>7</sup> The relative importance of the incompatibility of individual HLA antigens on GVHD is controversial.<sup>8</sup> Thus, it is not yet known whether antigens of class 1 (HLA A, B, and C) or class 2 (HLA-DR and -DQ) play a relatively more important role as triggers of GVHD. Other relevant factors have been identified as predictors of GVHD, and these include sex mismatch (female donor to male recipient),<sup>9</sup> minor histocompatibility antigens in HLA-matched transplants,<sup>10</sup> donor age,<sup>11</sup> source<sup>12</sup> and dose of hematopoietic stem cells (peripheral stem cells more than bone marrow),<sup>13</sup> the intensity of the preparative regimen<sup>5</sup> and GVHD prophylaxis,<sup>13</sup> or other forms of graft manipulation, such as T-cell depletion.<sup>14</sup> aGVHD predominantly affects the skin, the upper and lower gastrointestinal tract, the liver, and, occasionally, the eye and oral mucosa. The staging system is shown in Table 2, and it includes the first three systems but not eye or oral mucosa.<sup>15</sup>

## Pathophysiology

### Acute GVHD

Both acute and chronic GVHD are forms of immune dysregulation that occur when immunologically competent cells are given to an immunosuppressed or naive host. Donor T cells that recognize recipient alloantigens initiate the process.<sup>16</sup> Rarely, aGVHD may be seen after blood transfusions when viable T cells are given to neonates and fetuses or to patients with iatrogenic or congenital immunodeficiency disorders. To avoid this complication, irradiation of blood products has become the standard of care for immunocompromised recipients. A blood transfusion from a donor who is homozygous for one shared recipient haplotype may cause a similar problem. In this case, the donor lymphocytes recognize the second haplotype in the recipient and may cause an acute graft-versus-host reaction. This is seen most commonly with directed blood donations within family groups or in inbred populations with restricted haplotypes, such as those found in Japan.<sup>17</sup> Transfusion GVHD presents

Table 2 Clinical Staging of Acute Graft-versus-Host Disease

Stage	Skin	Liver	Gut
0	No rash owing to GVHD	Bilirubin, < 2 mg/dL	None
1	Maculopapular rash < 25% of body surface area without associated symptoms	Bilirubin, 2–< 3 mg/dL	Diarrhea, > 500–1,000 mL/d, nausea and vomiting
2	Maculopapular rash or erythema with pruritus or other associated symptoms covering $\geq$ 25 and < 50% of body surface area or localized desquamation	Bilirubin, 3–< 6 mg/dL	Diarrhea, > 1,000–1,500 mL/d, nausea and vomiting
3	Generalized erythroderma or symptomatic macular, papular, or vesicular eruption, with bullous formation or desquamation covering $\geq$ 250% of the body	Bilirubin, 6–< 15 mg/dL	Diarrhea, > 1,500 mL/d, nausea and vomiting
4	Generalized exfoliative dermatitis or ulcerative dermatitis or bullous formation	Bilirubin, $\geq$ 15 mg/dL	Severe abdominal pain with or without ileus

Adapted from Przepiora D et al.<sup>15</sup>

not only with cutaneous, liver, and gastrointestinal problems but may also cause marrow aplasia.<sup>17</sup> GVHD occasionally occurs after transplantation of solid organs that contain lymphoid tissue, such as small bowel transplants.<sup>16,18</sup> However, the most common cause of GVHD remains HSCT, and the most common organ system involved is the skin.<sup>19,20</sup> aGVHD occurs in about 20 to 40% of matched sibling transplants and 60 to 90% of mismatched related or matched unrelated transplants.<sup>20–23</sup>

In 1966, Billingham described the criteria necessary for the development of GVHD.<sup>24</sup> He stated that the graft must contain immunologically competent cells; the host must possess important transplantation alloantigens that are lacking in the donor graft so that the host appears foreign to the graft; the host must be incapable of mounting an effective immunologic reaction against the graft; and the graft must have security of tenure. Current concepts incorporate these criteria with an evolving understanding of the complex immunologic reactions that occur during and after stem cell transplantation.

The major histocompatibility complex (MHC) lies on the short arm of chromosome 6, also called the HLA region. It contains the genes that encode antigens used for tissue typing and the genes that are involved in immune activation. Even in HLA-matched transplants, minor antigens that are expressed on the cell surface as degraded peptides bound to HLA molecules, but not encoded by the genes of the MHC, may be implicated in the development of GVHD.<sup>17,25</sup> The controversy regarding the nature of GVHD after autologous (the donor is also the recipient) or syngeneic (the donor is an identical twin) transplantation complicates the issue even further.

That is, can HLA-identical donor cells produce GVHD without major or minor MHC differences? In these circumstances, what is seen as clinical aGVHD may actually represent the disruption of mechanisms governing self-tolerance, creating an environment conducive to autoreactive T cells.<sup>26,27</sup> The type of conditioning regimen, presence of thymic damage, and type of transplant may be key to this reaction. Removal of T lymphocytes by CD34 (a marker on hematopoietic stem cells) selection may promote this phenomenon of autoaggression and is clinically characterized by a rash, pruritus, eosinophilia, and, less frequently, fever.<sup>28</sup> The skin rash tends to be morbilliform (measles-like) and less severe than that associated with MHC antigen unmatched transplants. Depletion of T cells from the donor infusion may decrease the incidence of GVHD but also may down-regulate the antitumor immune response<sup>27</sup> and is therefore associated with a higher incidence of disease relapse. The introduction or withdrawal of cyclosporine or the addition of interleukin-2 may also potentially induce alloreactivity and GVHD.<sup>29</sup>

aGVHD contributes significantly to morbidity and mortality. Tissue destruction occurs via effector T-cell activation in response to disparate major or minor histocompatibility antigens. The skin reaction is mediated by dendritic cells, T lymphocytes, natural killer (NK) cells, macrophages, and cytokines interacting with cell surface antigens.<sup>20,30–33</sup> Both donor CD4<sup>+</sup> and CD8<sup>+</sup> cells, as well as NK cells, are found in the dermal infiltrate.<sup>34</sup> Once recruited to the skin, NK cells may mediate significant epidermal damage, despite lacking the ability to be specifically alloreactive.<sup>35</sup> Lymphocytes in apposition to necrotic keratinocytes, or satellite cell necrosis, are a

common histopathologic finding used in diagnosis. However, it is not clear if these cells are directly responsible for the apoptosis.<sup>31,36</sup>

A three-phase model of aGVHD has been proposed, with phase 1 initiated by injury to host tissue induced by the preconditioning regimen.<sup>17,32,37,38</sup> Either total-body irradiation or chemotherapy is necessary to treat residual tumor, as well as to ablate the recipient immune response sufficiently to allow engraftment. However, these modalities are toxic to healthy tissues, and the resultant damage not only releases chemokines and cytokines but also activates host dendritic cells in target tissues. This is confirmed in a skin explant model, where, after conditioning, activated dendritic cells in the dermis are primed for alloreaction at the time of donor T-cell infusion, and the apoptotic machinery in basal keratinocytes is activated.<sup>36</sup> Inflammatory mediators such as tumor necrosis factor (TNF)- $\alpha$ , interleukin (IL)-1,<sup>37,39</sup> and heat shock proteins<sup>30,36</sup> are produced, which then enhance the expression of HLA-DR. In a murine model, dendritic cells from old mice express more TNF- $\alpha$  and IL-12 than young mice, possibly explaining the increased incidence of aGVHD in older recipients.<sup>32</sup>

During the second phase of GVHD, donor T-cell activation and expansion occurs and NK cells, monocytes, and macrophages create an inflammatory milieu composed of activated and recruited immunocytes and soluble mediators. The greater the genetic disparity between host and donor, the greater the T-cell response.<sup>17</sup> If donor T cells are depleted from the infusion, there is a decreased incidence and severity of GVHD.<sup>40</sup> However, engraftment and, as previously mentioned, the desirable graft-versus-tumor effect may also be abrogated. Antigen-presenting cells present transplant recipient antigens to donor lymphocytes. These, in turn, secrete cytokines that damage tissues and further augment the immune response.<sup>17</sup>

Target tissue injury occurs in the third and final phase. Donor T cells respond to the activated host dendritic cells, and inflammatory mediators such as TNF- $\alpha$  perpetuate the apoptosis in basal keratinocytes and other target tissues. The subsequent “cytokine storm” in which IL-1, IL-2, TNF- $\alpha$ , and interferon- $\gamma$  play an important role continues the process, particularly in the rete ridges. Keratinocytes continue to die by apoptosis and direct satellite cell necrosis.<sup>35,36,41</sup> Fas(CD95)/Fas-Ligand apoptosis plays an important role in cell death, as does a Fas-independent pathway, employing perforin, a protein expressed in functionally active CD8<sup>+</sup> and NK cells.<sup>17,42,43</sup> In murine models, the graft-versus-tumor effect may be mediated by the perforin-granzyme pathway.<sup>44</sup> It is hoped that further definition of these processes will lead to unique therapeutic and pharmacologic strategies for regulating epidermal necrosis without losing the antitumor effect.<sup>45</sup>

The skin is further targeted for cytotoxic T-cell and NK cell injury by suprabasilar keratinocyte expression of vascular cell adhesion molecule 1 (VCAM-1)<sup>46</sup> and cytokeratin 15.<sup>47</sup> Modified vascular endothelial cells expressing adhesion molecules, including P-selectin, E-selectin, endothelial leukocyte adhesion molecule 1, and VCAM-1,<sup>34,48</sup> as well as up-regulated expression of shear-resistant adhesion molecules within endothelial sites, facilitate the effector cell migration through the vessel wall.<sup>49</sup> Hyaluronic acid expressed on dermal vessels in aGVHD confers this shear-resistant attachment and contributes to cutaneous lymphocytotropism.<sup>50</sup> Polymorphism of platelet endothelial cell adhesion molecule CD31 also increases the risk of GVHD, suggesting that donor lymphocyte recognition of a mismatched endothelial molecule is important.<sup>34,51</sup>

Langerhans' cells are cutaneous dendritic cells that are very important in the pathogenesis of cutaneous GVHD.<sup>52</sup> These cells may renew locally without reconstitution from bone marrow precursors but are replaced by bone marrow-derived precursors after inflammatory injury.<sup>53</sup> Their expression of MHC molecules is sufficient to initiate GVHD even in the absence of MHC expression on host epithelium.<sup>54</sup> Langerhans' cells process antigens and then migrate to the draining lymph nodes to present the information to T lymphocytes.<sup>55</sup> In a murine model, host Langerhans' cells remain for at least 18 months unless donor T cells are administered with the transplant, and these persistent host cells may be crucial targets in perpetuating tissue injury.<sup>38,52</sup> Alloreactive donor T cells may induce Langerhans' cell chimerism through Fas ligand-dependent depletion of host Langerhans' cells and induction of proinflammatory chemokines.<sup>52</sup> During autologous transplantation, dendritic cell activation may be self-limited, producing little or no cutaneous disease.<sup>36</sup>

The prominent role of Langerhans' cells in the initiation and perpetuation of GVHD has created interest into therapeutic modalities that specifically target them. Ultraviolet radiation (UVR) can deplete host Langerhans' cells, leading to their replacement with donor cell-derived cells. An intriguing approach aimed at GVHD prevention uses this modality to replace host Langerhans' cells prior to donor T-cell infusion.<sup>56</sup> A two-step procedure has been suggested, starting with a T cell-depleted stem cell transplant followed by host exposure to UVR. The subsequent depletion of host Langerhans' cells allows donor-derived hematopoietic cells to repopulate the skin. Retransplantation with stem cells plus donor T cells would then, theoretically, decrease the risk of cutaneous GVHD.<sup>52,56</sup>

## Chronic GVHD

This profound disorder of immune regulation may evolve from aGVHD or develop de novo in

about 20 to 30% of patients. It is characterized by global immune impairment and is seen in 33% of HLA-identical sibling transplants, 49% of HLA-identical related transplants, 64% of matched unrelated transplants, and 80% of 1-antigen HLA-nonidentical unrelated transplants.<sup>57-62</sup>

The exact pathogenesis of cGVHD is largely unknown and ambiguous. In addition to donor-derived alloreactive T cells that are important in aGVHD, post-thymic CD4<sup>+</sup> T cells are thought to play an important role in cGVHD. The T-cell precursors may undergo aberrant "thymic education" after HSCT that effectively makes them self-reactive or autoreactive. Additionally, the activation of different helper T-cell subsets (Th1 in acute versus Th2 in cGVHD) may be responsible for distinct manifestations of acute and chronic GVHD. The role of alloreactivity versus autoreactivity in the pathogenesis of cGVHD remains highly controversial. Alloreactivity to minor histocompatibility antigens is believed by some to explain cGVHD as a late phase of aGVHD. On the other hand, the importance of autoreactivity is highlighted by clinical manifestations of cGVHD that frequently mimic those of autoimmune or collagen vascular diseases, the finding of autoantibodies in some patients, and experimental data suggesting the importance of thymic education and damage in the pathogenesis of cGVHD.<sup>63</sup>

Animal studies suggest that transforming growth factor (TGF)- $\beta$  may be involved in the pathogenesis of cGVHD. Fibrosis in sclerodermatous GVHD may be driven by infiltrating TGF- $\beta$ <sub>1</sub>-producing mononuclear cells, and in the murine model, this may be prevented with antibodies to TGF- $\beta$  given early in the disease. Human latency-associated peptide, a naturally occurring antagonist to TGF- $\beta$ <sub>1</sub>, inhibits its up-regulation as well as that of connective tissue growth factor messenger ribonucleic acids and type 1 collagen synthesis in the mouse and may be a potential new therapy in diseases characterized by dermal sclerosis.<sup>64,65</sup>

## Clinical Manifestations

### Acute Cutaneous GVHD

Depending on the type of transplant and the degree of histocompatibility, the eruption of aGVHD commonly develops 2 to 10 weeks post-transplantation (mean of 10 days) and has suggestive, but not always diagnostic, clinical and pathologic features. Conventionally, GVHD developing before 100 days is called acute.<sup>34,66</sup> Hyperacute forms of cutaneous GVHD, seen almost immediately post-transplantation, are often explosive in onset, as well as complicated by severe systemic involvement, erythroderma, and fever.<sup>67</sup> Cutaneous eruptions resembling aGVHD are sometimes seen after 100 days, especially

after donor lymphocyte infusions or infections. They have also been reported with alterations in cyclosporine therapy. These acute-appearing skin changes may be accompanied by cGHVD in other target organs.<sup>68</sup>

Early cutaneous changes may include localized or generalized pruritus, dysesthesias, or pain on the palms, soles, and ears, often accompanied by subtle macular erythema and edema (Figure 1). Affected areas become progressively more edematous and violaceous, mimicking acral erythema or erythema multiforme (Figure 2). A maculopapular morbilliform eruption follows, which often starts on the trunk and becomes confluent (Figure 3) or even folliculocentric.<sup>69</sup> Histologically, follicular GVHD corresponds to involvement of the perifollicular bulge.<sup>70</sup> Erythroderma may result from damage to the epidermal barrier, with associated pruritus and pain. As the disease progresses, patients have difficulty regulating core body temperature and maintaining fluid and electrolyte balance and are at increased risk of infection. Resolution of the erythroderma is characterized by diffuse sunburn-like desquamation. Rarely, aGVHD may present with acquired ichthyosis or "fish scale"–

**FIGURE 1** Acute graft-versus-host disease (GVHD). Macular erythema on the palm associated with early acute cutaneous GVHD.

**FIGURE 2** Acute graft-versus-host disease (GVHD). Erythema on the sole accompanied by the typical morbilliform eruption of acute cutaneous GVHD.

**FIGURE 3** Acute graft-versus-host disease (GVHD). Morbilliform (measles-like) eruption of acute cutaneous GVHD.

like changes, which can be distinguished from acquired ichthyosis by biopsy. It is possible that such a condition has been underdiagnosed because acquired ichthyosis-like rashes are often not sampled.<sup>71</sup>

The formation of blisters and the detection of a positive Nikolsky sign (extension of epidermal denudation with pressure) are indicative of even more severe cutaneous disease.<sup>72</sup> Progression produces complete epidermal denudation consistent with toxic epidermal necrolysis (TEN), demonstrated in Figure 4. Loss of epidermal integrity in the setting of profound immunologic impairment places these patients at high risk of infection. The eye may also be severely involved (Figure 5), as well as other epithelial surfaces. Mucous membrane involvement is heralded by erythema, pain, or erosions and is often difficult to distinguish from the mucositis associated with chemotherapy or infection. Grade 3 and 4 GVHD produces bullae and epithelial denudation in the mouth, similar to that seen in TEN.

Localized bullous changes may coexist with a diffuse morbilliform papulosquamous eruption (Figure 6), stressing the importance of a comprehensive skin examination and directed skin biopsy. A clinical grading system as shown

**FIGURE 4** Toxic epidermal necrolysis/acute graft-versus-host disease. Islands of necrotic epidermis (white plaques) and exposed dermis.

**FIGURE 5** Graft-versus-host disease of the eye. Courtesy of Dr. Stella Kim.

**FIGURE 6** Bullous acute graft-versus-host disease (GVHD). Focal bullae associated with the morbilliform eruption of GVHD.

in Table 3<sup>73</sup> is used to define both the extent of involvement and the morphology of the skin changes.

Dyspigmentation of the skin is a postinflammatory change that is distressing to the patient and difficult to treat. Patchy depigmentation or vitiligo, although uncommon, may occur even in the setting of mild cutaneous disease, and the pathophysiology is unclear. Adoptive transfer of donor immunity has been implied when the donor has vitiligo, and the host subsequently develops the problem.<sup>74</sup>

### Histopathologic Changes

Skin biopsies are routinely employed to diagnosis acute cutaneous GVHD. However, early changes are not specific and are often difficult to distin-

guish from those induced by chemotherapy, total-body irradiation, or infectious agents. In addition, epidermal changes may be focal and do not always correlate with the clinical presentation.<sup>75,76</sup> Since the importance of therapeutic intervention usually precedes the biopsy results by days, the benefit of serial skin biopsies is questionable.<sup>75,77</sup> However, biopsies are sometimes useful for confirmation of the clinical impression or when entertaining an alternative diagnosis.<sup>78</sup>

Vacuolar change at the basal cell layer is a nonspecific finding but may be the earliest manifestation of disease. As acute cutaneous GVHD progresses, variable intensities of dermal mononuclear cell infiltration, exocytosis (lymphocytes in the epidermis), and spongiosis (inter- and intracellular edema) appear. These changes are also nonspecific and may be found in drug and viral rashes, as well dermatitis. The presence of eosinophils has traditionally been thought to favor a hypersensitivity or drug eruption but also is variably present in GVHD. Therefore, overreliance on the presence of eosinophils to diagnose drug reaction versus GVHD may delay therapy.<sup>77</sup> As aGVHD progresses, dyskeratotic cells become prominent and may be associated with a contiguous or “satellite lymphocyte” (Figure 7).<sup>79,80</sup> Hair follicle and eccrine duct involvement is common, and the presence of necrotic keratinocytes in these locations is quite consistent with the diagnosis. In severe cases, the vacuolar change at the

**FIGURE 7** Pathology of acute graft-versus-host disease. There is vacuolar change at the dermal-epidermal junction, dyskeratosis, satellite cell necrosis, and an inflammatory infiltrate (grade 2). Courtesy of Dr. Victor Prieto.

**Table 3** Overall Clinical Grading of Acute Graft-versus-Host Disease

Grade	Stage			Functional Impairment
	Skin	Liver	Gut	
0 (none)	0	0	0	0
I (mild)	1–2	0	0	0
II (moderate)	1–3	1	1	1
III (severe)	2–3	2–3	2–3	2
IV (life threatening)	2–3	2–3	2–3	2–4

dermal-epidermal junction progress to clefts and then to complete separation of the epidermis from the dermis with epidermal necrosis. Lerner and colleagues standardized these pathologic changes into a useful four-stage grading system as illustrated in Table 4.<sup>81</sup> This grading system is generally reproducible among pathologists, with the most disparity reported in distinguishing grades 1 and 2.<sup>82</sup> It has been suggested that the current system be changed to include dermal lymphoid infiltration as an additional criterion for grade 2 GVHD.<sup>83</sup>

### Differential Diagnosis

Early on, the changes of acute cutaneous GVHD are nonspecific. Other eruptions that start on the hands and feet, including acral erythema, must also be considered.<sup>84</sup> The latter is also characterized by pain and erythema of the palms and soles, often occurring after chemotherapy. The morbilliform rash classically associated with aGVHD is also commonly seen in drug and viral eruptions, particularly with human herpesvirus 6.<sup>34</sup> In an attempt to distinguish these entities, drug calendars and meticulous documentation of the onset and progression of the reaction are occasionally helpful. Cutaneous GVHD may be clinically, physiologically, and pathologically identical to erythema multiforme, a hypersensitivity reaction associated with a wide variety of causes. We have found that erythema multiforme-like histologic changes combined with a papulosquamous eruption in the appropriate clinical setting may suggest GVHD over other etiologies but are not diagnostic. Drug-induced erythema multiforme and TEN are often indistinguishable from grade 4 aGVHD. Immunophenotyping of TEN and aGVHD shows a predominance of CD8<sup>+</sup> cells and similar serum cytokine profiles, with increased IL-10, TNF- $\alpha$ , and IL-6 in the serum compared with controls.<sup>85,86</sup> This is not surprising since both TEN and aGVHD probably have similar mechanisms of epidermal apoptosis, including the production of TNF- $\alpha$ <sup>87</sup> and dysregulation of Fas expression and/or signaling.<sup>88</sup> The clinical course of the eruption and concomitant evidence of gut or liver GVHD is sometimes necessary to confirm the diagnosis.<sup>89,90</sup>

The cutaneous eruption of lymphocyte recovery can also be mistaken for early cutaneous aGVHD. This maculopapular eruption occurs at the earliest recovery of peripheral lymphocytes, usually starting on the trunk and proximal extremities. It is associated with a sharp transient rise in temperature and nonspecific pathology, demonstrating a superficial perivascular mononuclear cell infiltrate.<sup>91</sup> This transient eruption is less likely to demonstrate necrotic keratinocytes and is self-limiting.

Follicular mucinosis has been reported as a rare and transient reaction following bone marrow transplantation for acute lymphocytic leukemia and is readily identified by biopsy.<sup>92</sup> Both leukemia cutis and Sweet's syndrome (acute febrile neutrophilic dermatosis) may present with erythematous lesions post-transplantation, which are diagnosed by their distinctive pathology.

### Treatment of Acute Cutaneous GVHD

The initial management of aGVHD usually consists of corticosteroids. When these alone are ineffective, steroids in combination with cyclosporine<sup>19,93</sup> or, in the case of our center, tacrolimus<sup>94–96</sup> have been considered standard therapy for the initial management of acute GVHD.<sup>19,93,97</sup> Their mechanism of action is unclear but is probably related to suppression of cytokines and lymphocytic activities. Numerous dose schedules have been used in multiple clinical trials, but most centers use methylprednisolone at doses of 2.0 mg/kg. Higher doses are also effective but at the cost of significant side effects and severe catabolic damage, including hyperglycemia, fluid retention, muscular wasting, avascular bone necrosis, and increased rate of infectious complications.<sup>19,93,97–99</sup>

In steroid-refractory cases, antithymocyte globulin has been the most common form of immunosuppression used. Different studies have documented efficacy, but with significant morbidity and mortality, mainly owing to infectious complications.<sup>99,100</sup> Pentostatin, a nucleoside analogue that inhibits adenosine deaminase, is another immunosuppressant that has been increasingly used for the management of aGVHD.<sup>93,101</sup> Objective overall responses in up to

67% have been reported,<sup>93</sup> but the effect on overall survival remains unknown.<sup>102</sup> Other therapies, such as monoclonal antibodies, including daclizumab, visilizumab,<sup>103</sup> and infliximab,<sup>104</sup> as well as denileukin diftitox,<sup>105</sup> have been evaluated in the prevention and treatment of aGVHD, with variable response rates but so far no significant impact on the dismal prognosis of steroid-refractory acute GVHD.

### Topical Treatment

Grade 1 and 2 cutaneous GVHD is frequently treated with potent topical steroids, either alone or with occlusion. For symptomatic or extensive disease, “wet wrap” therapy may provide symptomatic relief. Topical steroids are applied to the eruption, followed by warm moist towels, and the patient is then wrapped in a plastic covering followed by blankets to avoid chilling, for approximately 30 minutes. This occlusive dressing increases topical steroid absorption and hydrates the skin. Treatments are repeated several times a day until symptomatic improvement is observed. Over a variable period of time, topical steroid absorption under occlusive dressings may cause enough systemic absorption to cause typical glucocorticoid side effects, as well as striae and skin atrophy. Children are at higher risk than adults for these complications.

Ultraviolet (UV) light initiates inflammation when directed at normal skin but, paradoxically, is useful in treating inflammatory dermatoses.<sup>106</sup> GVHD may occur after UV exposure, prompting the use of sunscreens and photoprotection after HSCT. However, various wavelengths of light, including UVB (290–320 nm), UVA (320–400 nm), and, most recently, narrowband UVB (312 nm), have immunomodulating effects that are useful in the treatment of established disease.<sup>107</sup> UV exposure inhibits contact sensitivity and the proliferative responses of lymphoid cells to mitogens and alloantigens by inactivation of T lymphocytes and antigen-presenting cells. The mechanism of action is not completely known but may reflect the depletion and morphologic alterations of Langerhans' cells and modifications in their capacity to present antigens.<sup>108</sup> Keratinocytes further modify the inflammatory response by producing and releasing immunosuppressive cytokines after exposure to UVB and psoralen plus ultraviolet A (PUVA).<sup>107,109–113</sup>

For many years, psoralens, a photoactivating compound, and UVA light (PUVA) have been successfully employed to treat chronic cutaneous GVHD,<sup>114</sup> but few patients have received PUVA therapy for acute disease. This may change as PUVA has been found to be useful in treating grade 2 to 4 skin changes, thus enabling steroid taper.<sup>115,116</sup> Narrowband UVB therapy has also shown promise in treating acute skin disease in patients who do not respond to systemic

**Table 4** Histopathologic Grading System for Acute Cutaneous Graft-versus-Host Reaction

Grade	Histopathologic Features
0	Normal epidermis
1	Focal or diffuse vacuolar alteration of the basal cell layer
2	Grade 1 changes plus dyskeratotic squamous cells in the epidermis and/or hair follicle epithelium
3	Grade 2 changes plus subepidermal vesicle formation
4	Complete separation of the epidermis from the dermis

Adapted from Lerner KG et al.<sup>81</sup>  
In grades 1 to 4, there is usually a superficial perivascular lymphocytic infiltrate with exocytosis of these cells into the lower half of the epidermis.

immunosuppression.<sup>112</sup> This approach has the added advantage of avoiding administration of oral psoralens, which may cause nausea and require special protective eyewear to prevent cataracts. There is some evidence that UVB and possibly narrowband UVB therapy carry less risk for cutaneous carcinogenesis than PUVA.<sup>117</sup> However, as all ultraviolet exposure carries with it an increased risk of skin cancer, cumulative doses should be carefully monitored, and patients must have regular skin examinations.<sup>112</sup>

The topical calcineurin inhibitors tacrolimus and pimecrolimus are promising therapeutic agents for diseases characterized by cytokine-induced inflammation. These drugs down-regulate cytokine production by binding to the FK 506 binding protein (tacrolimus) or to macrophilin (pimecrolimus) and blocking calcineurin. This prevents the dephosphorylation necessary for transcription of cytokine genes.<sup>118</sup> Both of these topical medications are marketed as steroid-sparing agents in atopic dermatitis, and they do not cause cutaneous atrophy and striae. In contrast to topical steroids, they do not affect Langerhans' cells, are poorly absorbed, and have a low potential for immunosuppression.<sup>119–121</sup> The long-term side effects of these topical agents in immunosuppressed patients are not known, and large controlled studies have yet to be performed in GVHD.

Topical treatment for grade 3 and 4 GVHD involves supportive care, often in an intensive care setting or burn unit. These patients have severe epidermal necrosis and are subject to all of the complications associated with widespread first-degree body and mucosal burns. The necessity for immunosuppression and the presence of pancytopenia post-transplantation further complicate their treatment. As with TEN in healthy patients, meticulous skin care, antimicrobial agents as indicated, and appropriate dressings are imperative, along with attention to fluid and electrolyte balance.

### Chronic Cutaneous GVHD

cGVHD is a multisystem disease with prominent cutaneous manifestations. Similarities to other autoimmune disorders, especially lichen planus, scleroderma, lupus erythematosus, and Sjögren's syndrome, are striking, and autoantibodies are variably present.<sup>122</sup> Skin changes may appear as early as day 31<sup>123</sup> or as late as 2 years after transplantation but most commonly appear at approximately 80 to 100 days. Disease activity may be triggered by infection, UVR, or even trauma. The hematologic system, liver, gastrointestinal tract, eyes, lung, and muscles are often involved, and patients may have problems with wasting. Eosinophilia may herald a flare of the disease in both acute and chronic disease.<sup>77,124</sup>

Classically, cutaneous cGVHD has been described as either lichenoid (lichen planus-like) or sclerodermatous. The lichenoid lesions of cGVHD may demonstrate the classic purple polygonal papules of lichen planus, with variable superficial scale. The distribution can be focal and become confluent (Figure 8), folliculocentric (Figure 9), or even dermatomal.<sup>125</sup> Vesicular lesions occasionally coexist with lichenoid papules and must be distinguished from herpes simplex or varicella-zoster virus superinfection.<sup>126</sup> Disfiguring postinflammatory hyperpigmentation is a common problem with both lichen planus and lichenoid GVHD, especially in darker-skinned individuals, and this may persist despite therapy (Figure 10).<sup>127</sup>

**FIGURE 8** Confluent purple papules and plaques of chronic lichenoid graft-versus-host disease.

**FIGURE 9** Follicular papules of chronic lichenoid graft-versus-host disease.

**FIGURE 10** Postinflammatory changes of chronic lichenoid graft-versus-host disease.

Although lichenoid GVHD is the most commonly described nonsclerodermatous variant of chronic cutaneous disease, other presentations are possible and not uncommon. Because of the variety of presentations, we prefer to descriptively categorize the lesions of chronic cutaneous GVHD, as shown in Table 5. By specifically describing their morphology, we hope to ascertain which skin lesions are most amenable to a particular therapeutic modality.

Early on, the skin lesions are often subtle and the progression is insidious. Patients complain of photosensitivity, and ambient UV light may flare their disease. There may be marked xerosis (dry skin), or ichthyosis-like changes (Figure 11). As is the case with aGVHD, dyspigmentation may reflect postinflammatory changes or may herald the onset of vitiligo. Extensive loss of pigment after treatment with ganciclovir has been reported in a patient receiving donor T lymphocytes expressing herpes simplex virus thymidine kinase,<sup>128</sup> although adoptive immunity from the donor may also play a role.<sup>74</sup>

Other chronic eruptions that have traditionally been designated “lichenoid” are, in fact, quite polymorphous. Erythematous papules and plaques, some with scale, that are not as well defined as lichen planus are not uncommon. These may be lupus-like in distribution and appearance (Figure 12) or even reminiscent of aGVHD. The morphology and distribution of these plaques are sometimes pityriasisiform (annular plaques demonstrating a branny scale) (Figure 13) or folliculocentric (Figure 14). Less common presentations include guttate (small drop-like lesions) (Figure 15) or plaque-like psoriasisiform lesions, as well as eczematous plaques (Figure 16). cGVHD of the palms and soles occasionally develops deep-seated vesicles suggestive of hand and foot eczema. Acral keratoses have also been reported.<sup>126,129</sup> After donor lymphocyte infusions, the eruption is often morbilliform and indistinguishable from that seen in acute cutaneous GVHD.

Table 5 Skin Changes in Chronic Graft-versus-Host Disease

Clinical Presentation	Description	Variable Features
Xerosis	Dry skin	Follicular prominence
Lichenoid	Purple, polygonal papules and plaques	Scale Vesicles Follicular Localized or confluent Dermatomal Dyspigmentation
Papulosquamous	Scaly patches and plaques	Pityriasiform Dermatitic Localized or confluent
Ichthyosiform	“Fish scales”	Localized or confluent
Depigmentation	Vitiligo-like	Localized or confluent Dermatomal
Psoriasiform	Well-circumscribed lesions with a micaceous scale	Guttate Plaque-like
Localized sclerodermatous	Morpheaform plaques	Bullae Ulceration Follicular plugging Joint restrictions Poikiloderma Dermatomal
Widespread sclerodermatous	Widespread dermal fibrosis	Bullae Poikiloderma Ulceration Vascular tumors Joint restriction Leopard-like
Fasciitis	Edema, erythema, rippling, peau d'orange changes	Erythema Joint restriction Coexisting fibrosis
Nail	Various stages of dystrophy	Longitudinal ridging Onycholysis Pterygium Complete destruction
Scalp	Scaling, fibrosis, alopecia	Scarring or nonscarring Psoriasiform

**FIGURE 11** Ichthyotic chronic graft-versus-host disease.

Sclerodermatous skin changes may develop concurrently with other lesions or de novo. In some cases, the onset is slow, with localized waxy, bound-down fibrotic plaques of morphea,

**FIGURE 12** Lupus-like, “butterfly” eruption of chronic graft-versus-host disease.

preceded by variable erythema (Figure 17). The overlying epidermis develops poikilodermatous changes, with prominent atrophy, telangiectasia, and dyspigmentation. Follicular plugging may also be prominent. The skin may appear rippled with linear bands of fibrosis, possibly related to septal panniculitis (Figure 18). Leopard-like changes, with hyperpigmented, scaly macules, may be localized or widespread and precede the

**FIGURE 13** Pityriasiform chronic graft-versus-host disease.

**FIGURE 14** Erythematous, folliculocentric chronic graft-versus-host disease.

**FIGURE 15** Guttate psoriasiform chronic graft-versus-host disease.

sclerotic eruption.<sup>130</sup> When widespread, diffuse sclerodermatous lesions are devastating, and patients are literally “hidebound” with limited mobility, cutaneous erosions, ulcers, and

**FIGURE 16** Papulosquamous chronic graft-versus-host disease.

**FIGURE 17** Sclerodermoid chronic graft-versus-host disease.

**FIGURE 18** Rippled sclerodermoid chronic graft-versus-host disease.

infections. Thalidomide, which is sometimes used to treat this problem, may itself produce ulcers, possibly on the basis of its antiangiogenic properties.<sup>131</sup> Raynaud's phenomenon and acrosclerosis, although common in scleroderma, is infrequently seen in sclerodermatous GVHD.<sup>34</sup> A painful polyneuropathy may be associated with dermal

fibrosis.<sup>132</sup> Extensive sclerodermatous involvement of the thorax may contribute to the restrictive lung problems already associated with chronic pulmonary GVHD.

Alopecia and loss of skin appendages occur as the skin becomes more fibrotic, leading to decreased sweating and hair loss, often with an irreversible scarring alopecia. Rarely, chronic cutaneous GVHD occurs in a dermatomal distribution at the site of antecedent zoster eruption. This striking presentation may reflect changes in keratinocyte antigenicity owing to the virus.<sup>133,134</sup>

The appearance of bullae heralds a particularly devastating variant of sclerodermatous GVHD and may be localized or widespread.<sup>135</sup> These lesions are not only uncomfortable but also are a nidus for infection, which is slow to heal because of immunosuppression, epidermal atrophy, and dermal fibrosis.

Nails are affected in 50% of patients with chronic cutaneous GVHD, demonstrating variable degrees of dystrophy, thickening, and onycholysis. Pterygium (matrix destruction and damage to the nail plate), similar to that seen in lichen planus, may develop (Figure 19) that affects single or multiple nail units. Longitudinal ridging is the most frequently observed change on both the fingernails and the toenails. Severe nail changes correlate with the duration of the disease and cause considerable morbidity for the patient.<sup>136</sup>

Abrupt and painful skin swelling associated with erythema and subcutaneous edema or a peau d'orange appearance characterizes fasciitis. This is a severe complication, with no specific immunogenetic profile, which resembles the eosinophilia-myalgia syndromes and is resistant to therapy.<sup>137</sup> Patients are functionally disabled,

**FIGURE 19** Destruction of the nail in chronic graft-versus-host disease.

with widespread skin tightness, joint limitation, and contractures (Figure 20). The face is usually spared, and this may occur independently or concurrently with sclerodermatous changes. Half of the patients also report myalgias, and laboratory evaluation demonstrates an eosinophilia.<sup>137</sup> A full-thickness biopsy through the fascia may be necessary to confirm the diagnosis. It is helpful to objectively document disease progression and treatment response by serial photographs, measurements of joint mobility, and noninvasive 20 MHz sonography.<sup>138</sup>

Mucous membrane are affected in approximately 80% of patients with cGVHD.<sup>61</sup> Oral pain and Sjögren's syndrome-like symptoms are a common and debilitating problem. The salivary glands are a target, resulting in xerostomia and dental caries after damage to major and minor salivary glands.<sup>139</sup> Symptoms of early oral GVHD include burning and erythema, which interferes with nutrition and quality of life. Because of the disturbance in the epidermal barrier, topical or oral antifungal prophylaxis is advisable, as are antiviral agents.

As the oral disease progresses, a lacy, white network called Wickham's striae develops on the buccal mucosa (Figure 21), lips (Figure 22), and palate. Although there may be some differences between oral lichen planus and lichenoid GVHD, both are most probably T cell mediated.<sup>140</sup> These mucosal and gingival lesions may become atrophic, erythematous, or erosive. Atrophy of the tongue is associated with shortened or absent lingual papillae,<sup>34</sup> although elongation of papillae, geographic tongue, and white nondetachable plaques are also seen (Figure 23). Esophageal

**FIGURE 20** Limitation of joint mobility with associated fasciitis—the "prayer" sign.

**FIGURE 21** Buccal mucosal changes of chronic graft-versus-host disease.

**FIGURE 22** Labial lesions of chronic graft-versus-host disease.

**FIGURE 23** Chronic graft-versus-host disease of the tongue.

strictures may develop in conjunction with these mucosal problems. Chronic mucosal lichen planus and lichenoid GVHD may predispose patients to squamous cell carcinoma, and biopsies should be performed if this is suspected.<sup>112,141</sup>

Genital involvement affects sexuality and overall quality of life.<sup>142</sup> After stem cell transplantation, symptoms of inadequate estrogenization can occur secondary to premature ovarian failure, and this should be distinguished from early cGVHD. Vaginal GVHD develops an average of

10 months from transplantation, and symptoms may include dryness, excoriations, ulcerated or thickened mucosa, narrowed or obliterated introitus, frequent vaginal infections, and symptoms of dyspareunia.<sup>143</sup> Similarly, phimosis may occur in men. Topical vaginal treatment includes hormonal therapy, steroids, calcineurin inhibitors, or cyclosporine. Mucosal strictures, such as those of the esophagus, may require dilatation.

### Skin Tumors and GVHD

Prolonged immunosuppression and conditioning regimens increase the risk of secondary malignancy of the skin and oral cavity.<sup>144,145</sup> Cutaneous tumors are usually squamous cell carcinoma, but the risk of basal cell carcinoma and melanoma is also increased. This is particularly a problem in individuals with actinic damage or those exposed to therapeutic ionizing irradiation.<sup>146</sup> The pathogenesis of the melanocytic malignancies is unclear as chemotherapy may stimulate nevus growth, but chronic cutaneous GVHD is associated with a decreased number of detectable nevi.<sup>146</sup> The long-term risk of melanoma may be increased when bone marrow transplantation is performed at a young age with a conditioning regimen high in alkylating drugs.<sup>146</sup> Benign vascular tumors have also been described<sup>147</sup> but are uncommon (Figure 24).

As is the case in lichen planus, there is an increased risk of squamous cell carcinoma of the oral mucosa. This may be complicated by coexisting papillomavirus infection. As these tumors may exhibit aggressive behavior, complete and regular skin and dental examinations are recommended.

### Pathology of cGVHD

Early disease manifests the vacuolar changes, dyskeratotic cells, and mononuclear cell infiltrate seen in acute GVHD, and this infiltrate may be perifollicular or perineural.<sup>34</sup> Acanthosis, hypergranulosis, and hyperkeratosis are variably present in lichenoid disease, along with a

**FIGURE 24** Benign vascular tumor associated with chronic graft-versus-host disease.

band-like infiltrate at the dermal-epidermal junction (Figure 25). The rete ridges demonstrate elongation or “sawtooth” changes. As in lichen planus, epidermal atrophy or erosive changes may be evident. Loss of appendages and dermal fat, epidermal atrophy, dermal fibrosis, sclerosis, and minimal infiltrate herald the development of sclerodermatous GVHD.<sup>148</sup> Pan-dermal and deep-dermal sclerosis are characteristic, along with mild vacuolar degeneration and dermal-epidermal junction. Follicular damage and plugging, as well as septal panniculitis, may be prominent.<sup>130</sup>

Patients with early fasciitis showed edema and fibrosis in the septa separating fat lobules and muscular fascia beneath the fat lobules. Later lesions demonstrate a dense lymphocytic infiltrate and thick fibrosis of the fascia.<sup>137</sup> Dermal sclerosis may coexist, as may septal panniculitis.<sup>130</sup> Mucin deposition interspersed between collagen bundles in the papillary and reticular dermis has been reported in association with severe chronic sclerodermoid changes.<sup>149</sup> Both sclerodermatous GVHD and scleroderma are characterized by extracellular matrix deposition of predominantly type 1 collagen. Ultrastructural differences, including absence of beaded filaments and the lack of pericapillary fibrosis, may distinguish the two.<sup>34,150</sup>

### Treatment of cGVHD

First-line therapy combines cyclosporine<sup>151,152</sup> or tacrolimus<sup>153</sup> with methylprednisolone. With conventional treatment, the reported response rates have been around 50%, including complete and partial responders. As in the case of aGVHD, patients who do not respond or those with incomplete responses will require an additional, systemic, “steroid-sparing” modality. Some of the most commonly used steroid-sparing immunosuppressants include thalidomide,<sup>154</sup> mycophenolate mofetil,<sup>155,156</sup> sirolimus,<sup>157</sup> and,

**FIGURE 25** Pathology of lichenoid graft-versus-host disease. Note the prominent granular layer, “sawtooth” rete ridges, and dyskeratotic keratinocytes.

more recently, extracorporeal photochemotherapy.<sup>158</sup> All of these modalities have shown activity in small series of patients but were never compared in terms of efficacy. Sirolimus and extracorporeal photochemotherapy have shown promising response rates in the treatment of cutaneous manifestations of cGVHD, particularly sclerodermoid forms. Pain management and psychological support are often necessary for this devastating problem.

### Topical Therapy

Topical steroids are routinely used to treat the lichenoid and papulosquamous changes, either alone or under occlusion. Chronic use of topical steroids has the potential to exacerbate the epidermal atrophy or problems with infection. The topical calcineurin inhibitors tacrolimus and pimecrolimus have enjoyed some degree of success in treating the erythema and pruritus of steroid-refractory, chronic cutaneous GVHD in selected patients. These agents are often used in conjunction with systemic therapies, including PUVA and extracorporeal photopheresis.<sup>90,118,119,159</sup> The optimal combination of topical therapeutic modalities is not currently known.

UVR is a useful therapeutic adjunct in certain types of chronic cutaneous GVHD. PUVA,<sup>114,160</sup> PUVA-bath photochemotherapy,<sup>161</sup> and UVA-1 (340–400 nm), alone or combined with other immunosuppressants, may be beneficial.<sup>162</sup> Therapeutic UVB or narrowband UVB has also demonstrated some efficacy.<sup>163</sup> Systemic retinoids have been reported to increase the range of motion, flatten cutaneous lesions, and improve the overall performance status of some patients.<sup>164</sup> Retinoids may act via induction of collagenase activity in fibroblasts or inhibition of fibroblast growth and decreased collagen production in dermal fibroblasts.<sup>165</sup>

Other novel therapies include the use of halofuginone cream. Halofuginone, used to treat coccidiosis in commercial poultry production,<sup>166</sup> is an inhibitor of collagen alpha1(I) gene expression and may inhibit de novo synthesis of collagen on a transcriptional level. The fibroblasts are targeted, and the effect is restricted to dermal fibroblasts. Other proliferating cells, such as keratinocytes, are not affected.<sup>167,168</sup> When applied daily on the left side of the neck and shoulder in one patient with sclerodermatous GVHD, collagen alpha1(I) gene expression, collagen synthesis, and collagen content in skin biopsy specimens were decreased, accompanied by increased neck rotation on the treated side. After cessation of treatment, the sclerosis, skin tightness, and collagen alpha1(I) gene expression returned to baseline levels. No adverse effects were observed, and no plasma levels of the drug were detected.<sup>168</sup>

### Oral GVHD

Oral lichenoid cGVHD, like oral lichen planus, is debilitating and difficult to treat. Once an infectious etiology has been excluded, topical steroids, often in the form of dexamethasone mouthwash or rinses, are the mainstay of treatment, along with antifungal and antiviral prophylaxis. As is the case in lichen planus, topical tacrolimus is potentially beneficial in the management of patients with this difficult problem,<sup>169–171</sup> with improvement reported within days to weeks. The major side effect noted by the patients is a burning sensation, and blood levels were very low or undetectable.<sup>171</sup> In some cases, the topical tacrolimus was even more effective for this problem than the systemic drug. Long-term effects, including the risk of intraoral neoplasia, are not yet known. Intraoral PUVA has been tried using a glass fiber extension of a UVA source.<sup>118,172,173</sup> Intraoral UVB irradiation may also be a potential treatment of resistant chronic oral GVHD.<sup>117</sup>

Vaginal GVHD may be treated with topical cyclosporine, which appears to be more efficacious than when used for intraoral disease. Lubricants, dilators, and surgical lysis also may ultimately be needed.<sup>143</sup> Topical calcineurin inhibitors may prove useful for recalcitrant cases, but no controlled studies have been performed.

### Future Directions

The indications for stem cell transplantation have increased in recent years, as have the number of transplants. To decrease the risk of GVHD, molecular matching of donor and host has replaced the older cellular or serologic techniques. Refinements in conditioning regimens, graft manipulation, and engineering, as well as stem cell sources, have made stem cell transplantation the treatment of choice for many diseases. GVHD, although often an undesirable effect of transplantation, has an antitumor effect that is used to treat relapsed malignancies. The goal is to control the reaction so that remission is maintained without unwanted side effects. Successful identification of the pathogenesis and improved treatment options will have far-reaching repercussions, not only for GVHD but also for other immunologic diseases.

Skin GVHD is common after HSCT and is associated with acute and chronic problems. Severe cutaneous disease produces significant quality of life issues, as well as chronic infections, deformities, and secondary skin tumors. In addition, the cosmetic sequelae of GVHD are often psychologically devastating. A multidisciplinary team approach is often helpful in the diagnosis, treatment, and complications of this disease.

# Radiation Dermatitis

Sharon R. Hymes, MD

Eric A. Strom, MD

Ionizing radiation is extensively used to treat a wide variety of primary tumors, as well as for the palliation of metastatic disease. Since the discovery of x-rays by Roentgen in 1895 dermatologists, have incorporated radiation into their practices to treat malignant and benign skin tumors, as well as benign skin diseases such as acne, eczema, and dermatophyte infection. In the last 30 years, other modalities have largely supplanted radiation in the treatment of these benign disorders. However, it may still be useful in the treatment of keloids, extraosseous bone formation after prosthesis placement, and post-coronary artery angioplasty.<sup>1,2</sup> Dermatologists today are asked to treat the cutaneous repercussions of radiation therapy (RT), which are a function of technique, target, total dose,<sup>3,4</sup> and individual variations. RT, either as monotherapy or in combination with other treatment modalities, is a powerful tool in tumor control, limited primarily by injury adjacent normal tissue.

Radiation-induced skin changes were recognized soon after the discovery of x-rays and were reported as early as 1902.<sup>5</sup> Even when the skin is not the primary target, it may be injured as an “innocent bystander” and develop profound alterations on a functional, gross, and molecular level. These changes occur not only after therapeutic radiation but also after interventional procedures. Serious radiation-induced skin injuries have been reported after unexpectedly high doses of kilovoltage irradiation exposure during fluoroscopic imaging, including cardiac catheterization.<sup>6,7</sup> Increasingly sophisticated therapeutic regimens and modern equipment have improved the delivery and ameliorated, but not eliminated, these adverse effects. Increased awareness of potential interactions between RT and concomitant chemotherapy has led to new treatment schedules designed to maximize antineoplastic effects while minimizing skin toxicity. However, radiation dermatitis remains a serious side effect, which may limit the duration of treatment and the dose delivered. Multidisciplinary collaboration is useful in identifying the patient at risk of complications and managing acute and chronic treatment problems. As research further defines

the mechanisms of radiation-induced cellular damage, new radioprotective agents and techniques have been developed to minimize cutaneous problems. Sophisticated wound care techniques also play an important role in the management of severe cases. This chapter reviews the relevant terminology, pathophysiology, and physical findings associated with radiation-induced skin injury. It also outlines skin care parameters in patients with acute and chronic radiation-induced changes.

## Terminology

Ionizing radiation refers to electromagnetic radiation with sufficient energy to eject one or more orbital electrons from an atom or molecule, with the subsequent formation of free radicals. These free radicals alter cellular chemical bonds and the normal structure and function of the cell. Deoxyribonucleic acid (DNA) alterations either are repaired or result in mutations or cell death. The high-energy photons commonly used in RT are known as x-rays when they are created electronically, usually by a linear accelerator (LINAC). This is a megavoltage unit that produces and delivers the desired dose of radiation by accelerating electrons that strike a tungsten target to produce photons. The beam then exits a gantry, which can be rotated around the patient. In general, the higher the photon energy, the more the skin is spared. The LINAC may also be programmed to produce an electron beam. Electron beam therapy, 5 to 20 meV, treats to a depth of 1 to 6 cm with a moderate skin dose that falls off after a few centimeters. These properties make it useful for boost dosing, or localized therapy used to re-treat a defined area of tumor. It is also sometimes used to treat nonmelanoma skin cancer (NMSC), metastatic skin disease, and mycosis fungoides, a form of cutaneous T-cell lymphoma. X-ray contamination of electron beam therapy is carefully monitored to minimize side effects.<sup>8</sup> To control the depth of treatment, correct for missing tissue, or purposely increase the skin dose, a bolus, or gelatin-like tissue equivalent material, is sometimes placed on the patient to bring the surface dose to 100%.

When high-energy photons are produced from the nucleus of radioactive atoms, such as cobalt 60, they are termed gamma rays. Grenz rays, low-energy x-rays in the range of 5 to 15 keV, are produced by orthovoltage units and absorb approximately half of their energy in the first 1 to 2 mm of skin. Although uncommonly used by dermatologists now, grenz rays were frequently employed to treat benign epidermal diseases such as psoriasis, tinea capitis, acne, warts, and dermatitis. In modern dermatologic practices, an arsenal of pharmacologic agents has largely supplanted its use for these benign conditions. Superficial x-ray, 30 to 125 keV, is sometimes used to treat primary or metastatic malignancies involving the skin and nodes and is also produced by an orthovoltage unit. Brachytherapy uses radioactive materials that are implanted directly into the tumor rather than using exogenous sources.

The most common form of measurement of absorbed radiation, the gray, replaces the older term, rad. One gray is the equivalent of 1 J/kg of absorbing material, or 100 rads. Radiation is commonly delivered in a series of smaller fractionated doses, rather than one large dose, to allow time for the recovery of normal tissue and to target the tumor. This technique significantly impacts the development of acute and chronic skin changes as normal stem cells exhibit variable degrees of radiosensitivity.<sup>9</sup> Hyperfractionation uses smaller doses per fraction, often twice daily, impacting both the treatment time and dose. Accelerated fractionation allows the delivery of the standard dose in a shorter period of time to overcome repopulation of rapidly growing tumors.

Depending on the type of tumor and the desired treatment parameters, a special cast, cradle, or mask may be created to immobilize the patient at each radiation session. Pretreatment computed tomography (CT) defines the target and the treatment position (simulation), or simulation may be performed using fluoroscopy. More recently, CT simulators can create a three-dimensional model and digitally reconstructed radiograph. This allows a geometric shaping of the radiation beam that conforms to the shape of the tumor (conformal radiation therapy),

allowing directed therapy, with less risk to normal tissue. The radiation physicist, dosimetrist (medical physicist), and oncologist use this information to plan the optimal dose, as well as the placement of physical blocks near the patient, or multileaf collimators mounted in the gantry, to reduce exposure. Wedges, filters using high atomic number material, are used to modify dose distribution. Lines of reference (fiducials) may be painted or tattooed on the patient to ensure proper positioning and localization of the target.

### Clinical Manifestations of Radiation Dermatitis

The majority of patients treated with RT develop minor and reversible skin changes. When cutaneous changes do develop, they are commonly graded as acute, consequential late, or chronic and may appear at both the entrance and exit portals.

### Acute Radiation-Induced Dermatitis

After RT or accidental exposure, acute changes usually occur within 90 days. The National Cancer Institute common toxicity criteria version 3.0 has become the standard for evaluation (Table 1). Generalized erythema, sometimes undetectable without special instrumentation, may occur hours after radiation exposure and fade within hours to days.<sup>10,11</sup> A second phase consisting of more sustained erythematous changes usually is apparent 10 to 14 days after dosing and is characterized by a blanchable reactive pink color, without other epidermal changes, most likely mediated by cytokines.<sup>12</sup>

Grade 1 changes, usually seen in the fourth or fifth week of therapy, include follicular or generalized erythema and dry desquamation. Other changes include pruritus, epilation, scaling, and dyspigmentation (Figure 1). The

**FIGURE 1** Grade 1 radiation dermatitis of the arm with erythema

dryness and hair loss are secondary to injury to sebaceous glands and hair follicles.

Persistent tender or edematous erythema, grade 2 changes, may progress to focal loss of the epidermis, producing moist desquamation in skin folds (Figure 2). This usually occurs after 4 to 5 weeks of therapy, with radiation doses to the skin of 40 Gy or greater.<sup>13</sup> Moist desquamation is characterized by epidermal necrosis, fibrinous exudates, and often considerable pain. Bullae may be present clinically and histologically, and these can rupture or become infected. Histologically, arterioles are obstructed by fibrin thrombi and edema is prominent.<sup>14</sup> At this stage, it is important to identify any superinfection, especially with organisms that may act as superantigens, such as *Staphylococcus aureus*. Superantigens up-regulate cytokine production and inflammation by activating antigen-presenting cells and T cells, resulting in increased skin damage (Figure 3).<sup>15</sup> Depending on the body site, this reaction peaks 1 to 2 weeks after the last treatment and gradually heals, accompanied by increased expression of epidermal growth factor receptors.<sup>16</sup> Epidermal regeneration occurs about the third to fifth week after radiation, with healing within 1 to 3 months.

Confluent moist desquamation in other than skin folds is typical of grade 3 dermatitis (Figure 4), and the formation of ulcers, hemorrhage, and necrosis heralds grade 4 changes

**FIGURE 2** Grade 2 radiation dermatitis with erythema of the breast and moist desquamation confined to skin folds

**FIGURE 3** Radiation dermatitis of the neck complicated by superinfection

**FIGURE 4** Grade 3 radiation dermatitis with confluent moist desquamation of the neck

(Figure 5). These problems may become chronic and lead to consequential late complications (Figure 6). The severity of the acute radiation response may also lead to a late effect in the gut, bladder, and oral mucosa.<sup>17</sup> Disruption of the epithelial basement membrane and breakdown of the barrier function substantially increases the risk of these injuries.<sup>18</sup>

As epidermal function becomes increasingly impaired, the permeability of the skin, as measured by transepidermal water loss, increases. Topical treatment may ameliorate radiation dermatitis, as measured by this parameter.<sup>11</sup> A

**FIGURE 5** Grade 4 radiation dermatitis with skin necrosis of the left chest wall

**Table 1** Radiation Dermatitis: National Cancer Institute Common Terminology Criteria for Adverse Events Version 3

Grade	Description
0	None
1	Faint erythema or dry desquamation
2	Moderate to brisk erythema or a patchy moist desquamation, mostly confined to skin folds and creases; moderate edema
3	Confluent moist desquamation, $\geq 1.5$ cm diameter, not confined to skin folds; pitting edema
4	Skin necrosis or ulceration of full-thickness dermis: may include bleeding not induced by minor trauma or abrasion

**FIGURE 6** Consequential late changes following non-healing acute radiation dermatitis of the neck. There is severe fibrosis complicated by erosions and telangiectasia

“comedo reaction,” comprising whiteheads and blackheads, is more prone to develop after head and neck radiation,<sup>19</sup> and pseudorecidives resembling keratoses sometimes appear in the immediate postradiation period. These should be distinguished from tumor recurrences and often spontaneously resolve without treatment.<sup>19,20</sup> Hair loss occurs at skin doses of approximately 30 Gy, and new hair may continue to return for up to a year. Alopecia owing to follicular fibrosis may be permanent at skin doses of 55 Gy or greater.

### Chronic Radiation Dermatitis

The skin may appear relatively normal for a varying length of time after RT, and chronic changes may not develop for months to years after exposure. These changes may be transient, such as the edematous peau d’orange appearance that appears in the postirradiation breast, usually resolving in the first year (Figure 7). Postinflammatory hypo- and hyperpigmentation is commonly seen after any disruption of the dermal-epidermal junction and, depending on the severity of the initial reaction and skin type of the patient, may persist or slowly normalize (Figure 8). Certain body sites, such as the scalp, exhibit relatively more tolerance for radiation than the skin of the face, neck, trunk, and extremities.<sup>21</sup> Textural changes, including xerosis (dryness), scale, and hyperkeratosis, are common, and hair follicles and sebaceous glands may be absent. Persistent telangiectasia is more common

**FIGURE 7** Peau d’orange changes in the irradiated breast.

**FIGURE 8** Dyspigmentation of the irradiated right breast

after boost dosing, acute grade 3 injury, and moist desquamation, possibly secondary to microvasculature damage (Figure 9).<sup>22,23</sup> However, the development of moist desquamation does not seem to predispose patients to the development of subcutaneous fibrosis,<sup>24</sup> and the boost is not associated with any other late changes.<sup>25</sup>

Poikilodermatous changes, characterized by persistent hyper- and hypopigmentation (dyspigmentation), atrophy, and telangiectasia, are an indication of more severe cutaneous injury (Figure 10). There may be permanent loss of nails and skin appendages, producing alopecia and decreased or absent sweating. The latter is clinically significant when large surface areas are treated, as in the case of electron beam therapy for

**FIGURE 9** Telangiectasia in a rectangular field after boost dosing.

**FIGURE 10** Chronic radiation dermatitis of the neck with fibrosis and poikiloderma.

mycosis fungoides. Fibrosis in response to growth factors such as transforming growth factor  $\beta$  (TGF- $\beta$ )<sup>26</sup> may be focal or widespread, producing tissue retraction, limitation of movement, and pain. Pathologically, the dermis and subcutaneous adipose tissue are replaced by atypical fibroblasts and fibrous tissue (Figure 11). Eccentric myointimal proliferation of the small arteries and arterioles may progress to thrombosis or obstruction, increasing the predisposition for ulcers and skin breakdown.<sup>13</sup> Skin atrophy, related to decreased population of dermal fibroblasts and the reabsorption of collagen,<sup>27</sup> also causes fragility and predisposes patients to erosions and ulcerations, which may be painful, slow to heal, and prone to superinfection (Figure 12). Subungual splinter hemorrhages have been reported on occasion.<sup>28</sup>

**FIGURE 11** Radiation induced fibrosis. Hematoxylin and eosin 50X. Courtesy of Dr. Victor Prieto

**FIGURE 12** Severe radiation fibrosis and a non-healing skin ulcer.

Radiation necrosis is more commonly a consequential late injury associated with high-dose RT, failure to heal acute dermatitis, and dermal ischemia.<sup>29</sup> It is particularly difficult to manage as impaired healing and superinfection are common in tissues rendered relatively avascular. These problems are exacerbated by peripheral vascular disease, diabetes, hypertension, and connective tissue disease.

## Pathophysiology

The skin is a continuously renewing organ, and RT not only interferes with normal maturation, reproduction, and repopulation of germinative epidermal and hair matrix cells but also targets fibroblasts and cutaneous vasculature.<sup>30</sup> The radiation-induced injury has been termed a “complex wound,” in which structural tissue damage occurs instantaneously, mediated by a burst of free radicals, resulting in DNA damage and alteration of proteins, lipids, and carbohydrates. Each additional exposure or fraction contributes to inflammatory cell recruitment and direct tissue injury.<sup>18</sup> Wound healing is further impaired by inhibition of normal granulation tissue, fibrogenesis, and angiogenesis.<sup>18,31</sup> Acute injury is, therefore, a consequence of reduction in and impairment of functional stem cells, endothelial cell changes, inflammation, and epidermal cell apoptosis and necrosis.

Cutaneous radiation syndrome, occurring after accidental radiation exposure, is also mediated by a combination of inflammatory processes. Alteration of cellular proliferation occurs as a result of a specific pattern of transcriptionally activated proinflammatory cytokines and growth factors.<sup>32</sup> Interaction between epithelial and mesenchymal cells is at least in part initiated by

interleukin-1 $\alpha$  secreted by the activated epithelial cell during skin injury. This, in turn, may modulate the synthesis of other proinflammatory mediators and proteases in surrounding fibroblasts.<sup>33</sup>

Repetitive radiation exposure delivers a series of tissue insults to skin that has not had time to repair existing damage. During dose fractionation schedules with gaps (extension of the nontreatment period), tissue-specific repopulation is initiated after a lag period. When accelerated repopulation is initiated, there is an increase in the radiosensitivity of the surviving stem cells and a decrease in time for cells to repair sublethal radiation-induced damage.<sup>9</sup> Ionizing radiation also produces epidermal basal cell and endothelial cell damage,<sup>31,34</sup> vascular injury,<sup>14,35</sup> and loss of Langerhans’ cells,<sup>36</sup> which are the chief antigen-presenting cells in the skin. Up-regulation of epidermal growth factor receptor<sup>16</sup> may aid in epithelial repair, whereas alterations in epidermal Langerhans’ cells may further impair immunologic integrity.<sup>36,37</sup> These events, combined with the intensive inflammation promoted by up-regulation of adhesion molecules such as intercellular adhesion molecule 1 (ICAM-1),<sup>38</sup> contribute to impairment of cutaneous barrier function, bacterial colonization, superinfection, and superantigen production.

Acutely irradiated skin demonstrates a perivascular inflammatory infiltrate around dilated blood vessels with swelling and sloughing of epithelial cells and growth arrest.<sup>39</sup> Lower doses produce clumping of nuclear chromatin, swelling of the nucleus, and apoptosis. Higher doses cause nuclear disfiguration or loss of the nuclear membrane, mitochondrial distortion, and degeneration of the endoplasmic reticulum, as well as direct cellular necrosis. Mitotic activity in the germinal cells of the sebaceous glands, hair follicles, and epidermis is inhibited, and basal layer stem cells are depleted.<sup>13,40</sup> Prostaglandins and thiol compounds are potentially radioprotective agents that have been used to protect normal tissue, with varying degrees of success. In animal models, both have been used to protect hair follicles and other skin structures.<sup>41,42</sup>

TGF- $\beta$ , a peptide that has a fundamental role in controlling proliferation of many cell types, is intricately involved in the development of chronic radiation dermatitis.<sup>43</sup> This cytokine acts as a “master switch” for tissue fibrosis, activating fibroblasts to secrete extracellular matrix protein.<sup>26,44–46</sup> In the irradiated tissue of pigs, TGF- $\beta$  also plays an important role in promoting and regulating the late fibrotic process.<sup>47</sup> Its main effect on connective tissues *in vivo* is to stimulate growth. Endothelial cell proliferation is also stimulated, but epithelial cell growth is inhibited. Mice lacking a downstream mediator of TGF- $\beta$ , Smad3, demonstrate decreased tissue damage

and fibrosis after irradiation, as well as accelerated healing.<sup>48</sup> Up-regulation of TGF- $\beta$  has been found in fibrotic tissue of irradiated patients but not in the nonirradiated controls,<sup>26</sup> confirming that its induction is a general response of cells to ionizing radiation. It is also chemotactic for mast cells, possibly increasing angiogenesis by inducing macrophages to release factors that lead to neovascularization.<sup>49</sup>

Radiation-induced endothelial cell damage activates components of the coagulation system,<sup>18</sup> which, in turn, promotes inflammation and cytokine overproduction. Thrombin, which is a regulator of cell proliferation, may also modulate the synthesis of TGF- $\beta$ ,<sup>50</sup> vascular endothelial permeability, inflammation, and tissue remodeling.<sup>18,51</sup> Subsequent matrix accumulation, fibrosis, endothelial cell dysfunction, and increased measurable cytokines may ultimately delay reepithelialization.<sup>50</sup>

Long-lasting impairment of the reparative process ultimately affects the integrity of the “healed” radiation-induced wound. Although healed traumatic wounds in nonirradiated skin remodel continuously for years following injury, this capacity is often compromised after RT because of persistent cellular dysfunction or changes in the supporting stroma.<sup>18</sup> Fibroblasts may be permanently altered, causing cutaneous atrophy, contraction, and fibrosis.<sup>52,53</sup> Although total dose is certainly critical in producing cutaneous problems, late effects may be more dependent on the volume, fraction size, and dose/fraction schedules.<sup>14</sup> The underlying pathogenesis of the development of telangiectasia is unknown but may be due in part to inflammatory damage to the microvasculature during the acute injury and the production of platelet-derived growth factor (PDGF) and fibroblast growth factor by damaged endothelial cells or macrophages.<sup>18</sup> Both vascular sclerosis and radiation fibrosis are, in part, related to endothelial cell damage and vascular injury. The identification of genes by microarray analysis may further define the molecular mechanisms of this microvascular insult.<sup>54</sup> Leukocyte infiltration, mediated in part by cell adhesion molecules, is also commonly observed at sites of irradiation and is likely to lead to parenchymal atrophy, fibrosis, and necrosis in normal tissues.<sup>35</sup>

## Risk Factors

### Dose Fractionation Schedules

The total dose, dose/fractionation, type and quality of the beam, volume, and surface area exposed influence the degree of damage to the epidermis, dermis, adnexal structures, and microvasculature.<sup>9,32,55–57</sup> When photons are absorbed, the energy released produces breakage of chemical bonds and subsequent electron

release. These free electrons react with other molecules, particularly water, to form free radicals, which then have the potential to diffuse and damage DNA. In the case of acute radiation dermatitis, the clinical consequences of this reaction are expressed during or immediately after therapy. Usually, these acute changes heal with mild changes. Rarely, the acute dermatitis never completely heals, resulting in consequential late changes, leading to chronic wounds and necrosis. Alternatively, chronic or true late radiation consequences may develop despite minimal acute radiation dermatitis. Unlike acute effects, true late reactions are unlikely to be self-repairing.

### Physical Factors

The severity of the skin reaction is both treatment and patient related.<sup>27,58</sup> Physical factors, including smoking,<sup>59</sup> poor nutritional status, problems with skin integrity, actinic damage, body site, obesity,<sup>60</sup> and overlapping skin folds, predispose patients to radiation dermatitis. About 25% of patients receiving parallel-opposed lateral fields will have skin reactions. The intentional use of boost doses to treat malignancies unavoidably produces overlapping fields, and the use of bolus material often results in an increase in the skin dose.<sup>57,61</sup> When the skin is purposefully targeted, as in the case of inflammatory breast cancer, primary skin cancers, or mycosis fungoides, and when dose escalation is used to treat regionally recurrent disease, cutaneous problems should be anticipated. The larger the targeted tumor, the more likely a severe skin reaction is to develop.<sup>59</sup> Tissue expanders, especially in the breast, present a unique dilemma both in delivering the desired dose and maintaining skin integrity (Figure 13). Positioning the patient to reduce apposition of skin folds, skin shields in sensitive areas, and delaying treatment until preexisting skin problems have been addressed may decrease the frequency and severity of radiation-induced skin problems. Deliberate exposure to ultraviolet radiation in treatment areas should be avoided as this may up-regulate cytokine production and serve as a cocarcinogen. Temperature extremes should also be avoided.

**FIGURE 13** Tissue expander of the breast deflated to deliver RT

### Genetic Factors

Patients with impaired cellular DNA repair capabilities are at increased risk of radiation-induced problems. Individuals with ataxia-telangiectasia, a rare autosomal recessive disorder resulting from mutations in both copies of the *ATM* gene, are especially prone to develop severe cutaneous complications after RT. It has been suggested that patients who develop serious, unanticipated radiation dermatitis may actually harbor a previously undetected abnormality in *ATM* or may be heterozygous for this trait. *ATM* heterozygosity occurs in approximately 1% of the general population,<sup>62</sup> and a single mutated copy of the DNA repair gene may predispose patients to cutaneous complications, necessitating dose alterations to reduce cutaneous toxicity.<sup>63</sup> Owing to their increased cellular radiosensitivity, heterozygous *ATM* breast cancer patients may qualify for dose and volume reduction trials.<sup>64</sup>

Other diseases with reduced cellular DNA repair capability call for dose alteration or avoidance of therapeutic radiation entirely. Patients with hereditary nevoid basal cell carcinoma (BCC) syndrome (Gorlin's syndrome) develop multiple BCCs, as well as a variety of phenotypic abnormalities. Abnormalities in the human homologue *Patched* (*PTCH*) gene, the impaired tumor suppressor gene associated with this syndrome, have been identified, and increased cellular proliferation occurs via the hedgehog signaling pathway.<sup>65,66</sup> *Ptc* heterozygous mice exhibit increased radiation-induced teratogenesis, suggesting the role of *ptc* in the response to ionizing radiation.<sup>67</sup> Nucleoli in fibroblasts of affected individuals are increased after x-radiation, apparently corresponding to increased ribonucleic acid (RNA) synthesis and metabolism.<sup>67,68</sup> Radiation of affected patients may produce devastating results, with the production of widespread cutaneous tumors (Figure 14).

Other chromosomal-breakage syndromes, including Fanconi's anemia, Bloom syndrome, and disorders characterized by defects in DNA repair, such as xeroderma pigmentosum, may experience increased frequency of chromatid breaks and gaps in skin fibroblasts when compared with normal controls after G2 phase x-irradiation. This has also been reported with familial polyposis, Gardner's syndrome, hereditary malignant melanoma, and dysplastic nevus syndrome.<sup>69-71</sup> However, even in patients without known genetic disorders, there may be individual differences in early and late radiation response in the skin. Whether these differences are determined by heterogeneity in intrinsic cell radiosensitivity or by other factors has yet to be elucidated.<sup>72</sup> Attempts have been made in breast cancer patients to predict radiosensitivity and subsequent fibrosis by measuring the number of lethal chromosome aberrations in in vitro irradiated lymphocytes,<sup>73</sup> but there is no clinically standardized method of

**FIGURE 14** A patient with hereditary nevoid basal cell carcinoma who received radiation therapy years earlier. The eroded areas represent basal cell carcinoma, and a bandage covers a biopsy site.

predicting individual variations in response to therapy. Measurements of DNA damage by p53 and p21 protein accumulation have been assayed in the irradiated breast, where no association between the p53 response and degree of erythema was found. Therefore, epidermal p53 response does not reliably predict the degree of radiation-induced epidermal injury.<sup>74</sup> Individual responses to radiation-induced DNA damage vary widely and may be independent of the type of radiation.

### Connective Tissue Disease

Preexisting connective tissue or autoimmune disease, including scleroderma, systemic lupus erythematosus (SLE), and perhaps rheumatoid arthritis (RA), unpredictably predispose patients to the development of severe radiation dermatitis.<sup>75-77</sup> Although the mechanism is not known, lymphocytes from patients with RA, SLE, and polymyositis are more radiosensitive than those from healthy volunteers or patients with conditions not associated with autoimmunity. Peripheral blood lymphocytes from patients with SLE, juvenile RA, and systemic sclerosis have significantly greater DNA damage after irradiation than do those from controls.<sup>78,79</sup> Because of this, the presence of connective tissue disease is a relative contraindication to RT.

### Infectious Disease

Patients with human immunodeficiency virus (HIV) disease may demonstrate a decreased skin and mucous membrane tolerance to treatment, independent of their risk of infection. They tend to develop cutaneous reactions at a lower dose, as well as more significant systemic problems.<sup>80-82</sup>

## Radiosensitizers

An increase in adverse events is well documented after the use of “radiosensitizers” (Figure 15). These are drugs given either immediately prior, during, or less than 7 days postradiation, causing increased cellular damage and impaired repair.<sup>83</sup> It is now known that the timing and dose of any such agents are crucial.<sup>84</sup> For example, when paclitaxel or docetaxel is used in conjunction with radiotherapy in the treatment of breast cancer, it produces synergistic cutaneous toxicity that is both schedule and dose dependent. The concomitant use of tamoxifen with radiation therapy has been implicated in the development of an increased incidence of subcutaneous fibrosis by some investigators.<sup>85</sup>

## Differential Diagnosis

Common cutaneous problems, including dermatitis (Figure 16) or infection, may manifest during or after treatment. Even after the acute effects of radiation have subsided, the treated skin may manifest a host of physical and functional changes. Compromised integrity and impaired barrier

**FIGURE 15** Radiation dermatitis in a patient receiving paclitaxel.

**FIGURE 16** Contact dermatitis from the pens used to paint fiducials.

function may produce a *locus minoris resistentiae*, a Latin phrase meaning “a place of less resistance” (Figure 17). It is not unusual to see dermatitis or infection confined to these sites. There have also been case reports of localized Sweet’s syndrome in the irradiated skin of the breast,<sup>86</sup> as well as lichen planus confined to a radiation port.<sup>87</sup> Reports of pemphigus, an autoimmune bullous disease, following ionizing radiation exposure are rare. Common to these cases is a prodromal persistent nonspecific dermatitic eruption that is often interpreted as radiation dermatitis and latency of variable duration before the onset of a vesiculobullous eruption that begins at the portal of irradiation.<sup>88</sup>

Cutaneous hypersensitivity syndromes, including erythema multiforme, have been reported to start in irradiated skin and generalize from there.<sup>89</sup> Localized Stevens-Johnson syndrome confined to radiation ports has been reported in conjunction with the administration of oral agents such as phenobarbital.<sup>90</sup> Other severe complications, including toxic epidermal necrolysis, a skin condition characterized by complete epidermal necrosis, has been reported to occur more frequently when phenytoin and related anticonvulsants are combined with cranial radiation. These reactions also have, on occasion, started in the radiation port,<sup>90-95</sup> prompting some clinicians to avoid phenytoin during RT.<sup>89</sup>

Radiation recall refers to the phenomenon of cutaneous inflammation, limited to the site of radiation, occurring at least 7 days after treatment or after the acute dermatitis has healed (Figure 18).<sup>96</sup> It is graded according to its severity, ranging from erythema to necrosis, ulceration, or hemorrhage (Table 2). Increasingly severe recall dermatitis tends to occur when the offending drugs, usually cytotoxic agents, are introduced shortly after the cessation of RT.<sup>96</sup> It has also been

**FIGURE 17** Eczema confined to a radiation site, and sparing the non-exposed skin.

**FIGURE 18** Radiation recall of the right neck 2 years after RT.

**Table 2** Radiation Recall Reaction: National Cancer Institute Common Terminology Criteria Version 3.0

Grade	Description
0	None
1	Faint erythema or dry desquamation
2	Moderate to brisk erythema or a patchy moist desquamation, mostly confined to skin folds and creases; moderate edema
3	Confluent moist desquamation, $\geq 1.5$ cm diameter, not confined to skin folds; pitting edema
4	Skin necrosis or ulceration of full-thickness dermis; may include bleeding not induced by minor trauma or abrasion

Reaction following chemotherapy in the absence of additional radiation therapy that occurs in a previous radiation port.

reported after the administration of nonsteroidal antiestrogens, interferon- $\alpha 2b$ , simvastatin, and antituberculosis medications.<sup>97</sup> Radiation recall occurs minutes to days after drug exposure and may occur weeks to years after radiation. It unpredictably recurs on reexposure but usually flares after the first exposure to the inciting drug. The longest well-documented hiatus between treatment and recall is 2 years after radiation exposure.<sup>98,99</sup> The etiology of this well-documented phenomenon is uncertain. Impaired cellular repair, gene mutation,<sup>100</sup> vascular damage,<sup>98</sup> epidermal stem cell inadequacy<sup>101</sup> and depletion,<sup>102</sup> drug hypersensitivity,<sup>96</sup> cumulative direct DNA damage and oxidative stress,<sup>103</sup> koebnerization,<sup>104</sup> nonimmune activation, and up-regulation of cytokines have all been implicated.<sup>97</sup> The latter theory is supported by cases that occur minutes after parenteral infusion, whereas it takes a median 8 days to manifest after oral medications. Although anecdotally beneficial, the role of topical or systemic steroids, mast cell inhibitors, and antihistamines in the prevention and treatment of this problem has not been evaluated in a controlled setting.<sup>96</sup>

Finally, recurrent or secondary tumor should be considered if atypical plaques and nodules develop within the radiation field (Figures 19 and 20). Although irradiated skin may present some difficulty with healing, a biopsy is useful in this clinical situation.

### Treatment of Acute Radiation Dermatitis

Early changes (grade 1) characterized by erythema and dry desquamation are best treated symptomatically. The affected area is washed gently with plain water alone or combined with a mild, low-pH cleansing agent that does not exacerbate the existing dermatitis. This has proven to be both physically and psychologically more beneficial than older practices of not washing at all.<sup>105-107</sup> Washing may also reduce the bacterial load and thereby reduce potential superantigen-induced inflammation. Patients should wear well-fitting, nonbinding clothing and avoid unnecessary topical irritants and friction. When required, soft burn nets or other modalities that hold dressings in place without adhesives should replace tape. In the case of breast cancer patients, a sports bra can be used for this purpose. While actively undergoing therapy, aluminum or magnesium salts, such as those found in antiperspirants and talcs, should not be used in the treated area as

they can potentially increase the radiation dose to the superficial skin. Ultraviolet exposure should be avoided, and photoprotection in the form of clothing, hats, and sunscreen should be used as tolerated.

### Topical Therapy and Wound Care

The goal of treating the erythema and dry desquamation is to avoid a bolus effect, minimize transepidermal water loss, decrease pain, and prevent progression to moist desquamation. Petrolatum-based emollients are commonly used, with or without hydrogel dressings. Radioemulsions containing trolamine were hoped to be “radioprotective” as they are macrophage cell stimulators that remove necrotic tissue, promote fibroblast proliferation, and, *ex vivo*, reduce vascular alterations, restore CD34 expression, promote epithelial cell proliferation, and decrease interleukin-1 expression and collagen secretion. The oil-in-water formulation also softens nonviable tissues. Although controlled studies show no clinical radioprotective effect over control, many patients express satisfaction with these ointments and find them soothing.<sup>108</sup> Newer non-petroleum-based products combining castor oil, balsam of Peru, and trypsin purportedly stimulate the capillary bed, improve epithelialization, and provide cutaneous protection.<sup>109</sup>

Recommendations for use of other topical skin agents are largely anecdotal, and few randomized studies have been performed. Consequently, a great variety of products have been studied, and many recommendations have emerged. Aloe vera, D-panthenol, hydrophobic and hydrophilic ointments, chamomile, and almond ointment have been tried, with variable results.<sup>110-113</sup> Multiple other creams, including aloe vera, CM-glucan, hydroxypropylsilan C, and Matrixyl (Theta-Cream), have shown no definite benefit in the treatment of radiation dermatitis.<sup>114</sup> The role of antioxidants, including vitamin C, has not been established, and topical ascorbic acid did no better than placebo in preventing skin toxicity after cranial RT.<sup>115</sup> However, when given systemically to mice, higher doses of radiation were required to obtain skin desquamation.<sup>116</sup> Sucralfate (sucrose aluminum), a widely used antiulcer drug, has anti-inflammatory properties and activates cellular proliferation. In a double-blind randomized study comparing the efficacy of sucralfate cream with a base cream in 50 breast cancer patients who received postoperative electron beam therapy to the chest wall, the acute radiation reaction of the skin was statistically decreased and the recovery of the skin was also significantly faster in the sucralfate cream group.<sup>112,113</sup> However, in another study comparing vehicle with vehicle plus 10% sucralfate, there was no significant difference in time to healing or

pain relief.<sup>117</sup> Topical hyaluronic acid has been helpful in some patients undergoing radiation therapy, demonstrating improved healing compared with placebo,<sup>118</sup> as has calendula, an extract from a plant of the marigold family.<sup>119</sup> Barrier films may also prove to be useful when compared with glycerine cream.<sup>120</sup>

The general consensus is that the majority of patients do not need a specific therapy except a moisturizer as tolerated, and there is no agreement on a specific topical agent to manage acute radiation dermatitis.<sup>121</sup> However, as with other forms of dermatitis, creams and ointments are generally better tolerated than lotions in irritated, dry skin. Since approximately 10% of patients have allergic-type reactions with topical agents, this should be considered if exacerbation of the dermatitis occurs.<sup>122</sup>

The use of topical corticosteroids to prevent or treat radiation dermatitis is somewhat controversial. Because these agents have documented anti-inflammatory effects and have been shown to inhibit the up-regulation of interleukin-6 in response to ionizing radiation,<sup>123</sup> they have been used for both treatment and prevention. Comparisons of different topical steroids, instituted either before or during the onset of acute dermatitis, show conflicting results. Some studies show no statistically significant difference between steroid (0.2% hydrocortisone valerate) versus placebo,<sup>124</sup> whereas other groups demonstrate decreased acute radiation dermatitis in the topical steroid group.<sup>125</sup> Comparison of two different steroid creams, 1% hydrocortisone cream and 0.05% clobetasone butyrate, in a double-blind trial was carried out in 54 patients undergoing RT for breast cancer. The cream was administered when patients reached a given dose of 2,000 rad, or earlier, if required. The majority of patients using either cream derived benefit from its soothing effects, but patients using clobetasone butyrate developed more severe skin reactions.<sup>126</sup> Although there is no consensus, at best steroids may ameliorate the dermatitis, but they do not entirely prevent it.<sup>127</sup> It is not known if infection, telangiectasia, or skin atrophy, known side effects of this group of topical agents, is increased. Other anti-inflammatory agents, such as 1% indomethacin cream, were not found to be helpful in preventing radiation-induced erythema.<sup>10,128</sup> The new topical calcineurin inhibitors (topical tacrolimus and pimecrolimus) are potent down-regulators of cytokine production and are currently approved for use in atopic dermatitis. There have been no controlled trials to date documenting their usefulness in radiation dermatitis.

### Wound Care for Erosions and Ulcers

Despite the fact that irradiated skin is significantly altered, the care of radiation-induced erosions

FIGURE 19 Recurrent breast cancer after RT

FIGURE 20 Recurrent breast cancer after RT

and ulcers is generally not specific and is adapted from the generic wound care experience (Table 3).<sup>18,52,53,129</sup> From a prognostic standpoint, it may be helpful to distinguish consequential late injury from secondary injury in an irradiated field. Wound dressings are used for multiple

**Table 3 Treatment of Radiation Dermatitis\***

Acute erythema
Emollients (lotions, creams, or ointments)

Superoxide dismutase
Interferon- $\gamma$

GM-CSF = granulocyte-macrophage colony-stimulating factor; RT = radiation therapy; Adapted from Hymes SR, Strom EA, Fife C. Radiation dermatitis: Clinical presentation, pathophysiology, and treatment 2006. *J Amer Acad Dermatol* 2006; 54:28–46.

reasons, including handling wound secretions and pain control, as well as protecting the skin from outside contamination. In addition, preserving a moist environment enhances reepithelialization, lyses necrotic tissue, and encourages phagocytosis of necrotic debris and bacteria.<sup>13,129,130</sup> To enhance barrier function, hydrophilic and lipophilic creams and ointments are often used alone or with hydrogel dressings. These dressings are soothing but, as they are not self-adherent, must be held in place and removed just prior to treatment. They may be cleaned and reapplied, especially on nonexudative wounds. When refrigerated before use and applied while still cool, patients often find them soothing.

Hydrocolloid dressings provide moderate absorption of secretions and hydrate the wound. Additional benefits include healing of established wounds, simplification of wound care, and pain control.<sup>131</sup> They are self-adherent, which may present a problem when the adhesive is placed on already damaged skin. These dressings are commonly left in place for several days and are, therefore, more useful after completion of RT.

Transparent films allow close observation of the wound, but as they do not absorb exudates, they are more practical in protecting the fragile epidermis or covering early erosions. Heavily exudative wounds are best treated with burn pads or the use of alginate or foam dressings, which are highly absorptive.

Persistent eschars can be removed manually under local anesthesia or treated with enzymatic débridement or autolytic dressings. Biosurgical débridement with sterile live maggots removes necrotic, infected tissue, leaving healthy tissue untouched.<sup>129</sup> Unfortunately, these techniques often leave significant skin and soft tissue defects. Biosynthetic dressings, artificial skin, and bioengineered skin have proved useful in the setting of persistent, nonhealing ulcerations.<sup>132</sup> Novel therapies, including low-intensity helium-neon laser, have benefited some patients with recalcitrant chronic skin ulcers after RT, perhaps by enhancing metabolic pathways, cell proliferation, and motility of fibroblasts and keratinocytes, as well as improving skin circulation and inducing angiogenesis.<sup>13,133,134</sup>

Topical or oral antibacterial agents should be considered in the treatment of wounds that are at high risk or are already infected. Silver-based dressings are antibacterial and have proven to be effective for this purpose. Patients with anal canal or some types of gynecologic tumors undergoing RT and chemotherapy experience close to 100% incidence of dermatitis, often grade 3 or 4. This not only interferes with quality of life but also mandates a hiatus in RT, potentially with a negative impact on patient outcome. In patients in whom the tumor was not close to the skin, silver leaf nylon dressings, removed during

treatments, have been found to be helpful, probably secondary to their antibacterial effects.<sup>135</sup> Cadexemer iodine-based dressings promote autolytic débridement, absorb exudates, control drainage, and are nontoxic to fibroblasts in vitro.<sup>129</sup> Multidextrin powder, a macrophage activator, reduces bioburden by increasing local osmolality and is helpful in odor control.<sup>129</sup>

### Targeted Biologic Therapy

Targeted therapy and biologic preparations may be useful in some types of radiation dermatitis. A series of 24 patients with acute radiation-induced vulvar dermatitis found topical granulocyte-macrophage colony-stimulating factor (GM-CSF) plus topical steroid more useful than steroid alone in reducing the severity and duration of the problem.<sup>136</sup> The presumed mechanism of action is the promotion of chemotaxis of monocytes into tissues and the maturation of monocytes into macrophages.

PDGFs are chemotactic for neutrophils, monocytes, macrophages, and fibroblasts. Theoretically, they also stimulate the synthesis of extracellular matrix components, collagen, and additional growth factors. These have shown anecdotal success in producing enough granulation tissue in a chronic radiation wound on the neck to support a skin graft.<sup>137</sup> Chronic radiation ulcers after electron beam therapy were treated successfully with PDGF gel and hydrophilic copolymer membrane.<sup>138</sup> If there is active tumor, there may be some theoretical risk in the use of growth factors, and some topical dressings may partially absorb or inactivate this expensive product.

### Treatment of Chronic Fibrosis

Chronic fibrosis is arguably one of the most difficult cutaneous complications to treat. Long thought to be irreversible, supportive measures are often necessary to avoid skin breakdown and infection. Multidisciplinary teams, including specialists in wound care, physical therapy, and pain management, often work together to address important cosmetic and quality of life issues. Physical therapy, deep massage, and active and passive range of motion exercises are important techniques used to maintain mobility and to minimize contractures. Chronic nonhealing ulcers and suspicious lesions may need pathologic examination to exclude the possibility of secondary skin malignancy. Unfortunately, these sites may heal poorly, so biopsies should not be performed early in the evaluation period.

Alternative approaches include the use of pentoxifylline (PTX), a methylxanthine derivative in common use as an inhibitor of platelet aggregation. This drug may also increase phagocytic activity of polymorphonuclear leukocytes and monocytes, as well as antagonizing tumor

necrosis factor (TNF)- $\alpha$  and - $\beta$ . By decreasing the cytokines GM-CSF and interferon- $\gamma$ , as well as modulating ICAM-1 expression,<sup>139,140</sup> PTX had a significant antifibrotic effect in vivo, reversing gamma ray-induced fibrosis in pigs.<sup>47</sup> The combination of PTX and the antioxidant vitamin E ( $\alpha$ -tocopheryl acetate) may further down-regulate TGF- $\beta$  expression by myofibroblasts and actually reverse the abnormal fibroblast phenotype that perpetuates fibrosis.<sup>44,47,141,142</sup> Other effects include blocking the induction of collagen by TNF- $\alpha$  and GAG synthesis in normal fibroblasts,<sup>143</sup> as well as lowering the levels of type I and III procollagen messenger RNA and of nuclear factor 1, a procollagen gene-activating transcription factor of human dermal fibroblasts.<sup>144</sup>

Studies examining the effect of prophylactic administration of PTX are ongoing. It may reduce late soft tissue pathology but does not affect acute radiation reactions in animals. In patients, late skin changes, fibrosis, and soft tissue necrosis were less severe in the PTX group than controls, possibly by a protective effect against vascular pathology. It also accelerated healing of soft tissue necrosis and reversed some late radiation injuries.<sup>140,145</sup> There were no positive effects on acute skin reactions or pain in some studies,<sup>146</sup> whereas others showed a decrease in pain.<sup>140,145</sup> When PTX was used with vitamin E, arm lymphedema was not prevented following axillary surgery and lymphatic radiotherapy.<sup>147</sup> However, both in patients and in the pig model, some antifibrotic action of this combination was found in established disease.<sup>47,141</sup> In a pig model, there was less subcutaneous fibrotic scar tissue and a decreased immunostaining for TGF- $\beta_1$  in the residual fibrotic tissue.<sup>43,47,147</sup> Lipid peroxidation and certain lipid peroxidation products induce genetic overexpression of fibrogenic cytokines, the key molecules in the pathomechanisms of fibrosis, as well as increased transcription and synthesis of collagen.<sup>43,148</sup> Both of these events can be down-regulated, at least in experimental models, by the use of antioxidants. The effect of oxidative stress on cytokine gene expression appears to be an important mechanism by which it promotes connective tissue deposition.<sup>149,150</sup>

Other modalities to treat chronic radiation fibrosis in animals have included intramuscular injections of liposomal CU/ZN superoxide dismutase (SOD) two times a week for 3 weeks. Liposomal SOD may down-regulate TGF- $\beta$  secretions by myofibroblasts, functioning as an antioxidant and anti-inflammatory agent.<sup>43</sup> Early animal studies show that it may have an immediate radioprotective effect if given prior to radiation, possibly changing genetic programming of cell differentiation and proliferation.<sup>142</sup> It also reverses the radiation-induced fibrotic process in

experimental animals and permits the regeneration of normal tissue in a zone of well-established postirradiation fibrosis.<sup>142</sup>

Another proinflammatory cytokine, interferon- $\gamma$ , may inhibit collagen production in dermal fibroblasts. When used subcutaneously three times a week for 6 months and then once per week for 6 months on five patients with chronic-stage cutaneous radiation syndrome, low-dose interferon- $\gamma$  was found to be useful for cutaneous fibrosis, as well as the chronic infection in fibrosed skin.<sup>151</sup>

In chronic radiation dermatitis, hyperbaric oxygen can result in reepithelialization of small areas and reduce pain, edema and erythema, or lymphedema,<sup>32</sup> but there is no effect on fibrosis or telangiectasia.<sup>152</sup> Pulsed dye laser treatment has been beneficial in clearing telangiectasia after radiotherapy.<sup>153</sup>

### Secondary Cutaneous Malignancy

Ionizing radiation may be used to treat established cutaneous malignancies, but it also increases the frequency of skin cancer and its precursor lesions. The strongest case is made for the increased incidence of BCC, and all available studies show that skin cancer risk is greater from radiation exposure at young ages.<sup>154,155</sup> These tumors arise not only in areas with typical chronic radiation changes but also on normal-appearing irradiated scalp in patients who were treated for tinea capitis.<sup>156</sup> These BCCs may present with aggressive or unusual variants, including keloidal, scarring, or aggressive varieties. Genetic instability may occur in irradiated cells many generations after treatment, possibly accounting for these tumors,<sup>157</sup> and mutations of tumor suppressor genes may play a role in some cases.<sup>156,158</sup>

The growth of other tumors, including radiation keratoses, squamous cell carcinoma, fibrosarcoma, dermatosarcoma, angiosarcoma, and melanoma, has not been as well documented. The observation that fewer skin cancers develop among irradiated African Americans compared with Caucasians despite a comparable dose of ionizing radiation implies that skin susceptibility to ultraviolet exposure may modify the risk from ionizing radiation (Figure 21). Available evidence indicates that the excess risk of skin cancer lasts for 45 years or more following treatment.<sup>154</sup> Most of the studies reporting an increase in NMSC have not distinguished between patients who received radiotherapy versus chemotherapy. Some, but not all, follow-up studies of cancer patients have reported excesses of malignant melanoma as second malignant neoplasms. It is not clear from the studies how much, if any, of the excess melanoma risk is attributable to radiotherapy.<sup>154,155</sup> However, the fact remains that the most common malignancy in the survivors of the bombing of Hiroshima and Nagasaki in

**FIGURE 21** Nodular squamous cell carcinoma in the setting of radiation fibrosis and actinic damage.

1945 was NMSC. Squamous cell carcinoma in radiation fields or scars is often ill defined and exhibits aggressive behavior and metastases. Because of this, surgical excision is the preferred modality of treatment. Microscopically monitored surgery with margin control (Mohs' surgery) has a high cure rate, is well tolerated, and is usually performed under local anesthesia in an office setting.

Angiosarcomas are a heterogeneous group of tumors with differing pathogenesis. They may be classified as primary in breast parenchyma, often in younger patients. When found following radical mastectomy with axillary node dissection, Stewart-Treves syndrome, they appear to be associated with chronic edema rather than radiation alone. Angiosarcomas developing in radiation sites should be considered in the clinical setting of late skin thickening, induration, edema, or dyspigmentation.<sup>159</sup>

Because of their premalignant potential, radiation-induced keratoses are often treated. Although there are no studies specifically addressing therapy in irradiated skin, in practice, they are treated like actinically induced premalignancies. Cryotherapy is widely used for localized lesions, but it is of limited usefulness if it does not address large numbers of lesions in the radiation port. Diffuse ill-defined keratoses are candidates for destruction with physical measures such as chemical peels, dermabrasion, or laser. Topical 5-fluorouracil, diclofenac, photodynamic therapy, and imiquimod have also proven beneficial.

Fluorouracil cream is an antineoplastic, antimetabolite drug that interferes with DNA and RNA syntheses, preventing the proliferation

of damaged cells.<sup>160</sup> Newer topical modalities, such as diclofenac, are cyclooxygenase 2 (COX-2) inhibitors, inhibiting the enzymes involved in arachidonic acid metabolism. Arachidonic acid metabolites have been shown to play a pivotal role in promoting epithelial tumor growth by stimulating angiogenesis, inhibiting apoptosis, and increasing invasiveness of tumor cells.<sup>161-164</sup> This suggests a possible role for COX-2 inhibitors administered at therapeutically achievable doses in the prevention of radiation-induced malignancy.<sup>165</sup> Diclofenac, a topical COX-2 inhibitor, is typically applied twice a day for 90 days.

Another modality used in the treatment of actinic keratoses and in situ squamous cell carcinoma is topical 5-aminolevulinic acid followed by photodynamic therapy.<sup>166</sup> This uses a photosensitizing compound applied to specific lesions and photoactivated by red-light irradiation. Case reports have found this useful for chronic x-ray dermatitis and particularly helpful in pain relief.<sup>167</sup>

A promising therapeutic option for both keratoses and superficial BCC is topical imiquimod. This immune response modifier affects both the innate and acquired immune responses<sup>168,169</sup> by binding to Toll-like receptor 7 (TLR-7).<sup>170</sup> Subsequent activation of the messenger RNA expression of cytokines, including interferon- $\alpha$ , TNF- $\alpha$ , and interleukin-12, promotes a T helper 1 cell-mediated immune response and reduced Bcl-2 expression, which induces FasR-mediated apoptosis in BCC.<sup>168,171</sup> Currently, imiquimod is approved by the US Food and Drug Administration to treat multiple actinic keratoses<sup>172</sup> and genital warts.

## Future Directions

Prevention and treatment of radiation dermatitis are optimally a multidisciplinary mission. Advances in the delivery of radiation include conformal RT, which will target the tumor and minimize exposure to normal tissue. Intensity-modulated RT further shapes the intensity using collimators that focus multiple beams on the target. This results in a smaller high-dose target, but at the cost of increasing the volume of tissue receiving low doses of radiation. CT imaging combined with the LINAC, as well as dedicated operating room suites equipped with a LINAC, provide precision and convenience for the patients and oncologists. The combination of positron emission tomography and CT further defines treatment targets. Newer modalities of therapy, including the use of protons, potentially will avoid the skin and more precisely target the tumor.

Advancements in immunology, including a better understanding of cytokines, inflammation, and their role in producing skin changes, have prompted ongoing investigation of compounds,

which may prove to be "cytoprotective." Identification of patients at risk, including those with genetic or autoimmune disorders, and modification of their treatment can help avoid severe complications. Finally, advances in basic wound care management have been invaluable in the treatment of acute and chronic radiation dermatitis. In the future, prospective studies of treatment of radiation dermatitis will provide additional information and guidelines in the treatment of this difficult problem.

# Alopecia

Asra Ali, MD  
Sanjay Mehta, MD

Alopecia, or hair loss, is a frequent occurrence in cancer patients. It is typically reported by the patient when approximately 25 to 40% of the person's hair is lost.<sup>1</sup> The precipitating process is often multifactorial and may result from direct or indirect actions on the hair follicles. Hair loss can often occur as a consequence of anticancer therapy, mainly from chemotherapy and radiation therapy.<sup>2,3</sup> A well-recognized but rare presentation of scalp metastasis is alopecia neoplastica,<sup>4</sup> usually owing to metastasis from breast cancer or other primary cancers. Endocrinopathies caused by a direct result of the primary cancer or cancer treatment may be the sole reason for hair loss or may exacerbate an already existing problem.<sup>5</sup> An iatrogenic immunocompromised state predisposes cancer patients to numerous infectious agents that may affect hair growth.<sup>6</sup> Lastly, these patients may suffer from dermatologic conditions that cause alopecia coincidentally with the presentation of their primary malignancy or treatment of their malignancy. Hair loss should be addressed by the physician since it can be a psychologically devastating aspect of cancer therapy. Preparation for such an event and proper interventions after its occurrence will help the patient cope better with this condition.<sup>7</sup>

## Hair Functions

Hair has several functions other than its aesthetic importance. It forms a barrier between the skin and environment, therefore helping protect the epidermis from minor abrasions and from ultraviolet light. Hair fiber may also increase the surface area for faster evaporation of sweat from neighboring apocrine glands. Some hair follicles have a highly developed nerve network around them and provide sensory, tactile information about the environment. A key role of hair is to provide protection against heat loss. Although its importance for human survival has diminished, it is still a significant biological entity.<sup>8</sup>

## Hair Development

During hair development, epidermal invaginations occur forming columns in the dermis. The

central portion of the columns (bulb) along with stem cells, found in the bulge area of the columns, induce hair follicle formation by the overlying epithelium.<sup>9</sup>

## Normal Hair Growth

Understanding normal hair growth often aids the physician in correctly interpreting the cause of hair loss. Each day, the scalp hair grows approximately 0.35 mm (6 inches per year); slower growth occurs in elderly people and in patients with a chronic illness. The scalp sheds approximately 100 hairs per day.

Scalp hair grows in an asynchronous pattern. Every hair follicle continually goes through three phases: anagen (growth), catagen (involution, or a brief transition between growth and resting), and telogen (resting) (Figure 2). Since each follicle passes independently through the three stages of growth, the normal process of hair loss usually is unnoticeable. Approximately 80% of hair follicles are in the active growing, or anagen, phase. Follicles remain in anagen for an average of 3 years (range 2–6 years). The hair on the arms, legs, eyelashes, and eyebrows has a very short active growth phase of about 30 to 45 days, explaining why they are so much shorter than scalp hair. The transitional, or catagen, phase, usually affects 2 to 3% of hair follicles from days to a few weeks. Fourteen percent of hair follicles in the resting, or telogen, phase will be shed in a 3 to 5 months period this accounts for normal daily hair shedding. During telogen, hair growth stops and the outer root sheath shrinks and attaches to the root of the hair. This causes the formation of what is known as a club hair. Pulling out a hair in this phase will reveal a solid, hard, dry, white material at the root.

Hair continually cycles through the three phases. Alteration of hair growth cycling can manifest clinically as increased shedding of scalp hair.<sup>10</sup>

## Hair Pigment

Hair pigment is formed by melanocytes in hair follicles located in the hair bulb, found at the

bottom of hair follicles. Melanocytes are located in other regions of the hair follicle; however, it is thought that these melanocytes do not significantly contribute to coloring the hair fiber.

Melanocytes produce melanin pigment proteins in their cell cytoplasm. The pigment is accumulated in membrane-bound vesicles in the cell called “melanosomes.” The melanocyte cells release their melanosomes to the keratinocytes through dendritic processes. Eumelanin is the pigment of brown or black hair. Pheomelanin is the pigment of blond or red hair. The appearance of white hairs seems to be caused by an interruption of the transmission of pigments from the melanocytes to the keratinocytes, or loss of melanocytes may also be the cause of graying of hair.<sup>8</sup>

## Hair Shape

The amount of natural curl a hair has is determined by its cross-sectional shape. The uneven distribution of disulphide bonds is responsible to a variable degree for curling. Hair that is most similar to a circle is straight, and hair that is flattened and elliptical is curly or kinky. In general, people of African origin have rather flat hair viewed in cross-section compared with Caucasian people, whereas people of Asian origin have the most round and even-sized hairs.

The cross-sectional shape also determines the amount of shine the hair has. Straighter hair is shinier because sebum from the sebaceous gland can travel down the hair more easily. The kinkier the hair, the more difficulty sebum has traveling down the hair and therefore the more dry or dull the hair looks.

## Evaluation of Hair Loss

The diagnosis of hair disorders is complex, requiring a thorough evaluation of the clinical presentation, history, physical examination, and diagnostic tests.

A careful history often suggests the underlying cause of alopecia. The history should include when the hair loss started; whether the loss was a gradual hair thinning (ie, gradually more scalp

appears) or a hair shedding (ie, large quantities of hair falling out); and if any physical, mental, or emotional stressors occurred within the previous 3 to 6 months. Other important components of the history include: The patient's diet, medications, present and past medical conditions (personal or family history of autoimmune conditions, thyroid disease, anemia), associated nail changes, hair care habits (shampooing, bleaching, perming), and family history of alopecia.

The pattern of hair loss can help establish a possible cause for the hair loss. (Table 1)

The physical examination has three parts. First, the scalp condition is noted. Evidence of erythema, scaling, inflammation, or scarring is noted. Follicular units, on the scalp, are present in nonscarring alopecias but absent in scarring types. Second, the density and distribution of hair are assessed. Third, the hair shaft is examined for caliber, length, shape, and fragility. The nails should also be examined.

Assessment of the amount of alopecia can be done using the World Health Organization criteria for alopecia: grade 0 = no hair loss; grade 1 = minimal hair loss; grade 2 = moderate hair loss; grade 3 = reversible complete hair loss; and grade 4 = irreversible complete hair loss.<sup>11</sup>

Numerous procedures can aid in diagnosing the etiology of the alopecia. One such procedure is the hair-pull test, which gives a rough estimate of how much hair is being lost. It is done by grasping a small portion of hair and gently applying traction while sliding the fingers along the hair shafts. Usually, one to two hairs are removed with this technique. The hairs are then examined under a microscope. A negative test (six or fewer hairs obtained) indicates normal shedding, whereas a positive test (more than six hairs obtained) indicates a process of active hair shedding. Patients should not shampoo their hair 24 hours before the test is performed.

In the hair-pluck test, approximately 50 hairs are grasped with a hemostat and removed with one motion. This test produces a trichogram to assess the telogen to anagen ratio but is rarely needed for clinical diagnosis of hair loss.

Light microscopy examination of hair fibers involves extracting hairs by a slow pull and mounting them between two glass slides. The roots are examined to determine the stage of the hair cycle and the presence of dystrophy. The free ends of the hair are checked to see if they are

tapered, cut, fractured, or weathered. Scrapings of scalp scales for bacterial and fungal culture should be performed if indicated. A 20% potassium hydroxide examination under light microscopy will reveal fungal spores and hyphae if present.

Another diagnostic test for alopecia is a scalp biopsy; a 4 mm punch is recommended for patients with a scarring alopecia or for patients with a nonscarring alopecia of unknown origin. Some authorities prefer examination with transverse horizontal sectioning to allow a greater number of follicles to be examined. The biopsy should be taken from an active inflammatory area with hair follicles present.

Laboratory workup, including a complete blood count (CBC), ferritin measurement, and thyroid screening, may also be helpful. Ferritin levels should be higher than 40 µg/L for normal hair growth.<sup>10</sup>

### Causes of Alopecia in Cancer Patients

Cancer patients are exposed to many stressors during their treatment regimens. Various etiologies, singly or in combination, may result in alopecia in these patients. The main mechanisms are discussed below. Disorders of alopecia can be divided into those in which the hair follicle is normal but the cycling of hair growth is abnormal (eg, telogen effluvium) and those in which the hair follicle is damaged and may result in a scarring alopecia.

### Anagen Effluvium

Anagen effluvium occurs after an insult to the hair follicle impairs its mitotic or metabolic activity. This is a generalized diffuse hair loss from follicles in the anagen growth phase with quite rapid development 1 to 4 weeks after the initial trigger.

Hair follicle growth is affected by many chemotherapeutic agents. Anticancer drugs such as antimetabolites, alkylating agents, and mitotic inhibitors impair metabolic and mitotic processes in actively growing hair follicles, causing an anagen effluvium.<sup>12-15</sup> Table 2 lists the chemotherapeutic agents commonly associated with alopecia. Drugs that are given orally or on a weekly schedule cause significantly less hair loss, even when the total dose of the drug given is greater.<sup>2</sup>

**TABLE 2** Anagen Effluvium Caused by Chemotherapies and Other Medications

Most common agents
Nitrosoureas
Cyclophosphamide
Bleomycin
Dactinomycin
Daunorubicin
Fluorouracil
Methotrexate
Less common agents
Levodopa
Bismuth
Cyclosporine

Adapted from Hesketh PJ et al.<sup>17</sup>

The use of multiple agents concurrently increases the risk of alopecia. The inhibition or arrest of cell division in the hair matrix leads to a thin, weakened hair shaft that is susceptible to fracture with minimal trauma; it can also result in complete failure of hair formation. The hair bulb itself may be damaged, and the hairs may separate at the bulb and fall out. Only actively growing anagen follicles are subject to these processes. Since hair bulb cells replicate every 12 to 24 hours, they are highly susceptible to the cytotoxic effects of chemotherapy.<sup>15</sup>

Hair loss usually begins 2 to 4 weeks after the initial chemotherapy dose. The hair loss is clinically most apparent after 1 to 2 months. Pruritus and/or scalp tenderness may be noticeable at the time of shedding. Hair may begin to regrow in about 3 to 6 months (the same time period as telogen).<sup>12,16</sup> The rate of growth can be reduced to 0.004 to 0.1 mm per day as opposed to the normal rate of 0.35 mm per day.<sup>17</sup> When directed at hair-bearing areas such as the scalp, high doses of radiation therapy also cause an anagen arrest. Both chemotherapy and radiation therapy are the main noninflammatory causes of anagen effluvia.<sup>16</sup>

The following list includes other causes of anagen effluvium that may occur concurrently during a patient's chemotherapy treatment regimen. Genetic hereditary diseases, such as Pollitt's syndrome and Marie Unna-type hypotrichosis, can cause anagen effluvium. Defective hormone production can result from hypopituitarism (hypopituitary dwarfism, Simmonds' disease, and Sheehan's syndrome), thyroid gland defects (hypothyroidism, hyperthyroidism), Cushing's syndrome, and, occasionally, juvenile diabetes. Nutritional deficiencies are seen when there is decreased intake of copper, iron, zinc, biotin, essential fatty acids, or vitamin C.

On examination, the hair is thin and tapers to a point (pencil point ends).<sup>16</sup> The slightest external trauma, such as gentle brushing, can cause the distal portion of the shaft to break. Only tapered shafts are shed, not all anagen hairs. Early in the course of an anagen arrest, a gentle hair pull

**TABLE 1** Correlation between Common Complaints and Cause of Hair Loss

Complaint	Hair Disorder
Gradual thinning without shedding	Androgenetic alopecia
Diffuse shedding	Telogen effluvium
Hair breakage or hair that does not grow	Structural hair shaft abnormality; tinea capitis
Shedding with circular areas of hair loss	Alopecia areata

test will extract numerous dystrophic hair shafts. As hairs are rapidly shed over a few weeks, fewer and fewer anagen shafts are left in the scalp. Therefore, after most of the hairs have fallen, the remaining hairs should show telogen hairs on a hair-pull test. A trichogram done late in the course of anagen arrest would therefore reveal almost 100% telogen hairs.<sup>16</sup>

On microscopic examination, anagen hairs have long, indented roots covered with intact inner and outer root sheaths and are fully pigmented.

A 4 mm punch biopsy sample of the scalp usually contains 25 to 50 follicles for inspection. Less than 15% of the follicles are normally in the telogen phase. An equal anagen to telogen ratio in a patient with hair loss is characteristic of anagen effluvium. The follicles should show no signs of inflammation, no dystrophic changes of the inner sheath, or traction. These features permit the distinction of anagen effluvium from alopecia areata, androgenetic alopecia, and traction alopecia respectively.<sup>16</sup>

An anagen effluvium is reversible if the underlying disease or treatment is stopped, but occasionally, the process causes irreparable injury. If doses of chemotherapy or radiation therapy are sufficiently high, the stem cells of the follicle may be injured, resulting in a cicatricial alopecia.

## Telogen Effluvium

Telogen effluvium is a non-inflammatory diffuse hair loss caused by any condition or situation that shifts the normal distribution of follicles from an anagen to a telogen-predominant distribution.<sup>16</sup> During the telogen phase of hair cycling, the production of hair shafts is temporarily halted. The interval between the inciting event in telogen effluvium and the onset of shedding corresponds to the length of the telogen phase, between 1 and 6 months (the average is 3 months). Acute telogen effluvium is defined as hair shedding lasting less than 6 months, whereas chronic telogen effluvium lasts longer than 6 months. The onset is often insidious, and it can be difficult to identify an inciting event.<sup>18</sup> In the cancer patient, there may be more than one precipitating event, including chemotherapy, radiation therapy, fever, chronic malnutrition, endocrinopathies (hypothyroidism or hyperthyroidism), or surgery. Chronic illness, such as malignancy, particularly lymphoproliferative malignancy; and any chronic debilitating illness, such as systemic lupus erythematosus, end-stage renal disease, or liver disease, can also lead to telogen effluvium.<sup>16</sup> Except for the disruption of hair cycling, hair follicles in telogen effluvium are otherwise normal. Patients with this disorder usually note an increased number of loose hairs on their hairbrush or shower floor. Normal daily loss is

around 100 hairs, whereas in telogen effluvium, the range is from 100 to 300 hairs. If hair loss is at the lower end of the range, it may not be apparent. Axillary and pubic areas often are involved, along with hair of the scalp.

Examination of the scalp may reveal a higher than expected number of short new hairs growing. Because hair grows at a nearly constant rate of approximately 1 cm per month, the duration of the hair shedding can be estimated by measuring the length of the short hairs.

In active telogen effluvium, the gentle hair-pull test will yield at least four hairs with each pull. If the patient's active shedding has ceased, the hair pull will be normal. Telogen hairs are identified by a white bulb, when pulled out, and the lack of a gelatinous hair sheath.

The hair-pluck test, forced extraction of 10 to 20 hairs, usually shows that up to 50% of hairs are in the telogen phase (in contrast to the normal 10 to 15%), although these results can vary.<sup>16</sup> In the typical case of telogen effluvium, the telogen count seldom exceeds 50%. Figures exceeding 80% of telogen hairs are not consistent with a telogen effluvium, and the physician should look for other causes of alopecia.<sup>16</sup>

Laboratory tests that may identify a systemic reason for the hair loss include a thyroid-stimulating hormone test and an antinuclear antibody test if the history suggests the presence of a connective tissue disease. Since iron deficiency is common in premenopausal women, evaluation of CBC, serum iron, iron saturation, and ferritin may be warranted.

Microscopic examination of telogen hairs shows short, club-shaped roots. The hairs lack root sheaths and show depigmentation of the proximal part of the shaft.

Histologic findings in telogen effluvium are subtle and are most easily seen on transverse sections of a punch biopsy. The number and density of hair follicles are normal, but an increased percentage of the hair follicles are in the telogen or catagen phase. If more than 25% of the follicles are in the telogen phase, the diagnosis is confirmed.

Generally, recovery is spontaneous and occurs within 6 months. Any reversible cause of hair shedding, such as poor diet, iron deficiency, hypothyroidism, or medications, should be corrected. No specific treatment for hair loss is required.<sup>16</sup>

## Apoptosis of Hair Follicles

Chemotherapeutic drugs may not only cause telogen or anagen effluvium, they may also stimulate premature apoptosis-driven hair follicle regression. Hair loss from apoptosis induced by chemotherapy is mediated by the tp53 and cyclin-dependent kinase 2 molecular signaling pathways. A study by Sharov and colleagues showed that

tp53 is essential for triggering apoptotic cell death in the hair follicle induced by cyclophosphamide (CYP).<sup>19</sup> This was shown through genetic loss of tp53, resulting in complete resistance of murine hair follicles to chemotherapy-induced hair loss.

The tp53 apoptotic pathway uses transcription-dependent and -independent mechanisms<sup>20-23</sup> that are mediated by Fas/APO-1 (CD95), a cell surface receptor and a direct tp53 target. Fas is a gene product that induces apoptosis in multiple cell types.<sup>22</sup> The Fas gene becomes activated when tp53 interacts with the Fas gene's tp53 consensus element in its promoter.<sup>24,25</sup> The Fas receptor requires interaction with the intracellular adaptor molecule Fas-associated death domain, which activates procaspase 8 and recruits it into the death-inducing signaling complex.<sup>23,26</sup> Following proteolytic activation of procaspase 8, caspase 3 is activated along the common final pathway of apoptosis.<sup>26</sup>

CYP up-regulates "death" receptors (Fas/APO-1, p55 kDa tumor necrosis factor receptor) and the mitochondrial proapoptotic protein Bax in the hair follicle. CYP-treated hair follicles display a strong up-regulation of tp53 in the proximal outer and inner root sheaths and in the hair matrix.<sup>19</sup>

The above mechanism raises the possibility of exploring pharmacologic blockade of Fas signaling as part of complex local treatment for inhibiting keratinocyte apoptosis and reducing hair loss induced by chemotherapy of Fas-negative tumors.<sup>19</sup> Another mechanism to inhibit keratinocyte inhibition was studied by Komarove and colleagues in which temporary suppression of tp53 has been suggested as a therapeutic strategy to prevent damage of normal tissues during treatment of tumors.<sup>23</sup> Thus, inhibitors of tp53 may be useful for reducing the side effects of cancer therapy associated with tp53 induction.

## Ionizing Radiation

X-rays and gamma rays affect all follicles in an anagen stage of active growth. Anagen effluvium results from the simultaneous inhibition of cell division in hair follicles, leading to a sudden stop in hair fiber production. As noted above, the rapidity with which hair cells grow that makes them sensitive to chemotherapeutic agents also applies to radiation therapy.

The end-organ damage, whether it is the kidney, bowel, or hair, is dependent on both the intrinsic radiosensitivity and the number of target cells comprise an functional subunit (FSU). To illustrate, epilation requires a lower dose of ionizing radiation than desquamation. This is not due to greater radiosensitivity of the hair follicle compared with the basal epithelium but rather to the fact that there are far fewer cells in the FSU that comprises a hair than in a population keratinocytes that can regenerate.<sup>3</sup> Similarly, the depigmentation of hair occurs at lower radiation

doses than epidermal depigmentation owing to the relative paucity of melanocytes found in hair follicles compared with the epidermis.<sup>28</sup>

### Alopecia Neoplastica

Neoplasia can directly cause permanent hair loss. *Alopecia neoplastica* is the term used for alopecia caused by the direct involvement of the hair follicle and surrounding skin by the neoplastic process. It presents as one or more areas of scarring alopecia and has been reported with both primary and metastatic tumors. The mechanism of alopecia neoplastica is not certain and may result from physical compression from the tumor, reactive fibrosis, release of cytokines, or a combination of factors. The scalp is a site of predilection, possibly because of its abundant blood supply.

The primary tumors associated with alopecia neoplastica are squamous and basal cell carcinomas, lymphoma, melanoma, and angiosarcoma.<sup>29,30</sup> Some other primary skin cancers can also cause alopecia.

Desmoplastic melanoma can cause a scarring alopecia with prominent desmoplasia and infiltration of the hair follicles by tumor cells.<sup>4</sup>

Two variants of mycosis fungoides (cutaneous T-cell lymphoma) can result in permanent alopecia. Alopecia mucinosa (follicular mucinosis) presents as eruptions of follicular papules and/or indurated plaques. The presenting sign of alopecia mucinosa is hair loss. Circulating immune complexes and cell-mediated immunity is associated with the condition.<sup>31</sup> Skin eruptions present as pruritic, pink to yellow-white, follicular papules and plaques. Lesions may be isolated or multiple and are most commonly found on the scalp and face. Usually, the alopecia is reversible unless follicular destruction has occurred owing to excess mucin in the outer root sheath and sebaceous glands. In patients with permanent alopecia, the whole follicle degenerates. On histology, T-cell infiltration and mucinous degeneration of follicular epithelium are seen. Treatments include topical, intralesional, and systemic corticosteroids. In addition, topical and systemic psoralen plus ultraviolet A light therapy, topical nitrogen mustard, and radiation therapy have demonstrated some success. The course of the disease is variable, and there is a likelihood of spontaneous resolution.

Follicular mycosis fungoides is another variant of mycosis fungoides in which the neoplastic cells and reactive inflammation target follicular epithelium.<sup>32</sup> It presents with follicular hyperkeratosis, comedo-like lesions, acquired epidermal cysts, and patchy alopecia. Findings of histopathologic and immunohistochemical studies showed atypical CD4<sup>+</sup> T lymphocytes infiltrating the follicles without follicular mucinosis.

Visceral carcinomas may directly invade underlying skin or metastasize to skin through lymphatics or the bloodstream. Brownstein and Helwig reported that the scalp was the site in 4% of all skin metastases.<sup>33</sup> They found that the source of the primary tumor was usually the lung, colon, stomach, or kidney in men, and metastasis appeared early in the course of the disease. Tumors of the breast and lung were commonest in women, in whom metastasis occurred late in the disease.<sup>34</sup> Other cancers include those of the rectum, ovary, and prostate. Rarely, a scalp metastasis arrives from a pancreas, liver, uterus, or bone primary tumor.

On examination, single or multiple, firm, nontender nodules that rapidly enlarge are the commonest presentation of scalp metastasis. Alopecia neoplastica usually presents as single or multiple areas of cicatricial alopecia. Scleroderma-like plaques may occur, and multiple nodules may simulate turban tumors. Recently, alopecia neoplastica without alopecia has been described. In this case, presented by Mallon and Dawber, there was a unique presentation of scalp metastasis in a patient with breast carcinoma in whom hair loss was clinically inconspicuous.<sup>35</sup>

Lobular breast carcinoma, which accounts for 10% of invasive breast carcinoma, usually elicits a reactive fibrosis that leads to cicatricial alopecia. It is difficult to explain the complete disappearance of the pilosebaceous units, but loss of hair follicles may be the result of fibrosis. Cohen and colleagues considered this to be the major mechanism.<sup>34</sup>

Histopathologic examination of the scalp demonstrates metastatic carcinoma cells in a dense collagenous stroma, which is seen in the deep dermis and the subcutaneous tissue, with loss of pilosebaceous units.

A scarring alopecia that is not readily explained by trauma, infection, or dermatosis should lead to the consideration of an underlying neoplastic process.

### Other Common Causes of Alopecia Nonchemotherapy Medication-Induced Alopecia

Some common medications can also cause either a telogen or anagen effluvium. Androgenic drugs that cause a telogen effluvium include systemic steroids and oral contraceptives.<sup>10</sup> Iatrogenic Cushing's syndrome caused by systemic steroids is also associated with alopecia. The alopecia occurs only after a few months of high-dose treatment with systemic steroids. Alopecia caused by excessive vitamin A is rare but is more commonly observed with vitamin A analogue medications, such as acetretin or isotretinoin. The effects are reversible once treatment stops. Anticoagulation

from warfarin and heparin is responsible for causing alopecia when treatment is long term (eg, 4–6 months) and occurs in more than 10% of patients. Antithyroid drugs cause a reversible alopecia. Several antihypertensive agents are known to cause hair loss, such as  $\beta$ -blockers and captopril. Telogen effluvium occurs in 20 to 30% of patients treated with interferon.<sup>10</sup> There is no relationship between dosage and onset or severity of the hair loss. Agents that block cholesterol synthesis can disrupt keratinization. Cholesterol is a component of cellular lipids, and its synthesis and metabolism are essential for the production of normal epidermal structures. Metal-based treatment, such as gold salt, lithium, and bismuth, may also lead to hair loss. Antiepilepsy medications, such as carbamazepine and sodium valproate-based medications, may also induce alopecia. Colchicine, used to treat gout, can harm the root of the hair after high doses, resulting in an anagen effluvium. Vasopressin can also cause a reversible anagen effluvium.

### Androgenetic Alopecia

Androgenetic alopecia is referred to as male pattern hair loss (MPHL) in men and female pattern hair loss (FPHL) in women and is due to the progressive miniaturization of scalp hair. It affects approximately 50% of men and 20 to 53% of women by the age of 50.<sup>36</sup> Dihydrotestosterone (DHT) is a key androgen in the pathogenesis of MPHL and FPHL. The androgen testosterone is converted to DHT by the enzyme 5 $\alpha$ -reductase. DHT causes a reduction in protein synthesis by inhibiting adenylyl cyclase in the hair bulb; the result is shorter and finer hair, referred to as miniaturized hair. As the hair growth cycle proceeds, hairs continue to become smaller and finer.<sup>36</sup>

The best treatment option for androgenetic alopecia is minoxidil 5% solution. If it is not effective after 1 year, then antiandrogens can be tried. Hair transplantation can be offered if the occipital donor area is sufficient. Finasteride, a type 2–selective 5 $\alpha$ -reductase inhibitor, is also helpful.

### Trichotillomania

Trichotillomania is a self-induced primary psychiatric disorder.<sup>10</sup> It results from repetitive hair manipulations by the patient's own hand. On examination, the alopecia patches have unusual shapes and sizes and show broken hairs. A scalp biopsy can be helpful if the diagnosis is difficult clinically. Trichotillomania can be a chronic problem. Treatments include: habit reversal training and selective serotonin reuptake inhibitors (SSRIs).

### Alopecia Areata

Alopecia areata is an autoimmune disease that targets actively growing (anagen) hair follicles in

humans.<sup>10</sup> It is a nonscarring type of hair loss that can affect any hair-bearing area. The process appears to be T cell mediated, but antibodies directed to hair follicle structures also have been found. On examination, there are round to oval, smooth, slightly erythematous, peach colored, or normal-colored patches of nonscarring alopecia. The presence of “exclamation point” hairs, hairs tapered near proximal end, is pathognomonic but is not always found. A positive pull test at the periphery of a plaque usually indicates that the disease is active, and further hair loss can be expected. Nail involvement is found in 6.8 to 49.4% of patients, with the most common finding being pitting.<sup>10</sup> Histologic evaluation shows a characteristic peribulbar lymphocytic infiltrate, which is described as appearing similar to a swarm of bees.

Treatment is not always necessary because the condition is benign, and spontaneous remissions are common. Since alopecia areata is an inflammatory condition, different immunomodulators have been used to treat this condition. These include topical, oral, and intralesional steroids. Topical potent contact allergens that induce an allergic contact dermatitis include squaric acid, dibutyl ester and diphencyprone. These agents are thought to work by inducing the introduction of a second antigen can initiate a new infiltrate containing T-suppressor cells that may modify the preexisting infiltrate and allow regrowth. Cyclosporine has also been used both topically and systemically in the treatment of alopecia areata, with mixed results. Response rates also vary with topical minoxidil 5% treatment. Topical anthralin may work by generating free radicals, which have antiproliferative and immunosuppressive actions.

### Tinea Capitis

Tinea capitis is uncommon after puberty.<sup>6</sup> When it occurs in adults, the clinical features may be atypical. Tinea capitis in adults generally occurs in patients who are immunosuppressed. The diagnosis of tinea capitis is suggested by erythema, scaling, and crusting locally on the scalp. When an adult, especially if immunocompromised, presents with a patchy, inflammatory scalp disorder, mycologic samples should be sent for laboratory analysis in all of these patients.

### Scarring (Cicatricial) Alopecia

Scarring (cicatricial) alopecia is characterized by follicular destruction and replacement of the interfollicular epidermis by atrophic skin. Hair stem cells are normally localized in the midportion of the follicles, in the mid-dermis. If this area remains undisturbed, the follicles recycle throughout one's life. However, inflammation in this area can destroy the stem cells. In that case, a cicatricial alopecia is established, and no follicle is

able to grow. Some systemic diseases can cause destruction of hair follicles, resulting in a scarring alopecia. Clinically, there is obliteration of the orifices of the follicles. The insult is usually to the bulge zone of the follicle. This process usually occurs as a result of intense inflammation. Some causes of cicatricial alopecia are infectious, (Table 3).<sup>10</sup>

### Effects of Chemotherapy on Hair Color

Chemotherapy can cause altered color of regrown hair since melanocytes also represent an unintended target for chemotherapeutic drugs.

An article by Fairlamb noted a graying effect in 40% of individuals, whereas a rejuvenation of color (loss of gray hair) was noted in 20% of patients.<sup>37</sup> Overall, 65% of patients reported some character change in their hair after cytotoxic therapy.

Certain chemotherapies, such as cyclophosphamide (CYP), induce profound changes in tyrosinase and dihydroxyphenylalanine (DOPA) chrome tautomerase activity in murine skin.<sup>38</sup> These are enzymes needed for melanin production. Also, electron microscopy data suggest that after CYP treatment, some melanocytes change their localization and migrate to the bottom of the hair bulb, whereas others undergo apoptosis.<sup>39</sup> Although selected hair bulb melanocytes underwent apoptosis 24 to 48 hours after CYP administration, no cell death was seen in the outer root sheath and bulge melanocytes. Seventy-two hours after CYP administration, the surviving hair bulb melanocytes were proliferative and later migrated up the outer root sheath to the inter-follicular epidermis. Five to 7 days after CYP treatment, numerous melanocytes expressing all

three melanogenic proteins had repopulated the epidermis and showed melanogenic activity.

Mitoxantrone, used as adjuvant chemotherapy for breast cancer, has been reported to cause selective loss of white hair.<sup>40</sup>

### Hair Loss Prevention

#### Scalp Tourniquets

This method to prevent hair loss in chemotherapy-induced alopecia (CIA) has been used as far back as 1966, initially by Simister and Hennessey.<sup>12</sup> The idea is to prevent the chemotherapeutic drug from reaching the hair.<sup>41</sup> Drugs with a short half-life and a rapid clearance of active drug and metabolites from the circulation are the most likely to have benefit seen with this procedure.<sup>2</sup> It involves the use of a pneumatic tourniquet placed around the hairline and inflated to a pressure above the systolic arterial pressure. Various studies with differing chemotherapy regimens have been published, making the evaluation of efficacy difficult. The main side effect with this treatment was head discomfort.

#### Scalp Hypothermia

The end point of scalp hypothermia is to temporarily decrease blood flow to the scalp by vasoconstriction.<sup>42</sup> The use of hypothermia may also result in a decreased metabolic rate of hair follicles, therefore reducing the exposure of hair follicles to the chemotherapeutic agents. Most published studies have evaluated the use of this procedure prior to the administration of doxorubicin since the half-life is short and plasma clearance of the drug and metabolites is rapid.<sup>43</sup> CYP has a longer half-life than doxorubicin, so insufficient hair loss prevention is found with hypothermia when both drugs are used in combination.

The procedure requires that the scalp temperature must be less than 24°C.<sup>44</sup> Different approaches have been used in studies to produce hypothermia. These included ice bags fastened to the patient's head, frozen gel packs that were initially molded around a wig stand,<sup>45-48</sup> and various other investigator-designed devices using circulating cold air or fluid.<sup>2</sup> There has not been a consistent protocol in the various published studies in terms of the amount of time that the cooling process was started before chemotherapy administration and the amount of time that the cooling device was left in place following chemotherapy administration. The chemotherapy regimens and dosages also varied. Therefore, it is difficult to compare the individual studies in regard to efficacy. A recent nonrandomized pilot study by Ridderheim and colleagues used a silicon cap with three temperature monitors.<sup>43</sup> Scalp cooling began 30 minutes prior to administration of chemotherapy, and the temperature was maintained at +5°C throughout the drug administration and

TABLE 3 Some Causes of Acquired Scarring Alopecia

Neoplasia

for at least 30 minutes after discontinuation. There were 74 treated patients with 13 different chemotherapy regimens used in the cohort study. The results were based on a visual analogue scale (VAS 0–10; 0 = no hair loss, 10 = total hair loss). See Table 4 for chemotherapy protocols and results. This study had a mean follow-up period of 15 months, with no scalp metastases noted among the 74 treated patients. Scalp cooling was well tolerated, with modest patient discomfort. The patients ranked a median value of 1.5 on a scale of 0 = no discomfort to 10 = extreme discomfort. The main complaints involved headache and “being chilled.” The time invested by nurses for the procedure was less than 10 minutes per patient. A large clinical trial employing efficient and controlled cooling systems with long-term follow-up is still needed.

The main concern with scalp hypothermia and tourniquet therapy is the potential for scalp metastases. Five cases of scalp metastases among 96 patients treated with hypothermia used for chemotherapy for metastatic breast cancer have been reported. No reports of scalp metastases during adjuvant therapy for breast cancer have been reported.<sup>49,50</sup> The ideal patients for the above two preventive therapies are those receiving single-agent chemotherapy with a palliative intent or for solid tumors that rarely metastasize to the scalp.

## Drug Therapies (Established and Experimental)

### $\alpha$ -Tocopherol (Vitamin E)

High-dose  $\alpha$ -tocopherol has been used at a dose of 1,600 IU orally daily starting 72 hours before chemotherapy to prevent hair loss. A study by Wood reported a 69% success rate using the above regimen prior to an unspecified dose of doxorubicin.<sup>51</sup> However, Martin-Jimenez and colleagues failed to confirm this finding in patients receiving 5-fluorouracil, doxorubicin, and CYP.<sup>52</sup> Another study by Perez and colleagues also did not find

significant benefit for patients receiving doxorubicin alone.<sup>53</sup> Powis and Kooistra revealed that Angora rabbits fed an  $\alpha$ -tocopherol-supplemented diet showed evidence of protection against doxorubicin-dependent inhibition of new hair growth.<sup>54</sup> Topical  $\alpha$ -tocopherol did not provide any protection from doxorubicin-induced alopecia.

### Minoxidil

The effect of induction of hair growth for this medication is thought to result from prolongation of the anagen phase of hair growth. This action has been shown in a mouse model. A few studies have evaluated the use of topical minoxidil to prevent hair loss in patients receiving chemotherapy. A study by Rodriguez and colleagues showed that patients who applied 2% minoxidil to the scalp, beginning 24 hours prior to chemotherapy and continuing throughout therapy with doxorubicin, did not have any improvement of hair loss compared with placebo.<sup>55</sup> A study by Duvic and colleagues revealed that patients who received doxorubicin, CYP, and 5-fluorouracil chemotherapy and applied 2% topical minoxidil solution twice daily throughout chemotherapy and up to 4 months following therapy showed an increased time to maximal hair loss.<sup>56</sup> The time to maximal regrowth from baseline was also improved with minoxidil. It appears that the use of this medication for prevention of hair loss is limited; however, it may decrease the length of time needed for hair regrowth.

### AS101: Ammonium Trichloro (dioxoethylene – O, O') Tellurate

The AS101 compound is an immunomodulator that appears to stimulate lymphocyte secretion of interleukin-1 (IL-1), colony-stimulating factor, and IL-12. It also has been found to have radioprotective effects. Sredni and colleagues evaluated the use of this compound at a dose of 3 mg/m<sup>2</sup> intravenously three times weekly in patients who

were receiving intravenous carboplatin on day 1 and etoposide on days 3, 5, and 7.<sup>57</sup> AS101 was begun 2 weeks before chemotherapy and was otherwise administered 30 minutes before chemotherapy. The results showed the absence of grade IV alopecia in all patients receiving the active drug versus 9.3% of patients who did not receive AS101. Thirteen percent of patients developed grade 3 alopecia in the AS101 group versus 43.5% of patients who did not receive the active medication. There was no significant difference in chemotherapy response in the two groups. The main side effects of the medication included postinfusional fever and garlic-like halitosis.

### Imuvert

Imuvert is an immunomodulator that stimulates IL-1, tumor necrosis factor, and IL-6. IL-1 is a hormone-like polypeptide that mediates a broad spectrum of activities in host defense and in a variety of disease processes.<sup>58–61</sup> Many cell types produce this cytokine, most notably mononuclear phagocytes. Imuvert has been studied in CIA in the newborn rat model. The mechanism of hair protection is based on the fact that IL-1 has been shown to be a potent stimulator for hair follicle keratinocytes.<sup>62</sup> Imuvert may treat alopecia since it is a potent inducer of IL-1.<sup>63,64</sup> Another study by Hussein showed that IL-1 protects against ara-C-induced alopecia in the newborn rats.<sup>65</sup> Imuvert and IL-1 failed to protect against CYP-induced alopecia, suggesting that cell cycle-specific agents (ara-C, doxorubicin) produce alopecia by a different mechanism from that of cell cycle-nonspecific agents, such as CYP.

### Calcitriol (1,25-(OH)<sub>2</sub>D<sub>3</sub>)

Vitamin D<sub>3</sub> analogues directly or indirectly inhibit the apoptosis of normal epithelial cells in vivo, as shown by Schilli and colleagues.<sup>66</sup> The study showed down-regulation of apoptosis in CYP-treated hair follicles by topical calcitriols. The effects are thought to result from genomic interactions of the ligand–vitamin D<sub>3</sub> receptor complex with apoptosis control genes. Certain genes, such as members of the Bcl family, seem to be involved in regulating keratinocyte apoptosis during spontaneous hair follicle regression and possibly during chemotherapy-induced apoptosis.<sup>36</sup> Calcitriol may also induce a change in hair matrix keratinocyte proliferation and/or terminal differentiation, thus rendering follicular keratinocytes less susceptible to the cytotoxic and/or proapoptotic effects of CYP. There may be direct interactions of the selected vitamin D analogues with the vitamin D receptors of follicular keratinocytes, perifollicular macrophages, and mast cells, which subsequently modulate follicular keratinocyte apoptosis. It is still not known if calcitriol may be used therapeutically to protect growing hair follicles without endangering the efficacy of cytostatic drugs.

TABLE 4 Study Results of Scalp Hypothermia

Chemotherapy Regimen	Number of Patients	VAS Scores, n (range)	Wig Necessary (%)
Anthracycline combinations or single taxane	24	0	0
Combined paclitaxel-carboplatin	30	2.5 (0–6.5)	63
Combined anthracycline and taxanes	6	6 (1.5–8)	
Epirubicin-gemcitabine	18	0 (0–2)	0
ABVD	8	1 (0–7)	0
BEP	2	9 (7.5–10)	100
Topotecan and etoposide	1	0	0
Topotecan	2	2.5 (0–5)	50

Adapted from Ridderheim M et al.<sup>43</sup>  
 ABVD = Adriamycin (doxorubicin), bleomycin, vinblastine, dacarbazine; \*\*\*BEP = bleomycin, etoposide, cisplatin; VAS = visual analogue scale 0–10; 0 = no hair loss, 10 = total hair loss.

Hidalgo and colleagues evaluated topical calcitriol to prevent CIA in patients with breast cancer receiving FAC (5-fluorouracil, Adriamycin [doxorubicin], and cyclophosphamide) chemotherapy.<sup>67</sup> Topitriol cream 0.0025% or 0.005% was administered twice daily; all patients developed grade 2 alopecia between days 20 and 30 postchemotherapy, therefore demonstrating the ineffectiveness of topical topitriol in preventing CIA.

Jimenez and Yunis, however, showed that 0.2 g of topical 1,25-dihydroxyvitamin D<sub>3</sub> protected rats from alopecia induced by etoposide, CYP, and a doxorubicin-CYP combination.<sup>68</sup> It is still not known whether the down-regulation of CYP-induced apoptosis by topical calcitriols reflects direct interactions of the selected vitamin D analogues with the vitamin D receptors of follicular keratinocytes or with those of other resident populations of cells, such as dermal papilla fibroblasts,<sup>69</sup> perifollicular macrophages, or mast cells, which modulate follicular apoptosis.

### Cyclosporine

Hussein and colleagues have shown that several agents will protect against CIA in the newborn rat animal model.<sup>70</sup> Such protective agents render the hair follicle keratinocytes resistant to chemotherapy, possibly by the expression of P-glycoprotein (Pgp). Cyclosporine is a potent inhibitor of Pgp. The efficacy of cyclosporine was tested in its effects on CIA in the newborn rat animal model. Cyclosporine, when applied topically, protected rats from local alopecia induced by various agents. The mechanism of protection by cyclosporine and its relationship to Pgp remain uncertain. Paus and colleagues showed that systemic cyclosporine shifts CYP-induced alopecia toward a mild form of dystrophic anagen, thus retarding alopecia and prolonging “primary recovery.”<sup>71</sup>

### Topical Estrogen

A number of nongenomic 17- $\beta$ -estradiol (E<sub>2</sub>)-dependent signaling transductions are involved in various biologic processes. The prototypic estrogen E<sub>2</sub> causes a hair follicle response and recovery from chemotherapy to follow a dystrophic catagen pathway.<sup>72</sup> If this pathway is followed, anagen is immediately terminated, followed by a dystrophic catagen and a remarkably shortened telogen phase. Therefore, the hair follicle is able to be reconstructed to a fully functional hair shaft at maximal speed. Hair follicles that follow the dystrophic catagen pathway will exhibit the most severe and fastest alopecia yet also have the fastest regrowth of normally pigmented hair shafts during the recovery phase. Ohnemus and colleagues showed that topical 17 $\beta$ -estradiol significantly altered the cycling response of murine follicles to CYP.<sup>72</sup> The

regrowth of normally pigmented hair shafts after CIA was significantly accelerated. Human studies still need to be explored using topical estrogens as a potential stimulant for hair regrowth after CIA.

### Prevention of Radiation-Induced Alopecia

Tempol (4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl) is a stable nitroxide radical that functions as a superoxide dismutase and can protect mammalian cells from both superoxide hypoxanthine/xanthine oxidase and hydrogen peroxide cytotoxicity. A study by Goffman and colleagues evaluated a topical application of tempol on guinea pigs receiving radiation.<sup>73</sup> There was an increase in the rate of new hair recovery on the skin that had tempol applied to it 15 minutes before radiation exposure compared with unprotected skin. No systemic absorption was noted.

Topical and subcutaneous 16,16-dimethyl prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) was studied by Hanson and colleagues in preventing radiation-induced alopecia in mice.<sup>74</sup> Both types of administration of PGE<sub>2</sub> protected the mice to some degree from hair loss.

### Parathyroid Hormone–Related Peptide Receptor Agonist

Parathyroid hormone–related peptide (PTHrP) normally causes malignancy-related hypercalcemia but can also regulate keratinocyte proliferation and differentiation.<sup>75</sup> Parathyroid hormone (PTH)/PTHrP-R agonists stimulate insulin-like growth factor 1 production by fibroblasts,<sup>76</sup> which acts as a cell cycle progression factor in keratinocytes. Schilli and colleagues showed increasing evidence that PTH/PTHrP-R mediated signaling is involved in hair growth control, specifically in hair follicle cycling.<sup>77</sup> Holick and colleagues showed that intraperitoneal synthetic PTH/PTHrP-R antagonist PTH (7-34) increased hair growth in hairless mice.<sup>78</sup> PTH (7-34) also accelerated anagen development in infantile C57BL/6 mice with normal hair growth patterns and inhibited spontaneous hair follicle regression (catagen) in adolescent mice. Peters and colleagues demonstrated that PTH/PTHrP-R agonist PTH (1-34) and PTH/PTHrP-R antagonists PTH (7-34) and PTHrP (7-34) can effectively manipulate the hair follicle response to CYP-induced damage as follows: PTH/PTHrP-R antagonists may be given initially during chemotherapy to prevent the acceleration of the hair cycle, thereby decreasing the sensitivity of the hair follicle cells to CYP. After the chemotherapy is completed, a PTH/PTHrP-R agonist may be given, which would accelerate the hair cycle and therefore stimulate regrowth.<sup>75</sup>

### Psychological Impact of CIA

CIA is a condition that has significant psychosocial effects, resulting in anxiety, depression, and a negative body image for cancer patients. Alopecia has been cited by 47 to 58% of women with cancer as the most disturbing anticipated aspect of receiving chemotherapy, with 8% of women in one study found to be at risk of avoiding treatment.<sup>79</sup>

Helping patients cope with CIA involves providing accurate information and appropriate support. Support groups and use of a wig can help alleviate some of the anxiety caused by this side effect of cancer therapy. Once alopecia has occurred, self-care strategies to protect the scalp and other areas of hair loss against the sun, cold, or trauma should be encouraged.

Cancer treatment–induced alopecia still remains one of the chief unresolved clinical problems for the oncologist and a substantial source of psychological anguish for the patient. A thorough history, physical examination, and laboratory evaluation should be employed to uncover the etiology of the alopecia in this patient population. Other etiologies, such as systemic disease or nonchemotherapy medications, should not be overlooked. A combination of any of these factors may result in the patient’s alopecia. Treatment and prevention will be guided by the etiologic factors. Physicians’ recommendations are the most influential factor in cancer treatment choice, but body image concerns are also highly influential factors.<sup>80</sup>

# Paraneoplastic Dermatoses

Jeffrey P. Callen, MD  
Bruce H. Thiers, MD

This chapter represents a substantive revision and update of a chapter coauthored by Drs. Thiers, Callen, and Cannick that was written for *Cancer of the Skin*, Rigel DS, Friedman R, Dzubow L, Reintgen DS, Bystry J-C, Marks R, editors), WB Saunders, Philadelphia, 2005 (with permission of the editors).

Paraneoplastic dermatoses are those disorders in which the skin serves as a marker for an internal malignancy. In its truest sense, the meaning of *paraneoplastic* requires that there be a direct and often parallel course of the dermatosis and the malignancy, or in other words, when the skin manifestation occurs, the malignancy is recognized and if the malignancy is effectively treated, then the dermatosis resolves as well. Most of the conditions that are discussed in this chapter do not have such a course, yet their presence serves as an important marker of a potential malignancy. A wide spectrum of inflammatory, proliferative, metabolic, and neoplastic diseases may affect the skin in association with an underlying malignancy.

Internal cancer may affect the skin both directly and indirectly.<sup>1</sup> Direct involvement may be defined as the actual presence of malignant cells within the skin and includes neoplasms that often first become manifested in the skin but eventually affect internal organs (such as mycosis fungoides), visceral neoplasms metastatic to the skin (such as the Sister Joseph nodule of gastric carcinoma), and tumors arising within or below the skin that ultimately spread to the cutaneous surface (such as Paget's disease of the nipple). In addition, cancer patients often develop skin changes that are reflective of the therapy directed at the malignancy, such as radiation-induced changes or changes related to chemotherapy. Indirect involvement of the skin in cancer patients implies the absence of tumor cells within the skin. Inherited syndromes associated with skin manifestations and an increased incidence of systemic neoplasia are included in this group, as are cutaneous changes resulting from hormone secretion by tumors and a wide spectrum of proliferative and inflammatory disorders occurring in conjunction with internal malignancy (Table 1).

**Table 1** Cutaneous Manifestations of Internal Malignancy

Inherited syndromes (see Table 2)
Hormone-secreting tumors
Ectopic ACTH syndrome
Carcinoid syndrome
Glucagonoma syndrome
Proliferative and inflammatory dermatoses
Hypertrichosis lanuginosa
Acanthosis nigricans
Leser-Trélat sign
Tripe palms
Acrokeratosis paraneoplastica (Bazex's syndrome)
Punctate palmar keratoses
Bowen's disease
Primary amyloidosis
Scleromyxedema
Kaposi's sarcoma
Sweet's syndrome
Pyoderma gangrenosum
Blistering diseases: pemphigus, paraneoplastic pemphigus, antiepiligrin cicatricial pemphigoid, dermatitis herpetiformis
Dermatomyositis
Digital clubbing
Vasculitis
Coagulopathies
Erythema gyratum repens
Eczematous and ichthyotic disorders
Cronkhite-Canada syndrome
Granuloma annulare
Extramammary Paget's disease

ACTH = adrenocorticotropic hormone.

## History

In *Cancer of the Skin*, Curth outlined a set of criteria that could be used to analyze the relationship between an internal malignancy and a cutaneous disorder.<sup>2</sup> Curth's postulates, consist of five characteristics: (1) a concurrent onset: the malignancy is discovered when the skin disease occurs; (2) a parallel course: if the malignancy is removed or successfully treated, the skin disease remits, and when the malignancy recurs, the cutaneous disease also recurs; (3) a uniform malignancy: there is a specific tumor cell type or site associated with the skin disease; (4) a

statistical association: based on sound case-control studies, there is a significantly more frequent occurrence of malignancy in a patient with a cutaneous disease; and/or (5) a genetic association. These criteria are extremely useful in the analysis of the relationship between skin diseases and malignancy. However, not all criteria must be met to believe that there is a relationship. We use these criteria as we analyze the disease entities that are discussed in this chapter.

## Inherited Syndromes Associated with Internal Malignancy

Multiple familial cancer syndromes have prominent dermatologic features, and at times, the potential for internal malignancy is first suspected when the skin disease is recognized. In a recent review, Tsao characterized these syndromes into four groups: (1) those with prominent skin cancers with occasional internal malignancies, (2) those with prominent benign cutaneous tumors or rare cutaneous malignancies with internal malignancies, (3) those with prominent non-neoplastic cutaneous features or rare cutaneous tumors with internal neoplasms, and (4) those with minimal well-documented cutaneous features with internal neoplasms (Table 2).<sup>3</sup> In this chapter, we discuss only some of these syndromes.

Cowden's disease, also known as multiple hamartoma syndrome (Mendelian Inheritance in Man [MIM] #158350), is inherited as an autosomal dominant trait but occurs more often in women than in men. This disorder has been linked to mutations in the *PTEN/MMAC1* gene on chromosome 10q22-23. The disorder displays a variety of cutaneous and mucosal manifestations that can occur at any time from childhood to middle age.<sup>4-6</sup> Small (1-4 mm) flesh-colored papules, known as trichilemmomas, are found mainly on the head and neck and may assume a wart-like appearance (Figure 1). Similar papules may coalesce and produce a cobblestone appearance on the tongue and gingiva. Waxy papules or nodules known as sclerotic fibromas are less common but are quite characteristic. Flat wart-like papules may occur on the dorsum of

Table 2 Familial Cancer Syndromes and the Skin

Syndrome	MIM Number	Internal Malignancies
<b>Group 1: prominent skin cancers with occasional internal malignancies</b>		
Nevoid basal cell carcinoma syndrome	109400	Medulloblastomas, meningiomas
Familial multiple atypical mole melanoma pancreatic syndrome	606719	Pancreatic, breast, and, in some families, possibly lung and laryngeal
Xeroderma pigmentosa	194400	10-fold increase in the risk of internal malignancies
<b>Group 2: prominent benign cutaneous tumors or rare cutaneous malignancies with internal malignancies</b>		
Multiple hamartoma syndrome (Cowden's disease)	158350	Breast, thyroid, and colon are the most common, but cancers in many other organs have been reported in individual cases
Gardner's syndrome	175100	Colon and rectal
Muir-Torre syndrome	158320	Colon, rectal, and genitourinary, but also breast, hematologic, and head and neck malignancies have been reported
Multiple endocrine neoplasia type IIA (Sipple's syndrome) and IIB	162300 and 171400	Medullary carcinoma of the thyroid, pheochromocytoma
Neurofibromatosis 1	162200	Neurofibrosarcoma, astrocytoma, pheochromocytoma. Children with juvenile xanthogranuloma and neurofibromatosis 1 have an increased risk of chronic myelomonocytic leukemia
Neurofibromatosis 2	101000	Schwannomas, glioma, astrocytoma, meningioma
Tuberous sclerosis	191100	Cardiac rhabdomyomas, renal malignancies
<b>Group 3: prominent non-neoplastic cutaneous features or rare cutaneous tumors with internal malignancies</b>		
Ataxia-telangiectasia (Louis-Bar's syndrome)	208900	Leukemia
Bloom syndrome	210900	Within the Bloom syndrome registry 71 of 168 patients had an internal malignancy
Peutz-Jeghers syndrome	175200	Gastrointestinal, breast, and ovarian, but a wide variety of cancers have been reported
Rothmund-Thomson syndrome	268400	Osteogenic sarcoma
Werner's syndrome	277700	Increased risk of sarcomas, thyroid cancer, and melanoma

MIM = Mendelian Inheritance in Man.

FIGURE 1 Cowden's disease (multiple hamartoma syndrome).

the hands and feet, and keratosis punctata may be present on the soles, sides of the feet, and palms. Lipomas and hemangiomas may also be found.

Internal manifestations are variable. Almost all affected women have fibrocystic disease of the breasts; many of them ultimately develop breast cancer, often bilaterally. Thyroid tumors, both benign and malignant, are frequent (75%). Cancers of the lung and colon have been reported

as well. Hamartomatous polyps of the gastrointestinal tract occur in one-third of patients and are generally benign. The significance of Cowden's disease lies in its value as a marker for the eventual development of breast cancer and, occasionally, thyroid tumors.

Gardner's syndrome (MIM #175100) is another autosomal dominant disorder that is associated with the *APC* (adenomatous polyposis coli) gene on chromosome 5q21. It is characterized by extensive adenomatous polyps of the gastrointestinal tract, especially the colon and rectum.<sup>7</sup> The potential for malignant degeneration of these polyps approaches 100% if not removed; therefore, prophylactic total colectomy should be discussed with the patient and family. The skin lesions that occur in Gardner's syndrome include large, deforming epidermoid cysts, fibromas, lipomas, leiomyomas, trichoepitheliomas, and neurofibromas. Osteomas involving the membranous bones of the face and head occur in about 50% of affected patients.<sup>8</sup> Congenital hypertrophy of the retinal pigment epithelium

has also been associated with Gardner's syndrome.<sup>7</sup>

Peutz-Jeghers syndrome (MIM #175200) is characterized by extensive hamartomatous polyps throughout the gastrointestinal tract. This syndrome is related to mutations in the *STK11/LKB1* gene on chromosome 19p13.3 and is inherited in an autosomal dominant manner. Bleeding and abdominal pain caused by intussusception are the most common gastrointestinal manifestations.<sup>9</sup> The potential for malignant degeneration for these polyps, although possible, is much less than for the adenomatous polyps that occur in Gardner's syndrome.<sup>10</sup> However, certain families appear to have an increased risk of breast and gynecologic cancers.<sup>11-13</sup> The characteristic feature of the condition is freckle-like pigmented macules on the lips, nose, buccal mucosa, and fingertips and in a subungual location.

In Muir-Torre syndrome (also known as Torre syndrome) (MIM #158320), multiple carcinomas, usually of the gastrointestinal tract, are associated with numerous sebaceous gland tumors (benign sebaceous adenomas, malignant sebaceous carcinomas, and others that are hard to classify), primarily on the face and trunk (Figure 2). Other visceral cancers and keratoacanthomas have also been reported.<sup>14</sup> Muir-Torre syndrome appears to be inherited as an autosomal dominant trait and is related to a mutation of the *MSH2* gene located at chromosomes 2p22-p21 and 3p21.3.<sup>15</sup> In contrast, solitary sebaceous gland tumors are not genetically determined, occur most often on the head and neck, and are not associated with visceral malignancy. The diagnosis of gastrointestinal cancer usually precedes the recognition of the cutaneous lesions. The cutaneous tumors can grow quite rapidly but usually do not metastasize. Similarly, the gastrointestinal cancers often behave as low-grade malignancies.

Howell-Evans' syndrome (MIM #148500) represents an association between nonepidermolytic palmoplantar keratoderma (also known as tylosis) and esophageal cancer and was first

FIGURE 2 Muir-Torre syndrome.

reported in two English families. The keroderma usually develops during childhood and is accentuated over pressure sites. Onset of the esophageal carcinoma is delayed until middle age. The genetic locus on chromosome 17q25 that appears to be associated with this syndrome is frequently deleted in sporadic esophageal squamous cell carcinoma as well.<sup>16</sup>

Birt-Hogg-Dubé syndrome (MIM #135150) is an autosomal dominant condition characterized by skin tags and benign hair follicle tumors (fibrofolliculomas and trichodiscomas) of the head and neck (Figure 3).<sup>17</sup> This disorder has been mapped to a mutation in the 17p11.2 gene, which encodes folliculin. The incidence of spontaneous pneumothorax, as well as chromophobe and oncocytic types of renal carcinoma, is increased. In some families, a link to colonic polyposis has occurred.<sup>18</sup> Another hereditary syndrome that is associated with renal cell carcinoma is known as hereditary leiomyomatosis and renal cell cancer syndrome (MIM #605839), which is characterized by multiple leiomyomas of the uterus and skin in conjunction with papillary renal cell carcinoma.<sup>19</sup> This disorder is due to a mutation of the gene encoding fumarate hydratase, an enzyme of the tricarboxylic acid cycle. The disorder has been mapped to chromosome 1q42.1.

Melanoma-pancreatic cancer syndrome (also known as familial atypical multiple mole melanoma pancreatic carcinoma syndrome [MIM #606719]) is related to a mutation of the gene encoding cyclin-dependent kinase inhibitor 2A (CDKN2A). In addition to the increased risk of melanoma and pancreatic cancer in these families, there have been reports that link this family cancer syndrome with breast cancer.<sup>20,21</sup>

Patients with the rare autosomal dominant disorder multiple mucosal neuromas syndrome display a constellation of abnormalities, including medullary carcinoma of the thyroid, pheochromocytoma, parathyroid hyperplasia or adenomas, and intestinal ganglioneuromatosis; the latter may give rise to persistent diarrhea.<sup>22</sup> Multiple neuromas appear as whitish nodules mainly on the lips and anterior third of the tongue but also may be noted on the buccal mucosa,

**FIGURE 3** Birt-Hogg-Dubé syndrome.

gingiva, palate, pharynx, conjunctivae, and cornea. Affected individuals have characteristic facies, with thick, protuberant, bumpy lips; the eyelids may be thickened and slightly everted. Many patients have a “marfanoid” habitus, with long, slender extremities, poor muscle development, sparse body fat, laxity of joints, pectus excavatum, and dorsal kyphosis. Although multiple mucosal neuromas syndrome is classified as one of the three familial syndromes of multiple endocrine neoplasia (MEN) (see below), many sporadic cases have been reported.

In type 1 neurofibromatosis (von Recklinghausen’s disease) (MIM+162200), multiple Schwann cell tumors, malignant degeneration of neurofibromas, and pheochromocytomas (often bilateral) may complicate the clinical course. Gastrointestinal stromal tumors have also been reported.<sup>23</sup> The salient features of this disorder have received extensive review in the recent medical literature.<sup>24</sup> Neurofibromatosis 1, like multiple mucosal neuromas syndrome, may be classified among the apudomas (see below).

### Skin Changes Resulting from Hormone-Secreting Tumors

Ectopic hormonal syndromes are best understood in the context of the APUD cell system (ie, cells with a capacity for amino precursor uptake and decarboxylation).<sup>25,26</sup> These cells, which may have a common origin from the neural crest, can secrete a variety of biologically active amines and polypeptide hormones. Neoplastic proliferation of these cells may result in characteristic symptom complexes associated with specific cutaneous changes.

Ectopic adrenocorticotrophic hormone (ACTH)-producing tumors cause many of the typical signs and symptoms of Cushing’s syndrome. Intense hyperpigmentation, present in only 6 to 10% of patients with Cushing’s disease, is especially common in association with ectopic ACTH production and should alert the clinician to the possibility of a hormone-secreting tumor.<sup>27</sup> Although the cause of the hyperpigmentation is unclear, it may be related to tumor production of the peptide  $\beta$ -lipotropin, which contains within its sequence of 91 amino acids the 22-amino acid sequence of beta-MSH (Melanocyte-stimulating hormone). A myasthenia gravis-like syndrome, including profound proximal muscle weakness, may be a striking clinical feature and may reflect either underlying hypokalemia or polymyositis. Oat cell (small cell) carcinoma of the lung is the tumor most often associated with ectopic ACTH production, although other malignancies have been reported.

Carcinoid syndrome is a second example of a hormonal syndrome associated with a nonendocrine tumor.<sup>28</sup> The disorder is probably most

often caused by the release of the enzyme kallikrein from tumor cells, with subsequent conversion of kininogen to vasoactive kinin peptides, including bradykinin; in addition, increased blood levels of histamine may be important in the rare metastatic gastric carcinoid. The most striking cutaneous manifestations are episodes of flushing, initially lasting 10 to 30 minutes and involving only the upper half of the body; as the flush resolves, gyrate and serpiginous patterns may be noted. With successive attacks, more extensive areas may be affected and the redness takes on a cyanotic quality, eventually leading to a more permanent facial cyanotic flush with associated telangiectasia, resembling rosacea. Persistent edema and erythema of the face may result in leonine facies. A pellagra-like picture, noted in some patients, may be due to abnormal tryptophan metabolism. Systemic symptoms associated with the cutaneous flushing include abdominal pain with explosive watery diarrhea, shortness of breath, and hypertension.

Carcinoid tumors are usually found in the appendix or small intestine; extraintestinal carcinoid tumors may arise in the bile ducts, pancreas, stomach, ovaries, or bronchi. The carcinoid syndrome occurs primarily when an intestinal carcinoid tumor metastasizes to the liver or with extraintestinal tumors; flushing attacks can be provoked by palpation of hepatic or abdominal metastases or by alcohol ingestion, enemas, emotional stress, or sudden changes in body temperature. When the syndrome is associated with bronchial adenomas of the carcinoid variety, the flushing is more prolonged and often associated with fever, marked anxiety, disorientation, sweating, salivation, and lacrimation.

The three clinical patterns of familial MEN (types I, IIA, and IIB) are examples of polyglandular endocrine disorders involving the APUD cell system. A carcinoid-like syndrome has been described in MEN IIA (Sipple’s syndrome)<sup>29</sup>; otherwise, mucocutaneous lesions occur only in MEN IIB (multiple mucosal neuromas syndrome), which has already been discussed.

Glucagonoma syndrome is associated with an apudoma involving the glucagon-secreting alpha cell of the pancreas.<sup>30</sup> The characteristic cutaneous eruption, necrolytic migratory erythema, usually occurs on the abdomen, perineum, thighs, buttocks, and groin. The perioral region and the distal extremities are often affected. Patches of intense erythema with irregular outlines expand and coalesce, resulting in circinate or polycyclic configurations. Superficial vesicles on the surface rupture quickly to form crusts, but new vesicles may continue to develop along the active margins. An eczema craquelé-like appearance may be noted. Pressure or trauma may initiate or aggravate the eruption, which seems to share features of staphylococcal scalded

skin syndrome and acrodermatitis enteropathica. Like the latter disorder, necrolytic migratory erythema sometimes responds to topical application of diiodohydroxyquin; however, zinc levels are normal, and zinc treatment is ineffective. Complete surgical resection is the only curative treatment for the tumor as chemotherapy yields only modest benefit.<sup>31</sup>

### Proliferative and Inflammatory Dermatoses Associated with Cancer

Many of the conditions to be discussed in this section are nonspecific and have been reported both in association with and in the absence of underlying malignant disease. Malignancy is most often only one of a number of possible provoking factors.

The association of acquired hypertrichosis lanuginosa (malignant down) with cancer is among the most consistent.<sup>32</sup> The extensive growth of silky, nonpigmented lanugo hair on the face (Figure 4), neck, trunk, and sometimes the extremities usually antedates the discovery of a malignancy. Other causes of hypertrichosis, such as porphyria cutanea tarda and endocrinopathies, should be excluded. The tumors associated with acquired hypertrichosis lanuginosa are often adenocarcinomas and frequently occur in the gastrointestinal tract; however, squamous cell carcinomas have also been reported, and multiple other sites have been associated. A painful glossitis, angular cheilitis, and swollen red fungiform papillae on the anterior half of the tongue may accompany the cutaneous changes.

Acanthosis nigricans is perhaps the best known of the cutaneous markers of internal malignancy.<sup>33</sup> Flexural areas, especially the axillae, groin, and neck, are most often involved; the skin has a hyperpigmented velvety appearance and in severe cases can become quite verrucous (Figure 5). Papillomatous changes may be noted in the oral cavity,<sup>34</sup> and hyperkeratosis in a rugose pattern may develop on the palms and dorsal surfaces of large joints. The cutaneous changes can occur before, coincident with, or after the dis-

FIGURE 4 Hypertrichosis lanuginosa.

covery of an underlying malignancy, which most often is an adenocarcinoma of the stomach. Tumors have also been found in other abdominal organs, with more than 95% being adenocarcinomas. Acanthosis nigricans also occurs in association with insulin resistance and other endocrinopathies, as well as owing to drugs; therefore, a detailed history must be included in the evaluation of all affected patients.<sup>35,36</sup> The possibility of underlying cancer should be strongly considered in any nonobese adult who develops acanthosis nigricans in the absence of a recognizable endocrinopathy. Such an individual should have an extensive gastrointestinal evaluation.

Leser-Trélat sign, the sudden appearance and/or rapid increase in the size of multiple seborrheic keratoses, may be associated with carcinoma of the gastrointestinal tract or female reproductive system.<sup>37</sup> Because most of these patients have coexistent acanthosis nigricans and the malignancy is often an adenocarcinoma of gastrointestinal origin, some clinicians believe that this condition may represent a generalized variant of acanthosis nigricans.

A third related condition is tripe palms. The skin changes manifest as rugose thickening of the palms and, occasionally, the soles (Figure 6). Patients will often have coexistent acanthosis nigricans and sometimes Leser-Trélat sign. Patients with tripe palms and acanthosis nigricans usually have adenocarcinomas of the gastrointestinal tract; however, when tripe palms occur in the absence of acanthosis nigricans, patients tend to have squamous cell carcinoma of the lung.<sup>38</sup>

Patients with Bazex's syndrome (acrokeratosis paraneoplastica) develop an erythematous to violaceous psoriasiform eruption, primarily on acral surfaces (Figure 7).<sup>39,40</sup> The ears, nose, cheeks, hands, feet, and knees are most often affected, but the nails may become dystrophic and the palms and soles may develop a keratoderma in later stages of the disease. The disorder may develop in stages and is associated primarily with carcinomas of the upper respiratory and

FIGURE 5 Acanthosis nigricans.

FIGURE 6 Tripe palms. (Courtesy of Dr. Jon Dyer, Columbian)

FIGURE 7 Bazex's syndrome.

digestive tracts (larynx, pharynx, trachea, bronchus, and/or upper esophagus), with the malignancy often being detected concurrently. If the tumor is effectively treated, the eruption may resolve but may return with tumor recurrence. There is no known effective treatment for the cutaneous eruption, although corticosteroids and keratolytic agents have been used.

The significance of punctate palmar keratoses as a sign of internal malignancy is controversial,<sup>41</sup> although they have been reported in Cowden's syndrome. Similarly, the purported relationship between Bowen's disease (intraepidermal squamous cell carcinoma) and systemic cancer was recently demonstrated to be nonexistent.<sup>42</sup>

Patients with primary systemic amyloidosis almost always have an underlying plasma cell dyscrasia, usually multiple myeloma.<sup>43</sup> The skin takes on a generalized waxy appearance and bleeds easily when traumatized ("pinch purpura"). Hemorrhagic lesions are especially common around the eyes. Macroglossia is an associated finding. Skin lesions are not seen in secondary amyloidosis.

Scleromyxedema, a cutaneous mucinosis representing the generalized variant of lichen myxedematosus, has been associated with a peculiar serum monoclonal paraprotein.<sup>44,45</sup> The paraprotein is a basic, electrophoretically homogeneous 7S gammaglobulin, usually of the immunoglobulin-

lin (Ig)G class, that almost always possesses light chains of the lambda type. Clinically, the disorder appears as a generalized eruption of 2 to 3 mm waxy lichenoid papules, often in a linear arrangement; lesions are most common on the hands, elbows, forearms, upper trunk, face, and neck but may be found anywhere. Induration of the underlying tissue may produce a resemblance to scleroderma; mucin deposition in forehead skin may be disfiguring and lead to longitudinal furrowing somewhat reminiscent of leonine facies. No correlation appears to exist between levels of the paraprotein and the extent or progression of the skin disease. Only a minority of patients with scleromyxedema, lichen myxedematosus, or papular mucinosis will develop an overt myeloma or a detectable plasma cell dyscrasia. Affected patients should have a serum protein electrophoresis, immunofixation electrophoresis, and measurement of Ig levels; these tests should be repeated every 6 months. Therapy of these disorders has been difficult, and although there are reports of chemotherapy and radiotherapy, or stem cell transplants being effective in individual patients, no consistent response has been noted. In a recent report of several patients, the use of thalidomide was promising.<sup>46</sup>

Sweet's syndrome (acute febrile neutrophilic dermatosis) appears to be associated with leukemia or preleukemic conditions in roughly 25% of patients. Sweet's syndrome has been linked to a variety of malignancies, but the vast majority affect myeloid cells.<sup>47,48</sup> The condition is manifest by the acute onset of erythematous, tender, papules, plaques, or nodules on the face, extremities, and upper trunk (Figure 8). The surface appears vesicular and may be studded with pustules. Fever, malaise, and neutrophilia frequently accompany the cutaneous eruption. Biopsy of the skin lesion demonstrates a dense dermal neutrophilic infiltrate, without vasculitis, but recent reports have suggested that some vascular inflammation is possible. The presence of moderate to severe anemia may be helpful in distinguishing Sweet's syndrome associated with a myeloproliferative disease from the idiopathic

variant. Sweet's syndrome will respond to oral corticosteroids, but in a recent report, a patient with recalcitrant Sweet's syndrome and myelofibrosis was successfully treated with oral thalidomide.<sup>49</sup>

Pyoderma gangrenosum is a neutrophilic ulcerative dermatosis. Its superficial form, known as atypical or bullous pyoderma gangrenosum, often occurs on the head and neck and has been associated with hematologic malignancy.<sup>50</sup> Most often the association is with acute myelogenous leukemia, but several cases of chronic myelogenous leukemia, acute lymphoblastic leukemia, and preleukemic states, such as myelofibrosis or agnogenic myeloid metaplasia, have also been reported. The skin and blood disease often present concurrently and run a parallel course.

Classic pyoderma gangrenosum has been associated with a monoclonal gammopathy (and, occasionally, myeloma), with several solid tumors, and with non-Hodgkin's lymphoma. The gammopathy, which has been noted in up to 20% of patients with pyoderma gangrenosum, results from an IgA paraprotein. However, in patients with coexistent pyoderma gangrenosum and IgA paraproteinemia or myeloma, there is no information to suggest a parallel course.<sup>50a</sup>

A variety of blistering diseases have been reported in patients with cancer. Various forms of pemphigus have been associated with thymoma. The occurrence of paraneoplastic pemphigus in patients with cancer, especially lymphoreticular malignancy, is well documented.<sup>51-53</sup> The proposed association of bullous pemphigoid with malignancy probably reflects the tendency of both of these conditions to occur in the elderly rather than any true association. An increased incidence of malignancy has also been reported in the antiepiligrin variant of cicatricial pemphigoid (Figure 9).<sup>54</sup> Individuals with dermatitis herpetiformis may have an increased relative risk of intestinal lymphoma similar to that noted in patients with sprue.<sup>55</sup> Epidermolysis bullosa acquisita has also rarely been reported in patients with lymphoreticular tumors.

Approximately 10 to 30% of adult patients with dermatomyositis have an associated malignancy.<sup>56,57</sup> The neoplasm may occur before, during, or after the diagnosis of dermatomyositis. An awareness of this potential should alert the physician to carefully evaluate all dermatomyositis patients for malignancy. Pathognomonic clinical manifestations include an edematous, violaceous eruption of the upper eyelids (heliotrope rash) and atrophic scaly papules over bony prominences (Gottron's papules) (Figure 10); photosensitivity, malar erythema, poikiloderma, and periungual telangiectasias are important, although less specific, findings. Dermatomyositis is not specific for any particular site or cell type of cancer; however, in Western countries, ovarian and breast carcinoma in women and lung and prostate carcinoma in men are especially frequent. The risk of developing cancer is highest the first 3 years after the diagnosis of dermatomyositis.<sup>56,57</sup> Raynaud's phenomenon or a sclerodermatous change in an adult with dermatomyositis suggests an overlap syndrome; this variant is rarely associated with malignant disease. Childhood dermatomyositis is not associated with malignancy.

A number of musculoskeletal disorders have been reported in patients with cancer. Clubbing is noted in about 10% of individuals with lung cancer and tumors metastatic to the lung.<sup>58</sup> Subperiosteal new bone formation in patients with clubbing (hypertrophic osteoarthropathy) occurs most commonly along the shaft of the phalanges but may affect other bones as well.<sup>59</sup> Joint swelling, synovitis, periarticular swelling, hyperhidrosis, and palmar erythema may be pronounced and create a picture similar to early rheumatoid arthritis. Hypertrophic osteoarthropathy associated with acromegaloid features (pachydermoperiostosis) can occur either in association with lung cancer or as a genetic disease unassociated with malignancy.

A purported association between cutaneous leukocytoclastic vasculitis and cancer has never been proven, although numerous individual case

FIGURE 8 Sweet's syndrome.

FIGURE 9 Antiepiligrin bullous pemphigoid.

FIGURE 10 Dermatomyositis.

reports have related various vasculitic syndromes to malignancy, including solid tumors and lymphoproliferative disorders.<sup>60,61</sup> Interestingly, both cutaneous leukocytoclastic vasculitis and systemic necrotizing vasculitis have been observed in patients with hairy cell leukemia (leukemic reticuloendotheliosis). Often the patient with coexistent neoplastic disease has the malignancy at the time of diagnosis of the vasculitis. In other cases, release of tumor antigens into the circulation, such as after radiation therapy or chemotherapy, may be the inciting event. A parallel course between the tumor and the vasculitis has not been evident except in a few instances.

Migratory superficial thrombophlebitis and multiple deep venous thromboses have been noted in cancer patients, especially those with tumors arising in the pancreas, lung, stomach, prostate, or hematopoietic system.<sup>62</sup> The neck, chest, abdominal wall, pelvis, and limbs are most frequently affected.

The figurate erythemas may be divided into at least three groups. Erythema chronicum migrans follows a tick bite and may be associated with Lyme disease. Erythema annulare centrifugum may be secondary to a variety of causative factors, including, although rarely, malignancy. Erythema gyratum repens (Figure 11) is almost always associated with cancer,<sup>63</sup> although no one tumor type or site seems to predominate. Multiple wavy urticarial bands with a fine scale migrate over the cutaneous surface, giving it an appearance similar to the grain of wood. The eruption usually occurs within a few months before or after the diagnosis of cancer.

Generalized pruritus, ichthyosis, and exfoliative dermatitis are seen as nonspecific features of lymphoproliferative disorders<sup>64,65</sup>; uncommonly, they may be associated with solid tumors. Pityriasis rotunda may be a variant of acquired ichthyosis; the eruption consists of geometrically perfect, circular patches of scales. The disease was first reported in the Japanese, South African blacks, and West Indian blacks, in whom an associated neoplasm was occasionally described. A familial

variant has been recognized in Europe that does not appear to be associated with cancer.<sup>66</sup> Although the exact status of pityriasis rotunda as a paraneoplastic condition remains to be delineated, it seems prudent to rule out concurrent malignancy in affected patients.

Infectious disorders are frequent in cancer patients and may either be directly related to depressed cell-mediated immunity associated with the neoplasm or secondary to pharmacologic immunosuppression. The increased incidence of herpes zoster, either localized or disseminated, in patients with leukemia and lymphoma has been appreciated for years, although such infection usually develops during the course of the illness rather than as a presenting sign.<sup>67</sup> Rarely, herpes zoster may be associated with an underlying carcinoma.

Diffuse cutaneous and, rarely, mucosal hyperpigmentation may also occur in Cronkhite-Canada syndrome; other cutaneous features include onychodystrophy and alopecia.<sup>14</sup> Hamartomatous polyps occur throughout the stomach and intestines, and the incidence of gastrointestinal cancer is approximately 15%.<sup>14</sup> The disease occurs in adults in a sporadic, nongenetic manner. The prognosis is poor.

Granuloma annulare is a common benign skin disease characterized by flesh-colored to erythematous annular dermal plaques. A suggestion of a relationship between granuloma annulare and malignant lymphoma was reported in 13 patients in 1994<sup>68</sup>; however, a subsequent report by Li and colleagues demonstrated no increased risk of malignancy in patients with granuloma annulare.<sup>69</sup>

Extramammary Paget's disease is manifest as an erythematous plaque on locations other than the breast, most often in the inguinal fold, vulva, or scrotum (Figure 12). Malignancy is more common in these patients and is often in a location near the cutaneous lesion but not contiguous with it.<sup>70,71</sup> Therefore, patients with extramammary Paget's disease should be evaluated for possible tumors in the lower gastrointestinal tract

(colon and rectum) and in the lower portion of the genitourinary tract (bladder and prostate).

# Cutaneous Reactions to Medications

Steven R. Mays, MD  
Joy Kunishige, MD

Cutaneous drug reactions occur both with conventional medications and with chemotherapy agents. The classification of a particular drug rash is primarily based on the morphology and anatomic location of the rash. A drug rash may be maculopapular, for example, or present as acral erythema (erythema of the hands and feet). Sometimes the morphology of a drug rash is highly characteristic and the clinical diagnosis of drug reaction is made without difficulty. Some drug reactions, however, are not so clinically distinct, and the differential diagnosis may easily include other diseases (such as viral exanthems and cutaneous graft-versus-host disease). The first responsibility of the physician in these situations is to decide whether a particular rash does indeed represent a cutaneous reaction to a drug. Once this has been established, the next step is to decide which medication is the culprit. This two-step process requires a familiarity with the common morphologic types of drug reaction and knowledge of the drugs associated with each type. This chapter reviews the relevant data.

Cutaneous reactions to conventional medications are ?? uncommon. One exception is the maculopapular type of drug exanthem that occurs fairly frequently, especially with systemic antibiotics. Some *chemotherapy* reactions (eg, actinic keratosis [AK] recall) are also uncommon. However, some chemotherapy reactions are so common as to be an *expected* result of therapy. Sixty percent of patients receiving capecitabine, for example, develop hand-foot syndrome. A similarly high percentage of patients receiving cetuximab develop an acneiform eruption. In general, in the setting of a cancer hospital, adverse cutaneous reactions to chemotherapy are much more common than those to conventional (non-chemotherapy) medications. This chapter therefore reviews in detail the various types of cutaneous chemotherapy reactions. We review cutaneous reactions to conventional medications as they arise within the differential diagnosis for each particular chemotherapy exanthem.

A single chemotherapy agent may cause different types of reactions in different patients. For example, a particular agent may cause hand-foot syndrome in one patient and cutaneous hyperpigmentation in another.

Most cutaneous chemotherapy reactions are mild to moderate in severity; acneiform eruptions and onycholysis are examples. By contrast, severe cutaneous reactions to chemotherapy (such as a severe episode of hand-foot syndrome) may require changes in the scheduled administration of the responsible agent.

Cutaneous reactions to chemotherapy fall into two broad categories. **Specific** cutaneous reactions are those that occur almost exclusively with chemotherapy agents, but not with other medications. **Nonspecific** cutaneous reactions are caused both by conventional medications and by chemotherapy agents. In a patient with a **nonspecific** skin reaction, it may be difficult to determine whether the culprit was a chemotherapy agent or a conventional medication.<sup>1</sup>

## Cutaneous Reactions Specific to Chemotherapy

This group of unique reactions occurs only with chemotherapy agents and not with other medications. Examples include hand-foot syndrome and actinic keratosis recall.

Some specific reactions occur with only one or two chemotherapy agents, such as the flagellate cutaneous hyperpigmentation caused by bleomycin. Other specific reactions, such as the hand-foot syndrome, occur with many different chemotherapy agents.

In a patient affected by one of these characteristic reactions, the correct identification of the causative agent is fairly straightforward; this is because one may immediately exclude any nonchemotherapy medications as the cause.

The following sections review the most clinically significant reactions of this type.

### Hand-Foot Syndrome

#### Clinical

Hand Foot Syndrome (HFS) is a localized cutaneous response to certain chemotherapy agents. This reaction is also known as acral erythema, erythrodysesthesia syndrome. Characteristic findings are edema, erythema, and tenderness of

the hands and feet. Associated chemotherapy agents are listed in Table 1. The most commonly involved agents are cytarabine, doxorubicin, fluorouracil, and capecitabine.

HFS initially presents with a tingling sensation of the palms or soles, usually within 1 week of drug administration.<sup>2</sup> The patient then develops erythema of the palms and the volar aspect of the fingers; there may also be erythema of the dorsal aspect of the fingers (Figures 1 and 2). The feet may be similarly affected but usually to a lesser extent.<sup>3</sup> There may be edema of the hands, feet, and digits. Tenderness of the palms and soles ranges from mild to severe in intensity. Some patients develop tense blisters of the palms and soles (Figure 3). Occasionally, patients develop a concomitant maculopapular eruption at other sites, such as the wrists, ankles, extremities, or trunk.

HFS usually resolves 1 to 2 weeks after the cessation of chemotherapy. When an episode resolves, there may be impressive desquamation of the palms and soles.

Severe episodes of HFS are a fairly common dose-limiting toxicity for some chemotherapy agents and may necessitate discontinuation of the drug. Severe HFS is defined by the presence of cutaneous ulcerations, bullae, or pain that interferes with the activities of daily living.<sup>4</sup>

The incidence of HFS varies from one chemotherapeutic agent to another. Capecitabine is the agent most likely to cause HFS.<sup>4</sup> Approximately 60% of patients treated with capecitabine develop HFS.<sup>4-6</sup> For other agents, the incidence is much lower. The incidence of **severe** HFS with capecitabine, for example, is 10 to 17%.<sup>4,7-10</sup> Severe HFS is the most common dose-limiting toxicity for capecitabine and for other chemotherapy agents as well.<sup>11,12</sup>

The **first** episode of HFS usually occurs during one of the early cycles of administration of a chemotherapy agent. In a series of 41 patients treated with capecitabine, 93% had their first episode of HFS within the first two cycles.<sup>4</sup> However, the first episode of HFS may occur much later in the treatment phase with some chemotherapy agents.

\*Most commonly associated agents.

**FIGURE 1** Hand-foot syndrome owing to clofarabine.**FIGURE 2** Hand-foot syndrome owing to paclitaxel.**FIGURE 3** Hand-foot syndrome with bullae in a patient receiving clofarabine.

The most severe episode of HFS also usually occurs early in the treatment cycle. In the same series of patients treated with capecitabine, 68% had their most severe episode within the first two cycles.<sup>4</sup> However, 14% of the patients in the series had their most severe episode at the fourth cycle or later. By contrast, in a series of 76 patients treated with cytarabine and daunorubicin/doxorubicin, the recurrences were always milder.<sup>2</sup>

In summary, if a patient has a severe episode of HFS with a particular chemotherapy agent, it can be difficult to predict the severity of HFS with future cycles. Subsequent episodes may be similar in intensity, more severe, or less severe. These are important considerations when oncologists are administering those chemotherapy agents for which HFS is a dose-limiting toxicity.

HFS seems to occur more commonly with continuous administration of chemotherapy agents than with bolus infusions.<sup>4</sup> However, bolus infusions seem to be associated with more severe episodes of HFS and more rapid time to onset.<sup>3</sup>

### Diagnosis

The diagnosis is made clinically in a patient who develops erythema (with or without edema and tenderness) of the palms and soles during the week following administration of a chemotherapy agent associated with HFS.

The differential diagnosis for HFS includes acute cutaneous GVHD. In the post-bone marrow transplantation period, the use of immunosuppressive agents (such as cyclosporine) may limit the expression of acute GVHD to areas of predilection such as the hands and feet; affected patients may present only with erythema and tenderness (sometimes with bullae) of the palms and soles. In this setting, it may be difficult to distinguish between acute cutaneous GVHD and HFS caused by the preceding chemotherapy.<sup>13</sup> Evidence of GVHD at other sites may suggest that hand erythema in a particular patient is an expression of cutaneous GVHD. This evidence may include macular erythema at other sites of predilection (such as the face or ears), the onset of the exanthem at the time of marrow recovery, and/or the presence of signs or symptoms of systemic GVHD

(eg, elevated bilirubin and liver enzymes, diarrhea, abdominal pain). In addition, HFS is likely to resolve by the tenth day post-transplantation, whereas acute cutaneous GVHD is likely to persist well beyond this date.

The histology of HFS is not specific: it may reveal scattered necrotic keratinocytes, vacuolization of the basal layer, and a perivascular lymphocytic infiltrate. This histologic picture is similar to that of cutaneous GVHD.<sup>2</sup> Skin biopsies are not a reliable way of differentiating HFS from acute cutaneous GVHD, especially in the early stages of the two diseases.<sup>3,13</sup>

For those patients who have received only chemotherapy (and no bone marrow transplant), the diagnosis of HFS is usually straightforward. Conventional (nonchemotherapy) medications do not cause HFS. However, when two chemotherapy agents are coadministered, and both may cause HFS, the identification of the actual culprit may be difficult.

### Therapy

Treatment of mild to moderate HFS is usually unnecessary. Patients may obtain symptomatic relief with pain medications, cold compresses, and elevation (to reduce edema).<sup>3</sup>

However, patients may be unable to tolerate recurrent episodes of severe HFS owing to intense palmoplantar tenderness, sometimes accompanied by painful blisters. When evaluating patients with an acute, severe episode of HFS, we have not found that potent topical corticosteroids or 4% lidocaine cream give any significant symptomatic relief. It has been our experience that some patients with an acute and severe episode may get relief with systemic steroids; however, this is not a practical therapy for recurrent episodes, nor is it strongly supported by other authors.<sup>14-19</sup>

Treatment of severe HFS is better managed by attempts to prevent future severe recurrences. The most successful approach is probably dose reduction, sometimes accompanied by interruption of therapy.<sup>4</sup>

Severe episodes of HFS caused by 5-fluorouracil may be ameliorated by prophylaxis with pyridoxine 50 mg daily.<sup>12,20</sup> This may also be effective for patients receiving docetaxel.<sup>21</sup>

### Onycholysis and Other Nail Disorders

#### Onycholysis

Chemotherapy agents may cause various disorders of the fingernails and toenails. The particular nail disorder that has the highest associated morbidity is onycholysis.

Onycholysis is the separation of the nail plate from the underlying nail bed. It may affect one or more fingers or toes (Figure 4). In mild onycholysis, there is slight elevation of the distal nail plate from the nail bed; in severe disease, there is complete separation, with resultant loss of the nail plate. Onycholysis is the precursor to the more

**FIGURE 4** Distal onycholysis owing to docetaxel.

unpleasant chemotherapy-associated nail disorders, such as nail plate infections and fingertip cellulitis.

Anthracyclines and taxanes (especially docetaxel) are the chemotherapy agents most likely to cause onycholysis (Table 2). Twenty to 35% of patients treated with docetaxel, for example, develop onycholysis.<sup>22</sup> In one study of weekly paclitaxel, the mean time to onset of onycholysis was 12 weeks.<sup>23</sup> Nonchemotherapy agents, such as tetracycline and captopril, may also cause onycholysis, although rarely.<sup>24</sup>

The onset of onycholysis is probably not related to dose but rather to dose frequency and/or the number of doses. Two separate studies reported patients who did not develop onycholysis with paclitaxel administered every 3 weeks. However, the same patients did develop onycholysis when started on a weekly schedule (even at a lower dose).<sup>23,25,26</sup> Among patients receiving weekly paclitaxel, those who had received more infusions had a higher incidence of onycholysis.<sup>26–28</sup>

### Onycholysis and Nail Plate Infections

The space between the nail plate and the nail bed is the subungual zone. When onycholysis occurs,

**Table 2** Chemotherapy Agents Associated with Onycholysis

Onycholysis as a complication of systemic chemotherapy. *Cancer* 2000;88:2367–71; Chen GY, Chen YH, Hsu MM, et al. Onychomadesis and onycholysis associated with capecitabine. *Br J Dermatol* 2001;145:521–2.

this space enlarges, facilitating bacterial colonization or infection. Secondary *Pseudomonas aeruginosa* infections of the subungual area are very common in this patient population and are suggested by green coloration of the nail plate and subungual debris (Figure 5). These infections are often minimally bothersome to patients; the infection may be odoriferous and slightly tender but rarely produces fingertip cellulitis. Daily soaking of the affected digits in 50% acetic acid (white vinegar) is often adequate therapy. Silver sulfadiazine cream also has activity against *Pseudomonas*.<sup>29</sup> Bacterial swab culture of the subungual debris will yield sensitivities should oral antibiotics be necessary. Oral fluoroquinolones are often helpful. Trimming the nail as far back as possible to remove the habitat for bacterial growth under the nail is helpful. In our experience, these infections rarely clear with oral therapy only, and will require topical measures as well.

Some patients with onycholysis develop a low-grade subungual infection with *Staphylococcus aureus* that results in a steady, malodorous, subungual, purulent discharge from beneath one or more nail plates. There may be mixed infections with accompanying *Pseudomonas* or *Candida*. These infections usually respond well to acetic acid soaks and oral antibiotics (as determined by culture sensitivities). Occasionally, this condition may evolve into a more acute, loculated *S. aureus* subungual abscess. In these patients, the nail plate is elevated above a painful purulent subungual mass, often with a cellulitis of the affected fingertip.<sup>22,25,30</sup> Treatment of this condition involves sterile avulsion of the affected nail plate and administration of systemic antibiotics; neutropenic patients should be followed closely.

Patients with chronic onycholysis often develop subungual debris. Although this may clinically resemble a dermatophyte nail infection, potassium hydroxide specimens are usually negative and the patient does not have nail fungus.<sup>25,31</sup> However, we routinely perform potassium hydroxide smears on our affected patients as a small percentage of the specimens do demonstrate fungal hyphae.

**FIGURE 5** Onycholysis owing to paclitaxel, with secondary *Pseudomonas* infection.

Patients with onycholysis may also have subungual hemorrhages, which occur as the nail plate splits off from the nail bed.

### Other Nail Disorders

The most common nail disorder caused by chemotherapy is nail pigmentation.<sup>32</sup> This is of cosmetic concern only. The pigmentation may involve the nail plate or the nail bed; there may be patchy pigmentation, longitudinal bands, or transverse bands. The pigment may be blue, gray, brown, black, or white. Many chemotherapy agents cause nail pigmentation.<sup>3,32</sup>

Intense chemotherapy may temporarily arrest nail synthesis and cause a narrow transverse depression of the nail plate (Beau's line) (Figure 6).<sup>25</sup> The number of Beau's lines parallels the number of prior infusions. In extreme cases, there may be resultant loss of the nail plate.

### Actinis Keratosis Recall Phenomenon

#### Clinical

Certain chemotherapy agents will cause inflammation of preexisting subclinical actinic keratosis (AKs). Shortly after the administration of these agents, multiple AKs may spontaneously appear in areas of previous photodamage, such as the forearms. In addition, patients may experience intense inflammation of previously evident AKs.

AK recall occurs most often with 5-fluorouracil but may also occur with other agents (Table 3). In one series of seven patients (who were treated with a variety of chemotherapy agents), the time to onset of AK recall was 2 to 7 days.<sup>33</sup> Typically, there will be an eruption of red scaly papules in a photodistribution. This especially involves the face, exposed scalp, dorsal forearms, dorsal hands, and, to a lesser extent, the chest and upper back (Figure 7). The eruption may be itchy or tender. Occasionally, there may be severe inflammation in and around the keratoses, with large areas of tender erythema of the face, exposed scalp, and dorsal forearms.<sup>33–36</sup>

#### Diagnosis

This is usually a clinical diagnosis. The differential diagnosis may include lichenoid cutaneous

GVHD. The morphology of the skin lesions of lichenoid GVHD and AK recall may be similar; however, lichenoid GVHD is not usually confined to photodistributed areas. Skin biopsy will reliably separate the two conditions.

### Therapy

Patients with AK recall may have pruritus or tenderness of the affected areas. This generally responds well to topical corticosteroids: low potency (1% hydrocortisone or desonide cream) on the face and medium potency (triamcinolone cream or ointment) at other sites.<sup>3,33</sup> The occurrence of AK recall is not a contraindication to further administration of chemotherapy.<sup>3</sup> Patients with severe, painful AK recall may benefit from dose adjustment of subsequent infusions and from potent topical steroids.<sup>35</sup>

The AKs that occur in the recall phenomenon will generally persist indefinitely, long after the cessation of chemotherapy. Additional infusions of chemotherapy may lead to resolution of some of the AKs.<sup>3</sup> Following the cessation of chemotherapy, residual lesions may be treated with conventional measures, such as cryotherapy and 5-fluorouracil cream.

## Acneiform Eruptions

### Clinical

Epidermal growth factor receptor (EGFR) inhibitors may cause a striking acneiform eruption; these agents include cetuximab (Erbix), erlotinib (Tarceva), and gefitinib (Iressa). EGFR inhibitors are chronically administered oral and intravenous agents currently being evaluated for the treatment of various solid tumors, especially non–small cell lung cancer. Occasionally, methotrexate, cisplatinum, and actinomycin D may also cause an acneiform eruption.<sup>37</sup>

Affected patients develop an eruption over the face, back, chest, and shoulders, usually within 5 to 12 days of starting therapy.<sup>38,39</sup> This eruption is clinically identical to inflammatory acne, with pustules and red papules on a background of erythema (Figures 8–10). Usually, there are no acneiform comedones or cysts.<sup>39</sup>

Patients may be distressed by the cosmetic appearance of this eruption. Typically, the acneiform eruption persists throughout the course of EGFR inhibitor therapy. Affected patients may also develop a secondary *S. aureus* impetiginization of the affected areas on the face, with yellow and black crusting superimposed on the pustular eruption (Figure 11). This is partly due to the high rates of nasal colonization in hospital patients.

Of patients treated with EGFR inhibitors, more than 50% develop the acneiform eruption; many develop widespread very dry skin as well.<sup>39–41</sup>

**FIGURE 8** Acneiform eruption owing to erlotinib: facial pustules.**FIGURE 9** Acneiform eruption due to cetuximab: involvement of the scalp, face, and chest.**FIGURE 10** Acneiform eruption owing to cetuximab: pustules on the back.

### Diagnosis

The diagnosis is made clinically in a patient who develops a pustular eruption, in the characteristic distribution, 1 to 2 weeks after starting EGFR inhibitor therapy. Skin biopsies are usually not necessary for diagnosis. Histology is not specific and reveals a follicular infiltrate of lymphocytes, neutrophils, and histiocytes. There may be destruction of the follicle in more advanced lesions.<sup>38,42</sup>

At the initial evaluation of the patient, we unroof some of the pustules for bacterial culture and sensitivity to rule out a coexisting *S. aureus* folliculitis or impetigo.

**FIGURE 11** Cetuximab-induced acneiform eruption, with secondary *Staphylococcus aureus* infection.

The differential diagnosis includes steroid acne, which also presents with pustules and red papules on the upper trunk; it is less likely to involve the face, however. Bacterial folliculitis may present as perifollicular papules and pustules on a background of erythema as well; however, it is unlikely to have the exact same distribution as the EGFR inhibitor eruption. Miliaria pustulosa is also in the differential diagnosis.

#### Therapy

Most patients will have at least a fair improvement after 3 to 4 weeks of therapy with oral doxycycline or minocycline (100 mg daily to twice daily), along with the daily application of clindamycin lotion to the face. There have been no controlled studies on the treatment of this problem. Some of us do not use tretinoin cream or clindamycin gel/solution in this setting, as those agents may make the patient's skin wendrier. More impressive results occur with oral isotretinoin (10–40 mg daily), if approved by the referring oncologist.

Patients with superimposed bacterial impetiginization may have thick crusting of their facial skin that is painful for them to remove. In this circumstance, we often do an initial saline soak in clinic, followed by gentle débridement. The patient must then wash the face at least twice daily and apply liberal amounts of mupirocin cream, including to the nares. A course of oral antibiotics may also be necessary as directed by the result of the sensitivities.

### Radiation Enhancement

Certain chemotherapy agents enhance the effect of radiation therapy, both on the target tissue and on other exposed areas.<sup>43,44</sup> The increased effect on the tumor is intended and desirable. However, the synergistic effect of radiation therapy and chemotherapy may also involve other tissues in an undesirable manner. The most common side effect of radiation enhancement (RE) is radiation dermatitis; however, RE may also adversely involve the mucosa, lungs, heart, gastrointestinal tract, bladder, brain, and eyes.<sup>3,43</sup>

RE occurs when the chemotherapy and radiation therapy are administered within 1 week of each other.<sup>45,46</sup> Table 4 lists causative agents. An augmented radiation dermatitis develops within the irradiated field and may extend locally.<sup>3</sup> There is tender erythema, edema, vesicles, and erosions of the affected skin. In severe cases, there is cutaneous necrosis and ulceration. The dermatitis usually resolves spontaneously within days or weeks after cessation of the radiation therapy. There may be residual hyperpigmentation, depigmentation, and/or telangiectasias. In severe cases, there may be permanent cutaneous atrophy or fibrosis.<sup>3,43</sup>

The severity of RE is related to the drug dosage, the time sequence of radiation and chemotherapy, and the pharmacologic mechanism of the drug administered.<sup>43</sup> Radiation enhancement may occur with orthovoltage radiation, megavoltage radiation, and electron beam therapy.<sup>37</sup>

### Radiation Recall

Radiation recall (RR) is a phenomenon whereby the administration of a chemotherapy agent induces an inflammatory reaction in a previously quiescent radiation field. Radiation recall dermatitis is the most common type.<sup>47</sup> However, RR may also adversely affect the oral mucosa, lungs, esophagus, heart, and intestinal epithelia.<sup>3,43,45</sup>

Doxorubicin-cyclophosphamide
Fluorouracil-cisplatin

Adapted from Susser WS et al.<sup>3</sup>

Usually, patients receive the causative chemotherapy agent a few weeks or months after the radiation therapy and shortly thereafter develop RR dermatitis. Occasionally, the causative agent is administered years later and causes RR at that time.<sup>45</sup> In RR, the minimum period of time between radiation therapy and the administration of the causative agent is 7 days (this distinguishes RR from RE).<sup>45</sup>

RR dermatitis develops in the previously radiated field within hours or days of administration of subsequent chemotherapy.<sup>45</sup> The onset is slower for oral administration than for intravenous administration. Patients develop red macules or plaques that may be painful. The dermatitis is well defined and corresponds exactly to the site of previous irradiation (Figure 12). There may be vesicles, erosions, and, occasionally, ulcerations.<sup>3</sup> Most affected patients had **not** originally experienced acute radiation dermatitis in the involved site at the initial time of radiation therapy.<sup>45</sup>

The differential diagnosis for RR dermatitis includes bacterial cellulitis (especially), early shingles, and cutaneous metastases. The correct diagnosis may initially be difficult for the clinician as some time may have elapsed since the patient received radiation at the involved site.<sup>44</sup>

RR dermatitis resolves spontaneously hours to weeks after the cessation of chemotherapy. It sometimes clears despite continued administration of the agent.<sup>3,45</sup>

The chemotherapy agents most likely to cause RR are doxorubicin, daunorubicin, docetaxel, and paclitaxel. Table 5 lists other associated agents. Rarely, rifampin, isoniazid, and pyrazinamide can cause RR.<sup>48</sup> The recall induced by gemcitabine (unlike other chemotherapy agents) is more likely to involve internal organs rather than the skin.<sup>47</sup>

In the postradiation period, RR usually occurs with the first administration of the causative chemotherapy agent.<sup>45</sup> Drug rechallenge usually causes either mild recurrence of recall or no recurrence.<sup>44</sup>

The severity of RR dermatitis is probably related to (1) the dose of radiation initially

received and (2) the time period between the radiation and the chemotherapy. Severe RR dermatitis is more likely to occur when that time period is short.<sup>3,45</sup> The radiation dose necessary to induce RR dermatitis when the drug is given weeks after radiation therapy may be inadequate to induce it were the drug to be given months later.

### Sunburn Recall

This is an unusual chemotherapy reaction usually caused by methotrexate. Administration of methotrexate to a predisposed patient in the period following sunburn leads to worsening or reactivation of the sunburn. This reaction occurs when methotrexate is administered from day 2 through day 7 after the sunburn (ie, in the subsiding phase of the burn). Patients develop tender erythema and edema (sometimes with vesicles) of the previously sunburned skin.<sup>49,50</sup> Severe reactions may progress to intense blistering and desquamation. The reaction gradually subsides over the following week.<sup>3</sup> Administration of a second dose of methotrexate sometimes leads to further worsening of the recall phenomenon.<sup>50</sup>

Sunburn recall does not occur when methotrexate is administered on the day of the sunburn or when administered more than 1 week after the burn. In general, if an affected patient receives another sunburn, the subsequent administration

of methotrexate should be held for at least 7 days.

Sunburn recall has occurred with methotrexate administered orally, intramuscularly, and intravenously.<sup>49–51</sup> Other occasional causes of sunburn recall are suramin, paclitaxel, and etoposide/cyclophosphamide.<sup>3,52</sup> Rarely, oral antibiotics (such as ciprofloxacin) induce sunburn recall.<sup>52</sup>

### Cutaneous Hyperpigmentation

Hyperpigmentation is a common cutaneous side effect of chemotherapy agents and has been reviewed at length.<sup>3,53</sup> Skin, hair, nails, and oral mucosa may all be affected. There are many different reaction patterns of cutaneous hyperpigmentation: photodistributed; pressure accentuated; under occluded areas; widespread (which may resemble Addison's disease); and patches in areas of predilection (such as the palms or soles).<sup>37</sup> An individual chemotherapy agent is often associated with a single type of reaction pattern.

Most chemotherapy agents have the ability to induce some form of hyperpigmentation. The pigmentation may persist long after cessation of the agent. Alkylating agents and antitumor antibiotics are the agents most likely to cause cutaneous hyperpigmentation.<sup>43</sup> Four particularly characteristic patterns are described below.

Bleomycin may induce narrow linear red streaks (flagellate hyperpigmentation) in areas of trauma, especially on the trunk and proximal extremities (Figure 13). This may be quite itchy; it occurs in at least 10% of treated patients.<sup>3,37</sup>

Fluorouracil may induce hyperpigmented serpentine streaks over the arm veins used for intravenous infusion (serpentine supravenuous hyperpigmentation). These streaks may extend proximally to the shoulder. This reaction can also occur with vinorelbine, fotemustine, and some multidrug regimens.<sup>3,37</sup>

Thiotepa may cause sharply circumscribed hyperpigmentation under occluded areas, such as bandages, and in intertriginous areas, such as the axillae (Figure 14).<sup>3,54</sup>

**FIGURE 13** Flagellate hyperpigmentation owing to bleomycin.

**FIGURE 14** Hyperpigmentation of intertriginous areas owing to thiotepa.

Busulfan may cause a diffuse brown or bronze hyperpigmentation (busulfan tan) over the face, neck, chest, abdomen, forearms, and palmar creases. This may clinically resemble Addison's disease.<sup>3,55</sup>

### Nonspecific Chemotherapy Reactions

Nonspecific reactions are those that are caused by both conventional medications and chemotherapy agents. Certain chemotherapy agents and conventional medications may, for example, produce clinically indistinguishable maculopapular eruptions. In a patient with a nonspecific skin reaction, it may be difficult to determine whether the culprit was a chemotherapy agent or a conventional medication. The correct identification of the single causative agent will be even more problematic.<sup>1</sup>

Nonspecific reactions include maculopapular eruptions, erythema multiforme, urticaria, anaphylaxis, and Stevens-Johnson syndrome toxic epidermal necrolysis.

The oncology literature often refers to these reactions collectively as hypersensitivity reactions, with a corresponding attempt to classify each as type 1, 2, 3, or 4. However, in many cases, the immunologic mechanism is unknown. In addition, the various types of chemotherapy/drug reactions in this group are clinically quite distinct from each other. We therefore prefer to classify these reactions by their clinical names: urticarial, SJS, maculopapular, etc.

### Maculopapular Eruptions

Maculopapular eruptions are usually a clinically trivial side effect of chemotherapy; this is probably why the literature on this subject is slim. In our experience, these eruptions are fairly common and can probably occur with most chemotherapy agents. Associated agents include etoposide, chlorambucil, procarbazine, 5-fluorouracil, melphalan, and hydroxyurea.<sup>1,56–58</sup>

Current knowledge about maculopapular drug exanthems derives mainly from experience

with conventional medications. Table 6 lists those conventional medications most likely to cause a maculopapular drug exanthem.

### Clinical

Maculopapular drug eruptions usually appear within 1 to 2 weeks of starting a new drug. Reexposure to a previous offender, however, can trigger the reaction in 1 to 2 days. Occasionally, a patient may develop a maculopapular eruption up to 1 week after discontinuing a medication.

The skin lesions are clustered pink or red macules or papules or both. Sometimes the skin lesions are edematous and appear to be urticarial. The eruption begins on the trunk and subsequently involves the proximal extremities and neck (Figure 15). It often spares the face and the dorsal aspects of the hands and feet. Occasionally, the eruption progresses to involve the entire cutaneous surface, and the skin lesions may become confluent. The most common complaint is pruritus. Patients often have a low-grade fever. There are no associated mucosal erosions and no cutaneous blisters; the presence of these features should elicit clinical suspicion instead for the Stevens-Johnson Syndrome.

In thrombocytopenic patients, the skin lesions may appear intensely purpuric, especially on the lower legs; this may prompt clinical consideration of a cutaneous small vessel vasculitis (Figure 16). Skin biopsy can reliably differentiate between these two entities.

A maculopapular drug eruption may take up to 2 weeks to resolve following discontinuation of the correct offending agent. In a patient who is receiving multiple medications, this delay in response may make it difficult to correctly identify the causative agent.

Thiazides

Adapted from Nigen S et al.<sup>83</sup>

**FIGURE 15** Maculopapular drug exanthem due to cephalexin.

**FIGURE 16** Chemotherapy-induced maculopapular eruption with purpura.

If the patient continues to receive the causative agent, the eruption may persist without further change. This may or may not be tolerable to the patient, depending on the severity of the pruritus. In some patients, the eruption will spontaneously resolve despite continued exposure to the medication. On the other hand, a maculopapular drug eruption will occasionally evolve into exfoliative erythroderma, which certainly necessitates discontinuation of the causative agent.<sup>57,59</sup> It is not definitively known whether maculopapular drug reactions may evolve into Stevens-Johnson Syndrome or Toxic Epidermal Necrolysis.<sup>59</sup>

### Diagnosis

The approach to the patient with a maculopapular eruption and fever begins with two questions: Does the patient have a drug reaction? If so, which drug is the responsible agent?

In the setting of a cancer hospital, the differential diagnosis may include acute cutaneous GVHD. The cutaneous presentation of maculopapular drug/chemotherapy reactions and cutaneous GVHD may be extremely similar; skin biopsy may not be helpful diagnostically. The diagnosis of acute cutaneous GVHD may be suggested by the presence of signs or symptoms of systemic GVHD (eg, elevated bilirubin and liver enzymes, diarrhea, abdominal pain).

The differential diagnosis also includes viral exanthems. These may be more likely than drug eruptions to start on the head and progress caudally and to display lymphadenopathy and a higher fever.<sup>57</sup> In the absence of suggestive clinical evidence, a drug etiology is favored in adult patients.<sup>59</sup> One rare type of drug reaction may, however, clinically simulate a viral exanthem; DRESS (drug reaction with eosinophilia and systemic signs) is most commonly caused by Dilantin and was previously known in that setting as Dilantin hypersensitivity syndrome.

Early Stevens-Johnson Syndrome (SJS) is also in the differential diagnosis for a maculopapular drug/chemotherapy reaction. The patient almost certainly has only an uncomplicated maculopapular eruption, rather than SJS, if he does not develop mucosal erosions or cutaneous blisters within the first few days of presentation.

Once the diagnosis of drug reaction is reached, an attempt can then be made to identify the probable causative agent. The creation of a drug calendar (Figure 17) is helpful. A patient may receive a new medication or chemotherapy agent for up to 2 weeks before developing a maculopapular eruption; therefore, the time span of the calendar should be at least that long.

Certain drugs (such as acetaminophen and digoxin) almost never cause drug eruptions and can be quickly excluded as candidates.<sup>60</sup> One can then attempt to classify the remaining drugs as a likely or unlikely cause based on the following: (1) time relative to the onset of the rash, (2) information regarding a specific agent from drug databases, (3) experience with other drugs from the same pharmacologic class, and (4) the patient's previous known drug allergies.

Sometimes this process leads to the identification of only one possible causative agent. However, it is often impossible to narrow the field to fewer than two or three highly probable agents. In some cases, it may be impossible to decide whether the eruption was caused by a chemotherapy agent or by a conventional medication.

### Therapy

Withdrawal of the causative agent will usually lead to resolution of the eruption within 2 weeks. Discontinuation is not necessarily mandatory if the drug reaction shows no sign of dangerous

progression and if the patient does not have intolerable pruritus. Obviously, in this scenario, the evolution of the rash should be closely monitored.<sup>59</sup>

Minor pruritus may be alleviated by twice-daily application of triamcinolone 0.1% cream to the affected areas, as well as scheduled dosing of oral hydroxyzine or doxepin (titrated to avoid excessive sedation). In more severe cases, twice-daily topical steroid wet wraps, left in place for 45 minutes, can give considerable relief. Occasionally, systemic steroids are warranted.

### Anaphylaxis and Urticaria

Anaphylaxis is a potentially life-threatening reaction that occurs within minutes of exposure to a foreign antigen. Respiratory distress and/or vascular collapse may lead to death. Anaphylaxis is a type I hypersensitivity reaction that involves the activation by a foreign antigen of immunoglobulin E bound to mast cells and basophils, with the subsequent release of inflammatory mediators. Responsible agents include drugs, chemotherapy agents, hormones, local anesthetics, and insect venom.<sup>61</sup>

Anaphylactoid reactions are clinically indistinguishable from anaphylaxis. Agents involved

in anaphylactoid reactions do not incite type I hypersensitivity but probably instead directly cause mast cell degranulation.

The diagnosis of anaphylaxis or anaphylactoid reaction requires the presence of at least one of the following: bronchial obstruction, upper airway obstruction, or acute hypotension. The spectrum of findings may include any of the following: urticaria, angioedema, flushing; laryngeal edema and bronchospasm with dyspnea and wheezing; diarrhea and vomiting; and vascular collapse with hypotension and tachycardia.<sup>61</sup>

Chemotherapy agents associated with these reactions are listed in Table 7. The most commonly Ruana involved agents are asparaginase, docetaxel, paclitaxel, and etoposide.<sup>62</sup>

Because anaphylaxis is a type I hypersensitivity reaction, it usually first occurs after repeated infusions of a chemotherapy agent. This is true of asparaginase, for example.<sup>62</sup>

Anaphylactoid reactions may involve direct mast cell degranulation and often occur with the first exposure to the agent; paclitaxel and docetaxel are examples of this process.<sup>62</sup>

Anaphylaxis usually occurs with intravenous administration of chemotherapy but may occasionally occur with oral administration.<sup>1</sup>

Weiss RB, Donehower RC, Wiernik PH.  
Hypersensitivity reactions from Taxol. J Clin Oncol  
1990;8:1263-8.

Intravesicle administration of cisplatinum may be as likely to cause anaphylaxis as intravenous infusion.<sup>1</sup>

Prophylactic regimens and desensitization protocols may be effective at preventing or minimizing further episodes of anaphylaxis for some chemotherapy agents but not for others.<sup>1,62</sup>

Some chemotherapy agents may cause isolated urticaria in the absence of other clinical findings.<sup>1,63</sup> However, the appearance of isolated urticaria (or other suggestive signs) *during infusion* may herald the onset of anaphylaxis; in that case, the infusion should be discontinued and supportive measures considered.<sup>62</sup>

### Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

TEN is a severe mucocutaneous drug reaction. Affected patients may experience erosive damage to their oral mucosa and lips and slough off large portions of their skin.

SJS can be considered a milder form of TEN, although the exact definition depends on the reference. There is severe mucous membrane involvement and less skin damage.

TEN and SJS likely represent two ends of a spectrum of a severe mucocutaneous drug reaction.<sup>64</sup> We refer to these two entities collectively as SJS-TEN. In some patients, SJS may evolve into TEN.<sup>57</sup>

TEN has an annual incidence of 0.4 to 1.2 per million persons, whereas SJS has an incidence of 1.2 to 6 per million.<sup>64</sup> SJS and TEN are best thought of as drug reactions (with an occasional case reportedly caused by vaccinations or infections).<sup>65</sup> Table 8 lists those drugs that are commonly associated with SJS-TEN. The most common offenders are anticonvulsants, nonsteroidal anti-inflammatory drugs, and antibacterial sulfonamides. Allopurinol and antimalarials follow a close second.<sup>65</sup>

**Table 8** Medications Commonly Associated with Stevens-Johnson Syndrome–Toxic Epidermal Necrolysis

Allopurinol
Amathiazone
Amoxicillin

Sulfamethoxazole-trimethoprim
Sulfasalazine
Valproic acid

Adapted from Nigen S et al.<sup>83</sup>

Chemotherapy agents also occasionally cause SJS-TEN. Table 9 lists those chemotherapy agents that were identified as the cause in published case reports. For most of these agents, there are only one or two reports of an associated SJS-TEN. The occurrence of SJS-TEN in the setting of chemotherapy is probably highly idiosyncratic. Most of our knowledge about SJS-TEN derives from cases caused by conventional medications.

### Clinical

SJS-TEN usually occurs 7 to 21 days after the first exposure to the culprit medication. In a review of

**Table 9** Chemotherapy Agents that Have Caused One or More Episodes of Stevens-Johnson Syndrome–Toxic Epidermal Necrolysis

Asparaginase
Bleomycin
Chlorambucil
Cytarabine
Docetaxel
Doxorubicin
Etoposide
Fludarabine
Gemcitabine with radiation therapy
Imatinib mesylate
Interleukin-2
Methotrexate
Mithramycin
Rituximab
Suramin
Thalidomide

Stevens-Johnson syndrome after treatment with rituximab. *Ann Oncol* 2002;13:1948–50.

69 cases of TEN, 78% occurred within 3 weeks of exposure.<sup>66</sup> However, patients may take phenytoin for up to 8 weeks before the onset of SJS-TEN.<sup>57</sup>

Reexposure to an offending medication often results in the onset of SJS-TEN within 48 hours.<sup>64</sup>

In 16 case reports of chemotherapy-associated SJS-TEN, the onset occurred during the first cycle in 56% of cases, during the second cycle in 19% of cases, and during the third cycle in 25% of cases. Of those episodes of SJS-TEN that occurred during the first cycle, the majority (7 of 9, or 78%) occurred 2 to 8 days after the first dose of chemotherapy.<sup>67–82</sup>

A febrile prodrome precedes the onset of cutaneous features by 1 to 14 days. Typical features are nausea, vomiting, headache, sore throat, diarrhea, and myalgias.<sup>65,83</sup> Subsequently, there is the abrupt appearance of painful red macules on the trunk and subsequently on the neck, face, and proximal extremities. The skin lesions become dusky or gray, and often coalesce to form large patches. Fragile blisters start to form within the patches; the necrotic blister roofs then slide off, leaving behind large areas of raw and bleeding dermis (Figures 18 and 19).<sup>64</sup>

Measurement of the detached and detachable epidermis allows classification of the patient into one of three groups:

**FIGURE 18** Toxic epidermal necrolysis: intact bullae and widespread erosions.**FIGURE 19** Toxic epidermal necrosis: intact bullae and large erosion.

- SJS <10% of body surface area (BSA)
- TEN >30% of BSA
- SJS-TEN overlap 10–30% of BSA<sup>64</sup>

Almost all patients with SJS-TEN have oral mucosal disease that may either accompany the onset of skin involvement or precede it by a few days. Patients initially report burning of the buccal mucosa, lips, and sometimes the conjunctiva. Oral mucosal blisters develop and quickly rupture to leave painful erosions on the buccal mucosa; sometimes also on the gingiva, tongue, pharynx, and nasal cavity. Hemorrhagic crusts cover the lips (Figure 20).<sup>65</sup> At this point, most patients are unable to eat or drink.

In the patient with suspected chemotherapy-induced SJS-TEN, it may initially be difficult to differentiate between routine chemotherapy-induced mucositis and the oral mucosal changes of SJS-TEN.

Erosive involvement of the conjunctiva and cornea is fairly common in patients with SJS-TEN. There may also be painful involvement of other mucosal surfaces, such as the genitals, anus, esophagus, nose, and bronchi. Mucous plugs and respiratory obstruction occasionally occur.

### Course and Complications

The initial active phase of SJS-TEN includes persistent fever, the formation of mucocutaneous blisters, and the progressive shedding of the oral mucosa and skin. This active phase is complete when the maximum BSA involvement has been reached and no new blisters are appearing. If the offending drug has been discontinued, the active phase lasts for approximately 5 days.<sup>65</sup> Reepithelialization of the denuded skin then occurs over the following 2 to 3 weeks.

During the period in which large cutaneous erosions are present, massive infection of the skin may occur, with subsequent bacteremia or fungemia. *S. aureus* and *Pseudomonas* are the main causative organisms and *Candida albicans* to a lesser extent. Pneumonia and infections of intravenous and urinary tract catheters may occur.<sup>57</sup>

**FIGURE 20** Toxic epidermal necrosis: crusting and erosions of the lips.

During this same period, dehydration and electrolyte abnormalities may also occur.

### Prognosis

For nonchemotherapy medications, the mortality rate of SJS is 5% and of TEN is 30%; the most common direct cause of death is infection.<sup>64,83</sup> The extent of epidermal detachment is a major prognostic factor.<sup>83</sup> Prompt withdrawal of the offending drug reduces the risk of mortality by 30% per day.<sup>64</sup>

The mortality rate for chemotherapy-induced SJS-TEN is unknown. In 10 case reports of chemotherapy-induced TEN, the cause of death was TEN related in 40%.<sup>67,69,71–74,76,77,79,80</sup> It would seem likely that chemotherapy-induced TEN has a higher mortality rate given that many of the affected patients are neutropenic and are at a greater risk of infection.

### Diagnosis

The clinical presentation of an established case of SJS-TEN is characteristic. The patient has fever; painful oral mucositis; hemorrhagic crusts on the lips; painful red macules and patches, especially on the trunk; fragile blisters; and large cutaneous erosions. This presentation often occurs within 7 to 21 days of receiving a drug that is associated with SJS-TEN.

The vigilant physician, however, may suspect the diagnosis of SJS-TEN before the full evolution has occurred. If a patient presents with an early morbilliform eruption and reports any tenderness of the oral mucosa or skin, the possibility of SJS-TEN should be considered. Some patients with early disease may present with painful red macules on the palms and soles.

The use of a drug calendar (see Figure 17) may be helpful in correctly identifying the causative medication. In general, most drugs that cause SJS-TEN have been first administered 1 to 3 weeks prior to the onset of the reaction. However, SJS-TEN may occur within 48 hours of reexposure to a previously offending medication.<sup>57</sup> A review of the literature may also point to those drugs that are frequently associated with SJS-TEN, and those that are not.

A medication is unlikely to be responsible for SJS-TEN if it was first given 24 hours previously or if the duration of treatment exceeds 3 weeks. An exception to this is with anticonvulsants (especially phenytoin), which may take up to 8 weeks to cause SJS-TEN.<sup>57</sup>

In general, the medication lists of patients with SJS-TEN should be reduced to a minimum and appropriate substitutions made.<sup>64</sup>

### Differential Diagnosis

The most important disease to rule out in the initial evaluation of a patient with possible SJS-TEN

is staphylococcal scalded skin syndrome (SSSS); this is because the respective therapies for each of these two diseases are very different. Patients with both disorders may have widespread tender cutaneous erosions. The erosions in SSSS are more superficial, however, “leaving a bed of intact epidermal layers instead of the wet and bright red tissue of TEN.”<sup>64</sup> In addition, patients with SSSS do not have oral mucosal involvement. We always perform skin biopsy for frozen section in our cancer patients with possible SJS-TEN; the results are available in a few hours. Frozen section reliably differentiates between SSSS (intraepidermal split) and SJS-TEN (subepidermal split). Some clinicians feel that they can reliably distinguish the two disorders without a biopsy based on the thickness of the sloughing skin and clinical appearance.

Grade IV (severe) acute cutaneous GVHD may strongly resemble SJS-TEN both clinically and histologically. It may be almost impossible to differentiate between these two disorders.<sup>72</sup>

Acute generalized exanthematous pustulosis (AGEP) is a pustular drug eruption. Affected patients have widespread areas of erythema studded with fragile micropustules.<sup>83</sup> Twenty percent of patients have oral mucosal involvement. Skin biopsy of AGEP shows a dense neutrophilic infiltrate with intraepidermal and subcorneal pustules; that of SJS-TEN reveals a necrotic epidermis, a subepidermal split, and a scant inflammatory infiltrate.

Also in the clinical differential diagnosis for SJS-TEN are paraneoplastic pemphigus and drug-induced linear immunoglobulin A disease (particularly associated with vancomycin). These diseases may be suspected when the clinical course of the supposed SJS-TEN seems unusual, for example, a very prolonged course with persistent blistering. Skin biopsy for histology and direct immunofluorescence reliably differentiate between these three diseases.

### Phototoxic Reactions

In some patients, the administration of certain drugs causes cutaneous sensitization to ultraviolet (UV) light. Subsequent exposure to UV light causes exaggerated sunburn. There is tender erythema and edema, sometimes with vesicles, in a photodistribution; the typical clinical course of a sunburn follows. Light-protected areas (such as the submental area) and areas covered by clothing are spared.<sup>84</sup>

Phototoxic reactions occur when the patient receives the photosensitizing medication and is exposed to UV light within the following 12 hours. (Sunburn recall is a different phenomenon, in which administration of a medication up to 1 week after UV exposure causes sunburn.)

Offending chemotherapy agents include dacarbazine, fluorouracil, tegafur, and vinblastine.<sup>3,85</sup> Other causative medications include furosemide, thiazide diuretics, phenothiazines, quinolones, sulfonamides, tetracyclines, and tricyclic antidepressants.<sup>84</sup>

Phototoxicity is the result of direct tissue injury caused by the phototoxic agent in conjunction with UV light.<sup>84</sup> (These are not hypersensitivity reactions.) Phototoxic reactions are probably dose dependent.<sup>86</sup> The amount of light necessary to cause a phototoxic reaction may be very low. Theoretically, a phototoxic reaction may occur in any individual exposed to the combination of adequate doses of the agent and the appropriate wavelength of light. UVA light causes most phototoxic reactions.<sup>84</sup>

# Orbital Cellulitis

Dominick I. Golio, MD  
Dan S. Gombos, MD, FACS

Orbital cellulitis is a sight- and potentially life-threatening periocular infection. In the cancer patient, early diagnosis and intervention are necessary to avoid secondary complications and negative sequelae. This chapter reviews the clinical features of periocular cellulitis, with an emphasis on rapid diagnosis, workup, and appropriate initiation of antimicrobial therapy.

## Presentation

It is useful to distinguish preseptal cellulitis from postseptal disease. In preseptal cellulitis, clinical findings are confined to tissues anterior to the orbital septum. Patients have good central vision, normal ocular motility, and no evidence of pupil or optic nerve abnormalities. Patients with orbital infections (postseptal cellulitis) have more advanced disease, with associated blurry vision, proptosis, and limitation of ocular motility. Abnormalities of the optic nerve or pupillary response can be a harbinger of vision that is potentially threatened.<sup>1,2</sup>

## Initial Examination

Patients who develop periocular swelling or injection should have an immediate and thorough ophthalmic assessment. This includes measurement of visual acuity, motility, pupillary response, and color vision and a dilated fundoscopic examination. Baseline photographs should be obtained of the periocular structures documenting the extent of the swelling and inflammation (Figure 1). Any proptosis should be measured using an exophthalmometer.

**FIGURE 1** Left periorbital cellulitis with associated ptosis, chemosis, and injection.

A careful history should be obtained reviewing the onset of symptoms and time course of visual complaints. In the cancer patient, it is important to review the current status of the underlying malignancy and any recent treatment, such as chemo- or radiotherapy. This should include a risk assessment for specific infectious etiologies (eg, neutropenia, recent surgery, central line placement). Once the diagnosis is entertained, a baseline computed tomographic (CT) scan of the orbits and sinuses is obtained, with contrast, thin cuts, and true axial and coronal images. Careful attention must be directed toward the intra- and extraconal space looking for signs of orbital abscesses or associated sinusitis (Figures 2 and 3).<sup>3-5</sup>

## Empiric Therapy

In practice, patients with isolated preseptal cellulitis who are in remission of their malignancy with no associated sinusitis can be treated in an outpatient setting with oral antibiotics such as amoxicillin-clavulanate or cefaclor. Close serial observation is necessary to ensure that the periocular findings are responding to treatment.

Patients with concurrent neoplastic disease, neutropenia, recent chemotherapy, and/or a history of bone marrow transplantation are at risk of a broad spectrum of orbital and sinus infections. These patients should be admitted

**FIGURE 3** Computed tomographic scan of the patient in Figure 1 demonstrating proptosis and adjacent ethmoidal sinusitis.

for empiric intravenous therapy. In the immunocompetent patient, *Staphylococcus aureus*, *Escherichia coli*, and *Streptococcus pneumoniae* are the most common organisms of concern. In the cancer patient, other organisms must also be entertained, including *Pseudomonas*, *Klebsiella*, and methicillin-resistant *S. aureus*. Prompt initiation of broad-spectrum intravenous antibiotics is indicated in most patients. A third- or

**FIGURE 2** A, External photograph of a 4-year-old boy with acute myelogenous leukemia and an anterior orbital abscess. B, Axial computed tomographic scan of the same patient demonstrates the radiographic appearance of the abscess.

fourth-generation cephalosporin (such as ceftriaxone or cefepime) or a carbapenem (such as imipenem) is generally indicated. Vancomycin is also administered to provide appropriate staphylococcus coverage. Individually, each patient should be assessed for the possibility of other rare infections. For example, those patients at risk of anaerobic organisms are also administered metronidazole.<sup>1-4</sup>

### Fungal Cellulitis

Cancer patients and those with a history of bone marrow transplantation are at particular risk of disseminated fungal infection. Potential organisms include *Aspergillus* and *Mucor*. These cases can present with fulminant sinusitis and rapid progression of disease in the orbit extending into adjacent structures (including the central nervous system). A biopsy of tissue may be helpful in confirming the diagnosis. In many cases, associated sinusitis can be assessed by the otorhinolaryngologist with débridement and identification of the offending organism.

When suspicion of a fungal cellulitis is made, a multidisciplinary approach works best. Involvement of infectious disease experts is helpful in selecting empiric antifungal coverage, such as liposomal amphotericin B, caspofungin, and/or voriconazole. Traditionally, fungal sinusitis with organisms such as *Mucor* appear in ketoacidotic diabetic patients. One approach is aggressive débridement owing to the fulminant nature of this disease entity. In the cancer setting, particularly among neutropenic and bone marrow transplant patients, a less surgically radical approach is preferred. The otorhinolaryngologist may perform minimal débridement of adjacent paranasal structures. Infectious disease services are consulted regarding the best selection of empiric antifungal agents. This is reviewed in light of the patient's overall systemic situation (ie, renal and hepatic function). Finally, underlying immunosuppression is addressed with granulocyte-stimulating factors.

### Follow-Up

Once treatment is initiated, close serial observation is necessary. Generally, frequent ophthalmic examination is recommended to review the patient's visual acuity, motility, and other ocular findings. External photographs can be helpful in documenting a response to therapy (Figure 4).

**FIGURE 4** Serial external photographs demonstrating resolution of orbital cellulitis in a patient with cutaneous melanoma.

Those who respond well can be discharged from the hospital on oral antibiotics such as amoxicillin-clavulanate or cefaclor. Serial CT can be performed in 3- to 4-day intervals if the clinical findings worsen. Progressive disease and a decline in vision or ocular motility should initiate repeat neuroimaging and a reassessment of any likely pathogens not adequately covered by empiric treatment. A punch biopsy or viral swab of the skin can augment cultures obtained from the blood. An alternative diagnosis should also be entertained (see Masquerade Syndromes).

### Surgical Intervention

Identification of an abscess on CT is generally an indication for incision and drainage. Those localized to the lid may be drained with a simple skin incision. More posterior lesions will require orbital surgery. Lesions close to or associated with significant sinusitis can be drained via an ethmoidal or maxillary approach. Tissue that is grossly necrotic should be débrided and sent for fungal stains and culture. Orbital decompression may be necessary in cases in which the optic nerve is compromised secondary to periocular edema. Severe pancytopenia may affect the timing and indications for surgical intervention.

### Masquerade Syndromes

In some cases, patients respond poorly to initial therapy and alternative diagnoses must be

entertained. Metastatic disease to the orbit can mimic orbital cellulitis. When the diagnosis is in question, an orbital biopsy should be considered. Other entities can also simulate an infection. These include secondary inflammation following radiation therapy, toxic and allergic reactions to medications, orbital inflammatory syndrome, thyroid eye disease, and, rarely, carotid cavernous sinus fistulae.

### Conclusion

Orbital cellulitis in the cancer patient can be a serious and life-threatening infection. Patients should be rapidly worked up with neuroimaging and baseline ophthalmic assessment. Treatment should be initiated with empiric broad-spectrum antimicrobials. The complex nature of these cases often lends itself to a multidisciplinary approach with contributions from ophthalmology, infectious disease, and otorhinolaryngology services.

# Endogenous Endophthalmitis

Dan S. Gombos, MD, FACS

Clinically, endophthalmitis refers to inflammation of the eye associated with an infectious etiology. Broadly speaking, endophthalmitis can be broken down into four different types: postoperative, traumatic, glaucoma associated, and endogenous. This chapter is limited to endogenous endophthalmitis, in which intraocular structures are infected via hematogenous dissemination from other sources.

## Risk Factors and Presentation

Patients who are immunocompromised are at particular risk of developing endogenous endophthalmitis. Neutropenia, indwelling catheters (such as central lines and ports), and immunosuppression (from chemo- and radiotherapy) are factors that put the cancer patient at particular risk of this phenomenon. Intravenous drug use further increases this risk.

The presentation of endogenous endophthalmitis can vary. Symptoms may include blurry vision, sensitivity to light, and red eye. There may be varying degrees of pain. Patients who are critically ill may be unable to elicit any symptoms. Restricted motility of the eye, associated inflammation of the lids and periocular structures, or findings of pus in the anterior chamber (hypopyon) are critical signs that necessitate ophthalmic consultation (Figure 1).

## Assessment and Workup

Ocular assessment should include measurement of visual acuity and intraocular pressure and a

**FIGURE 1** Anterior segment photograph of an eye with a hypopyon.

complete dilated fundus examination. If possible, a slit lamp examination is helpful in assessing inflammation in the anterior chamber and vitreous. An eye sonogram may be necessary if there is no view of the posterior segment. Additional workup depends largely on whether a bacterial or fungal etiology is suspected.

If bacterial endophthalmitis is suspected, a specimen should be obtained from the eye for culture. Aspiration of fluid from the anterior chamber (aqueous tap) or the vitreous body (vitreous tap or vitrectomy) is combined with an empiric injection of antibiotics into the eye. Broad-spectrum antibiotics, including third-generation cephalosporins and vancomycin, are injected via the pars plana into the posterior segment with a small-gauge needle.<sup>1</sup> The decision to proceed with a vitreous aspiration (which can be performed in the clinic or at the bedside) or surgical vitrectomy depends on the extent of involvement of the eye at presentation, baseline visual acuity, and the patient's overall general health. In advanced cases, vitrectomy may be indicated from a diagnostic and therapeutic perspective.

In addition, cultures of blood, urine, and any indwelling catheter are obtained on day 1. Systemic and topical antibiotics are administered and directed toward likely pathogens, including *Staphylococcus aureus*, *Bacillus cereus*, streptococci, and *Neisseria meningitidis*. Patients are serially monitored with continued topical and intravenous antibiotics.<sup>1,2</sup> In some cases, topical and systemic steroids are administered to address the associated intra- and periocular inflammation.

Fungal endophthalmitis can be distinguished clinically from its bacterial counterpart. It is generally a less fulminant process. Patients may notice redness, decreased vision, floaters, or pain. Examination findings can vary significantly from small yellow-white lesions limited primarily to the retina to (in advanced cases) involvement of the entire posterior segment. The vitreous may become increasingly opacified from cells and debris and obscure visualization of the underlying retina (Figure 2). In some cases, an associated retinal detachment occurs.

Fungal endophthalmitis that primarily infects the retina with no significant vitreal involvement can be treated with systemic intravenous

**FIGURE 2** Fundus photograph of an eye with a vitreous abscess.

antifungal medications. Amphotericin B, voriconazole, and caspofungin can penetrate the eye and provide adequate treatment.<sup>3,4</sup> When there is more significant ocular involvement associated with inflammation, diagnostic and therapeutic vitrectomy may be necessary. Intraocular administration of antifungal drugs is generally indicated in such cases.<sup>3,4</sup> The most common fungal etiology is disseminated *Candida*, but other species, such as *Aspergillus*, can occur.<sup>5-8</sup>

Patients with both bacterial and fungal endophthalmitis may require prolonged antimicrobial therapy. Patients may need topical cycloplegic agents and monitoring of intraocular pressure, which may become elevated. Management requires a multidisciplinary approach, with the ophthalmologist and infectious disease specialist coordinating care. Ocular prognosis depends greatly on the virulence of the offending organism and the promptness with which treatment is initiated.<sup>9</sup>

## Other Infectious Causes

Other potential infectious must be considered when an immunocompromised patient presents with redness of the eye, inflammation, and loss of vision. Viral infections, such as herpes and cytomegalovirus retinitis, can develop indolently. Bloodborne malignancies can also mimic intraocular infection with hypopyon, including leukemia, lymphoma, and retinoblastoma. The appearance of the posterior fundus can distinguish these masquerade syndromes from a true bacterial or fungal endophthalmitis.<sup>10</sup> In

these instances, consultation with an experienced ocular oncologist or retinologist is essential in arriving at the correct diagnosis.

### Conclusion

Intraocular inflammation can represent a host of ocular abnormalities in the cancer patient. The most serious is an infectious cause that can lead to rapid and irreversible loss of vision. Cancer patients who present with periocular redness, pain, decline of vision, and floaters should be evaluated by an ophthalmologist. When a bacterial or fungal endophthalmitis is suspected, empiric antimicrobials should be administered

as soon as possible. In advanced cases, therapeutic vitrectomy may be indicated. Prognosis is dependent on early diagnosis and intervention.

# Ocular Side Effects Associated with Chemotherapy

Angela W. Kim, MD

The treatment of cancer frequently includes chemotherapy, radiation therapy (RT), and bone marrow transplantation. In many cases, it is difficult to establish a cause and effect relationship between chemotherapeutic agents and ocular side effects because of overlap of multiple agents, as well as different treatment regimens and modalities used within a short period of time. Chemotherapy can result in direct ophthalmic toxicity. Secondary anemia, thrombocytopenia, and immunosuppression may cause intraocular hemorrhage and infection, which are discussed elsewhere. Drug-induced metabolic changes can also affect vision.

The central nervous system (CNS) is a partially protected environment by way of limited cell division and the blood-brain barrier. Greater CNS toxicity is found in the setting of increased CNS penetration, as occurs through intra-arterial versus intravenous delivery of medication, intrathecal delivery, direct intracranial intratumoral therapy and with osmotic disruption of the blood-brain barrier. Hyperosmotic agents also compromise the blood-retina barrier, which is formed at the tight junctions of the retinal pigment epithelium (RPE) and the retinal blood vessel walls.

The purpose of this chapter is to serve as a very brief summary of known ocular toxicities of different chemotherapeutic agents. For a more comprehensive review of the literature, the reader is referred to Moster's chapter in Walsh and Hoyt's *Clinical Neuro-ophthalmology*.<sup>1</sup>

## Antimetabolites

High-dose therapy with methotrexate is associated with reversible periorbital edema, photophobia, ocular pain, and burning associated with keratitis, seborrheic blepharitis, conjunctivitis, and decreased reflex tearing in about 25% of cases.<sup>2,3</sup> Intracarotid artery delivery can cause macular edema with central retinal pigmentary changes.<sup>4,5</sup>

Conjunctivitis and keratitis occur most frequently, with corneal epithelial defects occurring

in up to 50% of patients receiving 5-fluorouracil.<sup>2,6</sup> Other complications include blepharitis and other lid changes.<sup>2,7,8</sup> Reversible epiphora occurs in up to 50% of patients and is associated with increased drug concentration in the tears.<sup>6,9</sup> A reversible acute toxic optic neuropathy with optic disc swelling can occur.<sup>10,11</sup>

Cytosine arabinoside (Ara-C) causes a dose-related, reversible keratoconjunctivitis that affects the superficial and deep cornea (Figure 1).<sup>2,12</sup> Symptoms include pain, foreign body sensation, tearing, photophobia, and blurred vision. Bilateral, progressive optic neuropathies have been reported, possibly from potentiation of radiation effects or with intrathecal therapy.<sup>13</sup>

Optic neuropathy is a prominent complication reported with the purine analogue fludarabine (Fludara).<sup>14</sup>

Bromodeoxyuridine is a pyrimidine analogue that, in combination with RT, can cause eyelid erythema, induration, conjunctival chemosis, hyperemia, conjunctivitis, dry-eye syndrome, ectropion, and exposure keratitis.<sup>15</sup>

**FIGURE 1** Cytosine arabinoside keratopathy manifesting in epithelial opacities seen in the center of the microphotograph. A bright light reflection is seen in the lower right aspect of the photograph.

## Alkylating Agents

Intracarotid artery infusion of nitrogen mustard may cause a severe ipsilateral necrotizing uveitis.<sup>16</sup>

Delayed posterior subcapsular cataract may occur with busulfan and is related to the dose and duration of treatment.<sup>2</sup>

Nonspecific reversible blurred vision has been reported within 24 hours of high-dose intravenous administration of cyclophosphamide (Cytoxan).<sup>17</sup> Reversible keratoconjunctivitis sicca has been reported in up to 50% of patients.<sup>17</sup> Optic neuropathy has been reported.<sup>18</sup> Transient blurred vision and miosis may be caused by a parasympathomimetic action.<sup>17</sup>

High-dose intravenous therapy with the nitrosoureas causes mild conjunctival hyperemia and nonspecific blurred vision in a small percentage of patients.<sup>2</sup> A delayed, severe, ipsilateral neuroretinal toxicity (probably from ischemia) occurs in up to 70% of patients treated intra-arterially (often with concomitant intracarotid cisplatin), with an approximately 50% incidence of ipsilateral complete blindness.<sup>2</sup> Patients receiving intravenous carmustine (BCNU) and ipsilateral infraorbital cisplatin can develop maculopathy.<sup>19</sup> Damage to retinal and choroidal endothelial cells has been suggested as a possible mechanism.<sup>20</sup>

Intracarotid artery infusion of nitrosoureas may cause orbital congestion.<sup>21,22</sup> Ischemia may lead to optic neuropathy and orbital complications.<sup>21,23</sup> Optic neuropathy with and without disc swelling has been reported with intracarotid and supraorbital infusion of BCNU.<sup>24-26</sup>

Retinal and CNS toxicities frequently occur after intracarotid or high-dose intravenous delivery of cisplatin.<sup>2,27-29</sup> Cisplatin is associated with RPE changes and maculopathy. When combined with BCNU, patients develop signs of retinal vasculitis and infarction.<sup>20</sup> Toxic, progressive optic neuropathy, including retrobulbar, and papilledema occur in some patients.<sup>30-32</sup>

## Antibiotics

Suramin can cause a reversible toxic keratopathy with foreign body sensation and corneal epithelial deposits in approximately 17% of patients; visual blurring may occur from an induced change in the optics of the eyes.<sup>33</sup>

Ocular side effects of doxorubicin (Adriamycin) include excessive tearing, blepharospasm, and periorbital edema with severe keratoconjunctivitis in about 25% of patients during intravenous infusion.<sup>7,34</sup>

## Vinca Alkaloids

Optic neuropathy has been described with vincristine but is a diagnosis of exclusion. It may resolve partially or completely off therapy.<sup>2</sup>

Transient ptosis, paresis of extraocular muscles, and brief eye pain have been reported with vinblastine.<sup>35</sup>

## Taxoids

Docetaxel (Taxotere) may cause canalicular stenosis with symptomatic epiphora.<sup>36</sup> Transient positive visual phenomena lasting up to a few hours were reported in six patients during paclitaxel (Taxol) infusion at higher than recommended doses.<sup>37</sup>

## Hormones

Tamoxifen causes corneal opacities and retinal dysfunction, particularly with high doses.<sup>38</sup> White, refractile opacities, RPE depigmentation, and macular edema may develop. Vision can improve despite the persistence of retinal opacities.<sup>39</sup> Isolated cases of bilateral optic disc swelling with visual loss have been reported.<sup>40,41</sup>

Posterior subcapsular cataracts occur in 10 to 40% of patients who are chronically treated over months with corticosteroids.<sup>2</sup> Corticosteroids can also cause reversible elevation of intraocular pressure, acute myopia with blurry vision, subconjunctival and retinal hemorrhages, scleral discoloration and thinning, exophthalmos, myopathic extraocular muscle paresis, and ptosis.<sup>2,42,43</sup> Immunosuppression secondary to corticosteroids can predispose patients to opportunistic infections. Pseudotumor cerebri (PTC) is a well-documented complication of steroid treatment.<sup>42</sup>

## Biologic Response Modifiers

Vaso-occlusive retinopathy can occur in patients treated with interferon- $\alpha$ .<sup>44,45</sup> Preexisting diabetes mellitus is a risk factor. Descriptive cases of oculomotor nerve paralysis, eyelash hypertrichosis, and papilledema have been reported.<sup>46-48</sup>

Reversible dose-dependent effects, such as visual hallucinations, scintillating scotomata,

**FIGURE 2** Bilateral periorbital edema in a patient treated with STI571. There is soft tissue fullness of both upper eyelids and just below the eyelids, greater on the patient's right side than on the left.

homonymous defects, amaurosis fugax, and diplopia, may occur with interleukin-2.<sup>49-51</sup>

## Miscellaneous Drugs

Ocular side effects of retinoids such as retinol and retinoic acid include conjunctivitis and corneal opacities.<sup>52</sup>

Reversible xerophthalmia and nyctalopia have been reported at higher doses of fenretinide (4-HPR).<sup>52,53</sup> Patients with secondary hypervitaminosis A can develop elevated intracranial pressure and a PTC syndrome.

L-Asparaginase is associated with venous thrombosis and can cause dural sinus or cortical vein thrombosis with intracranial hypertension and a PTC syndrome.<sup>54</sup>

Periorbital edema (Figure 2) and epiphora are the most common ocular side effects of STI571 (Gleevec, imatinib mesylate).<sup>55</sup>

## Conclusion

Ocular and neuro-ophthalmic toxicity can involve any part of the eye, adnexa, or CNS. Visual abnormalities have numerous potential etiologies, and it is difficult to differentiate the toxic effects of medications from cancer, radiation, infection-related complications, and non-cancer-related diseases. The complexity of this challenge increases with the development of newer agents and protocols and with increased patient survival, often involving multiple therapies.

# Vascular Events, Optic Neuropathies, Paraneoplastic Syndromes, and Visual Loss

Angela W. Kim, MD

Acute and subacute visual loss occurs through many mechanisms and at various locations along the visual pathways. Visual loss can be the result of ocular surface abnormalities, intraocular infection, inflammation, tumor, and hemorrhage, to name a few causes. This chapter discusses retinal hemorrhage from thrombocytopenia and anemia, retinal vascular occlusive disease, optic neuropathies, and paraneoplastic syndromes that affect vision.

## Retinal Hemorrhage from Thrombocytopenia and Anemia

Thrombocytopenia and anemia are commonly seen in patients with an underlying hematologic malignancy or as a side effect of chemotherapy. The relatively anticoagulated state with decreased hemostasis may cause vascular leakage.

The diagnosis is based on the ophthalmoscopic presence of retinal hemorrhages in the setting of thrombocytopenia and/or anemia (Figure 1). The presence of multiple comorbid risk factors may make it difficult to pinpoint a single etiology. Therefore, the examination findings must be correlated with the patient's clinical history. With restoration of blood counts, retinal hemorrhages resorb over time. The prognosis is good unless the bleeding is extensive and/or chronic enough to cause permanent photoreceptor damage.

## Central Retinal Artery Occlusion

Central retinal artery occlusion (CRAO) is considered a retinal stroke from embolism or thrombosis.<sup>1</sup> It is usually caused by carotid artery disease and has a prevalence of vascular risk factors similar to that of cerebral stroke. The most common emboli are cholesterol, platelet-fibrin, and calcific plaques.<sup>2</sup> Cardiac myxomas can also embolize.

**FIGURE 1** A patient with chronic myelogenous leukemia experienced decreased visual acuity. On funduscopy examination, he was found to have prominent, intraretinal hemorrhages and scattered cotton wool spots secondary to thrombocytopenia and anemia.

CRAO usually causes acute unilateral visual loss and may be preceded by amaurosis fugax. The acute ophthalmoscopic findings are diagnostic and include diffuse pale retinal swelling, optic disc pallor, a “cherry-red” spot, attenuated vessels, boxcarring, and, rarely, an embolus. There is no definitive treatment, and the visual prognosis is poor. Patients have often undergone ocular massage, anterior chamber paracentesis, intraocular pressure-lowering medications, and inhalation of carbogen.<sup>3</sup> Early intravascular urokinase or tissue plasminogen activator (t-PA) may be helpful but has associated potential risks.<sup>4,5</sup> Carotid duplex ultrasonography is used to evaluate carotid stenosis, and echocardiography may reveal a cardiac source. In younger patients, cardiac embolism, hypercoagulability, and vasospasm should be sought as the potential etiology and appropriately treated.<sup>6</sup>

## Central Retinal Vein Occlusion

CRVO is a common ocular disorder with a strong association with atherosclerotic disease of the central retinal artery as they share a common sheath.<sup>7</sup> Many patients have vascular risk factors<sup>8</sup>; others have associated vasculitis, hyperviscosity, prothrombotic states, or external venous compression. Identification of a specific abnormality may determine a need for anticoagulation or other treatment.

CRVO usually causes acute monocular visual loss. Diagnostic funduscopy findings include dilated, tortuous veins and diffuse, scattered retinal hemorrhages. Severe cases produce the classic “blood and thunder” retinal appearance. The visual prognosis is inversely proportional to the degree of retinal ischemia.<sup>9</sup> There is no standard-specific treatment for the eye, except for potential secondary neovascular complications. Some newer advocated treatments include t-PA, laser-induced chorioretinal anastomosis, radial optic neurotomy, and intravitreal triamcinolone acetonide.<sup>10–13</sup>

## Optic Neuropathies

Optic nerve disorders have numerous etiologies. Optic disc edema results from obstruction of axoplasmic transport, which results in swelling of nerve fibers. Mechanical signs of optic disc edema include elevation of the optic nerve head, blurred disc margins, loss of the optic cup, nerve fiber layer edema, and concentric folds around the disc (Figure 2). Vascular signs of disc edema include disc hyperemia, venous dilation and tortuosity, peripapillary hemorrhages, lipid exudates, and nerve fiber layer infarcts (Figure 3). Unilateral or asymmetric involvement may result in a relative afferent pupillary defect (RAPD). Loss of visual acuity, color vision, and visual field may be associated. Permanent damage results in optic disc pallor (Figure 4). Optic neuropathies can be

**FIGURE 2** This fundus photograph demonstrates optic disc elevation with concentric folds best seen between the 1 o'clock and 2 o'clock positions. Below at the 4 o'clock position, lipid exudates are present.

**FIGURE 3** This fundus photograph shows a swollen, hyperemic optic disc with venous dilation and tortuosity. There are also nerve fiber layer hemorrhages and white, fluffy cotton wool spots on the disc (nerve fiber layer infarcts).

**FIGURE 4** Optic disc edema has been replaced with optic disc pallor. Vascular changes, hemorrhages, and infarcts have resolved (same patient as in Figure 3).

divided into many general categories. The following is a very brief discussion of papilledema and ischemic, compressive, and infiltrative optic neuropathies.

### Papilledema

Papilledema is optic disc edema caused by elevated intracranial pressure and is diagnosed by lumbar puncture. Acutely, patients typically have normal visual function, with possible blind spot enlargement seen on perimetry. They frequently have headache, nausea, and transient visual obscurations and may have diplopia. Chronic disc swelling can lead to ischemia and any pattern of visual field loss. Papilledema is a neurologic emergency that requires neuroimaging. In adults, the most common causes are primary intracranial tumor, metastasis, and pseudotumor cerebri; in children, it is most commonly caused by posterior fossa tumors.<sup>14</sup>

### Anterior Ischemic Optic Neuropathy

Anterior ischemic optic neuropathy (AION) is considered an optic disc stroke and causes sudden, painless infarction of the optic nerve head. It may be arteritic (giant cell arteritis) or nonarteritic (Figure 5). Posterior ischemic optic neuropathy (PION) is usually caused by vasculitis, and, by definition, there is no optic disc swelling. Other ischemic states that can cause disc edema include ischemic CRVO, malignant hypertension, and diabetic papillopathy.

Arteritic AION usually occurs in patients older than 55 years. Frequent symptoms include temporal headache, scalp tenderness, jaw claudication, and constitutional symptoms. Common

laboratory findings include an elevated erythrocyte sedimentation rate and C-reactive protein and anemia of chronic disease. A biopsy proving arteritis is best because of the need for chronic corticosteroid treatment, but highly clinically suspicious cases are also treated.<sup>15</sup> Treatment should begin immediately on suspicion of the possibility of giant cell arteritis.

Nonarteritic AION is the most common cause of acute optic neuropathy in patients over 45 years of age. Visual loss is often noticed on awakening. Often the patient has a crowded disc—the “disc at risk.” Most patients have risk factors for atherosclerosis, but some have associated coagulopathies, embolism, acute blood loss, anemia, or hypotension.<sup>16</sup> Greater than 40% of patients can show spontaneous improvement.<sup>17</sup> There is no definitive treatment. Patients may be placed on acetylsalicylic acid for stroke prophylaxis. Infectious, vasculitic, and hypercoagulable etiologies should be sought in patients younger than 50 years without known vascular risk factors.

### Radiation Optic Neuropathy

Radiation optic neuropathy (RON) is a rare PION. The pathogenesis is not fully understood, but it is a form of ischemic optic neuropathy. The total dose and daily fractionation size are critical factors and typically should not exceed 55 Gy<sup>18</sup> and 18 Gy,<sup>19</sup> respectively. Most patients experience rapid, painless, and progressive visual loss within 3 years, with a peak incidence at 18 months.<sup>20,21</sup> The diagnosis is clinically suspected and confirmed with T<sub>1</sub>-weighted magnetic resonance imaging with contrast, which reveals marked enhancement and enlargement

**FIGURE 5 A**, A patient with nonarteritic ischemic optic neuropathy. The right optic disc is elevated with blurred margins. There is a nerve fiber layer hemorrhage near the inferior pole with an adjacent whitish nerve fiber layer infarct. **B**, Visual field testing demonstrates a superior arcuate defect consistent with infarction in the inferior aspect of the optic disc.

**FIGURE 6** Postcontrast T<sub>1</sub>-weighted magnetic resonance imaging in a patient with radiation optic neuropathy demonstrates bilateral optic nerve enhancement.

of segments of the optic nerve or chiasm (Figure 6).<sup>22,23</sup> Prompt treatment with hyperbaric oxygen is the only treatment associated with any significant visual improvement<sup>24</sup> and should be used alone or in conjunction with other medications (such as high-dose corticosteroids, pentoxifylline, anticoagulation, or other agents).

### Compressive Optic Neuropathy

Compressive optic neuropathy causes progressive visual loss, often a central scotoma, and RAPD. The optic disc can be normal, swollen, or pale. Any unexplained optic disc pallor, progressive visual loss, or corticosteroid-dependent optic neuropathy is considered compressive, until proven otherwise, and the patient must undergo imaging. The differential diagnosis includes primary, secondary, and metastatic tumors;

dysthyroid orbitopathy; varix; mucocele; infectious cysts; and others (Figure 7).

### Infiltrative Optic Neuropathy

The optic disc may appear grayish-white with hemorrhage or a visible mass owing to infiltrating cancer, inflammatory disease, or infectious processes (Figure 8). Usually, it occurs in patients with leukemia, lymphoma, and other carcinomas that spread to the central nervous system. Lumbar puncture should include high-volume cerebrospinal fluid to look for cytologic evidence of leptomeningeal disease. Infiltrative inflammatory and infectious disorders include sarcoidosis, tuberculosis,<sup>25</sup> and cryptococcosis,<sup>26</sup> to name a few.

**FIGURE 7** A tumor is seen in the lateral aspect of the left orbit on this T<sub>2</sub>-weighted magnetic resonance image. Pathologic diagnosis was presumed primary orbital melanoma.

**FIGURE 8** This fundus photograph shows a grayish-white, fluffy optic disc with central hemorrhage. The patient had an infiltrative optic neuropathy secondary to lymphoma.

## Paraneoplastic Retinopathies and Optic Neuropathy

In 1976, Sawyer and colleagues postulated paraneoplastic retinal photoreceptor degeneration in three patients with small cell lung cancer.<sup>27</sup> Since then, several distinct paraneoplastic conditions that affect the eyes have been differentiated by unique clinical characteristics, electrophysiologic abnormalities, and, occasionally, the immunologic profile. The pathogenesis is considered immune mediated. The selected entities that are briefly described are cancer-associated retinopathy (CAR), melanoma-associated retinopathy (MAR), and paraneoplastic optic neuropathy (PON).

### Cancer-Associated Retinopathy

CAR is a group of autoimmune conditions that result in photoreceptor degeneration. Recoverin, a 23 kDa protein, was the first and most common retinal antigen linked to CAR.<sup>28</sup> Many other proteins have been identified as potential autoantigens.<sup>29</sup> CAR is the most frequent of the primary visual paraneoplastic disorders and is most commonly related to small cell lung carcinoma, although many other tumor types are also associated.

Most patients experience progressive symptoms of both cone and rod degeneration, including blurry vision, dyschromatopsia, prolonged glare, night blindness, prolonged dark adaptation, and peripheral scotomata, with an initially normal fundusoscopic appearance. Later, arteriolar narrowing, optic disc pallor, pigmentary changes, and cells may be seen. Electroretinography reveals significantly attenuated or nonrecordable tracings.<sup>30</sup> In the absence of a family history of retinal degeneration, the diagnosis of CAR should be considered. There is no definite effective therapy, and the visual prognosis is very poor. There have been some reports of mild to moderate visual recovery with the use of corticosteroids, plasmapheresis, and/or intravenous immunoglobulin in various combinations.<sup>31–33</sup>

### Melanoma-Associated Retinopathy

Berson and Lessell classified MAR as a paraneoplastic disorder that affects rod photoreceptors.<sup>34</sup> Symptoms include shimmering, flickering, pulsating photopsias, difficulty seeing in the dark, and peripheral or paracentral scotomata. Initially, the retinal appearance may be normal. Later, vessel narrowing, pigmentary changes, optic disc pallor, and infrequent vitreous cell or periphlebitis may be seen.<sup>35</sup> MAR produces a characteristic electroretinogram with a negative-appearing waveform.<sup>34,36</sup> Antirod bipolar cell antibodies help make the diagnosis but are not specific for MAR.<sup>37,38</sup> There is no specific therapy for MAR. Keltner and colleagues proposed cyto-reductive

surgery and radiation, followed by adjuvant immunotherapy.<sup>39</sup> However, there was no difference in survival between those treated and those not treated. A rare patient with MAR and associated uveitis improved after corticosteroid therapy.<sup>40</sup>

### Paraneoplastic Optic Neuropathy

PON has been associated with a number of malignancies, especially small cell lung carcinoma.<sup>41–44</sup> Photoreceptor cells, retinal ganglion cells, and nerve fibers exhibit collapsin response mediator protein 5 (CRMP-5, a 62 kDa protein) –specific immunoreactivity.<sup>45</sup>

Clinically, most patients develop subacute, progressive, bilateral, painless visual loss with optic disc edema. This may be accompanied by other neurologic symptoms, including a cerebellar syndrome.<sup>43,44</sup> Vitreous cells, retinal vascular leakage, and retinitis are commonly present.<sup>45</sup> CRMP-5 autoantibodies have been identified in the serum and cerebrospinal fluid of patients with cancer and PON and retinitis.<sup>45</sup> PON should be considered in patients with optic neuropathy and cancer without evidence of central nervous system metastasis. Treatment of the underlying cancer has resulted in significant visual improvement in some patients.<sup>42,44,46</sup> A patient reported by Hoh and colleagues responded to corticosteroids alone.<sup>47</sup>

### Conclusion

A number of potential causes of acute and subacute visual loss have been described. However, a vast number of other etiologies of visual loss have not been covered here. All possibilities must be differentiated from one another through careful history taking, examination, ancillary testing, and appropriate ophthalmologic follow-up.

# Metastatic Disease to the Eye and Orbit

Dan S. Gombos, MD, FACS  
Angela W. Kim, MD

Ocular metastasis to the eye and orbit was first described in the late 1800s by Horner and Perl. At the time, ocular metastasis was felt to be rare; primary uveal melanoma was thought to be the most common malignancy of the eye. In 1967, Albert and Scheie suggested that the incidence of metastatic disease might be higher than previously reported. Since then, numerous studies have confirmed that uveal metastasis from solid tumors is the most common intraocular malignancy.<sup>1-5</sup> Its incidence varies depending on clinical and pathologic surveys ranging between 4 and 12%. Some have suggested rates as high as 30% at the time of death.<sup>1,6</sup> In comparison, the incidence of orbital metastasis is significantly lower than that of intraocular disease. Orbital metastasis accounts for 1.5 to 10% of all orbital tumors. This chapter discusses the clinical presentation, workup, and management of solid tumors that metastasize to the globe (eyeball) and orbit. As these clinical entities differ, they are discussed separately in the sections that follow.

## Pathogenesis and Presentation of Intraocular (Uveal) Metastasis

Metastasis to the uvea occurs primarily via hematogenous dissemination through the 20 short posterior ciliary arteries that supply the posterior pole. Patients with intraocular metastasis generally complain of painless loss of vision associated with floaters and flashing lights, but up to 10% may be asymptomatic. The average age of presentation is between 40 and 70 years. Visual acuity can range from 20/20 to no light perception (blindness). Additional clinical findings may include changes in the refractive error (glasses prescription) and dilated injected episcleral vessels (red eye). Examination with an ophthalmoscope demonstrates a flat or dome-shaped subretinal mass with a creamy/yellow to yellow/white appearance (Figures 1 and 2). Larger lesions are often associated with a serous retinal detachment. The most common tumors that present in this fashion are from breast and lung primaries. Up to two-thirds of patients will have a history of cancer. Although less common, metastasis to the iris and ciliary body can also occur. In these cases, the patient may notice a visible mass on the

**FIGURE 1** Fundus photograph of a metastatic lesion to the uvea from lung cancer. Note the creamy white appearance of this lesion.

eye with pain and increased intraocular pressure (see Figure 2).

Once uveal metastasis is identified, additional workup should be obtained to ensure an accurate diagnosis. The differential diagnosis for an amelanotic intraocular lesion is broad and includes choroidal amelanotic melanoma, hemangioma, choroidal osteoma, posterior scleritis, cytomegalovirus retinitis, choroidal neovascularization with disciform scar, and retinal detachment. Features that assist in conferring the correct diagnosis include the shape, color, and vascular pattern of the lesion. Metastatic lesions have a tendency to grow rapidly; most are located in the posterior segment of the choroid. Additional

testing is often used to confirm the diagnosis. Fluorescein angiography will demonstrate a mottled hyperfluorescence with pinpoint leakage. Ophthalmic ultrasonography demonstrates a mass with medium to high internal reflectivity.<sup>7</sup> These diagnostic tests, in addition to fundus photography and retinal drawings, help serve as a baseline prior to treatment. In most situations, an experienced ophthalmologist can confirm the diagnosis without the need for a biopsy. In selected cases, choroidal biopsy may be necessary via a transvitreal or transcleral approach. Tumors in the iris can be accessed via a paracentesis or anterior chamber tap.

Once the diagnosis is confirmed, systemic workup is indicated. Uveal metastasis has a high association with central nervous system (CNS) involvement. All patients should undergo additional staging, including neuroimaging of the brain and orbits. Malignancies associated with specific tumor markers should have those blood tests reassessed. Management of uveal metastasis varies and depends on the size and intraocular location of the lesion, the presence (or absence) of concurrent CNS disease, and previous therapies administered to the patient.

Observation can be considered for small peripheral asymptomatic lesions that appear to be inactive. Generally, large lesions and those that threaten vision are treated. The most common form of treatment is radiation therapy, which can be administered via external beam or plaque

**FIGURE 2** Photographs of metastatic lesions to the choroid (A) and iris (B) from breast cancer. Note the injected episcleral blood vessels (B).

brachytherapy. Patients requiring systemic management and those with distant metastasis may be good candidates for chemotherapy.<sup>8,9</sup> All patients need close serial assessment by an ophthalmologist to ensure that their lesions are responding. In advanced cases in which there is no potential for vision and the eye is painful or associated with neovascular glaucoma, enucleation (removal of the eye) can be considered.

Lesions should be monitored closely by an ophthalmologist with serial examinations, photography, and ultrasonography. Over time, tumor foci generally fragment with pigment migration and associated resolution of serous retinal detachment. Even patients with significant visual loss at presentation can regain useful vision following treatment. Recurrences can occur, and patients should be instructed to monitor their vision closely. Those treated with radiation may develop secondary toxicities from treatment such as dry eye and cataract.

### Orbital Metastasis

Metastatic disease to the eyelid and orbit is less common than intraocular metastasis. However, with the prolonged survival of patients with cancer, the frequency of orbital metastasis is increasing. Patients may present with droopiness of the lid, a palpable mass, term exophthalmos, enophthalmos, limitation of extraocular motility, double vision, pain, paresthesia, headache, or decreased vision. In some instances, sudden clinical changes may occur owing to hemorrhage or necrosis within the tumor. Rarely, lesions may be pulsatile due to increased vascularity or erosion of adjacent bone with transmission of cerebrospinal pulsations. The lateral orbit is the most common quadrant in which metastasis occurs, followed by the superior, medial, and inferior quadrants. Symptoms precede the diagnosis of a systemic malignancy in up to 42% of patients.<sup>10</sup> Goldberg and colleagues defined five orbital syndromes associated with metastasis.<sup>10</sup> They included: mass effect (causing proptosis); infiltration of orbital tissues; functional (a decrease in cranial nerve function); acute or subacute inflammation; or silent (no orbital symptoms). These patients may be initially misdiagnosed as having alternative diagnoses, such as orbital inflammatory syndrome, cellulitis, or myasthenia gravis.<sup>10</sup>

Two orbital findings are highly associated with specific malignancies. Enophthalmos (an inward displacement of the globe) often occurs in the setting of metastatic breast cancer, but it can also be seen with gastrointestinal, lung, and prostate carcinomas. In this setting, cicatrization with contracture of myofibroblasts causes the retraction of orbital contents (Figure 3). In children, orbital metastasis from neuroblastoma frequently presents with sudden onset of ecchymosis and proptosis with a dramatic

**FIGURE 3** Magnetic resonance image demonstrating enophthalmos in a patient with metastatic breast cancer to the left orbit.

clinical progression. Mediastinal involvement may manifest as Horner's syndrome (ptosis, miosis, and anhidrosis); opsoclonus-myoclonus (a paraneoplastic effect) may also be seen.

### Workup and Treatment

Once suspected, orbital imaging is indicated. This should include neuroimaging of the brain and adjacent sinus structures. Magnetic resonance imaging (MRI) is helpful in distinguishing metastasis from other simulating lesions, such as optic nerve gliomas, optic nerve sheath meningiomas, and orbital inflammatory syndrome. An MRI should be ordered to include fat-saturated images in both coronal and axial planes, with and without gadolinium. Metastatic lesions are isodense to muscle on T<sub>1</sub>-weighted imaging and hyperdense to brain tissue on T<sub>2</sub>-weighted imaging. Computed tomography, including axial and coronal views with contrast, is helpful for tumor localization, to aid in identifying small orbital apex lesions, and to confirm or rule out adjacent bone involvement.

In patients with diffuse metastatic disease and involvement of other structures, treatment can proceed empirically. However, in cases for which tissue diagnosis is necessary, biopsy should be performed. This can be done via an open technique or fine-needle aspiration. Orbital metastases are generally treated with palliative radiotherapy or chemotherapy unless considered a solitary isolated metastasis. In the latter case, surgical excision can also be considered. Those tumors that are radiosensitive can respond quickly with dramatic improvement of symptoms. Some studies have suggested that up to 73% of patients show improvement after orbital radiotherapy. Of all symptoms, proptosis is the most responsive to radiation, whereas paresis and ptosis are the least responsive. Alternative modalities are also effective; neuroblastoma and small cell carcinoma

respond well to chemotherapy. Hormonal therapy can be effective in the settings of breast and prostate cancers.

### Prognosis

Metastatic lesions to the eye and orbit often respond well to treatment. In many cases, useful vision can be preserved. However, their presence is a grave prognostic indicator for patient survival. Those with orbital metastatic lesions generally live longer than those with metastatic disease to the uvea. The median survival following intraocular metastasis ranges from 9 to 10 months. Median survival following orbital metastasis ranges from 12 to 26 months. Breast, carcinoid, and thyroid tumors are associated with the longest survival, sometimes measured in years. Lung carcinoma, gastrointestinal carcinoma, and cutaneous melanoma usually present in the setting of fulminant dissemination. Accordingly, median survival of less than 6 months is commonly seen in patients with these primary tumors.<sup>1-5</sup>

### Conclusion

The diagnosis and management of ocular metastasis require a broad multidisciplinary approach. The primary clinician and oncologist should refer patients to an ophthalmologist whenever patients complain of blurry vision, floaters, pain, and redness. The ophthalmologist must communicate directly with the oncologist to ensure that the appropriate workup is initiated and that the patient is appropriately restaged. Once the extent of metastasis is identified, treatment should be initiated as soon as possible. Although many tumors will respond to therapy with preservation of some vision, the prognosis for patient survival is poor.

Diane C. Bodurka, MD

## The Pregnant Cancer Patient

The diagnosis of cancer is often overwhelming, especially for the pregnant patient. Medical decision making can become extremely complex as the health of both the mother and the fetus must be considered. Appropriate treatment planning is influenced by the indication for treatment, the safety issues associated with each treatment modality, and the patient's feelings regarding continuation of the pregnancy. The informed consent process disclosing all associated risks and benefits of therapy is crucial.

Maternal cancer complicates approximately 1 in 1,000 to 1 in 5,000 live births in the United States annually,<sup>1</sup> and there are approximately 4,000 cases of concurrent pregnancy and maternal malignancy in the United States each year.<sup>2</sup>

The most frequently diagnosed cancer in pregnancy is cervical cancer, followed by breast cancer, melanoma, ovarian cancer, thyroid cancer, leukemia, lymphoma, and colorectal cancer. Pregnancy does not increase the risk of malignancy, and the incidence of specific malignancies in pregnant women is similar to that in nonpregnant women of the same age range. The incidence of cancer complicating pregnancy may increase as more women delay childbearing until later in life.

## Chemotherapy and Pregnancy

All chemotherapeutic regimens are potentially teratogenic and mutagenic. Although controlled studies have been performed on pregnant laboratory animals, one must be cautious when extrapolating animal data to human pregnancies. Since it is not possible to perform prospective studies that evaluate chemotherapy during pregnancy, treatment regimens are frequently based on case reports and small retrospective studies.

Both the mother and the fetus may be affected by chemotherapy. When evaluating the potential effect of a specific antineoplastic agent on the developing fetus, it is important to consider both the maternal physiologic processes that accompany pregnancy and the developmental stage at which the fetus is exposed to the treatment.

Pregnancy may affect the absorption, distribution, and excretion of chemotherapeutic agents.<sup>3</sup> The increase in maternal blood volume affects the distribution of antineoplastic agents, whereas the absorption of oral agents may be influenced by changes in gastrointestinal motility. An increase in the glomerular filtration rate changes the rate of renally excreted agents. Virtually all chemotherapeutic agents cross the placenta.

The developmental stages of the embryo and fetus have been well documented. These stages are divided into the preimplantation period (fertilization to implantation), the embryonic period (gestational weeks 2 through 8), and the fetal period (week 9 to term). Several principles apply to the effects of chemotherapy on the fetus based on these stages.

The first trimester is the most crucial time period and is best characterized by the all-or-none principle in terms of impact on the fetus. Since its circulation has not yet been established, the blastocyst is resistant to teratogens in the preimplantation period. After this time, an exposed blastocyst may be severely damaged and result in a spontaneous abortion. Conversely, the blastocyst may survive without abnormalities.

During the period of organogenesis (gestational weeks 5 through 12), the fetal stem cell population is limited. This is the period of maximal susceptibility to teratogenic insults. Ten to 25% of fetuses exposed to cytotoxic agents during this time period have major malformations.<sup>4</sup> It is generally recommended that chemotherapy administration be delayed until after the first trimester if possible.

Organogenesis is completed by the end of the twelfth gestational week, with the exception of brain and gonadal tissue. Fetal growth restriction owing to chemotherapy surpasses the risk of structural birth defects. However, since the central nervous system continues to develop throughout the fetal period, cortical brain function may be affected by these agents.<sup>3</sup>

Both maternal and fetal physiology during the final weeks of gestation must be taken into

consideration when planning and administering chemotherapy. This should also be coordinated with the anticipated time of delivery. In an effort to decrease potential maternal chemotherapy-related complications from delivery, myelosuppressive regimens, which may cause neutropenia or thrombocytopenia, should be avoided approximately 3 weeks prior to the anticipated delivery.

Given that the placenta functions as a route for drug delivery and excretion, the timing of administration of chemotherapy may also affect the neonate. Elevated drug levels may be seen in the newborn if neoplastic agents are administered within close proximity to delivery owing to a lack of elimination. Additionally, a limited ability of the neonatal liver and kidneys to metabolize and excrete specific agents may also elevate the blood levels of these drugs, especially in the preterm infant. Several authors have reported that children born to mothers receiving chemotherapy during pregnancy experienced no physical, neurologic, psychologic, hematologic, or cytogenetic defects.<sup>5,6</sup> However, premature birth and low birth weight for gestational age are likely to be the most common complications associated with maternal chemotherapy administration, and these rates are most likely underreported.<sup>7</sup>

Many chemotherapeutic agents, including cisplatin, cyclophosphamide, doxorubicin, hydroxyurea, and methotrexate, can be found in breast milk. Because of this, breast-feeding is contraindicated in women receiving chemotherapy.<sup>8,9</sup>

## Radiation Therapy and the Pregnant Patient

As with chemotherapy, the administration of radiation during pregnancy requires careful consideration of therapeutic and ethical issues. It is difficult to establish accurate estimates of risks owing to a lack of clinical trial data. The majority of available data regarding radiation and pregnancy outcome are extrapolated from animal models or reported in small retrospective series. And as with chemotherapy, the period of fetal

development influences the impact of in utero radiation exposure.

The blastocyst is most sensitive to the in utero lethal effects of ionizing radiation during preimplantation and early implantation (the first 10 days after conception). Doses as low as 10 cGy have been shown to increase prenatal death and embryonic resorption in laboratory mice. Virtually all animal experiments, however, reveal that survivors of radiation exposure during this time period develop no congenital anomalies.<sup>10,11</sup>

The greatest incidence of malformations in animals irradiated in utero occurs during organogenesis. This time period is also the time of maximal susceptibility to chemotherapy-induced teratogenicity. Human exposure to radiation during this time period results in intrauterine growth retardation and central nervous system-related anomalies, such as eye abnormalities, severe mental retardation, and microcephaly. Structural abnormalities are not usually seen from radiation therapy. A dose threshold of 5 to 10 cGy has been suggested for the above anomalies, based on data from Japanese survivors of the atomic bomb.<sup>11</sup> This analysis, however, is somewhat compromised by a lack of accurate dosimetry on which to base risk estimates.

Although the fetal stage extends to 12 to 14 weeks' postconception in humans, the central nervous system continues to develop until term. The central nervous system remains sensitive to radiation through approximately 25 weeks after conception. Milder forms of microcephaly and other central nervous system anomalies can occur.<sup>12</sup> Growth retardation may be seen with doses greater than 50 cGy.<sup>11</sup>

The threshold dose below which radiation would not adversely affect a pregnancy is not known. Although several authors suggest that doses less than 10 cGy do not cause adverse effects, any dose of radiation may be capable of inducing genetic mutations, which may not be expressed until future generations.<sup>13</sup> It has been estimated that in utero radiation of 1 cGy may double the risk of childhood malignancies during the first 10 years of life, especially in terms of leukemias.<sup>14</sup> Despite this increase in risk, the absolute risk of future cancers remains low. Table 1 presents the estimated fetal dose of radiation from several common diagnostic procedures.

In utero exposure to 10 cGy is the cutoff point for consideration of therapeutic abortion.<sup>14</sup> Despite this, case reports of 50 cGy administered during the first trimester have not demonstrated a substantial risk of malformation.<sup>11</sup> Radiation therapy directed to the abdomen or pelvis during pregnancy will result in high doses of radiation to the fetus and should be avoided unless pregnancy loss owing to spontaneous abortion or evacuation is expected. Issues regarding radiation exposure of the pregnant patient, including the topic of

**Table 1** Estimated Fetal Dose from Common Diagnostic Radiologic Exposure

Type of Examination	Fetal Dose Range in cGy (rad)
Chest radiograph	0.00006
Abdomen flat plate	0.15–0.26
Lumbar spine	0.65
Pelvis	0.2–0.35
Hip	0.13–0.2
Intravenous pyelography	0.47–0.82
Upper GI series	0.17–0.48

 CT = computed tomography; GI = gastrointestinal.  
 \*For early pregnancy with uterus confined to the pelvis.  
 †Based on an ovarian dose of 0.015 cGy per mCi of <sup>99m</sup>Tc, with a typical injected dose of 10 mCi. Bladder drainage should be used owing to a high local dose from urinary excretion of the radiopharmaceutical.

therapeutic abortion, require consideration of all factors affecting the mother and the fetus.

#### Maternal Hypothyroidism in the First Trimester

Patients treated with radiation therapy, specifically for cancers of the head and neck, are at risk of developing hypothyroidism. Radiation treatment is well recognized as a cause of hypothyroidism. Almost 50% of patients develop hypothyroidism 5 years after radiation therapy, and by 8 years after radiation, almost two-thirds of patients develop hypothyroidism.

For women of childbearing potential, monitoring and correcting thyroid levels are important. Hypothyroidism has been associated with an increased risk of miscarriage, lower infant IQ, placental abruption, and preterm birth.

#### Prevention of Vaginal Hemorrhage in Cancer Patients of Reproductive Age

Cancer patients of reproductive age are often given treatments that may lead to vaginal bleeding. Once bleeding has started, and if this bleeding is treatment related, the underlying cause, such as thrombocytopenia, should be corrected. Intravenous estrogen (Premarin) may be given at a dose of 25 mg every 4 hours for 24 hours or until bleeding stops. Alternatively, oral contraceptives may be given three times a day for 3 days, then twice a day for 3 days, and then daily.

If there is an increased risk of vaginal bleeding, hormonal agents can be administered, which can function to prevent the incidence of bleeding. Progestins (megestrol, medroxyprogesterone) work by stabilizing the endometrium and

decrease cyclical bleeding if taken continuously. Similarly, oral contraceptive pills can be administered. Depending on the duration of therapy and the nadirs associated with the cytotoxic agents given, oral contraceptive pills can be taken daily for up to 3 months without inducing a menstrual cycle.

Gonadotropin-releasing hormone agonists (eg, leuprolide) have also been used to suppress vaginal bleeding during chemotherapy. In addition, these agents may function to enhance ovarian function and preserve fertility.<sup>15</sup> This is particularly important for adolescent females who are exposed to multiple chemotherapeutic agents.

#### Vaginal Hemorrhage

The appropriate initial management of the patient who presents with vaginal bleeding requires a stepwise approach to determine the etiology of the bleeding. Vaginal bleeding in postmenopausal women is abnormal. While common causes of vaginal bleeding include endometrial polyps, fibroids, hyperplasia, or atrophic changes (due to lack of estrogen), cancer needs to be considered in the differential diagnosis. In premenopausal women, bleeding may be due to pregnancy-related disease and should be further evaluated with a pregnancy test.

If the pregnancy test is positive, the differential diagnosis includes spontaneous abortion, missed abortion, molar pregnancy, gestational trophoblastic disease, and ectopic pregnancy (discussed later in this chapter). If the patient is bleeding vigorously, large-bore intravenous access should be obtained, fluids should be administered, and blood should be sent to evaluate hematologic and clotting levels. A type and screen should be ordered; a type and crossmatch may be necessary. Careful physical and pelvic examinations should be performed. Any visible lesion in the vagina that may appear bluish in color should not be biopsied as this may precipitate hemorrhage from choriocarcinoma. An obstetrician/gynecologist should be consulted for further evaluation and management.

Women with gestational trophoblastic disease may present with vaginal bleeding and a positive pregnancy test. Although a high index of suspicion is required to diagnose this disease, women may present with a history of multiple emergency room visits for threatened abortion, a uterus larger in size than the reported gestational age, and no fetal movement. They may also experience significant nausea, vomiting, and hypertension. On pelvic examination, the cervical os is usually closed and the uterus is larger than expected for the gestational age. Ultrasonography of the pelvis should be performed; pathognomonic findings include a multiechogenic pattern and absence of fetal parts. A chest radiograph

and quantitative serum  $\beta$ -human chorionic gonadotropin (hCG) should be obtained. The patient should be admitted to the hospital. An obstetrician/gynecologist should be consulted for appropriate evaluation, evacuation of the pregnancy, and follow-up.

If the pregnancy test is negative and the bleeding is heavy, a thorough physical examination and pelvic examination should again be performed, with careful attention given to visualization and inspection of the vagina and cervix. If the bleeding is due to an exophytic cervical lesion, a vaginal pack with Monsel's solution should be placed. The patient should be admitted to the hospital for more definitive diagnosis and potential emergent therapy. Treatment options for hemorrhage not controlled by packing include hypogastric artery embolization, transvaginal radiation, and hypogastric artery ligation.

If the cervix is grossly normal in appearance, consideration should be given to an endometrial biopsy if this can be performed. Any vaginal lesion should also be biopsied. If the patient is not bleeding heavily, she may be discharged with immediate referral to a gynecologist or to a gynecologic oncologist if malignancy is suspected.

The vulva and vagina should also be inspected, especially in older women. Packing and hospital admission may be required to establish a definitive diagnosis and begin appropriate treatment.

## Ectopic Pregnancy

Ectopic pregnancy is the leading cause of pregnancy-related death during the first trimester. The diagnosis and treatment of tubal pregnancy prior to tubal rupture significantly decrease the risk of maternal death. Early detection of tubal pregnancy increases treatment options, and some patients may be able to receive medical as opposed to surgical intervention.

Since the early 1970s, the incidence of ectopic pregnancy has tripled. In 1992, there were an estimated 109,000 ectopic pregnancies, representing approximately 20 per 1,000 pregnancies and almost 10% of all pregnancy-related deaths.<sup>16</sup> Current Centers for Disease Control and Prevention data do not include ectopic pregnancies diagnosed or treated in physicians' offices, thereby underestimating the true incidence of ectopic pregnancy.

Several factors have been identified as contributing to the increased incidence of ectopic pregnancy. These include the rising incidence of acute and chronic salpingitis, tubal ligation, tubal reconstructive surgery, and conservative management of tubal pregnancy, all of which cause structural damage to the tube; an increase in the use of intrauterine contraceptive devices (IUDs), which assisted reproductive technology/*in vitro* fertilization increase the risk of ectopic pregnancy by a factor of 4; and improved technology, which allows for more definitive diagnosis of

some patients whose condition may have been undetected in the past.

Many retrospective studies have shown that patients with an ectopic pregnancy may be evaluated by a physician on several occasions before the correct diagnosis is made. This delay in diagnosis is usually related to a low index of suspicion on the part of the clinician. An awareness of the risk factors associated with ectopic pregnancy is critical to a prompt diagnosis. Significant risk factors are as follows:

- A history of tubal infection (increases the rate of ectopic pregnancy from 1 in 200 to 1 in 24)
- Previous ectopic pregnancy (15–50% increase in the incidence of ectopic pregnancies in subsequent pregnancies),
- A history of tubal reconstructive surgery
- A history of tubal sterilization within the previous 2 years
- Pregnancy with an IUD in place or a history of IUD use

Although there are no pathognomonic symptoms of ectopic pregnancy, the classic triad consists of history of amenorrhea, new onset vaginal bleeding, and abdominal pain.

Amenorrhea or a history of an abnormal last menstrual period is associated with 75 to 90% of ectopic pregnancies. Vaginal bleeding, which may consist of light spotting or may be as heavy as a menstrual period, results from low hCG production by the ectopic trophoblast; this occurs in 50 to 80% of patients with an ectopic pregnancy. Abdominal pain is present in more than 90% of cases.

Identifying the correct diagnosis in a patient with an acutely ruptured ectopic pregnancy is fairly straightforward. The patient usually presents with symptoms of abdominal pain and distention, as well as hypovolemia (eg, tachycardia, orthostatic blood pressure changes, diaphoresis). Shoulder pain may be present owing to irritation of the phrenic nerve from blood in the peritoneal cavity.

The diagnosis of an unruptured ectopic pregnancy is more difficult to make. Physical examination findings in these patients are extremely variable. Although 90% of patients have abdominal tenderness, only 45% have rebound tenderness. Fifty percent of patients have a palpable adnexal mass. In half of these cases, the mass is contralateral to the ectopic pregnancy and is actually the corpus luteum.<sup>17</sup>

Several critical diagnostic tests should be obtained in patients suspected of having an ectopic pregnancy. These include a urine hCG, transvaginal ultrasonography, and quantitative serum  $\beta$ -hCG. The rapid hCG is obtained to diagnose pregnancy. The  $\beta$ -hCG should be drawn at the time of presentation and then repeated as

necessary. The doubling time of  $\beta$ -hCG in the serum varies from 1.2 days immediately following implantation to 3.5 days 2 months after the last menstrual period. It is important to understand that ectopic gestations may be associated with a normal rise in hCG levels, as well as with plateauing or decreasing titers. If serial quantitative levels of  $\beta$ -hCG do not fall into the normal range, ultrasonography should be performed to attempt to locate the pregnancy. Transvaginal ultrasonography permits the identification of an intrauterine gestational sac at as early as 5 weeks of amenorrhea (2 mm diameter), which virtually rules out an ectopic pregnancy.

The management of an ectopic pregnancy has changed significantly in recent years. Therapeutic options vary from medical therapy to emergent laparotomy. The appropriate treatment depends on the medical status of the patient and the characteristics of the pregnancy. Surgery (either laparotomy or laparoscopy) is indicated in patients with an unstable cardiovascular status, a vaginal sonogram identifies a gestational mass > 3.5 cm, the b-hCG is > 15,000 mIU/dL, or fetal cardiac activity is identified. A patient with stable cardiac status, a gestational mass < 3.5 cm identified on ultrasonography, and b-hCG < 15,000 mIU/dL is an appropriate candidate for medical management with methotrexate. For those patients who are eligible for methotrexate other criteria, such as a willingness to return for follow-up care, must be discussed by the patient and her physician.

The key to successful management of ectopic pregnancy is early diagnosis. Although the number of cases of ectopic pregnancy has steadily increased, the mortality has declined significantly in the past 10 years.<sup>18</sup> A high index of suspicion and vigorous efforts to make an early diagnosis must be made by all physicians evaluating women of reproductive age who present to the emergency room with abdominal pain and a positive pregnancy test.

## Rectovaginal Fistulae

A rectovaginal fistula is an epithelium-lined communication between the rectum and the vagina. Although most fistulae are related to obstetric trauma, carcinoma, whether it is primary, recurrent, or metastatic, can lead to a rectovaginal fistula. The most common cancers are rectal, cervical, vaginal, and endometrial. If a patient with a rectovaginal fistula has a history of any of these cancers, a biopsy of the fistula is necessary. Radiation of the pelvis or perineum is another cause of a rectovaginal fistula. The radiation results in tissue damage and decreased vascular supply, which can lead to a proctitis and subsequent ulceration of the rectal wall. The frequency of radiation-induced rectovaginal fistulae is 0.3 to 6%. The incidence increases with higher doses of

radiation. These fistulae are usually to the mid- or upper vagina and will occur within 2 years of treatment.

The majority of rectovaginal fistulae are symptomatic, with the patient complaining of the passage of stool or flatus via the vagina. If the fistula cannot be identified on examination, the patient may require additional studies. Contrast studies (eg, barium enema, computed tomography with rectal contrast) are useful.

The treatment of a rectovaginal fistula must be tailored to the individual fistula and the patient's long-term prognosis. A colostomy is often necessary. Depending on medical comorbidities, disease state, and body habitus, a patient can have either a transverse loop colostomy or an end-descending colostomy.

### Treatment of Menopausal Symptoms

Menopause, the cessation of ovulation and its accompanying symptoms, marks an important physiologic and social transition in a woman's life. The average age of natural menopause in the United States is 52.6 years.<sup>19</sup> Patients who are postmenopausal at the time of their diagnosis and treatment of cancer are now living longer owing to advances in therapy. Patients who are still having regular menstrual cycles at the time of their cancer diagnosis are often made menopausal by the treatment. For example, the majority of patients with leukemia and lymphoma are under 50 years, and a large proportion of them will be made menopausal with traditional chemotherapy, high-dose chemotherapy, bone marrow transplantation, or radiotherapy.<sup>20</sup> Almost 15% of patients with endometrial cancer will be premenopausal at diagnosis.<sup>21</sup> Standard treatment for these women includes bilateral salpingoophorectomy as part of the surgical staging of the disease. Owing to early detection and improved therapy, women who are iatrogenically made menopausal as a side effect of their cancer treatment may live many decades in a menopausal state.

Vasomotor symptoms are the most commonly reported and often the most distressing symptoms of menopause. Nearly 60% of menopausal women report hot flashes, night sweats, and/or sleep disturbances.<sup>22</sup> Genitourinary symptoms such as vaginal dryness or atrophy and accompanying dyspareunia are also well documented.<sup>22</sup> There is often an accompanying decrease in libido and sexual desire with menopause. The long-term effects of osteoporosis are of particular concern in those cancer patients with an excellent prognosis made menopausal at an early age. For them, the decades without estrogen put them at risk of fractures of the vertebrae, hips, and wrist. In postmenopausal white women, 90% of hip fractures are attributable to

osteoporosis and 20% of them will die within 1 year of sustaining the injury.<sup>23</sup> In addition, long-term deficiency in estrogen has been associated with increasing the risk and mortality of coronary artery disease, as well as the memory loss and cognitive deficits associated with Alzheimer's disease.

In the past, these symptoms and sequelae of the hypoestrogenemic state had been easily managed with hormone replacement therapy. Epidemiologic, observational, and animal studies had repeatedly shown that these medications provided excellent relief of vasomotor and genitourinary symptoms in addition to maintaining bone density. In addition, it was thought that the estrogen component of hormone replacement therapy had an added cardioprotective effect by lowering lipid levels.<sup>24</sup> However, the results from the Women's Health Initiative (WHI), a large randomized control study, showed a significantly higher risk of coronary heart disease in postmenopausal women receiving estrogen and progesterone hormone replacement when compared with controls.<sup>25</sup> Although there were fewer hip fractures in the hormone therapy group, there was a higher rate of breast cancer, stroke, and pulmonary embolism in women receiving estrogen and progesterone. The size and design of the study and the wide media attention to its findings resulted in a sharp decrease in women taking hormone replacement therapy almost immediately on its publication.<sup>26</sup> Over the past years, however, many physicians have reconsidered the initial adverse reaction to the WHI results as women have continued to suffer with vasomotor and genitourinary symptoms in the immediate period after entering menopause. For that reason, many expert panels have recommended the short-term use of hormone replacement therapy (5–7 years) for the control of vasomotor and genitourinary symptoms associated with menopause.<sup>27–29</sup> Women who have not had a hysterectomy should receive combination estrogen and progesterone therapy, whereas women who have had their uterus removed may receive estrogen alone. Continuation of hormone therapy after the initial 5- to 7-year period after entering menopause should be considered carefully and reevaluated on a regular basis.

Hormone replacement therapy for the control of vasomotor and genitourinary symptoms in the immediate postmenopausal period may not be appropriate for all women who have had a cancer diagnosis. Controversy remains as to the effects of hormone replacement therapy in breast cancer survivors. Observational data suggest no increase in the risk of recurrence in patients with breast cancer.<sup>30,31</sup> However, at least one prospective study has demonstrated an increased risk of breast cancer recurrence in women taking hormone replacement therapy when compared

with controls.<sup>32</sup> The hormonal dependence of breast cancer cells and the use of tamoxifen and letrozole (antiestrogenic drugs), coupled with the prospective study findings, make many physicians hesitant to prescribe hormone replacement therapy to women with a history of breast cancer. Likewise, hormonal replacement therapy for women with a history of ovarian and endometrial cancers is felt to be contraindicated by some clinicians owing to the hormonal dependence of the neoplastic cells. Other cancer survivors who should not receive hormone replacement therapy are those women who are at increased risk of thromboembolic events owing to the increase in hypercoagulability events in women taking estrogen with progesterone<sup>25</sup> and estrogen alone.<sup>33</sup> For most women with a diagnosis of cancer, a short course (5–7 years) of hormone replacement therapy for the control of vasomotor symptoms is a reasonable option.

For women with either contraindications to hormone replacement therapy or continued vasomotor symptoms after initial treatment with hormone replacement therapy, other options exist. Behavioral modifications, such as lowering ambient air temperature,<sup>34</sup> exercise,<sup>35</sup> and smoking cessation,<sup>36</sup> may decrease the number and severity of hot flashes. In addition, nonprescription remedies, such as isoflavones, black cohosh, or vitamin E, may be tried for mild hot flashes. These medications may have an effect on vasomotor symptoms. However, there are no conclusive studies demonstrating their efficacy or detailing their absorption. Selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine<sup>37</sup> and venlafaxine,<sup>38</sup> have been shown in randomized, double-blinded, placebo-controlled trials to significantly reduce hot flashes. These medications have an additional benefit of mood elevation in women with depression, a subclinical finding in many postmenopausal patients. The anticonvulsant gabapentin has also been shown to significantly reduce hot flashes.<sup>39</sup> This medication is also well tolerated and might also reduce somatic pain experienced by cancer survivors. Clonidine has been used successfully to treat hot flashes; however, many patients are unable to tolerate the drug-related side effects.<sup>40</sup> There are several treatment options for vasomotor symptoms in addition to hormone replacement therapy. Which regimen to choose will depend on the severity of the symptoms, other comorbidities, and patient and physician preferences. Without treatment, vasomotor symptoms will typically subside spontaneously, although this may take a long period of time.

Menopausal genitourinary symptoms of vaginal dryness, atrophy, and accompanying dyspareunia in addition to dysuria and incontinence can be made worse by cancer treatment. Tamoxifen has been noted to increase these

symptoms in women taking this medication for breast cancer.<sup>41</sup> Women who have received pelvic irradiation have significantly increased symptoms of vaginal dryness, atrophy, and dyspareunia.<sup>42</sup> Nonhormonal vaginal lubricants, such as Replens and K-Y jelly, can reduce vaginal dryness and dyspareunia. However, these remedies will not restore the atrophic vaginal and urethral epithelium and therefore will not relieve all of the vaginal or any of the urinary symptoms. Oral hormone replacement therapy has been the most effective in addressing all of these symptoms. Locally administered estrogen in the form of either a vaginal cream or an extended-release vaginal ring or pessary can also alleviate most of the genitourinary symptoms.<sup>43</sup> These routes of estrogen administration are attractive as they do not raise systemic levels of circulating estrogen.<sup>44</sup>

The reduction in libido in postmenopausal women may be partially related to vaginal dryness and dyspareunia. However, a lack of circulating hormones also affects sexual desire. Hormone replacement therapy may alleviate the associated vaginal symptoms that may be physical barriers to sexual intimacy. However, estrogen therapy has little effect on decreased sexual drive.<sup>45</sup> On the contrary, testosterone replacement may be necessary to restore libido.<sup>46</sup> Ongoing studies and drug development continue in an effort to help postmenopausal women regain sexual desire.

As mentioned, osteoporosis and its associated morbidities and mortality are an important consideration for the postmenopausal female. Women with hematologic malignancies such as leukemia, lymphoma, and myeloma are at increased risk of bone loss at baseline. Behavioral modifications such as smoking cessation and weight-bearing exercise help maintain bone strength and structure. Adequate daily intake of both calcium and vitamin D are also important.<sup>47</sup> For patients not taking hormone replacement therapy, other pharmacologic agents may be used to treat osteopenia or osteoporosis. Bisphosphonates have been shown to be equally effective as hormone replacement therapy in preventing postmenopausal bone loss.<sup>48</sup> Side effects such as gastrointestinal distress have made compliance with daily administration of bisphosphonates difficult in the past. However, patients can now take weekly or monthly doses, which greatly reduces the overall side effects and may increase compliance. Selective estrogen receptor modulators (SERMs), such as tamoxifen and raloxifene, also conserve bone mass, thereby reducing the risk fractures. This class of drug also has an additional benefit of reducing the risk of breast cancer and might also decrease the risk of coronary artery disease.<sup>49</sup> Unfortunately, these drugs have no effect on vasomotor or genitourinary symptoms and may actually worsen those symptoms in the acute period just after beginning the medication.

In summary, with more aggressive therapies and improved prognosis, women with cancer are becoming menopausal at a younger age and living longer in this state. Menopause is accompanied by acute vasomotor and genitourinary symptoms. Hormone replacement therapy remains the best treatment for the acute symptoms of menopause and can be safely used for a limited time (5–7 years) in most cancer patients. Patients with breast, ovarian, or endometrial malignancies should discuss this option with their oncologist. Other medications, such as SSRIs and gabapentin, may also alleviate vasomotor symptoms. For women not taking hormonal therapy or other medications, vasomotor symptoms will resolve with time. Despite this, the genitourinary symptoms will persist and worsen with age. For these women, vaginal estrogen may provide good relief of genitourinary symptoms. The decrease in libido, however, will not be affected by this formulation. Research continues as to the role of testosterone to help postmenopausal women maintain their sexual drive.

The long-term effects of menopause include osteoporosis, coronary artery disease, and possible changes in cognitive function. Women with hematologic malignancies are at an increased risk of osteoporosis and should be followed carefully. Exercise, smoking cessation, and dietary intake of calcium and vitamin D are recommended to maintain bone mineral density. Bisphosphonates and SERMs have also been shown to prevent osteopenia and osteoporosis. Newer formulations of the bisphosphonates make administration less frequent and side effects more tolerable. SERMs such as tamoxifen and raloxifene not only have a protective effect on bone, they also reduce the risk of breast cancer and may prevent coronary artery disease in postmenopausal women. They often, however, exacerbate the vasomotor and genitourinary symptoms of hypoestrogenism. To date, there are no recommendations as to how best to manage the heart disease and cognitive loss associated with menopause.

# Sexual Function Issues

Pamela T. Soliman, MD  
Kathleen M. Schmeler, MD  
Diane C. Bodurka, MD

Normal sexual function depends on multiple factors, including sexual desire, normal response to arousal, and the ability to achieve orgasm. Sexual dysfunction, for various reasons, is a common problem for both patients with cancer and those who survive cancer. Sexual dysfunction may develop early in a patient's disease course, during cancer treatment (related to surgery, radiation, chemotherapy, or hormonal therapy), as a result of symptom management, or after cancer treatment has been completed. Unfortunately, during cancer care, sexual difficulties are rarely addressed, and most patients receive little or no assistance in dealing with the effects of cancer care and treatment on intimacy.<sup>1</sup>

## Libido

Libido, or the desire to have sex, is often affected by multiple factors during cancer treatment. Psychological factors, including depression and anxiety, that are often associated with the diagnosis of cancer can have a significant impact on one's desire to be sexually active. Also contributing significantly to loss of sexual desire are the medical interventions that occur during cancer treatment. At the present time, a majority of cancers are treated with a combination of surgery, radiation, and/or chemotherapy. All of these modalities can have some impact on sexual desire.

## Surgery

Surgical treatment for cancer often requires hospitalization, anesthesia, exploration of body cavities, and the need to recover from the surgery itself. Postoperative pain and fatigue often affect sexual desire, particularly in the immediate weeks following surgery.<sup>2</sup> Surgeries that have the most impact on sexual desire and function are those involving the pelvis, such as radical prostatectomy, radical cystectomy, abdominoperineal resection for rectal cancer, and radical hysterectomy for gynecologic cancers. This is in part due to changes in body image; however, physiologic

effects from the surgery itself also affect sexual function.

Pelvic surgery for both men and women can interfere with the innervation of the pelvic organs and therefore can affect the physiologic response to sexual stimuli. The amount of dysfunction depends on the extent of injury to the sacral plexus. In men, surgery for bladder, rectal, or prostate cancer can affect the ability to have an erection by disruption of the parasympathetic sacral nerve fibers. Although there are procedures designed to spare the sacral nerve fibers, compression or trauma to the nerves can lead to a transient decrease in function, from which it may take a significant amount of time to recover.<sup>3</sup> A list of the most common side effects associated with radical pelvic surgery in men is shown in Table 1.

**Table 1** Most Common Physiologic Effects of Pelvic Surgery on Male Sexual Function

<i>Procedure</i>	<i>Common Effects</i>
Radical prostatectomy	Decrease in ability to have an erection May decrease intensity of orgasm Dry orgasm
Radical cystectomy	Decrease in ability to have an erection May decrease intensity of orgasm Dry orgasm Pain with intercourse (rare)
Abdominoperineal resection	Decrease in ability to have an erection May decrease intensity of orgasm Dry orgasm Pain with intercourse (rare)
Total pelvic exenteration	Impaired ability to have an erection May decrease intensity of orgasm Dry orgasm

In women, pelvic surgery can also lead to sexual dysfunction. Jensen and colleagues evaluated sexual function and quality of life in 173 women treated with radical hysterectomy for early-stage cervical cancer.<sup>4</sup> Lack of interest in sex was a common finding among women at 5 weeks (77%) and even up to 2 years after surgery (57%). Dyspareunia, or pain during intercourse, was more common in the immediate time period after surgery; however, a few patients reported dyspareunia 2 years after surgery. Sexual dysfunction associated with pelvic surgery in women is commonly attributed to vaginal shortening and stenosis. In addition, vaginal dryness owing to a lack of estrogen is common in women who undergo oophorectomy at the time of surgery.<sup>5,6</sup> These physiologic changes affect not only the ability to function normally but also the desire to engage in sexual activity. The extent of these side effects depends on the type of surgery performed and the organs involved. The most common side effects on sexual function owing to pelvic surgery in women are listed in Table 2.

## Radiation

Radiation therapy can result in both immediate and long-term side effects that influence sexual desire and sexual function. During radiation treatment, patients are often fatigued and nauseated and may have skin changes to the radiated areas of the body. All of these symptoms can have a significant effect on the desire to be sexually active, as well as an impact on body image. In a cohort of 118 women who were disease free after treatment with radiation for cervical or vaginal cancer, Jensen and colleagues reported that 91% of patients had low or no sexual interest 1 month after the completion of radiotherapy.<sup>5</sup> Other common symptoms in the immediate period after treatment included a moderate to severe lack of lubrication, vaginal irritation, foul-smelling discharge, and dyspareunia. These symptoms of sexual dysfunction resulted in a high level of distress in this population, and in many of these women, symptoms persisted for at least 2 years after the completion of treatment.

**Table 2** Most Common Physiologic Effects of Pelvic Surgery on Female Sexual Function

Procedure	Common Effects
Simple hysterectomy	Vaginal dryness Shortening of the vagina Pain with intercourse (rare)
Radical hysterectomy	Vaginal dryness Shortening of the vagina Pain with intercourse (rare)
Radical cystectomy	Vaginal dryness Pain with intercourse Vaginal dryness
Abdominoperineal resection	Vaginal dryness Pain with intercourse
Total pelvic exenteration and vaginal reconstruction	Loss of erotic zones Need to relearn how to reach orgasm Pain with intercourse (occasional)
Radical vulvectomy	Loss of erotic zones Severe vaginal dryness Need to relearn how to reach orgasm Pain with intercourse

In addition to the short-term side effects of radiation, prolonged external beam radiation can lead to fibrosis of soft tissues, the development of scar tissue, and loss of nerve function. This has a particular effect on patients who have high-dose primary radiotherapy for the treatment of prostate, bladder, cervical, or rectal cancer. External beam radiation to the pelvis also affects the small vessels that help supply the pelvic organs. In men, this can be as damaging as primary surgery to the nerves responsible for erectile function. In contrast to the vascular and nerve damage caused by surgery, the damage related to radiation therapy may not be apparent until months after the completion of therapy.<sup>7</sup> Finally, radiation can cause injury to adjacent normal tissues, including the bladder, rectum, and vagina, which may lead to symptoms that detract from sexual desire, including proctitis, cystitis, and vaginal stenosis.<sup>2</sup>

Improvements in radiation delivery, including the introduction of brachytherapy for the treatment of localized prostate cancer, seem to have had an impact on the side effects associated with pelvic radiation, including those that affect sexual function. Reis and colleagues compared the effects of prostatectomy and primary radiotherapy on sexual function in 158 men with localized prostate cancer.<sup>8</sup> In this cohort, erectile dysfunction was reported in 85% of men who were treated by radical retropubic prostatectomy and in only 23% of men treated with brachytherapy. Other studies have also found that erectile dysfunction may be higher among surgically

managed patients; however, there are data to suggest that, over time, the treatment modalities have similar effects on sexual function and desire.<sup>9,10</sup>

### Chemotherapy

The effects of chemotherapy on sexual function can also be divided into immediate and long-term effects. During the course of treatment with chemotherapy, many patients experience nausea, vomiting, fatigue, hair loss, and mucositis. Women in particular may experience vaginal or perineal mucositis, causing discomfort during intercourse. These short-term side effects vary depending on the chemotherapy agent used; however, they can all influence a man or woman's feeling of well-being and desire to engage in sexual activity.<sup>2</sup>

In a large cohort of breast cancer patients, Ganz and colleagues found that patients who had received chemotherapy as part of their primary treatment reported more sexual problems at the end of primary treatment than women who did not receive chemotherapy. Lack of interest in sex was reported in 23.4% of all patients in the study, with a greater frequency among women who had received chemotherapy ( $p = .002$ ). They also found that vaginal lubrication problems and pain during intercourse were more severe among women who received chemotherapy. These findings have been reported in previous studies.<sup>11,12</sup> A higher number of women (50%) who received chemotherapy reported that breast cancer had a negative effect on their sex life compared with women who had not received chemotherapy ( $p < .001$ ).<sup>13</sup>

The long-term effects of chemotherapy in women have also been described. These include premature menopause and loss of fertility.<sup>14,15</sup> Up to 50% of premenopausal breast cancer patients report changes in their menstrual periods after the diagnosis of breast cancer. These changes are seen more frequently in women who receive chemotherapy.<sup>13</sup> Goodwin and colleagues found that among patients with early-stage breast cancer, age and systemic chemotherapy were the strongest predictors of early menopause.<sup>16</sup> Physiologic changes associated with menopause, including vaginal dryness, atrophy, and dyspareunia, contribute to discomfort during sexual intercourse and affect a woman's desire to have intercourse and her ability to become aroused. These factors play a major part in a woman's libido and sexual function. There are limited data available on the long-term effects of chemotherapy on libido in the male population.

### Hormonal Therapy

In a subset of endocrine-sensitive cancers, hormonal therapy has been used for both prevention and treatment. This type of therapy can also affect

sexual desire and sexual function. Tamoxifen, an antiestrogenic compound used in the prevention and treatment of breast cancer, has been shown to increase vaginal discharge and vasomotor symptoms.<sup>11,17,18</sup> Although there are no clear data to suggest that sexual function is statistically different when comparing women on tamoxifen with those taking placebo, some studies have shown that almost 50% of women on tamoxifen complain of pain, burning, or discomfort with intercourse. In addition, a high proportion of these women require the use of vaginal lubricants during intercourse owing to vaginal dryness.<sup>17,19</sup>

Other hormonal therapies used to treat cancer in women include megestrol acetate, gonadotropin-releasing (Gn-RH) analogues, and aromatase inhibitors. Progesterone therapy with megestrol acetate is sometimes used in the treatment of breast or endometrial cancer. Megestrol acetate is also used as an appetite stimulant in cancer and noncancer patients. Consequently, one of the main side effects is weight gain, which can have a negative effect on body image and sexual desire.<sup>20</sup> Gn-RH analogues, which have been used in women with breast or ovarian cancer, are associated with menopausal symptoms, which have also been shown to have a negative impact on sexual desire and sexual function.<sup>21</sup> Aromatase inhibitors are the newest class of hormonal therapy used for postmenopausal breast cancer patients. Although the data are limited, there is some suggestion that use of aromatase inhibitors can result in vaginal dryness, which may result in problems with sexual function.<sup>2</sup>

In men, hormonal therapy is primarily used in the treatment of prostate cancer. Gn-RH analogues are used to eliminate the effects of adrenal androgens. The primary side effect from this therapeutic approach is decreased libido. Although many men can physically achieve an erection and ejaculation despite loss of testosterone, a decrease in libido is commonly reported. In fact, some men who are asymptomatic with a rising prostate-specific antigen choose to delay hormonal therapy for this reason. In men with advanced or progressive disease, other factors have an effect on erectile function and sexual desire, making it difficult to determine the additive effect of the hormonal therapy.<sup>2</sup>

Many patients receive a combination of surgery, radiation, chemotherapy, and hormonal therapy as primary treatment for their cancer. In addition, patients also receive various treatment modalities for recurrent or progressive disease. As such, it is not uncommon for patients to suffer side effects from each of these treatment modalities, which may compound the negative effects on sexual desire and sexual function.

### Side Effects of Therapy

In general, single- or multimodality cancer treatment is associated with fatigue, pain, and

declining physical function. These factors also have a significant influence on libido and sexual functioning. Fatigue is a common symptom associated with cancer diagnosis and treatment that is associated with decreased libido.<sup>22,23</sup> Chronic fatigue tends to affect most cancer patients but is more prevalent in certain types of cancer, including Hodgkin's lymphoma.<sup>24</sup> This may be related to specific side effects of treatment, such as anemia, but is likely multifactorial and represents the long-term side effects of both chemotherapy and radiation.<sup>2</sup>

Uncontrolled or chronic pain can also contribute to a loss of libido. Pain often manifests itself as psychological distress, poor appetite, and lack of sleep, all of which may have a negative effect on sexual interest. The association between pain and decreased sexual function is intuitive; however, few studies have been conducted to support this relationship. A small study on patients who received high-dose chemotherapy and autologous bone marrow for breast cancer patients found that pain was associated with a decrease in sexual function.<sup>25</sup> There are also some data to support the fact that pain increases psychological distress, which may increase sexual dysfunction.<sup>26</sup>

## Medications

In addition to the effects of primary treatment on sexual desire and function, cancer patients are often prescribed multiple medications during their cancer treatment. Many of these medications can affect libido and sexual function. In most cases, the benefits of taking these medications outweigh the side effects; however, it is important to understand what these side effects are to determine if appropriate changes in these medications can be made to alleviate some of the unwanted side effects.

Nausea is a symptom that commonly results from cancer treatment. It is one of the most common short-term side effects associated with both radiation and chemotherapy. In addition, patients who undergo surgery often require antiemetic agents in the postoperative recovery period. Although nausea itself can decrease libido, many of the medications used to treat nausea can also interfere with sexual desire. The primary reason for this effect is that many of these medications also act as sedatives. In addition, certain classes of antiemetics can affect hormone levels that alter sexual desire.<sup>27</sup>

Narcotics are also commonly prescribed at the time of diagnosis or for pain related to cancer treatment. In addition, these medications are often continued in patients who have persistent pain through the course of treatment or for those who have progressive disease. The dose and duration of narcotic use are patient dependent. When narcotics are taken for long periods of time,

tolerance can develop, and patients may require higher doses to achieve the same degree of pain control. When given in large doses, narcotic pain medications can decrease sexual desire.<sup>27</sup>

Difficulty sleeping, anxiety, depression, and chronic pain are often treated with sedatives, anxiolytics, or antidepressants in the cancer patient. In general, sedatives have a negative effect on sexual desire. Similarly, most medications that are used to treat anxiety also decrease sexual desire in men and women. Antidepressant medications, on the other hand, can have a variety of effects on sexual desire. If antidepressant use results in improvement in mood, this may enhance sexual desire. However, the physiologic effects of some of these medicines can have a negative effect on sexual desire. Many of these effects are patient and medication dependent.<sup>27</sup>

Finally, many cancer patients and cancer survivors have other medical comorbidities for which they require medications. Heart disease and hypertension are common medical problems in older men and women. Therefore, medications used to treat these comorbidities are not uncommon in cancer patients. These medications can also complicate the issue of decreased libido and sexual dysfunction.

Sexual desire and sexual function in the cancer patient and cancer survivor are very complicated issues. Multiple factors, including treatment modality, cancer-associated symptoms, medication side effects, and various psychological factors, contribute to a patient's desire or lack of desire for intimacy.

## Impotence

Erectile dysfunction is a relatively common problem in the general population. In a large national survey of 18- to 59-year-olds in the United States, 31% of men reported some type of sexual dysfunction. The most common problems reported were premature ejaculation (28.5%), anxiety about performance (17%), lack of interest in sex (15.8%), and inability to maintain an erection (10.4%).<sup>28</sup> As men grow older, the prevalence of erectile dysfunction increases, and by the age of 70, up to 50% of men are impotent.

Erectile dysfunction associated with cancer treatment is primarily due to damage to the sacral nerve plexus, devascularization of the pelvic organs, and changes in hormone levels. These effects can be due to surgery, radiation, chemotherapy, and hormonal therapies. Erectile dysfunction can also result from treatment of other non-cancer-related conditions, such as hypertension and heart disease.

A majority of the studies evaluating erectile dysfunction in cancer patients and survivors have focused on the men who are at the highest risk, those with prostate cancer. Several studies have

suggested that 30 to 50% of men have significant sexual dysfunction at the time of diagnosis with prostate cancer.<sup>29-31</sup> Following treatment with either surgery or definitive radiation therapy, the rates increase to 50 to 80%, and in men who require antiandrogen therapy for advanced prostate cancer, the rates of sexual dysfunction approach 80 to 90%.<sup>32</sup>

Because erectile dysfunction affects such a high proportion of men undergoing therapy for prostate cancer, changes in treatment have been made to help decrease erectile dysfunction. From a surgical standpoint, the nerve-sparing radical prostatectomy has been introduced and has been shown to have some effect on preservation of erectile function. One group reported that up to 86% of men who underwent bilateral nerve-sparing prostatectomy could achieve erections functional for intercourse within 18 months of surgery.<sup>33</sup> Although these data look promising, the patients in this cohort tended to be younger (median age 57 years). Other studies in older populations have reported that approximately 20% of men who undergo bilateral nerve-sparing radical prostatectomy recover to have erections firm enough for vaginal intercourse.<sup>34-37</sup> Although most studies have found that there is some benefit to this approach, further study will be required to determine exactly how effective this procedure is in preserving erectile function.

Modifications in the delivery of radiotherapy, including the use of brachytherapy, three-dimensional conformal therapy, and intensity-modulated therapy, may help preserve erectile function by sparing surrounding tissues.<sup>7,29,35,38-40</sup> Potency after radiation therapy for prostate cancer has been reported to be as high as 30 to 60%.<sup>41</sup> Several studies have suggested that preservation of erectile function is superior after radiotherapy than after surgical therapy; however, there are conflicting reports. Talcott and colleagues did the first prospective study comparing the two treatment modalities, using a validated quality of life questionnaire to evaluate sexual function.<sup>7</sup> They reported that erectile dysfunction was higher initially in the surgery group; however, over time, sexual function declined in the radiotherapy group and improved in the surgically treated group. The longer the follow-up period, the smaller the difference detected between the two treatment groups. This likely relates to the difference in the physiologic damage to the sacral nerve plexus and vasculature of the pelvis that was discussed earlier in the chapter.

Although physicians continue to modify treatments to help prevent erectile dysfunction, impotence continues to affect a large percentage of men treated for prostate cancer. As such, physician and health care workers should also focus on the treatment of erectile dysfunction and sexual rehabilitation.

## Psychosocial Issues

Although it is clear that treatment for cancer can affect the physiologic response to sexual stimuli, psychological factors can also have a significant impact on sexual desire and sexual function. Psychological distress is often associated with sexual dysfunction in healthy individuals, and this has also been identified in different cancer populations. Several studies have suggested that the symptoms of depression and anxiety are commonly identified in men and women with cancer. Major depressive disorder has been described in as many as 50% of cancer patients, which is significantly higher than in the general population (8%).<sup>42,43</sup> This is of particular importance because these conditions are often underdiagnosed and therefore undertreated.

Many of the studies evaluating the predictors of psychological distress among cancer patients have been disease specific. In ovarian cancer patients, 30 to 50% of newly diagnosed patients report moderate to severe levels of anxiety.<sup>44,45</sup> This high level of anxiety and psychological distress may be related to the diagnosis of ovarian cancer or related treatments. Completion of therapy and entering the “watching and waiting” period can also be equally distressing. More importantly, many of these women (60%) are not receiving mental health services or psychotropic medications.<sup>46</sup> This suggests that we need to improve detection and treatment of these conditions in cancer patients. Although anxiety and depression can have many implications in the cancer population, these conditions can also affect sexual desire and sexual function.

In a study of newly diagnosed breast cancer patients, Schag and colleagues found that women who were considered at risk of psychological distress based on an evaluation at the time of diagnosis were more likely to report problems with sexual function 1 month and 1 year after diagnosis than women who were categorized as low risk.<sup>47</sup> Reported problems with sexual function included a lack of interest in having sex, difficulty in being sexually aroused, and difficulty reaching orgasm. Similar findings have been described in patients with Hodgkin’s disease and acute leukemia.<sup>48</sup>

Cull and colleagues evaluated a group of early-stage cervical cancer patients who were treated successfully with either surgery or radiotherapy.<sup>49</sup> Two years after treatment, approximately 50% of women continued to report persistent tiredness and a lack of energy. There were no differences in outcome or psychological status when comparing the two treatment groups. Overall, the rates of anxiety and depression were higher in patients with early-stage cervical cancer than expected for the general population. Many

patients were found to have high levels of psychological distress, which correlated significantly with both physical complaints and functional outcomes. In the subgroup of women who were sexually active, they felt that their sexual function post-treatment was significantly poorer when compared with pretreatment. Approximately 50% of women reported that they would have liked to receive counseling for their psychological and sexual concerns.

### Body Image

In addition to a number of other factors that affect psychological well-being during cancer treatment and diagnosis, body image can have a significant impact on sexual desire and sexual function. The body image changes that are associated with cancer and cancer treatment can be very dramatic. These changes range from surgical defects and deformities (including limb amputation, loss of a breast, and pelvic exenteration) to total body alopecia (loss of scalp hair, eyebrows, pubic and axillary hair). More subtle changes can include weight loss secondary to disease or weight gain from treatment with corticosteroids. All of these factors affect a patient’s self-esteem and sexual attractiveness.<sup>2</sup> For some patients, the physical difficulties and the emotional sequelae are so disruptive that they no longer engage in sexual activity.<sup>50</sup>

In a comprehensive evaluation of multiple factors that affect sexual function in ovarian cancer patients, Carmack Taylor and colleagues determined that women who liked the appearance of their body were more likely to be sexually active.<sup>51</sup> Other predictors of sexual activity in these women included being married, being younger than 56 years old, not receiving active treatment at the time of the study, and a longer interval of time between treatment and evaluation of sexual function. This model confirmed that body image, in addition to other factors, was important in the evaluation of sexual function in cancer patients.

In women with breast cancer, breast-conserving procedures have been implemented to help preserve body image. Multiple studies have shown that breast-conserving surgery can have a positive impact on self-image after treatment for breast cancer.<sup>52–54</sup> Women treated with breast-conserving surgery had a more favorable body image, were more satisfied with their surgery, and had better cosmetic results when compared with women treated with mastectomy.<sup>55</sup> Several studies have suggested that issues of body image are more important in a younger population; however, body image has also been shown to be important in the older breast cancer population. Receiving treatment that was consistent with preferences about appearance was important in determining long-term mental health.<sup>56</sup>

A longitudinal study of women with gynecologic cancers treated with pelvic exenteration found that prior to surgery, patients were anxious about or uncomfortable with the body changes that were going to occur as a result of surgery. Many women reported feeling unattractive and uninterested in having sex. After surgery, body image, attractiveness, and self-confidence were all reduced. The extent of surgery and the amount of reconstruction also had a significant impact on body image. Women who had two ostomy sites (to drain bowel and bladder contents) had significantly more problems with physical, sexual, and marital issues when compared with women with one or no ostomy sites. In addition, women who did not have vaginal reconstruction also felt significantly less attractive and self-confident.<sup>57</sup> It is important to recognize that different surgical procedures can have a different impact on quality of life and body image.

It is clear that in the general population, body image and self-esteem have a significant impact on sexual desire and sexual function. Cancer treatment can result in dramatic changes in body image and self-esteem. More conservative organ-preserving surgical approaches and reconstructive surgery, where appropriate, may help alleviate some of the distress associated with these changes in body image.

## Sexual Rehabilitation

### Assessment

Sexual function is an important aspect of quality of life and should be assessed in all patients diagnosed with cancer. It is important to have a baseline assessment of sexual function to determine if a patient has difficulties with sexual function prior to the initiation of treatment. This may help prevent the patient and the physician from having unrealistic expectations of sexual function during and after completion of treatment.

Evaluating and assessing sexual dysfunction in a cancer patient may require a multidisciplinary approach. Although many oncologists do not have the time or training to address sexual issues, having the primary oncologist perform the initial assessment may have several advantages. It emphasizes to patients that the treating physician sees them as a whole person and not just as someone with a diseased body part. It also indicates to patients that the treating physician understands that sexual function is an important aspect of quality of life. Finally, it gives patients permission and freedom to talk about issues of sexual function during and after cancer treatment.<sup>1</sup>

The initial assessment may be as limited as asking patients if they have any sexual problems or concerns and reassuring them that these issues

are common among cancer patients. If a sexual problem is identified or if the oncologist does not feel equipped to address the issue, involvement of a multidisciplinary team may be warranted. This may include mental health professionals trained in sex therapy, gynecologists familiar with concerns regarding hormone replacement or dyspareunia, urologists who specialize in the treatment of erectile dysfunction, and infertility specialists if a patient desires to have children. Once a problem is identified, further questioning may help determine who should be involved in the care of a particular patient. Sample questions to further assess sexual function are shown in Table 3. Topics addressed should include desire, arousal, orgasm, and pain.<sup>2</sup>

The PLISSIT model, which was designed in the 1970s, provides a more structured approach to communicating with patients about sexuality and allows clinicians to gear this communication to their own level of comfort.<sup>58</sup> The acronym PLISSIT was developed from the concepts of permission, limited information, specific suggestions, and intensive therapy. This basic theory starts by giving patients permission to disclose their problem with sexual function and then allowing the clinician to provide information regarding the issues brought forward and make suggestions for future directions. This may include treatment by the primary team or referral to a specialist.

It is important to realize that psychological stressors not related to cancer diagnosis and treatment may also be affecting a patient's sexual desire and sexual function. This may include difficulty with relationships, a history of sexual trauma, unusual guilt about sexuality, other medical problems, and substance abuse.<sup>2</sup> It is also important to consider the influence of aging on sexual function because it is sometimes difficult to distinguish cancer-related changes from the normal slowing of sexual response that is associated with increasing age.

### Treatment of Sexual Dysfunction

Once a sexual problem has been identified, the level and type of intervention that are needed must be assessed.<sup>2</sup> In some cases, the sexual

problem can be addressed directly by an expert in that field (ie, gynecologist or urologist), although patients who have more complex problems may require referral to a mental health professional trained in sex therapy. The most important step an oncologist can take is to provide information to patients and their partners about sexual functioning, aging, and sexual problems related to cancer treatment. Schover's book, *Sexuality and Fertility after Cancer*, includes a wealth of information and detailed self-help instructions for many of the common sexual problems among cancer patients.<sup>27</sup> This may help ease patients' concerns and facilitate them getting help.

In women, one of the most common symptoms associated with cancer treatment and aging is vaginal dryness. In women who can safely receive estrogen replacement therapy (ERT) after cancer, this is the most effective treatment regimen. Studies suggest that in women who are good candidates for ERT, this should be considered early on in the treatment course to prevent any disruption in normal sexual function. This can be given either in pill form, as a vaginal cream, or as an estradiol-impregnated ring (Estring). Other options include vaginal lubricants and moisturizers such as Vagifem, Astroglide, or K-Y Jelly.

In men, the most common problem is erectile dysfunction. As discussed earlier, erectile dysfunction can be the result of a number of cancer-related issues. It may be related to surgery, radiation, or low testosterone levels after hormonal therapy, or it may be a side effect of a medication. To effectively treat erectile dysfunction, the cause or causes of impotence must be defined. Treatments can then be targeted toward the underlying cause. Some of these issues can be addressed only prior to the initiation of therapy, for example, performing a nerve-sparing prostatectomy or using targeted radiotherapy instead of external beam radiation. After primary therapy, medication changes or correction of abnormal hormone levels may also be effective. If these changes are ineffective, there are oral erectogenic agents and medical devices that can enhance erectile function. It is important that only physicians who have expertise prescribe these modalities as they are not safe for all men.

### Summary

Sexual dissatisfaction and/or sexual dysfunction can affect 20 to 90% of adult cancer patients.<sup>59</sup> This may be related to primary cancer treatment, a result of symptom management, or may occur after cancer treatment has been completed. It is clear that multiple factors affect each cancer patient and his or her desire for sexual activity. The assessment and treatment of these sexual problems can be equally complex.

It is important to have a multidisciplinary approach to effectively diagnose and treat patients with sexual dysfunction.

# Reproductive Issues

Kathleen M. Schmeler, MD  
 Pamela T. Soliman, MD  
 Diane C. Bodurka, MD

The overall survival and cure rates of children and young adults with cancer have improved significantly in recent years (Figure 1).<sup>1,2</sup> This has led to increased emphasis on quality of life issues, including the ability to have children. Many of the chemotherapy and radiation regimens used to treat these young patients are toxic to the gonadal tissues, resulting in infertility and other reproductive problems. These reproductive consequences associated with cancer affect a large number of people. Each year in the United States, over 50,000 men and women of reproductive age and 12,000 children under the age of 15 years are diagnosed with cancer. The most common cancer types diagnosed in children and young adults who develop infertility as a result of the disease or its treatment are shown in Table 1.<sup>1-3</sup>

## Effects of Cytotoxic Therapy in Men

Up to 90% of postpubertal young men become azoospermic during cytotoxic chemotherapy.<sup>4-6</sup> The type and dose of agents used for therapy determine the amount of time required for recovery of spermatogenesis. In approximately 50% of men, spermatogenesis is recovered in the 6 months to 5 years following treatment.<sup>7,8</sup> For the remaining patients, severe oligospermia or azoospermia is a permanent effect of treatment.

In men, age at treatment does not appear to be a major factor in recovery from gonadal damage owing to chemotherapy.<sup>9,10</sup>

The effects of radiation on the testes depend on fractionation. Doses given in 3- to 7-week regimens cause more gonadal damage than single doses.<sup>3,11</sup> This is in contrast to all other organ systems, including the female gonads, where fractionation decreases the toxicity of radiation. Azoospermia occurs at doses above 0.6 Gy, with

the duration of azoospermia dependent on the total radiation dose received.<sup>12-14</sup>

For male children undergoing cancer treatment, gonadal toxicity is also an important issue as the prepubertal testis is also susceptible to cytotoxic therapy. Similar to adult men, radiation and chemotherapy may produce permanent azoospermia.<sup>3,15</sup> Of note, pubertal development is not usually affected as most of the regimens used do not affect Leydig cell function or testosterone levels.<sup>3,16</sup>

## Effects of Cytotoxic Therapy in Women

Unfortunately, the effects of cytotoxic therapy on female gonadal function are almost always irreversible. The effects depend on several factors, including the type of agents used, the cumulative dose, and the patient's ovarian reserve prior to beginning therapy.<sup>17,18</sup> Ovarian reserve refers to the number of primordial follicles within the ovary. A woman is born with all of the primordial follicles she will ever have, and no new oocytes can be generated if all of the primordial follicles are destroyed by cytotoxic therapy. Loss of ovarian reserve owing to chemotherapy will result in early menopause, premature ovarian failure (POF), and infertility.<sup>19</sup> Older women are more susceptible to the sterilizing effects of cytotoxic chemotherapy as they tend to have lower numbers of pretreatment follicles compared with younger patients.<sup>3,19,20</sup>

In women, the degree and persistence of radiation therapy-induced gonadal damage are dependent on patient age, total radiation dose, and the number of treatment fractions.<sup>3</sup> Radiation is more toxic to the ovaries when given in a single dose compared with fractionated doses.<sup>17</sup> Similar to cytotoxic chemotherapy, older women are more susceptible to the sterilizing effects of radiation therapy as they tend to have fewer pretreatment primordial follicles when compared with younger women. The threshold at which POF occurs has been shown to be 3 Gy.<sup>21</sup> If treated with less than 3 Gy, only 11 to 13% of women

**FIGURE 1** Five-year cancer survival rates for children diagnosed under age 15 years.<sup>1</sup>

experience POF. However, treating with 3 Gy or higher results in POF in 60 to 63% of women.<sup>21</sup> It is difficult to say that there is a safe radiation dose as less than 2 Gy of radiation to the ovaries can destroy up to 50% of the oocyte population.<sup>20,22</sup> It is also important to note that even if reproductive function is maintained after treatment, cytotoxic agents will damage some primordial follicles and therefore shorten a patient's reproductive life span. In addition, the sterilizing potentials of radiation and chemotherapy are additive.<sup>20</sup>

Prepubertal girls are less susceptible to the gonadotoxic effects of cytotoxic therapy than young postpubertal women. Most chemotherapy regimens do not cause loss of primordial follicles, and the majority of girls undergo normal pubertal development and menarche. In addition, girls under the age of 12 years who are treated with chemotherapy and in particular with alkylating agents are less likely to experience premature menopause in their twenties or thirties, as is seen in those treated between the ages of 13 and 19 years.<sup>3,23</sup>

## Techniques to Protect Gonads

### Gonadal Shielding

For patients whose gonads are within or close to the radiation treatment field, special techniques, including field blocking and gonadal shielding, can sometimes be used to reduce gonadal dose. In men being treated with radiation therapy for Hodgkin's disease, testicular shields, also known as clamshells, significantly reduce the radiation dose to the testes.<sup>24</sup> In addition, a special positioning device can be used to retract the remaining testicle out of the radiation field in men being treated with radiation therapy to the hemiscrotum following unilateral orchiectomy for testicular cancer.<sup>25</sup> However, even with these techniques, an appreciable radiation dose may reach the gonads owing to leakage through the accelerator head, radiation scatter from collimators and beam modifiers, and radiation scatter within the patient from the treatment beams.<sup>26,27</sup>

### Ovarian Transposition

In women undergoing radiation therapy, surgically transposing the ovaries outside the radiation field can decrease the amount of radiation the ovaries receive and potentially prevent premature ovarian failure and infertility. For patients undergoing radiation treatment for Hodgkin's lymphoma, the ovaries are moved to an area behind the uterus, away from the pelvic lymph node radiation fields. In women with cervical cancer being treated with hysterectomy followed by radiation therapy, the ovaries can be transposed laterally out of the radiation field to potentially prevent premature menopause. This may retain the

possibility of future oocyte retrieval and pregnancy using a surrogate. Transposing the ovaries is estimated to reduce the radiation exposure to approximately 10% of the dose of in situ ovaries.<sup>28,29</sup> However, ovarian failure still occurs in up to 50% of women following ovarian transposition.<sup>30–32</sup> This may be due to not transposing the ovaries far enough out of the radiation field, radiation scatter, vascular compromise, or migration of the ovaries back to their original position.<sup>20</sup>

### Pharmacologic Protection

After noting that the prepubertal ovary is less sensitive to cytotoxic drugs,<sup>20,33</sup> investigators attempted to use medications such as gonadotropin-releasing hormone (GnRH) agonists during therapy to help preserve fertility.<sup>34–36</sup> The studies to date have reported conflicting results, and it remains unclear whether administering GnRH agonists during cytotoxic therapy provides any benefit in the prevention of POF. Further prospective study is needed to clarify this issue.

GnRH agonists have also been evaluated in men undergoing chemotherapy and/or radiation for lymphoma and testicular cancer. However, none of the studies have demonstrated a significant protective effect in maintaining spermatogenesis or increasing the rate of spermatogenesis recovery following cancer treatment.<sup>29,34,37,38</sup>

### Fertility Preservation for Men

Improved survival rates for many cancers have resulted in an emphasis on quality of life. This is particularly important in men who want to preserve their fertility. A survey of men diagnosed with cancer between the ages of 14 and 40 years was conducted by Schover and colleagues.<sup>39</sup> They found that 51% of men with cancer wanted children in the future, including 77% of men who were childless at the time of their cancer diagnosis. Only 60% of men recalled being informed about infertility as a side effect of cancer treatment, and only 51% had been offered sperm banking. Overall, 24% of men in the study banked sperm, including 37% of childless men. Lack of information was the most common reason cited for failing to bank sperm.

### Sperm Cryopreservation

It is difficult to predict which patients will become infertile after treatment for malignant disease. In addition, treatment may shift to a more sterilizing regimen owing to disease progression. Sperm banking or cryopreservation is a safe and effective means of storing sperm and should be offered to all men prior to undergoing cancer treatment that has the potential to impair fertility. Sperm banks are available in most large cities, with many cancer centers and large hospitals having their own sperm banks. If the patient does not live near a

sperm bank, a local laboratory can collect and freeze semen, which can then be shipped to a sperm bank.

The traditional recommendations for sperm cryopreservation are to collect a minimum of three semen samples with at least 48 hours of abstinence between sample collections. This process usually requires 5 to 8 days. However, in many cases, the need to initiate treatment may be urgent, resulting in fewer samples being obtained and shorter time intervals between sample collections. Fortunately, advances in assisted reproductive technology have reduced the number of cryopreserved sperm necessary for the fertilization of eggs. Intracytoplasmic sperm injection (ICSI) can now be performed when undergoing in vitro fertilization (IVF). This involves the injection of a single sperm cell directly into the cytoplasm of each oocyte.<sup>40,41</sup> As a result, even a single ejaculate before starting cancer treatment can provide a reasonable chance of having a biologic child. All semen samples should therefore be accepted for cryopreservation, even if they have only a few motile sperm.

### Donor Sperm

Using donated sperm is an option for couples if the male cancer survivor is azoospermic or if the couple is uninterested in pursuing IVF/ICSI. Donated sperm can also prevent transmitting a genetic risk from the male cancer survivor. Major sperm banks in the United States collect sperm from healthy donors who are paid for donating their sperm. The donors undergo detailed screening, including medical history, psychological history, and family history, and in some cases, genetic testing for some diseases is performed. All donors are also screened extensively for sexually transmitted diseases. Information is also provided about the donor's ethnicity, physical traits, education, and profession. Some sperm banks also provide information about the donor's personality and talents.<sup>42–44</sup>

The process of donor insemination is relatively straightforward. The woman who will carry the pregnancy undergoes intrauterine insemination, in which the donor sperm is inserted into her uterus at the time of ovulation. No hormonal treatments are usually needed if the woman has no history of fertility problems.<sup>45</sup>

### Sperm Retrieval Methods

#### Testicular Sperm Extraction

Previously, donor insemination and adoption were the only reproductive options available for azoospermic men who were prepubertal at the time of cancer treatment or who did not bank sperm prior to beginning therapy. Testicular sperm extraction (TESE) is currently being studied as an option for men with nonobstructive azoospermia. Even though these men have no

spermatozoa in the ejaculate, they often have small numbers of spermatozoa in the testis tissue.<sup>46</sup> TESE is a procedure involving removal of testicular parenchyma and isolating individual spermatozoa.<sup>47</sup> The spermatozoa are then used for IVF/ICSI.<sup>48-50</sup> Successful sperm retrieval with subsequent live births of healthy children has been reported by a few authors.<sup>47,51-53</sup>

TESE has also been studied as a method to obtain spermatozoa in men who are azoospermic prior to the initiation of cancer therapy. A study by Schrader and colleagues reported successful sperm recovery using TESE in 14 of 31 azoospermic men prior to treatment for testicular cancer or lymphoma.<sup>54</sup> These early findings suggest that TESE may also be an option for fertility preservation in men with pretreatment azoospermia.

#### Microsurgical Epididymal Sperm Aspiration

Pelvic surgery can result in obstructive azoospermia, where semen is no longer produced, but testicular function is preserved. In these patients, sperm can be retrieved using microsurgical epididymal sperm aspiration. The sperm are then used immediately for IVF/ICSI or cryopreserved for later use. Excellent fertilization rates have been reported using both freshly aspirated or cryopreserved epididymal sperm.<sup>55,56</sup>

#### Electroejaculation

Some patients with testicular cancer are required to undergo a retroperitoneal lymph node dissection as part of their treatment. Modified nerve-sparing techniques have reduced the extent of dissection necessary to preserve ejaculation; however, up to 50% of patients still experience anejaculation.<sup>57</sup> Medical treatment with sympathomimetics, including pseudoephedrine, ephedrine sulfate, phenylpropanolamine, or imipramine, is sometimes successful in producing emission and ejaculation in these patients. However, if these medications are unsuccessful, electroejaculation can be performed. Following administration of general anesthesia, a rectal probe is inserted and the sympathetic efferent fibers and smooth muscles are electrically stimulated, leading to ejaculation in over 70% of patients.<sup>58,59</sup> Intrauterine insemination can be used following electroejaculation; however, sperm motility tends to be low, so IVF/ICSI may be required to achieve pregnancy.<sup>60</sup>

#### Future Directions

Testicular stem cell banking is currently under investigation as a method of preserving the fertility of prepubertal boys undergoing potentially sterilizing cancer therapy. The procedure involves the harvesting and cryopreservation of spermatogonial stem cells that are capable of self-renewal, proliferation, and repopulation of the seminiferous tubules. These stem cells could potentially be

transplanted back into the patient's testis after cancer treatment is complete. Encouraging results have been reported in animal studies,<sup>61-63</sup>; however, further research is needed before these advances are applied to the treatment of male infertility.

#### Fertility Preservation for Women

In general, young female cancer patients, like their male counterparts, are poorly counseled on the effect of cancer treatment on ovarian function and on their options for fertility preservation. Fertility preservation for men is much simpler owing to the availability of sperm banking. The storage of gametes for women is more complex. Fortunately, recent advances in several reproductive technologies may provide the patient with the option of future pregnancy.<sup>18</sup>

#### Embryo Cryopreservation

Embryo cryopreservation is a widely used method of fertility preservation that has been available to cancer patients for several years. It is a technique that is used regularly by infertility clinics to bank spare embryos for couples undergoing IVF. The woman undergoes treatment with gonadotropins to stimulate her ovaries, followed by a minor surgical procedure to retrieve the oocytes. The oocytes are then fertilized with sperm from a partner or donor. Any resulting embryos are cryopreserved for future use.

Embryo cryopreservation can have several limitations for the woman newly diagnosed with cancer. It requires a male partner or the use of donor sperm. In addition, the woman needs to undergo ovarian stimulation and egg retrieval, possibly resulting in a delay of her cancer treatment. The probability of a successful future pregnancy depends on the number of IVF cycles performed and on the number and quality of embryos obtained. The more cycles performed, the longer the delay in her cancer treatment.<sup>18</sup>

Women with breast cancer make up the largest proportion of women seeking fertility preservation. Many breast tumors are estrogen receptor positive, raising concerns about the high levels of estrogen that result from ovarian stimulation with gonadotropins. Two strategies have been suggested to minimize the exposure to estrogen.<sup>18,20</sup> One is to retrieve oocytes from an unstimulated or natural cycle.<sup>64</sup> This strategy is limited by the possibility that only one or no oocytes may be retrieved, decreasing the probability of a successful future pregnancy. Another strategy is to include a chemopreventive agent such as tamoxifen or letrozole when performing an IVF cycle. These agents have been shown to be efficacious in the prevention of breast cancer recurrence<sup>65,66</sup> and coincidentally have ovulation-inducing properties.<sup>67,68</sup> These agents have been used in

combination with gonadotropins in IVF cycles with good embryo yields and no apparent increase in breast cancer recurrence.<sup>18,67</sup> These preliminary results are very promising; however, further study and long-term follow-up are needed to ensure the safety and effectiveness of using tamoxifen or letrozole in IVF cycles in women with breast cancer.

#### Oocyte Cryopreservation

Oocyte cryopreservation is an appealing option for women without partners. The patient is treated with gonadotropins to stimulate her ovaries, followed by a minor surgical procedure to retrieve the oocytes. The oocytes are then cryopreserved. Once the patient has completed cancer therapy and is ready to conceive, the oocytes are thawed and fertilized using IVF/ICSI and the embryos are implanted into the patient's uterus. Despite early disappointing results owing to technical challenges associated with cryopreserving oocytes,<sup>18,69</sup> recent studies have reported increased pregnancy rates using IVF/ICSI with thawed oocytes.<sup>70,71</sup>

#### Donor Eggs

Using another woman's oocytes is an option for women who have lost ovarian function owing to cancer therapy but still have a uterus. The oocytes are retrieved from a donor and are fertilized with sperm from the cancer survivor's partner using IVF. The embryo is then transferred to the cancer survivor's uterus to achieve pregnancy. Although egg donation involves IVF, the cancer survivor does not need to take ovarian-stimulating medications. Because women with ovarian failure no longer produce endogenous estrogen and progesterone, these hormones will have to be taken by the patient to prepare the uterus for implantation and to maintain the early pregnancy until placental function is adequate.<sup>42,72</sup>

Similar to men who donate sperm, women who donate their oocytes go through extensive screening and testing for sexually transmitted diseases. Oocyte donation can be significantly more difficult and expensive than sperm donation. Oocyte donors are required to undergo ovarian stimulation followed by a minor surgical procedure to retrieve the oocytes.<sup>42,44,72</sup>

#### Future Directions

Ovarian Tissue Cryopreservation and Transplantation

Ovarian tissue cryopreservation and transplantation is an emerging new option for women desiring fertility preservation. The technique involves removing ovarian tissue from the patient prior to undergoing therapy. The tissue is thoroughly examined for any evidence of metastatic disease.

The ovarian cortex is then cut into small strips and cryopreserved. Following completion of cancer therapy, the tissue is thawed and transplanted within the pelvis or in the subcutaneous tissue of the lower abdomen or forearm. The grafts become hormonally active 3 to 4 months after transplantation, at which time oocyte retrieval can be attempted with or without the aid of exogenous gonadotropins to stimulate follicular development.<sup>73-77</sup> Oktay and colleagues recently reported on the transplant of cryopreserved ovarian tissue into the subcutaneous abdominal tissue of a breast cancer survivor.<sup>78</sup> Hormonal function was restored, and percutaneous oocyte retrieval was performed following ovarian stimulation. A viable embryo was obtained following fertilization and implanted into the patient's uterus. Unfortunately, no pregnancy occurred.

The potential use of ovarian tissue cryopreservation and transplantation will offer several advantages as a method of preserving fertility. Similar to oocyte cryopreservation, no male partner is needed at the time of the procedure. In addition, pretreatment ovarian stimulation is not required. The ovarian tissue cryopreservation could be performed at any point in the cycle so that there would be no delay in beginning cancer treatment. In children, ovarian tissue cryopreservation could provide the only available fertility-preserving option as ovarian stimulation and oocyte collection cannot be performed in prepubertal girls. Significant progress is being made with the development of ovarian tissue cryopreservation and transplantation, and it may eventually become a viable option for fertility preservation for girls and women undergoing gonadotoxic cancer treatment.<sup>18</sup>

### Adoption

Adoption is also an option for both men and women who are infertile as a result of cancer therapy. Adoption can be domestic, international, public, or private. Most adoption agencies report that they do not exclude cancer survivors as potential parents, especially with documentation from a doctor regarding anticipated life expectancy and quality of life. Some agencies do require patients to be disease free for a certain amount of time, such as 5 years prior to being eligible to adopt.<sup>42,79</sup>

### Pregnancy Outcome

One of the major concerns for cancer survivors treated with radiation therapy and/or chemotherapy who retain fertility is whether they will be able to have healthy children. Common areas of concern include pregnancy complications, congenital malformations, and increased risk of cancer in their offspring.

### Pregnancy Complications

Several studies have provided information regarding prenatal and perinatal morbidity and mortality in cancer survivors previously treated with radiation and chemotherapy.<sup>80-85</sup> The outcomes vary with cancer diagnosis and with specific therapy. The offspring of female survivors of Wilms' tumor have been shown to have an increase in the risk of intrauterine and peripartum complications. A study by Li and colleagues reported an increased rate of spontaneous abortions, low birth weight babies, and neonatal deaths in women who received 20 to 35 Gy of abdominal radiation with or without chemotherapy for Wilms' tumor.<sup>81</sup> Compared with the general population, their relative risk was 7.9 for perinatal mortality and 4.0 for low birth weight infants (<2,500 g). These results were confirmed in a study by Byrne and colleagues.<sup>80</sup> The pathogenesis of these radiation-associated adverse pregnancy outcomes remains unclear. It has been hypothesized to be due to damage to the uterine musculature or vascular insufficiency from radiation.<sup>80,86</sup>

For other disease categories, the data are also limited. The available evidence suggests that the offspring of survivors of most other cancers, including acute lymphoblastic leukemia, do not have increased prenatal or perinatal complications.<sup>82,84,85</sup>

### Congenital Anomalies

Studies to date have shown no significant increase in congenital malformations over the general population in the offspring of cancer survivors who received radiation or chemotherapy.<sup>80,86,87</sup> In addition, a large case-control study of 45,000 children with congenital anomalies reported no increase in the incidence of parental exposure to alkylating agents or radiation proximal to the gonads in the parents of children with congenital abnormalities compared with the parents of the control group children.<sup>88</sup> A large study of Japanese atomic bomb survivors and their children also showed no significant increase in inherited genetic disease in 30,000 offspring born to radiation-exposed parents.<sup>89</sup>

Currently, a large, ongoing study, the Genetic Consequences of Childhood Cancer Treatment, is evaluating the offspring of childhood cancer survivors treated with chemotherapy and/or radiation.<sup>90</sup> The study population is composed of more than 25,000 childhood cancer survivors in Denmark and the United States who subsequently had nearly 6,500 children of their own. Radiation doses to the gonads are being reconstructed using radiotherapy records. This study will provide important information for cancer survivors who wish to have children.

### Cancer in Offspring

Although some cancers have a known genetic component, such as retinoblastoma and familial

cancer syndromes including Li-Fraumeni, Lynch syndrome/hereditary nonpolyposis colorectal cancer (HNPCC), and breast cancer, only a small number of cancers affecting children and young adults have any heritable genetic origin.<sup>91,92</sup> Sankila and colleagues studied 5,487 offspring of approximately 14,000 childhood cancer survivors and found that there was less than one excess cancer diagnosis for every 1,000 offspring.<sup>92</sup>

### Genetic Counseling

Approximately 5 to 10% of cancers are due to germline mutations in cancer susceptibility genes.<sup>93</sup> Genetic testing has become available for many hereditary cancer syndromes, including breast cancer and Lynch syndrome/HNPCC. Several factors are common in hereditary cancer syndromes and can be used to identify individuals at risk (Table 2).<sup>93</sup> High-risk individuals should be referred for genetic counseling and possible genetic testing. Genetic counseling involves obtaining a detailed family history, performing a risk assessment, providing an explanation of the testing available, and reviewing the options for surveillance and risk reduction.

Genetic counseling and testing can also be of assistance to couples deciding whether to try to conceive a child who may be at risk of cancer. In addition, preimplantation genetic testing may be an option for individuals with hereditary cancer syndromes undergoing IVF. It involves removing one cell from each developing embryo and testing it for the genetic mutation.<sup>94</sup> Only embryos that do not contain the genetic abnormality are then implanted in the woman's uterus. This technology has been used successfully for Tay-Sachs disease, cystic fibrosis, and other genetic disorders. Its use for genetic abnormalities leading to increased cancer risk is currently being evaluated.

### Summary

Infertility has become a significant issue for many cancer survivors. Young patients and their families should be informed of the potential effects that their cancer and its treatment can have on reproductive function, including the possibility of sterility. All reproductive-age men undergoing cancer treatment with the potential to impair fertility should be offered sperm cryopreservation. Although fertility preservation in women is more complicated, recent advances in reproductive technologies are providing an increasing number of options for potential future pregnancy.

Further information is available for cancer patients from Fertile Hope (<[www.fertilehope.org](http://www.fertilehope.org)>), a nonprofit organization dedicated to providing reproductive information, support, and hope to cancer patients whose medical treatments present the risk of infertility.<sup>79</sup>

**Table 2** Characteristics of Patients with Hereditary Cancer Syndromes

Cancer onset at an early age (usually  $\geq 10$  yr earlier than the mean age)  
 Synchronous or metachronous primary cancers in one individual  
 Multiple family members with the same cancer or clustering of cancers known to be caused by a single gene (eg, breast and ovary)  
 Unusual presentation of cancer, such as breast cancer in a male  
 Ethnicity (eg, Ashkenazi Jewish ancestry and breast cancer)

According to the *SEER Cancer Statistics Review, 1975–2001*, 5-year relative survival rates have increased in recent decades.<sup>1</sup> For example, the survival rate for patients with cancer at all sites in 1954 was 35% but in 2000 had increased to 65.5%. The number of cancer survivors is expected to increase from 1.3 million in 2000 to 2.6 million in 2050.<sup>2</sup> These numbers, in part, will reflect the attainment of a cancer-prone age by the “baby boomers”—hence the increasing annual incidence of cases and the increasing prevalence of cancer survivors.

An important factor complicating the understanding of the impact of cancer treatment on long-term survivors is how one defines “survivor.” Survivors’ groups have emphasized that one who has been diagnosed with cancer is a “survivor” from the very beginning. How does one differentiate the cancer survivor being treated for active disease from the survivor who has been treated and is now free of disease? Traditionally, cancer-free survival of 5 years or more has been designated as an important milestone; this concept may require revision in the years to come.

## Late Effects of Cancer and Cancer Treatment

Several investigators have addressed the presence and complexity of the lasting medical sequelae of cancer throughout the adult lives of the survivors of childhood cancer.<sup>3–5</sup> For example, Stevens and colleagues reported that 58% of survivors had at least one chronic health problem and 32% had two or more, including second primary cancers.<sup>6</sup> In contrast, much less is known about the lasting medical impact of cancer treatment on the survivors of adult-onset cancers. Despite the paucity of information on the physiologic late effects of adult cancers,<sup>7,8</sup> investigators are aware that multiple systems are often affected. For example, pelvic surgery can impair fertility, and splenectomy increases the susceptibility to bacterial infections. Moreover, certain chemotherapy agents and regimens can compromise the health of the cardiovascular, pulmonary, genitourinary, endocrine, and neurologic systems. Radiotherapy

may aggravate these complications, impair skeletal development and dental health, and contribute to the risk of second primary cancers. In addition, combining the treatments can increase the number and severity of long-term medical problems.

Recently, attention has been directed toward the impact of cancer treatment on long-term survivors, particularly as it concerns their quality of life. Several investigators have begun to characterize the physiologic health and psychosocial profiles of survivors of childhood cancers. Research regarding the psychosocial profiles of survivors of adult cancers has also increased. However, a stark paucity of data on the physiologic health profile of survivors of adult cancers remains.

## Life after Cancer Care Program

The Life After Cancer Care (LACC) program at The University of Texas M. D. Anderson Cancer Center was established to provide follow-up medical care to long-term cancer survivors. Its services include diagnosis and treatment and appropriate referral and consultation for the possible long-term effects of previously treated cancer. The LACC program began a systematic search for living, known cancer survivors who had been treated at the M. D. Anderson Cancer Center. Patients were included if they were diagnosed with a cancer, their cancer was diagnosed at least 5 years before, they were 18 years or older at diagnosis, they had a US address, and they were free of malignant disease at their last contact. Surveys developed to systematically collect health information reported by the survivors themselves were sent out to more than 20,000 individuals who met the above criteria. Simultaneously, the survey was made available through the Internet at [www.mdanderson.org/Departments/LACC](http://www.mdanderson.org/Departments/LACC). Our approach has been described in detail.<sup>9</sup>

Data from the more than 10,000 survivors who responded to the survey are presently available for analysis and constitute the focus of this chapter. Complete data are available on 8,739 survivors who are at least 5 years from diagnosis. Sixty-two percent of the sample is female, and

92% of the total sample is white. The mean age  $\pm$  standard deviation at diagnosis is  $47.9 \pm 14.2$  years. Fifty percent of survivors were diagnosed between the ages of 18 and 48 years, and 25% were diagnosed after the age of 59 years. Approximately 25% of the survivors in our database are more than 20 years from their original diagnosis, and 10% of the survivors are at least 30 years from diagnosis. Figure 1 shows the distribution of survivors by time from diagnosis. Figure 2 illustrates the distribution of survivors by cancer type. The representation of long-term survivors in our database is similar to the incidence of cancer type; for example, thyroid cancer occurs predominantly in women, and head and neck cancer occurs predominantly in men. This is congruent with our database of long-term survivors. In addition, the distribution of cancer survivors by their diagnoses reflects the likelihood of long-term survival with different cancers and perhaps M. D. Anderson referral patterns.

In the survey, the survivors were asked, “Has cancer affected your overall health?” Interestingly, only 37.4% of them replied “yes” to that question, and there were no significant differences between the replies of men and women or among the ethnic groups. Age at diagnosis appeared to be another predictor of how the survivor experienced long-term survival. Survivors who were older when their cancer was diagnosed were less likely to believe that cancer affected their overall health as they aged. On the other hand, survivors who were most likely to report that cancer had affected their overall health tended to be younger at diagnosis (Table 1). Forty-one percent of the survivors who were diagnosed between the ages of 18 and 40 years reported that cancer affected their health in comparison with 36% of those diagnosed between 41 and 65 years of age and 28% of those diagnosed after 65 years of age. Perhaps older individuals expected to develop a number of comorbidities and were less likely to consider them related to their earlier cancer and cancer treatments.

## Long-Term Health Problems

We previously reported that the specific health effects reported by long-term cancer survivors

**FIGURE 1** Distribution of cancer survivors by years from diagnosis.

**FIGURE 2** Distribution of cancer survivors by the 10 most frequent cancer types within the sample of adult survivors. GU = genitourinary; Gyn = gynecologic.

illustrate a complex interplay between age, gender, cancer type, and cancer treatment, as well as ethnicity, race, and social and cultural factors.<sup>9-11</sup> For example, the most frequently reported health problems were arthritis and osteoporosis (1,541 survivors; 26.4%). Men generally reported fewer specific problems; the most frequently mentioned were heart problems (17.2% of responding men), hearing loss (14.9%), and arthritis and

osteoporosis (15.5%). Women generally reported more specific problems; the most frequently mentioned were arthritis and osteoporosis (32.9% of responding women), heart problems (13.9%), and thyroid problems (12.1%). Women were more likely to report thyroid problems (12.1% vs 6.2%) or arthritis and osteoporosis (32.9% vs 15.5%). Men, on the other hand, were more likely to report kidney and bladder problems (14.2% vs

9.8%) or more hearing loss (14.9% vs 9.9%). These patterns likely reflect a complex interaction of gender-related cancer diagnoses and comorbidities. The pattern of perceived and reported health problems was different among the cancer types. For example, survivors of Hodgkin's disease prominently reported thyroid and lung problems (33.8% of responders with the diagnosis), whereas a previous diagnosis of lymphoma was associated with the frequent mention of memory loss (14.7%).

### National Health Interview Survey

A large number of health conditions have been reported by the National Health Interview Survey and categorized by age, ethnicity or race, and gender.<sup>12</sup> Five of these health conditions were comparable to those reported by our cancer-survivor cohort: arthritis symptoms, diabetes, migraine or severe headaches, heart disease, and hearing loss. The frequencies of these conditions in the general population (computed as the number of affected individuals/1,000 population) were compared with those in our cancer-survivor cohort relative to patient age, ethnicity or race, and gender. There were significant differences in the frequencies of these five health conditions between men and women and among ethnic or racial groups. The most common difference in our cancer-survivor cohort for all groups analyzed was a statistically significant loss of hearing.<sup>13</sup> Hispanic American women reported significantly higher rates of diabetes, and African American men reported significantly higher rates of heart disease than the race-adjusted national prevalence rates. Although apparent differences in the frequency of these health conditions may be due to the methodology of the questionnaires, previous cancer or cancer therapy may also play a role in the survivors' health profile. For example, the consistent overreporting of hearing loss may be related to ototoxic chemotherapy. Clearly, further detailed analysis is needed in this area. Further research about comorbidities may also provide information about the health effects from a past cancer diagnosis.

### Survivors of Thyroid and Breast Cancers

The importance of the uniqueness of cancer type was made obvious in two studies from our survey cohort of survivors of thyroid and breast cancer. We previously published a report on the thyroid cohort and noted several distinctions.<sup>10</sup> The survivors of thyroid cancer tended to be significantly younger at diagnosis, were significantly closer to their time of diagnosis at contact, were significantly more likely to be women, and reported significantly more specific health effects. We were impressed by the frequent complaints of symptoms that were reminiscent of thyroid

**Table 1** Survivors (*N* = 3,268) Who Responded “Yes” to “Has Cancer Affected Your Health?”

Cancer Type	Affected Health (%)	Mean Age at Diagnosis (yr)
Melanoma	16.7	43.4
Colorectal	31.3	50.2
Gynecologic	31.4	44.5
Breast	35.9	46.5
Genitourinary	36.4	55.5
Sarcoma	39.5	40.5
Head and neck	39.8	50.8
Acute leukemia	45.3	39.8
Thyroid	50.3	35.4
Lung	53.3	55.9
Lymphoma	56.9	46.3
Gastrointestinal	57.0	56.0
Chronic leukemia	60.2	49.3
Hodgkin's disease	61.7	30.3

hormone imbalance and described these effects as “thyroid dysregulation.” We found that the lifetime supplementation of thyroid hormone was associated with unique problems that compromised the patients’ perception of their overall health.

In another study, 291 patients with breast cancer were asked whether they had symptoms commonly associated with menopause, including hot flushes, painful sexual intercourse, inability to concentrate, fatigue, and sleep disturbance.<sup>14</sup> Forty-six percent of these breast cancer survivors indicated that breast cancer had affected their overall health, especially those who had received chemotherapy alone or in combination with radiotherapy. We had a problem differentiating the symptoms of natural menopause from the sequelae of cancer treatment and other physical health problems that affect quality of life. Even though hot flushes and painful sexual intercourse are typically attributed to menopause, in our sample, it was difficult to determine whether they represented normal menopausal symptoms or long-term sequelae of cancer treatment because of the close relationship between these symptoms and the ability to concentrate, fatigue, sleep problems, and general unhappiness.

These findings show that it is sometimes difficult to determine whether specific symptoms should be attributed to cancer treatment or to associated but not causally related conditions. For example, in the case of thyroid and breast cancers, are fatigue and cognitive impairment a result of inappropriate thyroid hormone dosing, a consequence of normal menopause, or a result of cancer treatment? These questions need further clarification.

### Ethnic and Racial Influences on Cancer Survivorship

We previously reported that there were significant differences among Caucasian Americans,

Hispanic Americans, and African Americans in the types of specific health effects they experienced as long-term survivors of cancer.<sup>11</sup> Moreover, we found significant ethnic or racial differences with respect to age at diagnosis, interval since diagnosis, marital status, educational level, insurability, regular medical care, and the impact on family relationships. These differences among Caucasian Americans, Hispanic Americans, and African Americans probably reflected not only ethnicity or race but also cancer type, gender, type of treatment, and disease stage, to name a few. A complex relationship existed between ethnic or racial group, family and intimate relationships, and treatment types for the survivors of cervical cancer.

Published literature that specifically focuses on the impact of ethnic or racial factors on long-term (> 5 years from diagnosis) cancer survivors is scarce at best. Ethnic or racial differences in the incidence and mortality of various cancers are generally attributed to disparities in the ability of patients to access health care, resulting in their having more advanced disease at the time of diagnosis, the socioeconomic inequities of health care, or both.<sup>1,15-17</sup> In a study examining information from the National Survey of Functional Health, Ren and colleagues reported that race and class discrimination were pervasive and adversely affected the health status of ethnic or racial minorities.<sup>18</sup> Although studies addressing the impact of ethnic or racial differences on health are generally related to diagnosis and treatment-related outcomes, it is plausible that they may also influence other physiologic and psychosocial aspects of health.

When reviewing the information provided by cancer survivors, we found, for the most part, that cancer survivors had a similar view of the impact, or lack thereof, of their cancer experience on their overall physiologic health. There were, however, differences with respect to specific health concerns. For example, African Americans were more likely than Caucasian Americans or Hispanic Americans to report arthritis and osteoporosis, whereas Hispanic Americans were more likely to report abdominal pain and diabetes mellitus. Such differences in health profile and patterns may be partially related to other ethnic or racial propensities; for example, Brooks and colleagues showed that the poor outcomes of African American women who had cervical cancer were associated with preexisting comorbidities.<sup>19</sup>

Grenier and Lipshultz found that African American patients who had been treated with anthracyclines for cancer during childhood might be at a higher risk of cardiotoxicity and suggested that this could also be true for adult cancer survivors.<sup>20</sup> We also found a higher incidence of self-reported heart disease in African American cancer survivors than in Caucasian American or

Hispanic American cancer survivors. Although such differences may have a biologic basis, socioeconomic parameters may also play a role.

It is generally thought that marital status is closely related to health.<sup>21</sup> Unmarried people tend to have a higher mortality from all causes, use more health services, and have more psychological distress, and their perceptions of general health are poorer than those of married people. We found differences in health perception among the ethnic or racial groups according to marital status when we did our survey. We did not consistently find a protective effect of marriage; however, our results suggested that there is a positive association between the perception of overall health and the perceived positive impact of the cancer experience on family relationships. It is clear that socioeconomic, psychological, and cultural factors interact with the physiologic factors. Further research on larger, ethnic or racially diverse populations is needed to better understand these interactions.

### Work-Related Issues for Cancer Survivors

We analyzed survey information from 4,264 long-term survivors of cancer in which the survivors were asked to respond to questions about their ability to work, job discrimination, and quality of life.<sup>22</sup> Thirty-five percent of the respondents were working at the time of the survey, significantly more men than women and proportionately more Hispanic American than Caucasian American or African American survivors. The younger the survivors were at the time of diagnosis, the more likely they were to be working; age and cancer type were important parameters as well. For most cancer types, the survivors who were working were significantly younger at diagnosis and had a significantly higher quality of life score than those who were not working. Of the survivors working at the time of the survey, 7.3% indicated that they had experienced job discrimination; this was independent of age, gender, or ethnic grouping.

Approximately 10% of survivors indicated that they were unable to work as a result of the effects of cancer, cancer treatment, or both. Significantly more women than men and significantly more African Americans than Caucasian Americans or Hispanic Americans reported being unable to work. Cancer type was also a relevant factor. The role of socioeconomic factors in these findings was not clear. A reassuring finding was that most cancer survivors did not perceive employment-related problems and assimilated back into the workforce. However, for those who did have cancer-related issues, little is known about their experiences because research data for this group were scanty and heterogeneous.

## Internet Message Board for Cancer Survivors and Their Families

As a component of the LACC program, a message board was created on the Internet, through which cancer patients and their family members or other loved ones could communicate with and provide support for other patients and families. The message board was accessible to anyone who visited the M. D. Anderson Web page. This message board was monitored, and the findings from the postings were used to further understand the cancer experience and facilitate support for cancer patients.<sup>23</sup> During the initial 16 months since its creation, 972 individuals logged onto the message board (“users”) and 284 persons posted 619 messages (“posters”). The messages were read and analyzed for content. The most common cancer types represented by the posted messages were breast, gastrointestinal, lung, gynecologic, head and neck, and colorectal. The most frequent themes were questions about treatment, support, and long-term effects. The message themes differed between those posted by the posters who had cancer and those who were posting a message on behalf of someone who had cancer. For example, friends and relatives who did not have cancer asked most frequently about treatment, whereas most individuals who had cancer posed questions about the long-term effects of cancer. Questions about support and diagnosis appeared to be of similar interest to both groups of posters.

Message board entries reflected yet another aspect of the cancer survivors’ experience. In general, literature pertaining to health care and the Internet highlights the significance of this resource. However, little information is available about the types of cancer-related information the Internet users seek. Having such information would allow health care providers and educators

to develop materials that are better suited to respond to the needs of consumers and patients.

## Concluding Thoughts

Successfully treated cancer patients have much to teach us. Traditionally, cancer research has focused on the diagnosis and treatment of cancer, appropriately so. We have studied those who have not responded to treatment, seeking answers to develop better treatments. We should, in our quest to eradicate cancer, look not only to patients who have succumbed to the disease but also to those who have survived because they provide a living laboratory for the understanding of cancer. We have only scratched the surface in understanding how the cancer survivor has arrived at the place of long-term survivorship. We have accumulated the responses of more than 10,000 cancer survivors to a survey designed to shed some understanding on the cancer survivors’ long-term sequelae of cancer treatment. This survivorship project has raised many questions that need further research. For example, this work requires longitudinal and prospective studies of large numbers of survivors. Through programs such as the LACC, the M. D. Anderson Cancer Center is poised to lead the initiative to learn more about cancer survivorship.

# Cancer Screening in Cancer Survivors

Sai-Ching Jim Yeung, MD, PhD

Continued advances in cancer treatment have led to improvements in treatment outcomes. The number of cancer survivors aged 18 years and older continues to increase because more childhood cancer patients are surviving to adulthood and adult cancer patients are surviving longer. Currently, more than 70% of pediatric cancer patients will survive long term, and approximately 60% of adult cancer patients will survive for at least 5 years after diagnosis.<sup>1,2</sup> In fact, there are almost 10 million cancer survivors in the United States.

Cancer survivors have a high risk of recurrence of the original cancer and development of second primary malignancies as a result of cancer therapy and other risk factors. In a review of 282 consecutive patients suspected to have a malignancy but no tissue diagnosis, a history of malignancy was a statistically significant predictor of a cancer diagnosis among other predictors, including advanced age, weight loss, thrombocytosis, and monocytosis.<sup>3</sup> Lifelong monitoring and screening for malignancies are thus necessary for cancer survivors. Yet a recent study showed that adult survivors of childhood cancer were not adequately screened for cancer.<sup>4</sup> Often cancer survivors cease to follow up with oncologists because of the lack of active oncologic issues. Furthermore, approximately 70% of cancer patients have comorbid conditions,<sup>5</sup> requiring a comprehensive approach to medical care. Therefore, internists and primary care providers should not only manage active noncancer medical problems but should also ensure continued surveillance for malignancies and provide preventive care.

This chapter summarizes the incidence of and risk factors for second or secondary malignancies and recommendations for cancer screening so that cancer survivors may reap the benefits of early detection. Screening practices for survivors of breast, colorectal, and prostate cancers; childhood acute lymphoblastic leukemia (ALL); and Hodgkin's disease are discussed. These cancers were selected on the basis of their high prevalence or high rates of survival.

## Etiologic Factors for Secondary Malignancies

### Ionizing Radiation

Many cancer patients have received multimodal therapy, and the separate contributions of

chemotherapy and radiotherapy to treatment-related malignancies are not definitively known. Radiation is well known to cause primary cancers. When used as a treatment, radiation is associated with the development of secondary malignancies, including leukemia and brain, bone, thyroid, skin, and breast cancers, which usually develop several years to decades afterward. Typically, these radiation-induced malignancies occur at the margin of or within the irradiated field. Soft tissue sarcomas and osteosarcomas are the most frequent secondary neoplasms after radiotherapy.<sup>6-8</sup>

The risk of developing radiation-induced breast cancer is significantly higher in girls treated with mantle radiation before the age of 21 years than in women treated in their adult years.<sup>6,9</sup> The risk of secondary cancers increases with the total dose of radiation. In one study, a 40-fold increase in the risk of developing bone sarcomas was observed after doses of 60 Gy or more.<sup>7</sup> In another study, a 10-fold increase in the risk of soft tissue sarcoma was seen in retinoblastoma patients receiving  $\geq 60$  Gy, but even as little as 5 Gy increased the risk 2-fold for this genetically susceptible group.<sup>10</sup> However, high radiation doses do not appear to affect the risk of leukemia and thyroid cancer.

The risk of secondary cancers increases with time since radiation therapy.<sup>11</sup> In the Late Effects Study Group, the median time to develop a secondary neoplasm was 10 years after radiotherapy, but secondary neoplasms might develop as late as  $> 30$  years after radiation exposure.<sup>12</sup> Radiogenic leukemias appear earlier, with a latency of 4 to 8 years, than radiation-induced solid tumors, which are usually diagnosed 10 to 40 years after radiation exposure.<sup>13</sup>

### Chemotherapy

Acute myelogenous leukemia (AML) is the most common type of secondary malignancy after chemotherapy, and other types of hematologic malignancies, such as ALL, chronic myelogenous leukemia, and myelodysplastic syndrome, have also been reported.<sup>14</sup> Secondary myeloid leukemias induced by chemotherapy have a low cure rate of 10 to 20% and may be refractory to subsequent chemotherapy, which makes prevention very important.<sup>15</sup> Chemotherapeutic agents

that carry a high risk of secondary leukemias are alkylating agents and etoposide, although chemotherapy using multiple drugs, particularly when doxorubicin is included, may increase the risk as well. Alkylating agents, including ifosfamide, cyclophosphamide, melphalan, busulfan, nitrogen mustard, procarbazine, carboplatin, and cisplatin, cause leukemias with deletions on chromosome 5 or 7. Inhibitors of topoisomerase II, such as epipodophyllotoxins, teniposide, and etoposide, cause leukemia with translocation of the *MLL* gene at chromosome band 11q23, and these topoisomerase II inhibitor-induced leukemias have relatively short latency periods of 1 to 3 years. An increase in the risk of secondary leukemia was noted with increasing doses of epipodophyllotoxins;  $< 3\%$  of germ cell tumor survivors who received  $< 2$  g/m<sup>2</sup> of etoposide would develop therapy-related acute myeloid leukemia (t-AML), but the incidence of t-AML increased to  $> 11\%$  in survivors who received  $> 2$  g/m<sup>2</sup> of etoposide.<sup>13</sup> In survivors of childhood cancers, such as rhabdomyosarcoma, Ewing's sarcoma, and Hodgkin's disease, a dose-response relationship has been demonstrated: alkylating agents increased the risk of a secondary leukemia almost 5-fold, and with the highest doses of alkylating agents, that risk increased to almost 24-fold.<sup>14</sup> Doxorubicin may further increase that risk when used together with high-dose alkylating agents.<sup>14</sup> Alkylating agents may also further increase the risk of radiation-induced secondary bone cancers. In one study<sup>7</sup>, the relative risk (RR) of secondary bone sarcomas after radiation therapy was 2.7, but the RR increased to 4.7 when alkylating agents were also used.

### Splenectomy

The mechanism by which asplenism aids in the induction of secondary cancers or second primary cancers is unknown, but the spleen may play a significant role in immunosurveillance against malignancies.<sup>16</sup> Standard therapies for Hodgkin's disease and other lymphomas often include splenectomy and splenic irradiation. In a study of 892 Hodgkin's disease survivors, splenectomy increased the risk of treatment-related secondary cancers.<sup>17</sup> In another study of 979 Hodgkin's disease survivors, splenectomy had

borderline significance ( $p = .09$ ) in increasing the incidence of secondary malignancies.<sup>18</sup>

### Genetic Predisposition

Patients with a genetic predisposition for cancer develop multiple cancers in their lifetime. For instance, patients with Li-Fraumeni syndrome have a 50% probability of developing cancer by age 30 years.<sup>19,20</sup> Genetic predisposition certainly plays a role in the development of secondary cancers. Germline mutations in tumor suppressor genes (eg, the *TP53* tumor suppressor gene mutation in Li-Fraumeni syndrome) and gene mutations for hereditary cancers (eg, hereditary breast cancer genes *BRCA1* and *BRCA2*) may interact with therapeutic exposures, leading to an increased incidence of secondary cancers. Failure to induce apoptotic cell death after deoxyribonucleic acid (DNA) damage, defects in DNA repair, and dysfunction of DNA damage check points are potential mechanisms involved in the development of secondary malignancies after therapeutic exposure to radiation and DNA-damaging chemotherapeutic agents.

### Bone Marrow Transplantation

For patients who underwent allogeneic or syngeneic transplantations, the cumulative incidence for secondary solid malignancies was 2.2% at 10 years and 6.7% at 15 years.<sup>21</sup> Patients who have undergone allogeneic transplantation have an increasing risk of new solid malignancies over time.<sup>22,23</sup> The rate of new malignant disease was two- to fourfold higher in these patients than in age-matched control subjects.<sup>21,24</sup> The types of solid malignancies that increased after allogeneic or syngeneic bone marrow transplantations include cancers of the buccal cavity, brain, liver, bone, and connective tissue and melanoma. Higher doses of total-body radiation were associated with a higher risk of solid cancers; and chronic graft-versus-host disease and male sex were closely linked with an increased risk of squamous cell cancers of the buccal cavity and skin.<sup>25</sup> The incidence of secondary solid malignancies after autologous transplantation is estimated to be lower than that after allogeneic transplantation.<sup>22,26</sup> After autologous stem cell transplantation in non-Hodgkin's lymphoma patients, the incidence of second malignancies after 10 years is 21%, with about 10.0% having nonhematologic malignancies.<sup>26</sup> New malignancy after autologous transplantation is the most frequent cause of non-relapse-related death.<sup>27</sup>

### Smoking

Continuing to smoke increases the risk of second cancers at the same site or at different sites, regardless of whether the initial cancer is smoking

related.<sup>28</sup> When the prognosis is relatively good for the initial malignancy, continued smoking will increase the risk of new primary malignancies for up to 20 years after the initial cancer diagnosis. In survivors of early-stage small cell lung cancer (mostly stages I and II), the risk of a secondary cancer (mostly non-small cell lung cancer) was 3.5- to 4.4-fold higher than that of the general population.<sup>29-31</sup> Continuing to smoke further increases the risk of secondary cancer, particularly in those who had undergone chest irradiation (RR = 21.0) or had received alkylating agents (RR = 19.0).<sup>30</sup> In survivors who ceased to smoke at the time of diagnosis, the risk was the same as in those who had quit smoking at least 6 months before the initial cancer diagnosis. Another study confirmed that patients with small cell lung cancer who survived at least 2 years had a greatly reduced likelihood of a secondary cancer if they quit smoking.<sup>32</sup> In a study of breast cancer survivors who subsequently developed lung cancer, the relationship between lung cancer and thoracic radiation therapy alone was negligible, but the relationship between lung cancer and smoking was substantial and was even stronger for the combination of thoracic radiation therapy and smoking.<sup>33</sup> Similarly, the effect of smoking on the risk of secondary lung cancer has also been observed in Hodgkin's disease survivors.<sup>34,35</sup> In one study, very high risks for subsequent lung cancer were identified for smokers: RR = 20.2 for radiation treatment and smoking and RR = 49.1 for radiation, alkylating agents, and smoking.<sup>34</sup>

## Second Primary or Secondary Malignancies in Specific Cancer Survivor Groups

### Breast Cancer

The treatment used for breast cancer may affect the subsequent risk of secondary malignancies. For breast cancer patients who were treated with doxorubicin-based regimens, the rates of secondary cancers were 3.8% at 10 years and 7.0% at 15 years.<sup>36</sup> Postmastectomy radiotherapy can increase the risk of secondary lung cancer, particularly in smokers.<sup>37-39</sup> Chemotherapy with alkylating agents increases the risk of acute leukemia, particularly if the patients also receive radiotherapy.<sup>40</sup> Postirradiation sarcomas may also occur.<sup>41</sup> Breast cancer survivors have an increased risk of developing cancer in the breast contralateral to the one where the initial breast cancer has been found. However, radiotherapy does not appear to contribute much to this risk.<sup>42</sup> Antiestrogens and breast cancer screening can reduce the incidence of second breast malignancies and improve survival.<sup>43</sup> Tamoxifen has antiestrogenic effects on breast tissue and significantly decreases the incidence of contralateral breast cancer, but it has proestrogenic effects on

the uterus and increases the risk of endometrial cancer.<sup>42</sup> Thus, patients who have undergone long-term adjuvant hormonal therapy should undergo regular gynecologic examination with endometrial screening.

Breast cancer survivors also have increased risk of cancers of the ovaries, endometrium, and colon or rectum.<sup>42,44</sup> These organs share risk factors with breast cancer, that is, diet, obesity, and female hormonal status. Breast cancer genetics has also implicated mutations in *BRCA1* and *BRCA2* as risk factors for breast and ovarian cancers. Screening for ovarian, endometrial, and colorectal cancer should be performed regularly in breast cancer survivors.<sup>45,46</sup>

### Prostate Cancer

Radiotherapy for prostate cancer increases the risk of subsequent bladder cancer.<sup>47</sup> Nevertheless, the increase in risk appears to be small and late (some years after radiotherapy).

### Testicular Cancer

Testicular cancer is one of the solid tumors with a very favorable outcome, whether it occurs unilaterally or bilaterally.<sup>48</sup> Patients with testicular cancer often receive combination chemotherapy with cisplatin, etoposide, and bleomycin. Although both etoposide and cisplatin can cause secondary leukemia, the risk correlates to the total cumulative dose of etoposide received. Testicular cancer patients treated with a combination of radiotherapy and chemotherapy are at an increased risk of secondary cancers, particularly in the pelvis.<sup>49</sup>

### Endometrial and Ovarian Cancer

Survivors of endometrial cancer have increased risk of ovarian, colorectal, and breast cancers.<sup>44,46,48</sup> Therefore, surveillance and screening for these cancers should be performed in survivors of endometrial cancer. Bilateral oophorectomy at the time of hysterectomy for the endometrial cancer may be considered if appropriate because removal of the ovaries will reduce the subsequent risk of ovarian cancer.

### Skin Cancer

It is well known that basal cell and squamous cell carcinomas (nonmelanoma skin cancers) tend to develop in the same skin cancer patients. This pattern represents the effect of the shared risk factor: sun exposure. Thus, those who have nonmelanoma skin cancer should avoid sun exposure and should have regular surveillance for new skin malignancies by dermatologists. Patients with dysplastic nevi may develop multiple melanomas. These patients and melanoma survivors should have regular full-body skin examinations by experienced clinicians.<sup>50</sup>

## Colorectal Cancer

There are more than 1 million colorectal cancer survivors in the United States now. Colorectal cancer cases are sporadic (approximately 60% of all cases), familial (approximately 30%), or hereditary (approximately 10%, mainly as part of genetic syndromes, such as hereditary nonpolyposis colorectal cancer [HNPCC] and familial adenomatous polyposis [FAP]). FAP has a classic presentation, with the formation of numerous adenomatous polyps in the colon and rectum at a young age. Patients with FAP have almost a 100% probability of developing colorectal cancer by the age of 50 years. Persons with HNPCC have a high risk of colorectal cancers and cancers of the ureter, renal pelvis, and small bowel. Females with HNPCC have a risk of 30 to 60% of developing endometrial cancer in their lifetime. Survivors of colorectal cancer have an elevated risk of second primary malignancies of the colon and rectum, as well as of the breasts, uterus, and ovaries.<sup>46</sup> For colorectal cancer survivors, prompt detection of new primary cancers or recurrent disease can improve subsequent survival. The risk of recurrence is highest during the first 5 years after resection of colorectal cancer; thus, frequent surveillance examination and follow-up care are recommended during this period.

## Upper Aerodigestive Tract Cancer

The rate of esophageal cancer that occurs after lung cancer increases after radiotherapy for the initial lung cancer, suggesting a carcinogenic effect of radiation in esophageal cancer's etiology. Even in the absence of radiotherapy, the risk of esophageal carcinoma is still increased after the diagnosis of lung cancer.<sup>51-53</sup> Quitting smoking and discontinuation of tobacco consumption after the diagnosis of the initial primary cancer in the upper aerodigestive tract reduce the risk of other tobacco-related malignancies and thus remain an important strategy to prevent cancer.<sup>54</sup> Particularly in the case of an initial head and neck cancer, it is very important to look carefully for synchronous multiple primary tumors in the upper aerodigestive tract and respiratory system at presentation. For instance, the prognosis is poor if a lung nodule is a recurrence or metastasis from an initial oropharyngeal primary tumor, but cure may still be possible if a lung nodule is a second primary lung cancer that can be surgically removed.

## Retinoblastoma

Hereditary retinoblastoma patients are at high risk of developing a secondary malignancy after radiotherapy, and this is primarily due to the genetic predisposition of the retinoblastoma gene (*RBI*) mutation. In the largest study of retinoblastoma survivors, Wong and colleagues

reported an RR of 30 for secondary cancers compared with an age-matched control group.<sup>10</sup> The cumulative incidence of secondary cancers for patients with hereditary retinoblastoma was 51% at 50 years compared with 5% at 50 years for patients with the nonhereditary form of retinoblastoma. Two-thirds of the secondary malignancies were soft tissue or osteogenic sarcomas. A radiation dose-response relationship was found for soft tissue sarcomas, with as little as 5 Gy increasing the risk of secondary malignancy 2-fold and >60 Gy increasing the risk 10-fold.

## Wilms' Tumor

The National Wilms' Tumor Study Group found an eightfold increase in secondary malignancies in survivors of Wilms' tumor.<sup>49</sup> Most cases of the secondary leukemias were t-AML, which was diagnosed between 1 and 6 years after the original therapy for Wilms' tumor. Secondary lymphomas had similar latency periods. In contrast, much longer latency periods of 3 to 21 years were observed for secondary solid tumors, which were mostly sarcomas and carcinomas (parotid gland, thyroid, breast, hepatocellular, and colon) but also brain tumors. Survivors who received abdominal radiotherapy had twice the risk of secondary cancers compared with those who did not. Doxorubicin may also have potentiated the carcinogenic effect of radiation. In another study, the 20-year cumulative incidence of secondary malignancies after treatment for Wilms' tumor was 3 to 6%.<sup>55</sup>

## Hodgkin's Disease

Hodgkin's disease survivors have a RR of 2 to 4 for developing secondary malignancies. The overall cumulative incidences of developing a secondary malignancy, most of which are solid tumors, are 10% at 20 years after treatment for Hodgkin's disease and 26% at 30 years. Young age when treatment began and the use of radiotherapy were important risk factors for secondary cancers in Hodgkin's disease survivors.<sup>56</sup> Compared with the normal population, patients with Hodgkin's disease are more likely to die from secondary cancers and cardiovascular diseases.<sup>57</sup> The RR was 6.6 for death owing to a secondary cancer in a Hodgkin's disease survivor compared with the normal population.

The common secondary solid tumors, in order of incidence, were breast, thyroid, bone, colorectal, lung, and stomach cancers. Breast cancer in the context of Hodgkin's disease is related to mantle radiation therapy and chemotherapy at a young age. Secondary breast cancer differs from sporadic breast cancer because it develops in younger women, is associated with a higher incidence of bilateral disease (both breasts),

and is located closer to the midline of the body than sporadic breast cancer.<sup>58</sup>

Hodgkin's disease survivors also have a high risk of acute leukemia<sup>59</sup> and non-Hodgkin's lymphoma<sup>60</sup> after treatment. As many as 25% of the secondary malignancies in Hodgkin's disease survivors are secondary leukemia or lymphoma.<sup>61-63</sup> Regimens that contain procarbazine and nitrogen mustard (such as MOPP [nitrogen mustard, Oncovin [vincristine], procarbazine, and prednisone]) convey the highest risk of secondary leukemia compared with regimens that contain cyclophosphamide.<sup>63</sup>

## Non-Hodgkin's Lymphoma

Over the past three decades, the combination of cyclophosphamide, doxorubicin, vincristine, and prednisone has cured a significant number of patients with non-Hodgkin's lymphoma. Less than 3% of patients developed secondary cancers after treatment with cyclophosphamide, doxorubicin, vincristine, and prednisone;<sup>64</sup> compared with a control population of patients without non-Hodgkin's lymphoma, this increase was not statistically significant.

## Acute Lymphoblastic Leukemia

Current treatment cures more than 80% of children with ALL, but these ALL survivors are at risk of secondary cancers. Radiotherapy appears to be the main contributor to the risk of developing a secondary cancer. Patients with ALL who underwent cranial or craniospinal radiotherapy (about 24 Gy) as central nervous system prophylaxis have an RR of 22 for developing central nervous system tumors. Patients who were less than the age of 5 years at the time of radiotherapy have the highest risk.<sup>65</sup> A high cranial radiation dose is associated with the development of brain tumors; for patients who received >30 Gy, the cumulative incidence of brain tumors is 3.23% at 20 years.<sup>66</sup> Therefore, in recent treatment regimens for ALL, young children (under 10 years old) who have no evidence of central nervous system disease at diagnosis are treated with intensive intrathecal chemotherapy rather than cranial irradiation. The risk of chemotherapy-induced t-AML in ALL survivors varies with the dose and schedule of epipodophyllotoxins, and chemotherapy including epipodophyllotoxins administered weekly or twice weekly resulted in a cumulative secondary AML incidence of 12%.<sup>67</sup>

## Screening Recommendations for Secondary Cancer in Cancer Survivors

### General Recommendations for All Cancer Survivors

1. Obtain a detailed medical history, including a family medical history. (Discuss the referral

with a clinical genetics service if a significant family history of cancer is identified.)

2. Perform lifelong clinical assessments at yearly intervals that include symptom review, a clinical examination, and screening for secondary malignancies. A careful physical examination with special attention to the radiotherapy field should be performed at long-term follow-up clinic visits; prompt evaluations are needed to address and evaluate new or suspicious signs and symptoms. In the event of unexpected changes in the complete blood count, such as the appearance of macrocytosis, dysplastic changes of any blood cell type, or cytopenia, a bone marrow biopsy and aspiration should be performed.
3. Educate patients regarding the risks of secondary malignancies and the importance of promptly reporting new symptoms or masses.
4. Advise patients on the reduction of risk behaviors, especially smoking and sunbathing.
5. Encourage patients to perform self-examination, such as of the breast, oral cavity, and skin.

### Childhood Cancer Survivors

There are more and more survivors of childhood and adolescent cancers in the United States. Late cancer-related complications in these survivors include an increased risk of premature mortality caused by secondary cancers and cardiovascular diseases. The Children's Oncology Group has published guidelines for the long-term follow-up care of survivors of childhood cancers (<<http://www.survivorshipguidelines.org>>). However, whether surveillance results in measurable reductions in morbidity or mortality has not been proven.

The risk of secondary AML usually manifests within 10 years after treatment; therefore, monitoring should include a complete blood count with differential annually for at least 10 years after therapy (Table 1). Most solid secondary malignancies are related to radiation exposure; therefore, the annual physical examination should pay special attention to the skin and soft tissues in the radiation field together with radiographic (eg, chest radiography if the chest was in the radiation field) or other cancer screening evaluations (eg, dental examination if the mouth was in the radiation field) if indicated.

For female cancer survivors who have undergone radiation therapy with potential effects on the breast (ie, mantle, mediastinal, or lung), a monthly self-breast examination should begin at puberty; clinical breast examination should be performed annually beginning at puberty until 25 years old and then every 6 months; and

**Table 1** Cancer Screening for Childhood Cancer Survivors

Cancer	Surveillance	Screening for Second Primary or Secondary Cancers
ALL	Individualized based on chemoradiation treatment regimen*	Brain radiation: central nervous system tumors Acute myelocytic leukemia Cyclophosphamide therapy: bladder cancer
Hodgkin's disease	Individualized*	Breast cancer (in women only) Lung cancer Colorectal cancer Bone cancer Thyroid cancer Nonmelanoma skin cancer

Adapted from guidelines for the long-term follow-up care of survivors of childhood, adolescent, and young adult cancer developed by the Children's Oncology Group. Specific recommendations can be accessed at <<http://www.survivorshipguidelines.org>>.  
ALL = acute lymphoblastic leukemia.  
\*Frequency based on cumulative anthracycline and chest radiation dose and age at treatment.

mammograms and routine Cleopatra views to screen the inner quadrants should be obtained annually starting 8 years after radiotherapy or at age 25 years. The effectiveness of frequent self- and physician examinations in younger women (<40 years old) with dense breast tissue may be low. However, Hancock and colleagues found that 56% of secondary breast cancers were discovered by physician examination during follow-up and 16% by self-examination.<sup>68</sup> Magnetic resonance imaging (MRI) examinations may be helpful to screen younger females with dense breast tissue and for patients who have undergone mantle field irradiation to treat childhood malignancies.

Although male survivors of childhood cancers are at risk of developing various types of second primary cancers as much as female survivors, they do not appear to have the same risk of breast cancer as do females. A Finnish review of 470,000 registered cancer patients and a Nordic study of 30,880 childhood cancer survivors found no male survivors with secondary breast cancers.<sup>69,70</sup>

Screening for secondary colorectal cancer in cancer survivors at risk (ie, those having received radiation doses of  $\geq 25$  Gy to the spine, abdomen, and/or pelvis) involves colonoscopy every 10 years starting at the age of 35 years or 10 years after radiotherapy. Chronic hepatitis, often associated with blood product exposure prior to 1992, increases the risk of hepatocellular carcinoma, which can be screened by measuring serum  $\alpha$ -fetoprotein annually; patients who have developed cirrhosis should have annual right upper quadrant ultrasonography.

### Breast Cancer Survivors

More than 2.1 million females in the United States are breast cancer survivors. Most breast cancer recurrences occur within the first 5 years after treatment. Nonspecific symptoms (eg, weight loss, persistent cough, or body ache) or physical findings (eg, breast or chest wall changes or

lymphadenopathy) are common in breast cancer recurrence and should be investigated thoroughly during regular follow-up physician visits (Table 2). In addition to monitoring for recurrent disease, cancer screening may benefit breast cancer survivors as they have an increased risk of second primary cancers involving the breasts, colon, rectum, and ovaries.

Current recommendations for surveillance in breast cancer survivors include monthly self-examination of the breasts and chest wall, annual mammography of the remaining breast tissue, and a careful medical history and physical examination every 6 months for 5 years and annually thereafter. Many breast cancer survivors receive treatment with tamoxifen. Although tamoxifen reduces the risk of recurrent breast cancer and maintains bone density, it increases the risk of uterine cancer. To screen for uterine cancer, a pelvic examination and a PAP smear should be performed annually, and vaginal sonography should be performed at 3 and 5 years after the start of tamoxifen therapy to evaluate the endometrium.

Careful compilation of the family history may reveal hereditary breast cancer. Approximately 5 to 10% of breast cancers are caused by germline gene mutations (*BRCA1* and *BRCA2*). Identification of a hereditary component should prompt referral to clinical genetics services for consultation and screening of close relatives.

Mammography may have limited utility in females with dense breast tissue. Other new breast imaging modalities may trivialize the problems encountered in screening women with dense breasts. Ultrasonography may avoid unnecessary biopsies of cysts and may supplement mammography and clinical examination. However, ultrasonography has never been recommended as a routinely used screening tool.<sup>71</sup> Digital mammography and MRI have been introduced for breast cancer screening,<sup>72</sup> and MRI is the most accurate method to determine the size and number of lesions in the breast.<sup>71</sup>

Table 2 Cancer Screening for Survivors of Selected Cancers

Cancer Site	Surveillance for Recurrence	Screening for Second Primary or Secondary Cancers	Genetic Considerations
Breast	Monthly breast self-examinations Medical history and physical examination (including clinical breast examinations) every 6 mo for 3 to 5 yr and then annually Annual mammogram	Ipsilateral and contralateral breast Ovarian cancer Colorectal cancer Annual pelvic examination to screen for uterine cancer if patient is taking tamoxifen	Age at diagnosis Family cancer history Consider referral to genetic counseling for <i>BRCA1</i> or <i>BRCA2</i> mutations
Colorectal	CEA and clinical examination every 3 mo for 2 yr and then every 6 mo for 3 to 5 yr CT (optimal interval undetermined) Colonoscopy after 1 yr, 3 yr, and then every 5 yr*	Metachronous colorectal cancer Breast cancer Cervical cancer	Family cancer history Genetic counseling and assessment for familial adenomatous polyposis and hereditary nonpolyposis colorectal cancer
Prostate	Clinical evaluation PSA every 6 mo for 5 yr and then annually Digital rectal examination annually	Bladder cancer Colorectal cancer	Age at diagnosis Family cancer history Consider referral for genetic counseling and assessment if strong family history

Adapted from Kattlove H and Winn RJ.<sup>73</sup>  
CEA = carcinoembryonic antigen; CT = computed tomography; PSA = prostate-specific antigen.  
Surveillance recommendations from the National Comprehensive Cancer Network can be accessed on-line at <<http://www.nccn.org>>.

## Colorectal Cancer Survivors

Survivors of colorectal cancer have a high risk of second malignancies within the lower gastrointestinal tract, as well as in the breasts, uterus, and ovaries.<sup>46</sup> Those with HNPCC have an elevated risk of small bowel and endometrial cancers. The risk of recurrence is highest in the first 5 years after resection. For over 1 million survivors of colorectal cancer in the United States, prompt detection of new or recurrent cancer can improve survival. A meta-analysis has demonstrated a survival benefit of 19% at 5 years among patients undergoing intensive follow-up.

The National Comprehensive Care Network and the American Society of Clinical Oncology guidelines recommend follow-up evaluations to include a medical history, a physical examination, carcinoembryonic antigen (CEA) testing, and colonoscopy. History taking, physical examinations, and measuring CEA are recommended every 3 months for the first 2 years after treatment and then every 6 months for the next 3 years (see Table 2). A CEA blood test should be performed every 3 months for the first 2 years after the initial colon cancer diagnosis and then every 6 months for approximately 5 years after that. CEA measurement, combined with computed tomography (CT) body imaging studies, can improve survival. Colonoscopy should be performed 1 year after the initial colon cancer surgery and then every 3 years.

Patients with elevated CEA levels (which may precede symptoms by as many as 3 to 8 months) should be examined by CT, positron emission tomography, and colonoscopy, as appropriate, to identify the site of recurrent cancer and evaluate whether the recurrent disease can be surgically removed. Surveillance colonoscopy is recommended 12 months after surgery or at 6 months after surgery if a full colonoscopy has not been performed before surgery. If no abnormalities are detected by colonoscopy, then it should be repeated every 3 to 5 years.

## Prostate Cancer Survivors

Approximately 98% of prostate cancer patients survive 5 years after diagnosis; thus, the number of prostate cancer survivors is now estimated to exceed 1.7 million in the United States. Disease surveillance of prostate cancer survivors includes a nannual rectal examination and monitoring prostate-specific antigen (PSA) levels every 6 months for 5 years and then annually (see Table 2). Serum PSA declines to undetectable levels after radical prostatectomy; a slower decline occurs after radiotherapy. Elevated serum PSA levels after the initial decline achieved by definitive therapy indicate disease recurrence. Radiotherapy for prostate cancer may be associated with an increased incidence of bladder cancer among prostate cancer survivors;<sup>47</sup> therefore,

signs of hematuria should be thoroughly investigated.

The family history of prostate cancer survivors should be reviewed. Many cases of prostate cancer may have a familial component, and the risk of prostate cancer increases with the number of affected family members. Moreover, men with close relatives affected by breast or ovarian cancer may be at elevated risk of prostate cancer owing to *BRCA1* or *BRCA2* mutations. If a hereditary or genetic component is suspected, referral to a clinical geneticist for risk assessment and genetic testing may be indicated.

## Disclaimer

It is not possible for cancer screening recommendations for cancer survivors to be based on evidence from randomized or controlled trials because secondary cancers are consequences of cancer therapy and cannot be objectives in prospective studies. Therefore, recommendations are based on retrospective studies that have identified secondary cancers in long-term survivors. Under no circumstances should the recommendations be considered as mandatory, and it is common sense that certain recommendations may be inappropriate or contraindicated in individual patients. Furthermore, recommendations must be adapted regularly as our knowledge improves.

# Disturbances of Growth and Pubertal Development in Childhood Cancer Survivors

Wassim Chemaitilly, MD  
Charles Sklar, MD

Cancers occur less frequently during childhood than during adulthood. Around 12,500 individuals under 20 years of age are diagnosed with a new malignancy every year in the United States.<sup>1</sup> Before the age of 15 years, the most frequently observed cancers are leukemia (30.2%, with a majority of patients diagnosed with acute lymphoblastic leukemia [ALL]), central nervous system (CNS) cancers (21.7%), and lymphomas (10.9%, including 6.2% of patients diagnosed with non-Hodgkin's lymphoma [NHL]).<sup>2</sup> The incidence of newly diagnosed malignancies increases during adolescence, with a change in the etiologic distribution due to the rise in the incidence of Hodgkin's disease in that age group. Thus, in adolescence, the most frequently diagnosed cancers are lymphomas (23.6%, including 16.1% of patients diagnosed with Hodgkin's disease) followed by leukemia (10.6%, with a majority of patients diagnosed with ALL) and CNS cancers (10%).<sup>3</sup>

The modest increase in the incidence of childhood and adolescence cancers over the past 20 years comes in sharp contrast to the significant drop in the mortality rates over the same period of time. Cancer incidence rates increased by 1% yearly between 1974 and 1991.<sup>4</sup> In parallel, the five-year survival rates continuously improved and currently exceed 70% in children and adolescents, and reach more than 80% for ALL and 90% for Hodgkin's disease.<sup>2</sup> These improvements are the results of remarkable advances in supportive care and, most importantly, changes in therapy occurring over the past 30 years. Currently, many individuals diagnosed with a malignancy during childhood will receive combined modality therapies, including surgery, aggressive multi-agent chemotherapeutic regimens and radiotherapy.

Approximately two-thirds of pediatric cancer survivors will develop medical complications or

disabilities, which can be attributed to their previous cancer treatments.<sup>5</sup> Endocrine disturbances have been documented in 20 to 50% of survivors and frequently occur as late effects of cancer therapy. Survivors of CNS tumors, Hodgkin's disease and those undergoing stem cell transplantation (SCT) are at particular risk of developing endocrine complications as a result of their exposure to radiation therapy and high doses of alkylating agents. These treatments can cause damage to the hypothalamus-pituitary axis, the thyroid gland, and the gonads. The following discusses the common endocrine and growth problems that are observed in survivors of childhood cancer.

## Growth Failure

Impaired linear growth with resultant adult short stature occurs frequently in survivors of childhood cancer, particularly in individuals treated at a young age. A variety of factors, including high-dose radiation therapy (particularly to the brain and spine), early pubertal development, hypothyroidism, and growth hormone deficiency (GHD), contribute to the short stature in adult survivors. Both endocrine and non-endocrine factors can contribute to growth retardation.

## Non-endocrine Factors

The non-endocrine factors affecting growth are primarily related to intensive chemotherapy and irradiation of skeletal structures.

## Chemotherapy

The administration of chemotherapy is often associated with mild to moderate reduced growth. In many instances, the observed growth deceleration is only temporary; however, the adverse effects on growth can persist more long term.<sup>6-8</sup> In a report on a large series of childhood brain

tumor survivors, Gleeson and colleagues found that chemotherapy was a significant cause of standing height loss.<sup>7</sup> This is in contrast to a report by Gurney and colleagues on a cohort from the Childhood Cancer Survivor Study of 921 survivors of a childhood brain tumor in which the investigators showed that adjuvant chemotherapy was not an independent risk factor for adult short stature.<sup>8</sup> The negative effects on growth are dependent on the number and dosage of the drugs and the duration of treatment, all of which reflect the intensity of the regimen. Glucocorticoids, mercaptopurine and methotrexate are specific drugs implicated in the inhibition of normal growth. While the mechanisms of chemotherapy-induced growth failure remain uncertain, the data suggest that chemotherapy may act both directly on bone growth by suppressing osteoblast and osteoclast activity and through alterations of the growth hormone-insulin-like growth factor 1 (GH-IGF-1) system.<sup>9,10</sup>

## Radiotherapy

Direct external beam radiation to the spine and, to a lesser degree, to the long bones can produce profound losses in growth potential in children. The ultimate impact on final height depends on the dose of radiation therapy, the volume irradiated, and the age of the subject at the time of treatment. Several authors have reported on the skeletal dysplasia that follows total body irradiation (TBI), especially when administered in a single dose, and caused by exposure of the growth plate to radiation.<sup>11-14</sup> In this context, the sitting height is more affected than the standing height, indicating that the irradiation of the vertebrae contributes more to the observed growth impairment.<sup>11-15</sup> Younger patients are more likely to incur a greater loss in final height, and are at risk of having altered body proportions when

they reach adulthood.<sup>15</sup> The height reduction that occurs following contemporary radiation regimens for the treatment of diseases such as Hodgkin's disease and Wilms' tumor, where the dose of radiation to the spine and other bones is given at lower doses and in a more conformal fashion, is generally quite modest and usually not clinically important.<sup>16,17</sup>

## Endocrine Factors

The most important endocrine factors that disrupt the normal pattern of growth in survivors include GHD and central precocious puberty (CPP). Both of these neuroendocrine disturbances usually are the consequence of hypothalamic-pituitary irradiation. Primary hypothyroidism also may contribute to poor linear growth in these children and will be discussed in the section on thyroid abnormalities.

### Growth Hormone Deficiency

**Causes** (1) Direct insult by tumoral expansion or ablative surgery: Tumors, such as craniopharyngiomas, germinomas, and optic nerve gliomas, which arise near the region of the hypothalamus and pituitary, produce GHD as a direct result of the tumor or of the surgery required to remove it.

(2) Radiotherapy: Cranial irradiation can cause damage to the hypothalamus and, less often, to the pituitary. Growth hormone deficiency is indeed the most common and frequently the only anterior pituitary deficit to develop after cranial irradiation.<sup>18</sup> The site of the damage caused by irradiation is more frequently the hypothalamus, which is more sensitive to radiation than the pituitary.<sup>19</sup> There are two major hypothalamic regulators of GH secretion: growth hormone releasing hormone (GHRH) and somatostatin. The secretion and release of GH by the pituitary is stimulated by GHRH and inhibited by somatostatin. Low doses of radiation (ie, 18 gray [Gy] of conventional fractionated radiotherapy) to the hypothalamus/pituitary region are sufficient to cause the loss of the GHRH tone without influencing somatostatin, thus causing GHD.<sup>20</sup> The pituitary gland is damaged at higher doses of irradiation.<sup>19</sup> Risk factors for GHD following radiotherapy can relate to patient characteristics and to the dose of radiation administered to the hypothalamus and pituitary.

(a) Patient characteristics: Younger patients are at an increased risk of developing GHD after radiation of the hypothalamus/pituitary region.<sup>21,22</sup> In a series of 27 patients receiving 24 Gy of cranial prophylactic irradiation for ALL or lymphosarcoma, Brauner and colleagues demonstrated that the GH peak response in stimulation tests strongly correlated with patient age at irradiation, despite similar time

intervals since the completion of treatment, confirming previous reports with similar results from Shalet and colleagues.<sup>21,22</sup>

(b) Dose delivered and time since completion of treatment: Radiation therapy is followed by GHD in both a time- and dose-dependent relationship (Figure 1).<sup>23</sup> External beam radiation doses >30 Gy typically produce GHD within 5 years of treatment; after lower doses, such as 18 to 24 Gy, GHD may not become evident for 10 or more years.<sup>24</sup> In survivors of pediatric SCT, GHD has been shown to develop after TBI, often several years after the completion of cancer treatments.<sup>6,25,26</sup> Once established, radiation-induced GHD is usually permanent.<sup>27</sup> Several authors have reported on a possible improvement in GH secretion in a minority of patients; their findings suggest that retesting patients diagnosed during childhood with irradiation-induced GHD when they reach their final height is warranted before this treatment is continued through adulthood.<sup>28-30</sup>

(3) Chemotherapy: The effects of chemotherapy on the GH-IGF-1 axis are unclear. Slow growth and GHD following chemotherapy have been reported by some authors. Bakker and colleagues recently reported a high incidence of abnormal growth patterns in children receiving a combination of high doses of cyclophosphamide and busulfan for SCT conditioning, with laboratory results suggesting GHD in 4 out of 10 tested patients.<sup>31</sup> Nevertheless, the changes on which the authors based their conclusions were not statistically significant. Rose and colleagues also suggested that some patients may develop

hypothalamic dysfunction, including GHD, following chemotherapy.<sup>32</sup> Out of 800 cases reviewed by the authors, 31 patients had slow growth patterns and had been exclusively treated with chemotherapy. Out of these 31 patients, 15 were diagnosed with GHD based upon results of stimulation tests alone.<sup>32</sup>

**Diagnosis** Establishing a diagnosis of GHD can be problematic in childhood cancer survivors. There is no "gold standard" diagnostic tool for GHD in general, and some of the available tests are known to be unreliable in cases of hypothalamic or pituitary injury following radiation. The diagnosis is based on the convergence of clinical features and laboratory results.

(1) Clinical features: GHD should be suspected in patients with decreased growth velocity (ie, growth rate below the fifth percentile for age) observed over at least six monthly visits.<sup>33</sup> It is also important to monitor the sitting height in patients who received irradiation to the spine in order to look for the skeletal dysplasia associated with this treatment.<sup>15</sup> Special attention should be paid to the patients' pubertal status because the clinical signs of GHD may be masked by seemingly normal growth rates owing to the inappropriate secretion of sex steroids in patients with precocious puberty, another endocrine complication that can be encountered in this context.<sup>34</sup> As in any pediatric evaluation, the nutritional status (reflected by body weight and body mass index [BMI]), is a key clinical element that can influence linear growth and needs to be taken into account.

(2) Laboratory results: There are three main laboratory diagnostic tools for GHD.

(a) GH provocative tests: The GH peak value is measured after administration of a pharmacologic agent known to stimulate the secretion and release of GH. Several agents are used, but the insulin tolerance test is believed to be the most reliable, despite exposing the patient to the risk of hypoglycemia.<sup>35,36</sup> Although widely used, these tests are non-physiologic and often yield non-reproducible results. The normal peak value has been arbitrarily defined at 10 ng/mL although several authors have lowered the threshold to 7 ng/mL. Despite these caveats, failure to achieve a peak response >10 ng/mL following two pharmacologic stimulation tests is considered part of the standard criteria for a diagnosis of GHD. Nevertheless, failing one stimulation test was considered enough for diagnosing GH deficiency in patients who received irradiation to the hypothalamus and/or pituitary by the GH research society in its consensus guidelines.<sup>27</sup>

(b) GH frequent sampling studies: Spontaneous GH secretion is assessed by obtaining blood samples every 20 minutes over a 12 to 24 hour

**FIGURE 1** Percentage of normal insulin-tolerance tests (ITTs) compared to time from irradiation in patients receiving <math>< 30\text{ Gy}</math> or <math>\ge 30\text{ Gy}</math> to the hypothalamic-pituitary axis. Reprinted with permission from Clayton PE, et al.<sup>23</sup>

period. More frequently, the samples are drawn only at night, during sleep (“overnight sampling”), a time when the bulk of GH is produced. GHD is unlikely if a GH peak above 10 ng/mL is observed or if a mean plasma concentration of 3ng/mL or above is derived from the GH levels measured in the collected samples. The overnight sampling appears to be more reliable than the provocative tests, with fewer false negative and false positive results, but it is labor-intensive and continues to be available only in a few academic centers.<sup>37,38</sup>

(c) Measurements of surrogate markers of GH: Growth hormone induces skeletal growth indirectly by stimulating the secretion by the liver of insulin-like growth factor-1 (IGF-1). The effect of IGF-1 on skeletal growth is regulated by its association with IGF binding protein-3 (IGFBP-3). Unlike GH, plasma IGF-1 and IGFBP-3 levels are stable and their measurement does not require performing dynamic tests. They are routinely used as a screening test for the GH status of individuals with short stature.<sup>38</sup> However, IGF-1 and IGFBP-3 are not reliable indicators of the GH status following cranial irradiation, or in cases of a CNS lesion.<sup>39,40</sup> In patients with documented hypothalamic/pituitary injury due to irradiation or tumoral expansion, IGF-1 and IGFBP-3 levels can be in the normal range, despite the presence of GHD.

#### Central Precocious Puberty

CPP is defined as the onset of puberty before the age of 8 years in girls and 9 years in boys due to the premature activation of the hypothalamic-pituitary-gonadal axis.<sup>41</sup> Over several years, it became evident that cranial irradiation at both lower doses (18 to 35 Gy) and higher doses (35 to 50 Gy) is associated with the development of CPP.<sup>42–44</sup> The presumed mechanism of this activation is the disruption of the cortical inhibitory influence by radiation. Roth and colleagues showed, using animal models, that low-dose hypothalamic irradiation leading to sexual precocity is associated with lower release rates of  $\gamma$ -amino butyric acid (GABA). These findings suggest that irradiation disrupts the inhibitory influence of the GABA-ergic tone, causing the observed activation of the gonadotropin-releasing hormone (GnRH)-gonadotropin-gonadal axis.<sup>45</sup> The age-inappropriate sex steroid secretion can cause rapid bone age progression and further decrease the growth potential of children, the vast majority of whom also suffer from GHD.

**Risk Factors** Girls seem more likely than boys to enter puberty at an early age following hypothalamic irradiation.<sup>46</sup> Age at the onset of puberty is directly correlated with age at treatment and inversely correlated with the BMI.<sup>43</sup>

While earlier studies suggested that the tempo of puberty is also accelerated in these patients, recent data have been unable to confirm this.<sup>46</sup> Irradiation doses to the hypothalamus in the range of 35 to 50 Gy can result in CPP, while doses >50 Gy are generally associated with hypogonadotropic hypogonadism within the context of combined hormonal pituitary deficiencies.<sup>47,48</sup>

**Diagnosis** (1) Clinical features: Precocious puberty is a clinical diagnosis. In the general pediatric population, it is best characterized by the onset of sustained breast development before the age of 8 years in girls, and by testicular enlargement (testicular volume >4 cc) before the age of 9 years in boys.<sup>41</sup> In childhood cancer survivors, testicular volume may not be a reliable indicator of pubertal growth in boys, and clinicians should be alerted by the early onset of other secondary sexual characters (eg, pubic hair) as well. One of the first signs of pubertal development is an increase in the growth rate, due to the action of the sex steroids. In children who also are likely to have GHD, this may result in falsely reassuring normal growth velocity, as mentioned previously. Therefore, pubertal staging using the Tanner classification is an important part of the regular clinical follow-up of these patients, and any concerns regarding the possibility of early onset of puberty should lead to a referral to an experienced pediatric endocrinologist.<sup>49</sup>

(2) Radiologic findings: The bone age is estimated by performing the standard x-ray examination of the left wrist.<sup>50</sup> Advancement of the bone age more than 2 standard deviations (SD) for chronological age is a consistent finding in children with precocious puberty and is helpful in corroborating the clinical impression of inappropriate sexual development. In girls with CPP, symmetrical uterine growth is evidence of estrogen impregnation, and is an earlier finding than bilaterally enlarged ovaries. It is not, however, a necessary procedure when clinical features and laboratory findings are consistent with the diagnosis.

(3) Laboratory results: In CPP, pubertal development results from the premature activation of the hypothalamic pituitary axis. Therefore, luteinizing hormone (LH) and follicle stimulating hormone (FSH) levels tend to be detectable at baseline and to rise after stimulation by GnRH. An LH/FSH peak ratio above 0.6 unit per liter (U/L) in girls and above 1 U/L in boys indicates a pubertal response.<sup>51</sup> In patients who received gonadotoxic treatments, the LH/FSH response to GnRH will be altered; the FSH response will be augmented, making the results harder to interpret. The plasma estradiol levels in girls and testosterone levels in boys are also important markers of pubertal development.

## Management

The final height is most affected in individuals who are diagnosed with cancer at a young age, particularly if they are treated with high doses of radiotherapy (>30 Gy) to the hypothalamus or the hypothalamus and spine.<sup>8</sup> In this context, both GHD and CPP can reduce the growth potential and result in a very impaired final height. While both GHD and CPP are amenable to therapy, growth arrest due to radiation-induced boney dysplasia is not.

Growth hormone replacement therapy improves the growth rate of children who develop GHD following cancer therapy, at least in the short term. Data accumulated several years ago suggested that most patients, however, achieved a final height significantly below their target height.<sup>45,52</sup> The poor response to GH therapy has been attributed both to patient factors, such as spinal irradiation, early pubertal onset, and variables in treatment, such as suboptimal dosing schedules, as well as to the older age of most children started on GH. Recent data suggest that improvements in growth and final height can be achieved with contemporary dosing regimens.<sup>7,53,54</sup> Thus, Gleeson and colleagues reported a significant improvement in the final heights of survivors of childhood brain tumors treated after 1988, compared to patients treated in an earlier era.<sup>7</sup> In a more heterogeneous patient cohort, Adan and colleagues had previously reported a similar trend with a significant improvement of the adult heights in patients treated with contemporary GH replacement regimens.<sup>53</sup> In both studies, the improvement was even more striking in patients with combined GHD and CPP and who received a gonadotropin-releasing hormone agonist to suppress puberty in addition to GH replacement.<sup>7,53</sup> In a more recent report from the Childhood Cancer Survivor Study, supported by final height data on 183 childhood cancer survivors treated with GH, Brownstein and colleagues showed that younger bone age at the beginning of GH replacement and higher doses of GH-positively correlated with a better final height outcome.<sup>55</sup> GH-releasing hormone (GHRH) therapy also may improve growth in subjects with radiation-induced GHD, but the data are quite limited.<sup>20</sup>

Concerns over the safety of GH therapy relate to the fact that GH and IGF-1 are potent growth-promoting agents with anti-apoptotic, mitogenic, and proliferating properties. However, large-scale studies assessing the risk of tumor recurrence in brain tumor survivors treated with GH have now been reported. All have consistently reported no increased risk associated with GH replacement therapy.<sup>56–58</sup> In a report from the Childhood Cancer Survivor Study on 361 GH-treated individuals, including 122 survivors of acute leukemia and 43 survivors of soft tissue sarcomas, Sklar and colleagues did not find

evidence for an increased risk of disease recurrence or death following GH-replacement therapy.<sup>58</sup> However, the data suggested that treatment with GH may slightly increase the risk of a secondary solid tumor, especially in survivors of acute leukemia. In view of the small number of second tumors and the wide confidence intervals, the clinical importance of that finding remains uncertain.<sup>58</sup> The risk of developing slipped epiphyses may be increased in cancer survivors (particularly survivors of leukemia) who were treated with GH, compared with children treated with GH for idiopathic GHD.<sup>59</sup>

Young adult survivors with either childhood- or adult-onset GHD, such as that following low-dose cranial irradiation at a young age, also may benefit from GH therapy, especially if they manifest any of the metabolic derangements, such as increased body fat, raised plasma lipids, and decreased bone density and/or quality-of-life issues that have come to be recognized as adult GHD. Murray and colleagues reported on the effects of GH replacement in adulthood in a series of 27 GH-deficient survivors of childhood cancer.<sup>60</sup> After 12 months of replacement, small but significant improvements occurred in the body composition in males and in the cholesterol and triglyceride levels in females. Mild improvement of the bone mineral density occurred after 18 months of treatment. However, the patients reported a significant improvement in their overall quality of life 3 months after beginning the treatment, and this improvement was maintained at 12 months.<sup>60</sup>

## Disorders of the Thyroid

Thyroid dysfunction is among the most common endocrine complications of childhood cancer treatments. Thyroid hormones are important for growth and development in childhood, and early recognition of thyroid dysfunction in childhood cancer survivors should be among the objectives of their long-term follow-up.

### Hypothyroidism

Apart from its well known neurocognitive and metabolic signs observed in adults, childhood hypothyroidism causes growth deceleration often associated with excessive weight gain. Central hypothyroidism is secondary to hypothalamic and/or pituitary insults and is seen relatively infrequently in this population. In contrast, primary hypothyroidism, due to direct damage to the thyroid following exposure to radiation, is by far the most frequently observed thyroid dysfunction in childhood cancer survivors.

#### Central Hypothyroidism

Central hypothyroidism is reportedly the second most frequent endocrine disturbance following

radiation of the hypothalamus/pituitary region.<sup>61</sup> Its association with chemotherapy, however, remains controversial.

**Radiotherapy** While early puberty and GHD are the most common neuroendocrine disturbances secondary to irradiation of the hypothalamus/pituitary region, clinically evident alterations of the other hypothalamic-pituitary axes, including thyrotropin thyroid stimulating hormone (TSH) secretion, occur less often and generally only following doses in the range of 30 to 40 Gy.<sup>18,62</sup> Interpretation of the literature about these deficits is complicated by the fact that different investigators employ different hormonal tests and use varying criteria for what constitutes abnormal. For example, Rose and colleagues reported a very high incidence of “hidden” central hypothyroidism secondary to TSH-deficiency following cranial irradiation.<sup>63</sup> According to the authors, the establishment of a diagnosis of TSH-deficiency often requires performing both a thyrotropin-releasing hormone (TRH) test and an assessment of the nocturnal TSH surge. These tests require obtaining multiple blood samples during the day and night. At present, it is unclear whether this subtle form of TSH dysfunction correlates with any clinical findings, and, thus, whether one can justify on clinical grounds the time and expense involved in this diagnostic protocol.

**Chemotherapy** There are few reports in the literature on the contribution of chemotherapy to the development of central hypothyroidism in childhood cancer survivors. In one report, Rose and colleagues suggested that subtle TSH deficiency was found in as many as 53% of patients exclusively treated with chemotherapy for extracranial malignancies and who were assessed for abnormal growth.<sup>32</sup> The clinical significance of these findings is, again, debatable. Those patients had normal free thyroxine (FT4) levels, and the diagnosis of central hypothyroidism was based upon the absence of a nocturnal surge in TSH secretion. In a previous study including 205 patients, Van Santen and colleagues did not find any damaging effects of chemotherapy on the hypothalamic-pituitary-thyroid axis in young adult survivors of childhood cancer.<sup>64</sup> Schmiegelow and colleagues also reported that chemotherapy did not have a significant influence on the hypothalamic-pituitary-thyroid axis in their 71-patient cohort of childhood brain tumor survivors.<sup>62</sup>

#### Primary Hypothyroidism

Primary hypothyroidism is the most common thyroid disturbance that occurs in patients whose thyroid gland has been irradiated. It is often detected in survivors who have been treated with neck/mantle irradiation for Hodgkin’s disease,

craniospinal irradiation for brain tumors, or TBI for cytoreduction before SCT.<sup>25,61,65</sup> Primary hypothyroidism has also been described in individuals treated with a radio-labeled monoclonal antibody such as Iodine-131-meta-iodobenzylguanidine (I<sup>131</sup>-MIBG) for neuroblastoma. Chemotherapy alone does not seem to be associated with primary hypothyroidism.<sup>66</sup>

As in other dysfunctions following radiation therapy, the prevalence is determined primarily by the total dose to the thyroid and by the duration of follow-up. In a recent study of 1,791 young adult survivors of Hodgkin’s disease, a cumulative incidence of hypothyroidism of 28% was observed.<sup>65</sup> Moreover, the actuarial risk of developing an underactive thyroid 20 years after treatment was 50% for survivors who had received thyroid irradiation with doses  $\geq 45$  Gy (Figure 2). Additional risk factors for developing hypothyroidism included female gender and/or being older than 15 years of age at the time of diagnosis. Of great clinical importance, new cases have been observed more than 25 years following diagnosis and treatment of Hodgkin’s disease. Consequently, all patients previously treated with radiation therapy to the region of the thyroid require lifelong surveillance.

### Hyperthyroidism

While far less prevalent than hypothyroidism, hyperthyroidism does develop at an increased rate in certain subsets of childhood cancer survivors. A common setting is following external beam radiation to the neck for Hodgkin’s disease, where the chances of becoming hyperthyroid are eight times greater than those observed in the

**FIGURE 2** Probability of developing an underactive thyroid after diagnosis of Hodgkin’s disease. Patients are grouped according to dose of thyroid irradiation. RT = radiation therapy. Reprinted with permission from Sklar, et al.<sup>65</sup>

general population.<sup>65</sup> The major risk factor for development of hyperthyroidism is irradiation of the thyroid involving doses >35 Gy. A second but less common cause of hyperthyroidism is the appearance of autoimmune thyroid disease following allogeneic SCT. The published data are most consistent with the hypothesis that the thyroid disorder is due to adoptive transfer of abnormal clones of T or B cells from donor to recipient.<sup>25</sup> Various types of autoimmune disease have been demonstrated to occur at increased frequency following SCT.

### Thyroid Neoplasms

Thyroid neoplasms, both benign and malignant, do occur following irradiation of the thyroid gland as the result of both direct exposure to radiation and scatter irradiation (for example, after prophylactic CNS irradiation in patients treated for ALL). Children at greatest risk are those <10 years of age at the time of treatment and those treated with doses of radiation in the 20 to 29 Gy range. The risk is linear at lower doses of irradiation (0.1 to 1 Gy), but this association seems to become more complex at doses above 30 Gy, showing a downwards curvature in radiation-dose response for thyroid cancer.<sup>67</sup> Nonetheless, the risk of developing a thyroid neoplasm remains elevated following even relatively high-dose radiation therapy. Thyroid nodules are particularly common in females and often occur after a long latency period (>10 years). Sklar and colleagues reported that the risk of thyroid cancer was increased 18-fold in a large cohort of young adult survivors of Hodgkin's disease.<sup>65</sup> The median dose of radiation to the thyroid was 35 Gy, with a range of 25 to 35 Gy. Fortunately, the vast majority of cancers noted after radiation therapy are well differentiated and have excellent prognosis. In a more recent study, Acharya and colleagues studied the characteristics of all patients at our center who developed a thyroid neoplasm after therapeutic radiotherapy during childhood or adolescence.<sup>68</sup> The median dose of radiation to the gland was 24 Gy, with a median interval of 13 years between radiation exposure and clinical recognition of the thyroid neoplasm. Malignant neoplasms represented a high proportion of the observed lesions (39%). Patients who developed malignant lesions differed from those who developed benign lesions only in that the median dose to the thyroid was lower compared to those with benign lesions (20 Gy vs. 29.5 Gy). All of the thyroid malignancies observed after therapeutic radiation were differentiated carcinomas, with papillary carcinoma being most common. In general, the post-irradiation thyroid cancers did not behave in an aggressive fashion.<sup>68</sup> The pathogenesis of irradiation-induced thyroid

neoplasms remains unclear. They may be related to rearrangements of the RET proto-oncogene induced by the exposure to radiation, although the data are conflicting.<sup>69,70</sup> Thyroid neoplasms following radiotherapy may not become evident for many years after irradiation, therefore all individuals at risk require lifelong follow up.<sup>65,68</sup>

### Management of Thyroid Disorders

#### Clinical Assessment

A careful clinical assessment, which includes careful palpation of the neck, should be performed at least annually by an experienced physician to look for a thyroid neoplasm in all childhood cancer survivors who have been treated with neck/mantle irradiation, craniospinal irradiation, or TBI. Linear growth and weight gain, monitored during childhood by plotting on growth curves the heights and weights recorded at visits, can also give some evidence of thyroid dysfunction. Children with hypothyroidism tend to have a deceleration in growth associated with excessive weight gain. Hyperthyroid children tend to have an accelerated growth rate, often associated with weight loss.

#### Laboratory Assessment

Annual thyroid function tests, including plasma TSH and FT4, should be systematically performed in order to ensure early diagnosis and treatment in patients who received neck/mantle irradiation, craniospinal irradiation, or TBI.

#### Imaging and Pathology

The role of ultrasonography in screening for thyroid neoplasms in patients treated with radiotherapy remains controversial due to the high prevalence of benign and clinically undetectable thyroid nodules in the general population.<sup>68</sup> Even when the subclinical neoplasms discovered by ultrasonographic screening turn out to be malignant, their clinical importance remains to be proven because their rate of progression into significant lesions may be very low.<sup>71</sup> The diagnostic procedure of choice in evaluating a thyroid nodule in cancer survivors with a history of thyroid exposure to radiation is the fine needle aspiration biopsy.<sup>68</sup>

#### Treatment

Thyroxine replacement is warranted in patients diagnosed with compensated (normal T4 levels with high TSH) and decompensated (low T4 and high TSH levels) hypothyroidism. The benefit of treating "subtle" forms of hypothyroidism diagnosed by more complex laboratory procedures remains unclear.<sup>32,63</sup> There are no specific guidelines regarding the management of hyperthyroidism and second thyroid neoplasms in

childhood cancer survivors, in whom the same treatments are applied as for the general population.

### Disorders of Pubertal Development

#### Impairments of the Hypothalamic-Pituitary-Gonadal Axis

##### Central Precocious Puberty

Along with GHD, CPP is one of the most frequent disorders observed after the radiation of the hypothalamus/pituitary region. It was discussed previously, under the growth section of this text.

##### Hypogonadotropic Hypogonadism

In childhood cancer survivors, insufficient LH and FSH secretions have been reported in the context of hypothalamic and/or pituitary injury following tumor invasion/expansion or the treatments, surgery, and radiation therapy directed against such tumors. Deficits of LH and FSH secretion following irradiation of the hypothalamus/pituitary region, occur less often than GHD, and generally only following doses to the sellar region in the range of >30 to 40 Gy.<sup>18,62,72,73</sup> In female ALL survivors, Bath and colleagues reported lower LH secretion in the 12 adolescents and young adults enrolled in their study, based upon the measurement of the amplitude of the urinary LH surge.<sup>74</sup> The authors attributed this disorder to cranial irradiation, and suggested that doses of 18 to 24 Gy can be sufficient to cause such "subtle" deficits.<sup>74</sup> Byrne and colleagues, in a study of the fertility of women treated with cranial radiotherapy for childhood ALL, found that irradiation of the hypothalamus and/or pituitary with doses in the 18 to 24 Gy range around the time of menarche may affect fertility and suggested that this may be secondary to the impairment gonadotropin secretion.<sup>73</sup> Additional long-term follow-up and data on the fertility of these patients will provide a better sense of the ultimate effect of these lower doses of cranial irradiation.

Little is known on the effects of chemotherapy on LH and FSH secretion. In their recent report on hypothalamic dysfunction after chemotherapy, Rose and colleagues found that three patients out of 27 patients old enough to be assessed for pubertal development, had pubertal delay due to insufficient gonadotropin secretion.<sup>32</sup> Given the lack of clinical information on these patients, and the multiplicity of factors (eg, nutritional, psychological, social) influencing the timing of puberty in a child recovering from cancer, caution is warranted in interpreting these results.

##### Hyperprolactinemia

Hyperprolactinemia can be observed following high-dose irradiation, particularly when the

hypothalamus is exposed to more than 50 Gy. Constine and colleagues reported on a series of 32 patients who received high-dose cranial radiotherapy (39.6 to 70.2 Gy, with a mean 53.6 Gy) as treatment for brain tumors, and showed that 75% of the adult patients and 30% of pediatric patients had elevated baseline prolactin levels.<sup>75</sup> Hyperprolactinemia was symptomatic, however, only in three adult patients, who reported decreased libido.

## Primary Gonadal Dysfunction

### Males

The human testis is the site of both sex steroid and sperm production. Testosterone, the major male sex steroid, is responsible for normal male secondary sexual characteristics and is also a necessary cofactor in the production of sperm. Although these two functions are interconnected to a certain degree, they are under separate controls, which include a multitude of endocrine, paracrine, and autocrine factors.<sup>76</sup> The testis is composed primarily of three types of cells: germ cells that ultimately form sperm; Sertoli cells that support and nurture developing germ cells and are also the site of production of inhibin; and interstitial Leydig cells responsible for the biosynthesis of testosterone. These three cell types are organized into two functional compartments: germ cells and Sertoli cells form the seminiferous tubules where spermatogenesis takes place, and the network of Leydig cells is responsible for the production of testosterone. Leydig cells lie in close proximity to the basal compartment of the seminiferous tubules, where they can deliver high concentrations of testosterone, which are necessary for normal spermatogenesis.<sup>77</sup> Despite their interconnection, these two functional compartments are affected in different ways by the treatments (eg, chemotherapy, radiation) given to individuals with cancer.

**Leydig Cell Dysfunction** Treatment-induced Leydig cell failure and/or dysfunction results from damage or loss of the machinery required for testosterone synthesis and release. Leydig cell failure and androgen insufficiency are relatively uncommon compared to the damage to germ cells and infertility following cancer therapy.

**Diagnosis** If it occurs prior to or during normal puberty, individuals with Leydig cell failure will experience delayed/arrested pubertal maturation and lack of secondary sexual characteristics. If the insult is sustained following the completion of normal pubertal development, one can observe lack of libido, erectile dysfunction, decreased bone density, decreased muscle mass and other metabolic disturbances.<sup>78</sup> Raised plasma concentrations of LH combined with low

levels of testosterone are the hormonal hallmarks of Leydig cell dysfunction. It is important to note, however, that these changes may not become apparent until the individual has reached mid-adolescence.<sup>79,80</sup> Thus, it can be very difficult to assess or predict Leydig cell function in the preadolescent male.

**Chemotherapy-Induced Leydig Cell Failure** In general, Leydig cells, with their slow rate of turnover, are much less vulnerable to damage from cancer therapy than are germ cells. Chemotherapy-induced Leydig cell failure resulting in androgen insufficiency and requiring testosterone replacement therapy is quite rare.<sup>78,81,82</sup> Nonetheless, prior studies suggest that Leydig cell dysfunction may be observed following treatment with alkylating agent regimens.<sup>78,83-85</sup> These reports indicate that from 10 to 57% of male subjects can develop elevated serum concentrations of LH following treatment.<sup>72,83,86-89</sup> Insofar as the majority of males undergo a normal puberty, and most produce adult levels of testosterone, it appears that Leydig cell dysfunction is generally subclinical when it occurs. For instance, in a report by Kenney and colleagues on 17 male survivors of childhood sarcoma treated with high-dose cyclophosphamide, while baseline LH was elevated in 40% of the patients, testosterone secretion was normal in 93.8% of the cases.<sup>86</sup> Young boys and adolescent males who receive standard-dose cyclophosphamide alone (200 mg/kg) as conditioning regimen before SCT for aplastic anemia appear to retain normal Leydig cell function; the vast majority are reported to have normal plasma concentrations of LH and testosterone and to normally enter and progress through puberty.<sup>90</sup> In patients whose SCT conditioning regimen combined high doses of busulfan and cyclophosphamide, Leydig cell function also appears to be preserved in most adult males despite damage to the germinal epithelium.<sup>31,91</sup>

### Radiation-Induced Leydig Cell Failure

External irradiation is more likely than chemotherapy to cause Leydig cell damage. The doses required are much higher than the doses needed to cause germ cell failure. The interpretation of the impact of radiation on Leydig cell function is confounded by the concurrent use of chemotherapy in most subjects as well as the potential effects of the malignancy itself (eg, testicular relapse in ALL). Nonetheless, the data obtained from individuals treated with radiation therapy for a variety of malignancies show that the likelihood of sustaining radiation-induced Leydig cell failure is directly related to the dose delivered and inversely related to age at treatment.<sup>92-95</sup> Normal amounts of testosterone are produced by the majority of males who receive

≤20 Gy fractionated radiation to the testes.<sup>78</sup> Shalet and colleagues noted that Leydig cell function was preserved in a group of adult males who, as children, were exposed to doses up to 9.8 Gy of testicular irradiation.<sup>96</sup> Both, Sklar and colleagues and Castillo and colleagues described age-appropriate levels of testosterone and normal pubertal maturation in males who were treated prophylactically with 12 Gy of testicular irradiation for ALL.<sup>82,97</sup> Because raised plasma concentrations of LH, both at baseline and following GnRH stimulation, are found in many of these young men, one must assume that subclinical injury to the Leydig cell is common at this dose range. A dose of > 24 Gy of fractionated irradiation as therapy for young males with testicular relapse of ALL is associated with a very high risk for Leydig cell dysfunction. One should anticipate that the majority of boys who are prepubertal at the time they receive 24 Gy testicular irradiation will develop frank Leydig cell failure and require androgen replacement.<sup>80,94,95</sup> Most, but not all, boys who are older and/or in early puberty at the time they are treated with 24 Gy will also ultimately need therapy with testosterone.<sup>95</sup> It has been estimated that testicular doses in excess of 33 Gy are needed to induce Leydig cell failure in 50% of adolescent and young adult men.<sup>98</sup> Of note, Sklar reported normal adult testosterone levels in two young men who received in excess of 40 Gy testicular irradiation during late adolescence.<sup>78</sup>

**Germ Cell Dysfunction** Treatment-induced germ cell failure in males occurs frequently, in contrast to what occurs in Leydig cells, which are resistant to most chemotherapeutic agents and lower doses of radiation.

**Diagnosis** Infertility resulting from radiation therapy or chemotherapy is often associated with reduced testicular volume, increased FSH concentrations, and reduced plasma concentrations of inhibin B. While there are good correlations overall between these markers and sperm counts in large groups of survivors, considerable overlap occurs between normal and abnormal individuals; many males with documented azoospermia fail to manifest either a reduced testicular volume or an elevated level of FSH.<sup>86</sup> Thus, currently, there is no substitute for sperm analysis to determine a male's current fertility status.<sup>99</sup>

### Chemotherapy-Induced Germ Cell Failure

The chemotherapeutic agents most commonly associated with impaired male fertility include the alkylating agents listed in Table 1. Importantly, the concept derived from studies suggesting that the germ cells of younger individuals were less vulnerable to the toxic effects of chemotherapy compared with older boys and young adults has been called into question by more recent studies.<sup>86</sup>

**TABLE 1** Chemotherapeutic Agents Associated with Germ Cell Damage**Alkylating Agents**

Cyclophosphamide

Ifosfamide

Procarbazine

Busulfan

Melphalan

Thiotepa

**Nitrosoureas**

BCNU (carmustine)

CCNU (lomustine)

**Etoposide****Cisplatin**

Impaired fertility occurs in 40 to 60% of young adult survivors of childhood cancer. A high probability of oligospermia, azoospermia and infertility exists in those exposed to  $>20$  g/m<sup>2</sup> of cyclophosphamide. In contrast, many individuals treated with a cumulative dose of 7.5 to 10 g/m<sup>2</sup> or less retain normal sperm production.<sup>72,86</sup> Procarbazine, another alkylating agent commonly used in the treatment of Hodgkin's disease has also been shown to induce gonadal dysfunction in a dose-dependent fashion. In a study by van den Berg and colleagues, patients with Hodgkin's disease who received three mechlorethamine, vincristine, procarbazine, and prednisone (MOPP) cycles alternating with three cycles of doxorubicin hydrochloride, bleomycin, vinblastine, and dacarbazine seemed to suffer less testicular damage than patients who received 6 MOPP cycles.<sup>100</sup> The sperm counts available in this study were too few to enable any definite conclusions, but these findings are consistent with an earlier report from Mackie and colleagues.<sup>89</sup> Most of the young men treated with the combination of busulfan and cyclophosphamide in preparation for SCT do appear to sustain damage to their germinal epithelium. Anserini and colleagues, in a small sample of post-SCT patients, demonstrated that recovery of some spermatogenetic activity occurred in 50% of cases after such conditioning regimens, but semen quality was impaired.<sup>101</sup> Grigg and colleagues had previously suggested that recovery of spermatogenetic activity occurred more frequently in patients receiving lower doses of cyclophosphamide (120 mg/kg) and busulfan (16 mg/kg) than in patients who receive the usual higher doses.<sup>102</sup> Overall, the ultimate effect of this combination on male fertility remains unclear.

**Radiotherapy-Induced Germ Cell Failure**

Testicular irradiation in doses as low as 0.15 Gy has produced impaired sperm production. If the dose is under 1 to 2 Gy, recovery is generally common. At doses  $>2$  to 3 Gy, recovery of sperm production is rare.<sup>103</sup> Germ cell dysfunction is

present in essentially all males treated with TBI.<sup>104</sup> The vast majority of subjects will have increased plasma levels of FSH as well as reduced testicular volume, indices that correlate with impaired spermatogenesis. Azoospermia is the rule for patients studied in the first few years after treatment with TBI. Recovery of germ cell function has occurred rarely and primarily following single-dose irradiation.<sup>105</sup> A few men have been reported to father a child following TBI.<sup>104</sup>

**Females**

Ovarian failure results in disruption of and damage to both ovarian germ cells and the hormone-producing cells. This results from the structural and functional interdependence within the follicle between sex-hormone-producing cells and oocytes.<sup>78</sup> This contrasts with testicular pathology where, despite the loss of the germ cells following cytotoxic therapy, production of sex hormones is often preserved. As the ovarian follicular reserve decreases naturally with age, older patients are more at risk of ovarian failure following childhood cancer and its treatments.<sup>78</sup>

**Diagnosis** Ovarian failure that occurs prior to the onset of puberty will result in delayed puberty and primary amenorrhea. If ovarian function is lost during or after pubertal maturation, one generally observes arrested puberty, secondary amenorrhea, and menopausal symptoms (ie, hot flashes, vaginal dryness). Women who experience premature loss of estrogen production are also predisposed to developing osteoporosis and coronary artery disease.<sup>106</sup> Increased plasma concentrations of gonadotropins, especially FSH, and reduced levels of estradiol are typically found in the adolescent and young adult with ovarian failure. As in the male, plasma levels of LH/FSH may remain normal in the prepubertal child, despite coexisting ovarian failure.<sup>107</sup> Thus, it may not be possible to establish the status of ovarian function in young girls until they reach 10 to 12 years of age.

**Chemotherapy-Induced Ovarian Failure** The ovaries of prepubertal females, with their greater complement of follicles, are relatively resistant to chemotherapy-induced damage compared with the ovaries of adults.<sup>102,107</sup> Nonetheless, certain chemotherapeutic agents (see Table 1) when given at high doses are toxic, even to young ovaries, especially alkylating agents, including cyclophosphamide, ifosfamide, busulfan, cisplatin, carmustine (BCNU), and lomustine (CCNU).<sup>108-110</sup> Fortunately, the majority of prepubertal girls and adolescent females receiving standard combination chemotherapy will retain or recover ovarian function during the immediate post-treatment period.<sup>78,111-113</sup> However, histologic examination of ovarian tissue in prepubertal and postpubertal

girls treated for solid tumors or leukemia has revealed a decreased number of ovarian follicles and inhibition of follicular growth compared to age-matched controls.<sup>114,115</sup> In a recent study combining data from strictly timed ovarian ultrasonography and hormonal assessment, Larsen and colleagues reported on the ovarian function of 100 childhood cancer survivors.<sup>116</sup> Interestingly, the authors found that survivors with spontaneous menses at the time of the study (70 patients) had similar LH and FSH concentrations but smaller ovarian volumes, lower numbers of antral follicles per ovary, and lower inhibin B levels when compared to age-matched controls, suggesting a reduced ovarian reserve in the survivors' group.

Increased plasma concentrations of FSH, a sensitive index of ovarian damage and reproductive aging, have been noted in young women treated with alkylating agents for acute leukemia, brain tumors, and Hodgkin's disease.<sup>89,113,117-122</sup> Fortunately, many of these women demonstrate normalization of their FSH levels over time, and only a minority seem to experience irreversible ovarian failure requiring long-term hormone-replacement therapy. Of note, however, recovery may not occur for many years following the completion of therapy.<sup>78,123</sup> However, some of these young women may experience a premature menopause when they reach their 20s and 30s.<sup>124</sup> Females who receive high-dose myeloablative therapy with alkylating agents such as busulfan, melphalan, and thiotepa in the context of SCT are at high risk of developing ovarian failure.<sup>31,91,125</sup> This has been observed in patients treated before and after pubertal development, is characterized by menopausal levels of LH and FSH, delayed or arrested puberty, and amenorrhea. Recovery of function has been recorded only rarely, but the follow-up time has been relatively brief for most of the patients.<sup>104,126</sup> When female childhood cancer survivors treated with chemotherapy do get pregnant, no adverse pregnancy outcomes were identified in a large study conducted by Green and colleagues within the framework of the Childhood Cancer Survivor Study.<sup>127</sup>

**Radiotherapy-Induced Ovarian Failure**

Females receiving abdominal, pelvic, or spinal irradiation are at increased risk of ovarian failure, especially if both ovaries were within the treatment field.<sup>26,128-130</sup> The data suggest that the ovary of a younger individual is more resistant to damage from irradiation than is the ovary of an older (adult) individual.<sup>111,131-133</sup> Thus, while radiation doses of 6 Gy may be sufficient to produce irreversible ovarian damage in women  $>40$  years of age, doses in the range of 10 to 20 Gy are needed to induce permanent ovarian failure in the majority of females treated during childhood.<sup>128,129,131,133</sup> Moreover, it is important to keep in mind that,

if irradiation is being given in association with alkylating agent chemotherapy, ovarian dysfunction may occur despite the use of lower doses of radiation.

Administration of spinal radiation for the treatment of ALL and brain tumors appears to result in clinically significant ovarian damage in some young women.<sup>44,118,120,121</sup> The incidence of raised plasma concentrations of FSH was 19% and 67% in young women treated for ALL with 18 and 24 Gy spinal irradiation, respectively. Long-term follow-up data, however, indicate that the majority of these young women go on to experience normal puberty and menarche, albeit at an older age.<sup>44</sup> Several groups report raised plasma concentrations of FSH in the majority (64 to 86%) of female subjects treated with chemotherapy and craniospinal irradiation.<sup>120,121</sup> Normalization of FSH levels occurs over time in the majority of these young women.<sup>120</sup> In our experience, essentially all female brain tumor survivors treated with craniospinal irradiation and standard doses of chemotherapy have entered puberty at a normal or early age and few have required hormone-replacement therapy.<sup>43</sup>

Girls treated with whole abdominal and/or pelvic irradiation for Hodgkin disease or Wilms' tumor or other solid tumors (eg, rhabdomyosarcoma, neuroblastoma) are at high risk of ovarian failure.<sup>122,128,134</sup> In the study by Wallace and colleagues, 27 of 38 females treated with whole abdominal radiation therapy (total dose 22 to 30 Gy) during early childhood for a variety of solid tumors failed to undergo or complete pubertal development.<sup>128</sup> A further 10 experienced an early menopause at a median of 23.5 years of age, including three who had conceived at an earlier time. When ovarian transposition is performed prior to radiotherapy, however, ovarian function is retained in the majority of young girls and adolescent females.<sup>78,133</sup> In a report from the Childhood Cancer Survivor Study including data on 1,915 female survivors and 4,029 pregnancies, Green and colleagues reported, however, a significant risk of low birth weight in the offspring of female survivors treated with pelvic irradiation.<sup>127</sup>

The outcome of ovarian function following TBI appears to be determined to a large extent by the age of the patient at the time of irradiation.<sup>135</sup> Our data, as well as the data of others, indicate that approximately 50% of prepubertal girls given fractionated TBI will enter puberty spontaneously and achieve menarche at a normal age.<sup>82,92,136</sup> While plasma gonadotropins have been elevated in up to two-thirds of these patients early after transplant, normalization of the plasma concentrations of LH and FSH can occur over time.<sup>92</sup> Ovarian failure is seen in essentially all patients who are greater than age 10 years at the time they are treated with TBI.<sup>92,135-137</sup> Patients require

hormonal support in order to achieve normal sexual development and to maintain normal menstruation. Recovery of ovarian function has been documented in a small number of women who have received TBI.<sup>104</sup> These women had increased risks of miscarriage and premature delivery of low birth weight infants.<sup>104</sup> This can be due to the uterine consequences of TBI. Holm and colleagues, Bath and colleagues, and Larsen and colleagues demonstrated that the uterine volume of patients treated with TBI is smaller than in normal controls and cancer survivors exclusively treated with chemotherapy.<sup>138-140</sup> The blood supply of the uterus was significantly decreased after TBI, suggesting a vascular mechanism for the observed abnormalities, with increased risks in younger patients.<sup>138-140</sup> Overall, the full impact of SCT on reproduction and on the health of future offspring will remain in question until we have data from large numbers of survivors followed long-term.

## Hormone-Replacement Therapy

### Males

Testosterone-replacement therapy is indicated in Leydig cell failure resulting from both primary hypogonadism and hypogonadotropic hypogonadism. In boys with pubertal delay, defined as the lack of signs of puberty and/or prepubertal levels of testosterone after 14 years of age, testosterone replacement therapy induces the development of secondary sexual characters and the pubertal growth spurt; it also contributes to the restoration of normal body composition and normal bone mineral density (BMD).<sup>141</sup> Low doses of long-acting testosterone esters (eg, testosterone enanthate starting at doses of 50 mg administered intramuscularly every month) are used to induce puberty, the dose being gradually increased thereafter to full replacement doses at adulthood.<sup>142,143</sup> The transdermal forms of testosterone, available for adult patients, deliver high doses of treatment and are not suitable for pediatric use. Oxandrolone, a non-aromatizable androgen is sometimes used to stimulate the growth velocity and induce the pubertal growth spurt without advancing the bone age.<sup>142</sup> Its benefits in comparison to the low doses of testosterone used to induce puberty are uncertain, and it lacks the virilizing effect of testosterone.<sup>143</sup>

Young men with mild testosterone deficiency (borderline low plasma testosterone levels and raised LH levels) may have a low BMD and some impairment of their sexual function.<sup>144</sup> However, in a randomized, placebo-controlled study of patients from that population, Howell and colleagues showed that testosterone replacement therapy did not result in significant changes in BMD, body composition, and quality of life. The authors concluded that androgen replacement

in this population cannot be recommended as a routine practice.<sup>145</sup>

In patients with hypogonadotropic hypogonadism retaining the potential for spermatogenesis, treatment with chronic GnRH or human chorionic gonadotropin will stimulate testicular growth and germ cell production. This treatment is generally restricted to adult men at the time they desire paternity.

### Females

Despite recent reports on the possible association between cardiovascular disease, breast cancer and estrogen replacement without progesterone in post-menopausal women estrogen-replacement therapy is still indicated in young girls with ovarian failure in order to induce secondary sexual characters and optimal bone density<sup>146,147</sup>. Treatment can be initiated with a low dose of estrogen (eg ethinyl estradiol, 2 to 10 micrograms, conjugated equine estrogen 0.15-0.3 mg according to age at which replacement therapy is started). The dose can be slowly escalated over an 18-24 month period of time, followed by cyclic estrogen-progesterone therapy (eg low estrogen birth control pill). If breakthrough bleeding occurs on estrogen monotherapy, cyclic estrogen-progesterone should be initiated earlier<sup>142</sup>.

## Alterations in Body Composition

### Overweight

The most widely accepted measurement to define childhood adiposity uses the BMI, calculated as the ratio between the weight (in kilograms) divided by the height<sup>2</sup> (in m<sup>2</sup>) and expressed in percentiles with regards to both gender and chronological age. Overweight is defined in children whose BMI is above the 95th percentile for gender and chronological age. Patients whose BMI is between the 85th and 95th percentile are described as "at risk" for being overweight.<sup>148</sup> Obesity and being overweight are well-established sequelae of cancer therapy and are often observed in survivors of acute leukemia and various brain tumors.

Sklar and colleagues examined BMI in a group of 126 survivors of ALL, and a high incidence of being overweight was observed but was confined to those survivors who received cranial irradiation (Figure 3).<sup>149</sup> Additional risk factors for obesity other than cranial irradiation include female gender and exposure to dexamethasone. van der Sluis and colleagues compared the body composition parameters (BMI, lean body mass, and percentage of body fat measured with dual X-ray absorptiometry [DEXA]) of childhood ALL survivors exposed to high-dose dexamethasone and cranial irradiation to those of patients only treated with dexamethasone.<sup>150</sup> Their findings suggest that the deleterious effects of dexamethasone on body composition may be

**FIGURE 3** Change in body mass index (BMI) — standard deviation score (SDS) [mean  $\pm$  Standard Error of Mean (SEM)] in survivors of acute lymphoblastic leukemia according to type of central nervous system prophylaxis. CRT = cranial irradiation. Reprinted with permission from Sklar, et al.<sup>149</sup>

temporary. Oeffinger and colleagues, in a report from the Childhood Cancer Survivor Study using data from 1,765 adult survivors of childhood ALL, found that cranial radiotherapy  $\geq 20$  Gy, especially in females treated at a young age ( $< 4$  years) was significantly associated with obesity (ie, BMI  $\geq 30$ ).<sup>151</sup> The mechanisms underlying these propensities remain unsolved. One possible explanation is that radiation damages centers within the brain that normally control eating behaviors and/or regulate body composition. For instance, Brennan and colleagues found higher leptin levels in ALL survivors treated with cranial radiotherapy (18 to 25 Gy), when compared to BMI-matched controls, suggesting that cranial irradiation may induce a state of relative leptin resistance.<sup>152</sup> Growth hormone deficiency in adulthood has been associated with obesity and may contribute to the observed changes in body composition in ALL survivors who received high-dose cranial radiotherapy.<sup>153</sup> Childhood ALL survivors have also been shown to have reduced physical activity, even a long time after remission, but the contribution of this behavioral factor has yet to be proven.<sup>154</sup> Premature adiposity rebound, believed to be a predictor of adult obesity, was also described in childhood ALL survivors in a study by Reilly and colleagues, and may partly explain the increased risk for obesity in patients treated at a very young age ( $< 5$  years).<sup>155</sup>

Brain tumors developing near the sellar region and their treatments can also disrupt hypothalamic and pituitary functions and induce severe states of morbid obesity.<sup>156</sup> In a large retrospective study, Lustig and colleagues analyzed data compiled over 30 years on 148 patients surviving childhood brain tumors.<sup>157</sup> Their findings showed that the development of obesity in those patients was associated with the degree of hypothalamic damage (tumoral proximity to the hypothalamus, hypothalamic exposure to radiation, especially to doses above 51 Gy, and extent of the surgical resection) and with the histology of

the tumor (craniopharyngioma, pilocytic astrocytoma and medulloblastoma). In a report on 921 patients from the Childhood Cancer Survivor Study, Gurney and colleagues also showed that hypothalamic/pituitary irradiation was associated with a greater risk of obesity in female patients, and that this association was dose dependent.<sup>8</sup> However, the authors did not find an overall significant difference in BMI in their population of childhood brain cancer survivors compared to the general population and related that observation to the exclusion of patients with craniopharyngioma from their study.<sup>8</sup> While the hypothalamic insult is believed to alter satiety centers and cause hyperphagia, another mechanism involving an increased parasympathetic tone leading to hyperinsulinemia (the latter promoting fat storage) has been suggested as a contributing factor to obesity in these patients.<sup>158</sup> It is with regards to that latter mechanism that treatment with octreotide has been tried in a small number of patients with hypothalamic obesity and has yielded some encouraging results.<sup>157</sup> Otherwise, there are no specific strategies for the prevention and treatment of obesity in childhood cancer survivors.

### Osteoporosis

Young adult survivors of childhood cancer have reduced BMD, and many of them are at an increased risk for osteoporosis and fractures.<sup>106</sup> Osteopenia and osteoporosis can occur in childhood cancer survivors for several reasons. Firstly, the disease itself and its progression can affect bone structure and metabolism. For instance, in a prospective study, Crofton and colleagues had findings consistent with a low bone turnover in children who had just been diagnosed with ALL and before starting any treatments.<sup>9</sup> Secondly, chemotherapy and exposure to glucocorticoids can also adversely affect the bone mineral density. Methotrexate, in particular, a cytotoxic drug frequently used in treating ALL, has been shown to alter bone metabolism and to be associated with an increased risk for fractures.<sup>159,160</sup> Finally, the hormonal deficiencies associated with cancer and its treatments (and described earlier in the text), GHD, and sex-hormone deficiencies, are additional factors for osteoporosis.<sup>106,161</sup>

Subjects deemed at high risk for the development of osteoporosis should undergo periodic bone density studies. While the DEXA remains the most widely used tool for measuring bone mineral density, its results should be interpreted according to age, pubertal stage and height in the pediatric population using the z-score values. Failure to take these elements into account may result in over-diagnosing osteoporosis.<sup>162</sup> Preventive measures (for example, supplementation with calcium and vitamin D, smoking cessation, weight-bearing exercise) should be encouraged

in all individuals with low or borderline bone mineral density. Therapeutic interventions (for example, sex hormone therapy, GH replacement, bisphosphonates) may prove beneficial for those with abnormally reduced bone density, but long-term follow-up data are currently not available.

### Conclusion

Endocrine sequelae occur frequently following childhood cancer and its treatments. Our understanding of the consequences on growth and pubertal development of cancer therapy, as well as the alterations it induces on body composition, has increased substantially over the past few years. Radiation therapy and chemotherapy are capable of causing damage to the endocrine systems, which control these functions. These endocrine abnormalities may remain subclinical for many years. Physicians who follow children or adolescents who have been treated with chemotherapy and/or radiation therapy for cancer must encourage the patients to continue lifelong surveillance for potential endocrine disease. The prevention, early recognition and treatment of these complications will help reduce long-term morbidity and improve the quality of life of childhood cancer survivors.

# Preoperative Considerations in the Cancer Patient Undergoing Surgery

Sean Malone, MD, FACP  
Harrison G. Weed, MD, MS, FACP

General internists and family practice physicians frequently act as primary care physicians or consultants in the perioperative assessment and management of patients with cancer. Approximately 75% of patients with solid tumors undergo surgical resection for cure, and about 90% undergo surgery for cure or palliation. Perhaps the primary consideration is the patient's cancer diagnosis, including the extent of the disease and cancer-related treatments that are planned or have already been performed. The natural history of the cancer, including prognosis, and the possible side effects of any previous chemotherapy or radiation therapy should also be considered. For example, some chemotherapies can cause permanent adverse effects on pulmonary or cardiac function that should be considered prior to surgery.

In the preoperative evaluation of a cancer patient, as with any preoperative evaluation, the physician should have a basic understanding of the surgical procedure and should know whether the surgery is intended for cure or palliation. The physician must also obtain a thorough medical history and physical examination to adequately

assess comorbid conditions, such as hypertension, diabetes, cardiac, pulmonary, or renal disease. The preoperative medical evaluation should include an assessment of the patient's functional status, nutritional status and pain. Patients with cancer vary widely in their performance status. Some patients are ambulatory and fully functional in activities of daily living, whereas others are severely debilitated. A patient's performance status depends on many factors, including the type of cancer, extent of disease, side effects of cancer-related treatments, and presence of comorbid medical conditions. The Karnofsky performance status scale is a general and robust prognostic indicator for both cancer and surgical outcome and mortality. However, to assess risks for specific perioperative complications, such as cardiac complications or deep vein thrombosis, it is important to use more specific measures of risk as are described in the following sections. In addition, a careful assessment of nutritional status can help identify patients who might benefit from delaying surgery for a week of intensive nutritional supplementation.

In general, organ dysfunction is managed with standard treatments, regardless of the

patient's cancer. Physicians should pay particular attention to pain management, which is too frequently overlooked by clinicians despite the high priority patients place on this aspect of their care. Finally, because most patients with cancer who are undergoing surgery have many caregivers, including surgeons, oncologists, and radiation oncologists, one common role of the primary care physician is to coordinate the patient's overall care. Frequently, the physician knows the patient well enough to have a frank conversation with the patient and the patient's family about their expectations. This conversation can provide an opportunity to ascertain the patient's wishes regarding resuscitation. In summary, primary care physicians frequently play an important and complex role in the perioperative care of patients with cancer. Indeed, the complexity of this role has led to proposals that hospitals should implement coordination mechanisms to improve delivery of multidisciplinary care to patients with cancer.<sup>1</sup>

# Perioperative Nutritional Issues

Sean Malone, MD, FACP  
Harrison G. Weed, MD, MS, FACP

Malnutrition has been recognized as a risk factor for poor surgical outcome for at least 70 years.<sup>1,2</sup> It is associated with infection, poor wound healing, prolonged postoperative recovery, and sepsis with multiorgan failure. Clinical trials, many of them exclusively or predominantly in cancer patients, have demonstrated the benefits of vigorous perioperative nutritional support for severely malnourished patients.<sup>3</sup> The nutritional state of all cancer patients should be evaluated prior to surgery, and, in general, patients with a recent, sustained loss of more than 15% of body weight or with a severely cachectic appearance and with a serum albumin below 2.5 gm/dL should be considered for at least a week of vigorous nutritional support prior to surgery.<sup>3,4</sup> Whenever feasible, enteral feeding is preferred, because it provides more benefit with less risk than does parenteral feeding.<sup>5,6</sup>

## Causes and Effects of Malnutrition on Surgical Outcome

From 40 to 80% of patients anticipating major cancer surgery are malnourished.<sup>7</sup> There are many causes of malnutrition in cancer patients, including pain-induced and medication-induced anorexia, mechanical obstruction of the oropharynx or gastrointestinal tract, the side effects of chemotherapy and radiation therapy (including anorexia, nausea, and stomatitis), the use of restrictive alternative diets or dietary supplements, and a fear of “feeding” the cancer. In addition, an inflammatory response to the cancer can lead to the release of tumor necrosis factor- $\alpha$  (formerly called cachectin), interleukin 6 (IL-6) and other inflammatory mediators causing both anorexia and a general catabolic state. The catabolic state is manifested by insulin resistance, depletion of fat stores, and increased protein turnover.<sup>8</sup> Malnutrition can be exacerbated by the metabolic demands of the cancer and by surgery-related fasting and stress. Immune suppression as a direct consequence of the cancer, or as a side effect of treatments makes patients more susceptible to infection, and infection causes additional inflammation that can further exacerbate cachexia. Whatever the causes of preoperative

malnutrition, it is associated with worse surgical outcomes, including poor surgical site healing, more frequent infection, and increased 30-day mortality.<sup>9</sup>

## Preoperative Nutritional Assessment and Treatment

Most single measures of nutrition are relatively poor predictors of postoperative outcome because people can be sustained on a wide variety of diets, because there is a broad range of normal for body habitus, and because most measures are affected by factors other than nutritional status. Anthropometrics (measures and formulae of weight, height, limb circumferences and skinfold thicknesses) do not predict surgical outcome. Although serum albumin concentration is a simple and robust measure of nutrition, it has a relatively long half-life (up to 20 days) and is affected by factors other than nutrition, including the patient’s hydration status. Nonetheless, an observational trial of more than 54,000 patients undergoing major noncardiac surgery at Veterans Administration hospitals found that, in a multivariable model, serum albumin concentration was the single best predictor of 61 variables for 30-day operative morbidity and mortality.<sup>9</sup> As serum albumin concentration dropped from 4–6 gm/dL to below 2.1 gm/dL, mortality increased from 1% to 29%, and morbidity increased from 10% to 60%. Combining serum albumin with gross measures of nutrition, including recent weight loss, body mass index, and patient appearance, yields a subjective nutritional index that is perhaps the most robust indicator of nutritional status: the Subjective Global Assessment.<sup>10</sup>

One purpose of assessing risk is to help decide which patients might benefit from perioperative nutritional support. There have been a number of studies that showed apparent benefit of total parenteral nutrition (TPN); however, they were poorly controlled and meta-analysis showed a high complication rate that negated the benefits.<sup>5</sup> Complications that are more frequent in patients receiving TPN include pneumothorax, sepsis, and abdominal abscesses.<sup>11</sup> A Veterans Affairs Medical Center (VAMC) trial of almost

400 malnourished patients undergoing major abdominal or thoracic surgery, who were randomized to receive perioperative TPN or usual care, showed no benefit overall but a trend toward benefit in severely malnourished patients (as measured by the Subjective Global Assessment) or by just considering those who had lost more than 15% of their baseline weight.<sup>12</sup> Over 60% of these patients had cancer. Therefore, general surgery should not be delayed for intensive preoperative nutritional support except for patients who are severely malnourished as assessed by a greater than 15% loss of body weight, a cachectic appearance with a low body mass index, and a serum albumin below 2.5 gm/dL. Furthermore (when feasible), enteral nutrition, either oral or via feeding tube, is preferred over TPN because enteral nutrition yields a lower complication rate, including a lower rate of infections.

## Postoperative Nutritional Support

Although the benefits of preoperative nutritional support are often diminished by the continued presence of the factors that led to malnutrition and must be weighed against the risks of postponing surgery, postoperative nutritional support is more uniformly effective and beneficial. Many patients are unable to maintain adequate nutritional intake after cancer surgery. This can be due to postoperative compromise in the gastrointestinal tract (for example, postoperative ileus) or to medication side effects such as anorexia and slowed bowel transit from narcotic analgesics or chemotherapy. It can also be due to mechanical compromise of chewing and swallowing. Over 93% of patients who undergo resection of oropharyngeal cancers required at least some postoperative nutritional support. The National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society for Clinical Nutrition jointly reviewed prospective, controlled trials of perioperative nutritional support involving over 2,500 surgical patients, most of whom had cancer. They reached three main conclusions: (1) TPN given to severely malnourished patients with gastrointestinal cancer for 7 to 10 days before surgery decreases

postoperative complications by approximately 10%; (2) routine use of early postoperative TPN in malnourished general surgical patients who did not receive preoperative TPN increases postoperative complications by approximately 10%; and (3) postoperative nutritional support is necessary to prevent starvation of patients unable to eat for more than a week after surgery. In sum, most patients will benefit from postoperative nutritional support if they are malnourished and/or will be unable to eat for more than a week after surgery; however, TPN should be reserved for patients without enteral access who are severely malnourished.

# Perioperative Neurologic Issues

Herbert B. Newton, MD  
Harrison G. Weed, MD, MS, FACP

Neurological complications are common in patients with cancer. Delirium is perhaps most common, but seizures, stroke, focal weakness, back pain, and gait disturbances also occur.<sup>1,2</sup> These complications can be due to medication toxicity, infection, metabolic abnormalities, and both direct and indirect effects of cancer on the nervous system. It is important to detect and address neurologic complications before surgery, to continue appropriate treatments through the perioperative period, and to anticipate special risks and needs that may arise after surgery.

Brain metastases can present with headache, confusion or new focal neurologic deficits, such as hemiparesis. Papilledema is unreliable as a diagnostic sign of brain metastases because it occurs in less than one-fourth of patients. Leptomeningeal metastases should be suspected in patients who develop multifocal neurologic deficits, especially the combination of cranial neuropathies with spinal nerve root deficits. Lung and breast cancers, melanomas, and lymphomas are common causes of leptomeningeal metastases. Spinal cord compression presents with severe acute back pain and myelopathy. Myelopathy can include the physical findings of leg weakness and spasticity, lower extremity hyperreflexia, abnormal Babinski's reflex, and urinary incontinence. Emergent treatment of spinal cord compression with high-dose corticosteroids, radiation therapy, or surgical decompression is necessary to preserve neurologic function.

## Delirium

Delirium, including confusion and encephalopathy is common in cancer patients and has many potential causes, including medication side effects, metabolic disturbances, metastatic intracranial tumors, strokes, seizures, and side effects of cancer treatments (Table 1). Patients undergoing chemotherapy often have both baseline and chemotherapy-induced cognitive dysfunction in areas such as attention, learning, and processing speed. Chemotherapy-induced effects resolve in some, but not all patients.<sup>3</sup> Delirium is often due to medications, especially narcotics, sedatives, and antiemetics exacerbating underlying age or

**Table 1 Disorders Associated with Postoperative Mental Status Changes in Cancer Patients**

Pneumonia  
Urinary tract infection  
Sepsis  
Surgical site infection

disease-related deficits; however, infections (eg, sepsis, pneumonia, meningitis, encephalitis) must be kept in mind as possible causes. Delirium can be the only manifestation of infection in patients who are immunosuppressed from the cancer and/or chemotherapy.

## Stroke

Stroke can be caused by a variety of tumor-related conditions, including direct tumor invasion, side effects of chemotherapy, cancer-related coagulopathy, and thrombotic (marantic) endocarditis.<sup>1</sup> Certain types of operations can also place patients

at risk for stroke due to arterial embolus from manipulation of the heart and great vessels or the cerebral vasculature. In addition, perioperative hypotension can cause ischemia distal to a narrowed vessel that was adequately perfused at the patient's usual blood pressure.

## Seizures

Prior to surgery, it is important to thoroughly assess any new or chronic seizures. New onset seizures can be caused by cancer metastatic to the brain, brain hemorrhage or infarction, infection, or metabolic disturbances. The preoperative report should include a basic description of the patient's usual seizure pattern, including seizure frequency, when the most recent seizure occurred, and the current anticonvulsant regimen. The patient's baseline anticonvulsant serum concentrations should be determined. Often, this information is available from the physician who usually prescribes the patient's anticonvulsant medication, but it can be obtained as a preoperative blood test. For patients whose seizures are well controlled, a baseline anticonvulsant level can help to determine whether any postoperative seizure might be due to insufficient medication or if another explanation must be sought. If feasible, before surgery a neurologist should evaluate and adjust the medications of any patient whose seizures are not fully controlled. In general, on the day of surgery, anticonvulsant medications should be taken with a sip of water. During the time a patient is unable to take enteral medications, there are several alternative intravenous anticonvulsants that can be considered, including phenytoin (Dilantin), fosphenytoin (Cerebyx) and valproate sodium (Depacon). A substitute intravenous anticonvulsant should be selected and ordered prior to surgery to minimize the patient's risk for breakthrough seizure activity in the perioperative period.

## Neuromuscular Disorders

Paraneoplastic syndromes that affect neuromuscular function are rare but are of particular concern in the perioperative period because treatment with anesthetic agents can exacerbate muscular

weakness leading to delayed recovery of mechanical lung function or even respiratory failure. Symptoms and signs of Eaton-Lambert syndrome include proximal muscle weakness, diminished or absent deep tendon reflexes, and autonomic neuropathy with varied manifestations, including gastroparesis and orthostatic hypotension. Some medications, such as calcium channel antagonists, can exacerbate symptoms, and treatment of the cancer can occasionally improve them.<sup>4</sup>

## Pain Management

Pain is also common in patients with cancer who are anticipating surgery and almost universal immediately after surgery. Cancer-related pain can be due to tumor compression or invasion of nerves, to healing of the surgical site, to side effects of treatments, and to other causes.<sup>5</sup> At the time of the preoperative evaluation every patient should be asked specifically about pain. The cause of any new pain should be adequately investigated, and the patient's need for pain medication should be addressed. New or worsening pain in the spine should suggest epidural spinal cord compression and warrants an immediate evaluation, probably including spinal MRI. Treatment of pain should not wait for a determination of cause, but should be initiated simultaneously with any indicated evaluation.

In general, pain medications should be taken as usual on the day of surgery with a sip of water. Because nonsteroidal anti-inflammatory analgesics can increase perioperative blood loss, it is important to establish the surgeon's wishes for use of these medications around the time of surgery. In general, aspirin is discontinued one to two weeks before surgery, and other nonsteroidal anti-inflammatory drugs are discontinued at least two days before surgery. Acetaminophen and opiates can be taken up to the time of surgery.

Because cancer patients are sometimes taking substantial doses of opiate pain medication, an accurate record of a patient's opiate use prior to surgery is helpful in estimating approximate doses of medication needed for pain control after surgery. Ensure that all caregivers are aware if the patient is receiving a transdermal analgesic, such as fentanyl, because it can be overlooked and the patient inadvertently under- or overdosed.

## Preoperative Evaluation

In the preoperative period, it is important to obtain a complete neurologic history. In particular, it is helpful to obtain any prior history of stroke, TIA, or seizure disorder.

It is equally important to seek a few specific neurologic physical findings in the preoperative evaluation of cancer patients. A standard screening neurologic evaluation should include assessment of alertness, orientation, gross cranial nerve function, gross motor function, major deep tendon reflexes, gross sensation to light touch, speech, and gait. Any suggestion of somnolence, forgetfulness, confusion, or agitation should be further characterized with a Mini-Mental Status examination. Depression should be in the differential diagnosis of causes. Any asymmetry of strength or reflexes, or any evidence of speech or gait dysfunction should be investigated by a more thorough neurologic examination. Patients at risk for neuropathy from chemotherapy should also be tested for fine touch, vibration, and proprioception in their distal extremities.

## Postoperative Evaluation

In the postoperative period, a neurologic assessment is an important part of the patient evaluation. Postoperative delirium is usually due to medication and the stress of surgery exacerbating

underlying age or disease-related deficits; however, metabolic disturbances, stroke, seizure, and infection must be kept in mind as possible causes (see Table 1). Some types of chemotherapy are more commonly associated with seizures, including cisplatin, ifosfamide, interferon, L-asparaginase, and methotrexate.

## Hospital Discharge

Medications, pain control, follow-up and communication are four fundamentals to ensure a patient is adequately prepared for hospital discharge. Ensure that the patient is on the appropriate medications and that medications have not been accidentally duplicated or dropped when therapeutically equivalent medications were substituted to conform to the hospital formulary. Prior to discharge, ensure that every patient has adequate access to pain control, including both medication and non-medication methods. Ensure that the patient has all necessary follow-up appointments, including follow-up with a neurologist for any new neurologic developments. Finally, ensure that all of the patient's many physicians and other health care providers receive reports of the hospitalization.

# Hematologic Issues

Spero R. Cataland, MD

## Anemia

### Causes

Anemia in patients who have been, or are actively being, treated with chemotherapy or radiation therapy may require special attention during the perioperative period because of the patients' inability to respond adequately to acute blood loss. This compromise of marrow function can have several causes, including recent marrow-suppressive chemotherapy, reactive anemia of cancer, replacement of the bone marrow by infiltrating malignant cells, and, rarely, a myelodysplastic syndrome secondary to chemotherapy or radiation therapy. In the perioperative period, patients undergoing chemotherapy may require transfusion with packed red cells more frequently than comparable patients who are not actively receiving chemotherapy. However, as with any patient, red blood cell transfusion should not be based on an arbitrary hemoglobin level, but upon need demonstrated by the patient's clinical condition.<sup>1,2</sup> The risk for chemotherapy-related anemia does not completely disappear after patients have been cured of the cancer and have recovered from adverse treatment effects. Within five years, about 1% of patients who receive adjuvant chemotherapy for breast cancer may develop a chemotherapy-induced myelodysplastic syndrome or acute myeloid leukemia. Higher rates are seen with more intense chemotherapy regimens.<sup>3</sup>

### Treatment

The acute perioperative treatment of anemia in patients actively receiving cancer therapy is not different from that for non-cancer patients; packed red cell transfusion is the mainstay of therapy. Patients being actively treated for a malignancy may require transfusion support sooner and may require more transfusions in the perioperative period than comparable patients not undergoing chemotherapy or radiation therapy. If the surgery is not urgent, then delaying surgery until the patient's marrow function recovers can help to minimize transfusion requirements; however, this usually requires several months. For some patients, it might be appropriate to stimulate bone marrow function with erythropoietic medications. One month of treatment with epoetin alpha (Epogen, Procrit) or darbepoetin alpha (Aranesp) can usually

stimulate erythropoiesis sufficiently to significantly increase hemoglobin levels.<sup>4</sup>

## Neutropenia, Lymphopenia, Lymphocytosis

### Causes

The most common clinically significant effect of cancer chemotherapy is neutropenia. Although the administration of granulocyte colony stimulating factors can reduce the severity and the duration of neutropenia, patients can still have a period of neutropenia that is associated with a significantly increased risk of postoperative infection and other complications. In one series of 56 neutropenic cancer patients requiring urgent abdominal surgery, half had a major postoperative complication, and 30-day postoperative mortality was 32%.<sup>5</sup> Hematologic malignancies can also cause neutropenia directly. Patients with acute myeloid and lymphoid leukemias, as well as patients with advanced chronic myelogenous leukemia, may have a clinically significant neutropenia, not because of chemotherapy, but because of replacement of normal bone marrow by cancer cells. Finally, patients with chronic lymphoblastic leukemia (CLL) are likely to be at higher risk for postoperative infectious complications because of both neutropenia and hypogammaglobulinemia from CLL and from chemotherapy.

### Treatment

Patients with neutropenia are at increased risk for perioperative complications, including death. The administration of granulocyte colony stimulating factors can shorten the duration of neutropenia after chemotherapy, but is unlikely to have a significant effect on neutropenia that is caused directly by an underlying hematologic malignancy. If feasible, postpone elective and semi-elective surgeries until the patient's granulocyte count rises above 1,000/mm<sup>3</sup>.

## Thrombocytopenia and Thrombocytosis

### Thrombocytopenia

#### Causes

Transient thrombocytopenia is a frequent finding in patients undergoing chemotherapy. Similar to

neutropenia, the severity and duration of thrombocytopenia depends on agent-specific factors as well as patient-specific factors that include age and previous response to myelosuppressive therapy.<sup>6</sup> Although studies rarely report rates of myelosuppression and complications, almost all chemotherapeutic agents will produce some degree of myelosuppression, with most agents producing a nadir 7 to 14 days after treatment, and recovery requiring 21 to 28 days.<sup>7</sup> Patients with a lymphoproliferative disorder can also develop immune-mediated thrombocytopenia (ITP). In addition, thrombocytopenia can be caused by infiltration of the bone marrow by the cancer, independently of the myelosuppressive effects of chemotherapy. Finally, up to 1% of patients previously treated with chemotherapy or radiation therapy develop a recalcitrant chronic thrombocytopenia due to a therapy-related myelodysplastic syndrome.

### Treatment

Thrombocytopenia can pose a significant danger in the perioperative period. If the thrombocytopenia is likely to be transient (for example, if it is caused by recent chemotherapy) and the surgery can be safely postponed, then the procedure should be postponed until the thrombocytopenia resolves. If the surgery cannot be safely postponed, then platelet transfusions can usually achieve a platelet count sufficient to provide hemostasis. In contrast to chemotherapy-induced thrombocytopenia, thrombocytopenia due to ITP in patients with an underlying lymphoproliferative disorder is less likely to respond to platelet transfusion, and hemostasis is unlikely to be adequate for surgery. Direct treatment of the ITP with corticosteroids and intravenous immunoglobulins is a reasonable approach, but is also often ineffective. However, successful treatment of the underlying lymphoproliferative disorder usually leads to resolution of the ITP. Therefore, if feasible, the surgery should be postponed to allow time for treatment of the underlying lymphoproliferative disorder.

### Thrombocytosis

#### Causes and Treatment

Because platelets are an acute phase reactant, patients can develop a reactive thrombocytosis as

part of the inflammatory reaction to a cancer or to cancer treatments. Reactive thrombocytosis can reach platelet counts of  $106/\text{mm}^3$ ; however, regardless of the platelet count, reactive thrombocytosis does not increase the risk of thrombosis.<sup>8</sup> Therefore, cytoreductive therapy is unnecessary and anticoagulant treatment beyond that indicated for the patient's clinical situation is unnecessary. As the inflammatory reaction resolves, the patient's platelet count will also gradually return to baseline. In contrast to a reactive thrombocytosis, a thrombocytosis caused by an underlying myeloproliferative disorder (eg, myelofibrosis, essential thrombocytosis, or

polycythemia vera) is characterized by qualitative abnormalities in platelet function. Patients with this type of thrombocytosis are at increased risk, both for thrombotic and for hemorrhagic perioperative complications. Cytoreductive therapy or acute removal of platelets via apheresis can improve surgical hemostasis and may be appropriate.

# Prevention of Postoperative Venous Thromboembolism and Perioperative Management of Anticoagulation in the Cancer Patient

Amir K. Jaffer, MD  
Daniel J. Brotman, MD

Venous thromboembolism (VTE) is one of the most common complications of cancer. Patients with cancer have an approximate sixfold increased risk of VTE compared to those without cancer.<sup>1</sup> Active cancer accounts for  $\approx$  20% of all new VTE events occurring in the community.<sup>1</sup> The estimated annual incidence of VTE in cancer patients is about 1 in 200.<sup>2</sup> The number may be higher in patients undergoing chemotherapy and in those with indwelling central venous catheters. There may also be a relationship between VTE and the stage of disease, type of malignancy and type of ongoing cancer therapy.<sup>3</sup> Cancer is also a well-recognized major risk factor for the development of postoperative VTE. The incidence of fatal pulmonary embolism (PE) after major abdominal and pelvic cancer surgery may be as high as 5% in the absence of VTE prophylaxis.<sup>4</sup> Therefore, when a patient with cancer is planning to undergo surgery, close attention to prevention of this potentially fatal illness is essential.

## Cancer and Thrombosis

All three components of Virchow's triad, namely hypercoagulability, endothelial damage and stasis, are responsible for the increased risk of VTE in surgical patients with cancer. In cancer, macrophages and monocytes interact with malignant cells to release tumor necrosis factor (TNF), interleukin-1 (IL-1), and interleukin-6 (IL-6), causing endothelial injury. Chemotherapy also leads to the release of these factors.<sup>5</sup> Interactions between cancer cells and macrophages also activate platelets, factor X, and factor XII, which lead to thrombin generation. Tissue factor and other procoagulants released by cancer cells can

activate factor VII and factor X directly.<sup>5</sup> Additional prothrombotic insults affecting cancer patients may include cytotoxic chemotherapies, hormonal therapy such as tamoxifen, and growth factors such as granulocyte colony stimulating factor (GCSF) and erythropoietin.<sup>5</sup>

The increased risk of VTE in breast cancer patients treated with tamoxifen plus chemotherapy is clear. In two large clinical trials of women with node negative breast cancer, the 5-year incidence of VTE was 4.2% in those who received chemotherapy and tamoxifen, 0.9% in those receiving tamoxifen alone, and 0.2% in the placebo group.<sup>6,7</sup> In general, cancer patients receiving chemotherapy or immunosuppressive therapy have about a 6.5-fold increased risk of VTE compared to non-cancer patients.<sup>8</sup>

## Pharmacologic Prophylaxis

Commonly used antithrombotic pharmacologic options include unfractionated heparin (UFH), low-molecular-weight heparins (LMWHs), and vitamin K antagonists (eg, warfarin). Newer agents such as subcutaneous fondaparinux (a synthetic pentasaccharide that inhibits factor Xa) and direct thrombin inhibitors (DTIs) show promise in clinical trials. UFH has been evaluated in clinical trials for the prevention of VTE after cancer surgery. UFH is a heterogenous mixture of repeating polysaccharide chains of varying sizes, averaging about 15,000 daltons. It binds antithrombin (AT-III) and facilitates AT-III-mediated inactivation of factors IIa, Xa, IXa and XIIa. Of these, IIa and Xa are most responsive to inhibition. Due to its large size, UFH is not well absorbed from subcutaneous tissue, and it has a

variable anticoagulant response due to interactions with plasma proteins, macrophages, and endothelial cells.<sup>9</sup> It also binds to platelets and platelet factor-4 (PF4), and may precipitate heparin-induced thrombocytopenia (HIT). LMWHs have also been evaluated in clinical trials for the prevention of VTE after cancer surgery. LMWHs are derived from UFH through a chemical depolymerization or de-fractionation process. They are about one-third the size of UFH, with a molecular weight of approximately 5,000 daltons. These smaller molecules are readily absorbed from the subcutaneous tissue, eliciting a more predictable anticoagulant response than UFH. Unlike UFH, LMWHs have only minimal non-specific binding to plasma proteins, endothelial cells, and monocytes,<sup>9</sup> resulting in a predictable dose response, which obviates the need for lab monitoring. The longer plasma half-life of LMWH compared to UFH allows these drugs to be dosed subcutaneously once or twice daily. LMWHs do not bind platelets as readily as UFH and may carry a lower risk of heparin-induced thrombocytopenia than UFH. Because of their smaller size, LMWHs tend to preferentially inhibit factor Xa, whereas UFH tends to inhibit both factor Xa and IIa equally.<sup>9</sup>

Fondaparinux is a synthetic analogue of the unique pentasaccharide sequence that mediates the interaction of heparin with antithrombin. It inhibits both free and platelet-bound factor Xa. It binds antithrombin with high affinity, has close to 100% bioavailability, and has a plasma half-life of 17 hours that permits once-daily administration. The drug is excreted unchanged in the urine and is contraindicated in patients with severe renal impairment (ie, CrCl < 30 mL/min). It does

not bind PF4 and therefore should not cause HIT. At this time, there is no antidote for fondaparinux; however, if uncontrolled bleeding does occur, a procoagulant such as recombinant factor VII might be effective.<sup>9</sup> Fondaparinux effectively prevents thrombosis following major abdominal cancer surgery, and can also be used in the acute treatment of VTE.

Warfarin is a coumarin derivative that exerts its anticoagulant effects by limiting hepatic production of the biologically active vitamin K-dependent clotting factors (factors II, VII, IX, X). Additionally, warfarin interferes with the production of the anticoagulant proteins C and S and can potentially exert a transient procoagulant effect following initiation of treatment. In addition, it takes approximately 96 hours to decrease the levels of factor IIa enough to provide a clinical anticoagulant effect, even though depletion of the short-lived factors VII and IX can increase the international normalized ratio (INR) in less than 24 hours. Although warfarin monotherapy has been shown to be effective in preventing VTE after orthopedic surgery in several trials, a recent meta-analysis<sup>10</sup> and a case-control study suggest that it is inferior to LMWH. Therefore, it is our own preference to avoid warfarin monotherapy as VTE prophylaxis after major surgery, especially since the patient is unprotected from thrombosis during the first few days of treatment.

Ximelagatran is an oral direct thrombin inhibitor. It is a prodrug that is rapidly hydrolyzed to form melagatran, the active drug that binds thrombin. It has a plasma half-life of 4 to 5 hours and is given twice daily in fixed doses. It does not have drug and food interactions like warfarin. It is renally cleared. The drug has been shown in phase III trials to be effective for VTE prevention after major orthopedic surgery, for stroke prevention in atrial fibrillation, for acute treatment of VTE, and for secondary prevention of VTE after an acute episode.<sup>11</sup> The drug, however, has not been evaluated for VTE prevention in cancer patients undergoing surgery. Although ximelagatran was approved for use in several European countries for VTE prevention after major orthopedic surgery, it was later withdrawn. The United States Food and Drug Administration (FDA) recently declined to approve its use in the United States based on its potential hepatotoxicity as shown in clinical trials.

The details of selected trials evaluating UFH, LMWH, and fondaparinux in cancer surgery patients are outlined in Table 1. There is evidence that UFH effectively reduces the risk of VTE after cancer surgery; however, the dose of the UFH may be important. In an early gynecologic cancer surgery trial, UFH 5,000 units (U) subcutaneously (SC) twice daily (bid) was not significantly superior to placebo with rates of VTE 14.8% and 12.4%, respectively.<sup>12</sup> Other clinical trials outlined in Table 1 suggest that UFH 5,000 U SC every 8 hours (q8h) or three times

a day (tid) is as effective as LMWH (eg. enoxaparin sodium 40 mg SC four times a day [qd] or Dalteparin 5,000 U SC qd) with similar bleeding rates in most studies.<sup>13</sup> Although some studies have reported fewer wound hematomas with LMWH than with UFH, other studies have suggested the opposite. It is our recommendation, therefore, for cancer surgery patients to receive either UFH 5,000 U SC q8h or tid or a LMWH for most types of cancer-related surgeries.

The results of the 2,927-patient, randomized, double-blind, dalteparin-controlled, Pentasaccharide in General Surgery Study) trial show that fondaparinux is at least as safe and efficacious as a low molecular weight heparin (dalteparin) for the prevention of VTE following major abdominal surgery. The rate of VTE in the fondaparinux and dalteparin groups were 4.6% and 6.1%, respectively ( $p = .14$ ). For those patients who underwent abdominal cancer surgery (approximately 70% of the overall sample), VTE incidence was significantly reduced for fondaparinux recipients compared to dalteparin recipients (4.7% to 7.7%,  $p = .02$ ). Fondaparinux's adverse effect profile was reassuring in patients with and without malignancy.

The duration of prophylaxis has also been evaluated in at least two clinical trials.<sup>14,15</sup> The evidence suggests that cancer patients undergoing major orthopedic surgery, pelvic surgery, or abdominal surgery should receive extended prophylaxis with an LMWH for up to 28 days postoperatively; extended prophylaxis may reduce the risk of postoperative thrombosis by 60% compared to standard prophylaxis that is stopped after 6 to 10 days of treatment.<sup>14</sup>

### Mechanical Prophylaxis

The options for mechanical prophylaxis include graduated compression stockings (GCSs) and intermittent pneumatic compression (IPC) devices. They are attractive options in those patients who are actively bleeding or at high risk for bleeding. Studies in gynecologic surgery patients suggest that the patients most likely to fail IPCs are those with underlying cancer.<sup>16</sup> In another study, the rate of VTE was 4% with IPCs and 6.9% with UFH 5,000 U SC bid, these results were not statistically different, and UFH 5,000 U bid is probably inferior to tid dosing, as suggested in Table 82-1. Therefore, the potential role of IPCs for preventing postoperative thrombosis in cancer patients remains ill-defined. Some practical problems with IPCs include that they need to be on for at least 15 hours a day to achieve maximal benefit; ambulation is restricted if patients wear the IPCs all day, and sleep may be adversely affected.

Three meta-analyses demonstrated that GCSs are superior to placebo.<sup>17-19</sup> In the Cochrane

review, the rate of DVT with placebo was 27% and, while with GCSs, about 13% (an NNT of 7).<sup>18</sup> However, this was in all general surgery patients and not just cancer surgery patients. GCSs in combination with UFH may provide added efficacy, increasing the protective effect of UFH by as much as 75%.<sup>18</sup> Therefore, combining this modality with either LMWH or UFH in cancer surgery patients may be helpful, although this dual modality has never systematically studied specifically in cancer surgery patients. Some practical problems with GCSs include difficulty with fitting and poor compliance by patients and health care providers.<sup>13</sup>

Our recommendations for VTE prophylaxis in surgical patients with cancer are evidence-based and adapted from recent guidelines of the American College of Chest Physicians.<sup>13</sup> These recommendations are outlined in Table 82-2.

### Non-Surgery Cancer Patients

Primary prevention of VTE in non-surgical cancer patients has only been studied to a limited extent; limited data do support using warfarin, but this has not been embraced in clinical practice. The data with LMWH for primary prevention of VTE in the cancer patient not undergoing surgery do not show any benefit. In a trial of 311 women with metastatic breast cancer, warfarin at an INR of 1.3 to 1.9 was found to be both clinically effective (rate of VTE = 0.6% vs. 4.4% in the placebo group;  $p = .031$ ) and cost-effective, with no increased risk of bleeding compared to placebo.<sup>20,21</sup> In a recently published trial termed the fragmin advanced malignancy outcome study,<sup>22</sup> 382 patients with advanced cancer were randomized to receive either a once-daily subcutaneous injection of dalteparin (5,000 IU) or placebo for 1 year. The survival rates in the dalteparin group were 46%, 27%, and 21%, at 1, 2, and 3 years, respectively, compared with 41%, 18%, and 12%, respectively, for patients receiving placebo ( $p = .19$ ). The rates of symptomatic venous thromboembolism were no different at 2.4% and 3.3% for dalteparin and placebo, respectively, and with bleeding rates of 4.7% and 2.7%, respectively.

### Cancer Patients with Central Venous Catheters

Central venous catheters (CVCs) predispose to upper extremity DVT in the general population.<sup>8</sup> Cancer patients with indwelling catheters are probably at even higher risk for developing upper extremity DVT, but the overall incidence of clinically apparent CVC-associated DVT is still low at  $\approx 3.4\%$  (1.14 per 1,000 catheter days) amongst those with peripherally inserted central catheters.<sup>13</sup> There is one study that supports the use of a 1 mg daily dose of warfarin for DVT

**Table 1** Selected Randomized Control Trials of LMWH, UFH, and IPC Trials in Cancer Surgery

Study	Type of Surgery	No. of Patients	Prophylaxis	Rate of VTE	Diagnostic Modality
Enoxacan I <sup>53</sup>	Abdominal or pelvic surgery for cancer	1115	UFH 5,000 U SC tid vs Enoxaparin 40 mg SC qd	18.2% (UFH) 14.7% (enoxaparin) ( <i>p</i> = NS)	Venography Venography or ultrasonography
McLeod et al <sup>54</sup>	Colorectal surgery (1/3 of patients with cancer)	936	UFH 5,000 U SC tid vs enoxaparin 40 mg SC qd	9.4% (UFH) 9.4% (enoxaparin) ( <i>p</i> = NS)	
Clarke-Pearson et al <sup>55</sup>	Gynecologic cancer surgery	208	UFH 5,000 U bid vs IPC*	6.9% (UFH) 4.0% (IPC) ( <i>p</i> = NS)	I-125 fibrinogen
Clarke-Pearson et al <sup>12</sup>	Gynecologic cancer surgery	185	UFH 5,000 U bid vs placebo	14.8% (UFH) 12.4% (placebo) ( <i>p</i> = NS)	I-125 fibrinogen + IPG <sup>†</sup>

**Table 2** Patients with underlying cancer undergoing surgery for a non-cancer related condition

Type of Surgery	Type of Prophylaxis	Duration
Moderate risk general surgery	UFH 5,000 U SC tid or LMWH*	Until ambulation or discharge
High risk general surgery	UFH 5,000 U SC tid or LMWH plus IPC or GCSs	Up to 28 days
Vascular surgery	UFH 5,000 U SC tid or LMWH	Until ambulation or discharge
Laparoscopic gynecologic surgery > 30 min.	UFH 5,000 U SC tid or LMWH plus IPC or GCSs	Until ambulation or discharge
Major gynecologic surgery	UFH 5,000 U SC tid or LMWH plus M IPC or GCSs	Until ambulation or discharge
Urologic surgery other than low-risk	UFH 5,000 U SC tid or LMWH plus IPC or GCSs	Until ambulation or discharge
Major orthopedic surgery	LMWH or VKA or Fondaparinux <sup>†</sup>	28 to 35 days
	Neurosurgery	
	Extracranial	
	Intracranial	
	LMWH plus IPC ± GCSs	
	LMWH plus IPC ± GCSs	
	Until ambulation or discharge	

Adapted from Geerts et al.<sup>13</sup>

GCSs = graded compression stockings; IPC = intermittent pneumatic compression; IU = international units; LMWH = low-molecular-weight heparin; qd = four times a day; SC = subcutaneously; tid = three times a day; U = units; VKA = Vitamin K antagonists (warfarin).

\*LMWH dosing = enoxaparin 40 mg SC qd, dalteparin 5,000 IU SC qd or tinzaparin 75 IU/kg qd

<sup>†</sup>2.5 mg SC qd

prevention. In this trial, the rate of upper extremity DVT by mandatory venography at day 90 was 37.5% with placebo and 9.5% with warfarin (*p* < .001).<sup>23</sup> However, two subsequent trials failed to show any benefit from 1 mg daily dosing

compared to placebo in preventing clinically apparent DVT.<sup>13</sup> In addition, the safety of 1 mg of daily warfarin without monitoring in cancer patients may be of concern because these patients may be more susceptible to small doses of

warfarin due to their nutritional status and their vitamin K stores.

LMWH has also been evaluated for prevention of CVC-associated thrombosis. In one small study, dalteparin 2,500 U SC once daily was superior to no therapy for the prevention of venographically detectable thrombosis.<sup>24</sup> In a larger trial of 425 cancer patients receiving chemotherapy, dalteparin 5,000 IU SC once daily did not show superiority over placebo. The rate of clinically relevant VTE was ≈3.5% in both groups.<sup>25</sup> Therefore, based on this evidence, we and the ACCP do not endorse routine prophylaxis for cancer patients with CVCs.

### Postoperative VTE in Cancer Patients

Patients with cancer are at higher risk for postoperative VTE than patients without cancer undergoing similar surgeries,<sup>26</sup> and clinicians should have a high index of suspicion for postoperative VTE in these patients. Objective radiographic tests, such as lower extremity duplex ultrasonography or helical computed tomography, should be used for diagnosis in postoperative cancer patients. Given the ongoing hemostatic activation in postoperative hospitalized patients,<sup>27</sup> there is no role for D-dimer testing.<sup>28</sup>

**Table 3** Recommendations for VTE prophylaxis for Cancer Surgery

UFH 5,000 U SC q8h or tid at least until ambulation or discharge with a preoperative dose of 5,000 U SC given 2 hours prior to surgery  
 OR  
 LMWH (enoxaparin 40 mg SC qd or dalteparin 5000 U SC qd) or Fondaparinux 2.5mg SC qd  
 Extended prophylaxis for 28 days with LMWH for major abdominal, pelvic or orthopedic surgery in cancer patients.

LMWH = low-molecular-weight heparin; q8h = every 8 hours; qd = four times a day; SC = subcutaneously; tid = three times a day; U = units; VTE = venous thromboembolism.

When postoperative VTE is diagnosed in a patient with cancer, the treatment options are similar to the options in patients without cancer. However, the optimal management strategy may be different. Cancer patients who undergo successful curative surgery are probably no different from patients without cancer and can be viewed as having situational thromboses. In such cases, 3 months of anticoagulation is reasonable. However, many cancer patients are not cured of their disease and have ongoing chronic activation of the clotting cascade, particularly those with adenocarcinomas of the viscera, brain tumors, or certain hematologic malignancies. In these patients, although the precipitating event (surgery) may be situational, ongoing hypercoagulability places them at higher risk for recurrent thrombosis following discontinuation of therapy. Indefinite anticoagulation may be considered in patients who suffer VTE following surgery who have uncured malignancies known to be associated with hypercoagulable states (such as visceral adenocarcinomas or brain tumors), but this strategy may expose patients to a high risk of bleeding<sup>29</sup> and should be considered only on a case-by-case basis.

Given the high rates of warfarin-resistant thrombosis and warfarin-associated bleeding in patients with cancer,<sup>29</sup> consideration of long-term LMWH treatment is justified when a cancer patient develops a thrombosis. The CLOT investigators<sup>30</sup> recently examined the safety and efficacy of dalteparin (200 IU/kg/d for the first month, followed by 150 IU/kg/d for 5 months) compared to oral anticoagulation for the treatment of VTE in cancer patients. Of 336 patients, 27 (8.0%) in the LMWH group suffered recurrence, compared to 53 of 336 (15.8%) in the oral anticoagulation group (hazard ratio 0.48;  $p = .002$ ). Most recurrences occurred while on anticoagulation. The frequencies of major and minor bleeding were similar. Although this trial did not specifically enroll patients with postoperative

VTE, the relatively high recurrence rates illustrate that cancer patients with VTE are at high risk for recurrence even in the face of ongoing warfarin treatment. A smaller study using enoxaparin 1.5 mg/kg/d demonstrated a similar risk reduction that failed to reach statistical significance.<sup>29</sup> However, any increased efficacy of LMWH in the treatment of cancer-associated VTE compared to oral anticoagulation must be weighted against the cost of the drug<sup>31</sup> and the willingness of the patient or family members to administer daily injections.

### Inferior Vena Cava Filters

Inferior vena cava (IVC) filter placement has increased during the last two decades in patients with PE, patients with DVT alone, and patients at risk for VTE who have not yet had an event.<sup>32</sup> Some authors have argued against placement of IVC filters in patients with advanced cancer because the filters may have little overall clinical benefit in terminally ill patients, and may not be cost-effective. In a case series of 308 patients with cancer-associated VTE who received IVC filters,<sup>33</sup> the filters appeared to be safe and effective in preventing PE-related deaths. Although overall mortality was high in these patients (median survival < 1 year), less than 5% of patients suffered PE-related death. It is our opinion, however, that IVC filters be reserved for cancer patients with contraindication to anticoagulation, recurrent thromboembolic disease despite LMWH therapy, or a significant complication from anticoagulation therapy. The FDA recently approved three different types of retrievable filters. Although long-term safety data for these devices was not available as of this writing, they may be attractive options for cancer surgery patients who have a very high risk of developing perioperative VTE and transient contraindication to anticoagulation (such as intracranial surgery). In our opinion, prophylactic filter placement is not generally warranted and should be tested in prospective trials before we can recommend this strategy for our patients.

### Perioperative/Periprocedural Management of Warfarin in Cancer Patients

Although some patients with cancer may suffer recurrent VTE despite warfarin treatment, warfarin is effective for treatment and secondary prevention of VTE for most cancer patients.<sup>30</sup> Other cancer patients may be on warfarin for other indications, such as atrial fibrillation or valvular heart disease. When a cancer patient on warfarin is scheduled to undergo surgery, there are a few key questions that must be addressed. First, does the nature of the procedure warrant discontinuation

of therapeutic anticoagulation? Second, if anticoagulation must be reversed, is the patient at high enough risk for short-term thrombosis to justify “bridging” anticoagulation with short-acting anticoagulants prior to the procedure? If so, which agent should be used? Finally, which anticoagulation regimen should be employed following the procedure? Although these questions need to be addressed prior to surgery for all patients on warfarin—regardless of whether or not they have cancer—the second and third questions require special thought for cancer patients who are often at particularly high risk for VTE and VTE recurrence.

Some minor procedures, such as dental, cutaneous, and ophthalmologic surgeries and gastrointestinal endoscopy without biopsy, can be performed safely in patients who are fully anticoagulated.<sup>35–39</sup> Cancer patients requiring such procedures can continue their warfarin without interruption. If this approach is considered, the surgeon must agree that the procedure can safely be performed while the patient is anticoagulated, and care should be taken to ensure that the patient does not have a supra-therapeutic INR on the morning of the procedure. Other procedures such as prostate biopsy, endoscopic biopsy, and even herniorrhaphy may be performed with a reduced dose (but not full reversal) of oral anticoagulation, targeting an INR of 1.5 to 2.0 on the morning of surgery.<sup>40</sup> If anticoagulation must be discontinued, then approximately 5 to 6 days are required for anticoagulant effects of warfarin to wear off in most non-cancer patients.<sup>41</sup> Provided that hepatic synthetic function is normal or near-normal, there is no reason to suspect that a longer duration of cessation is needed in patients with cancer.

During the few days prior to surgery, while the oral anticoagulation is wearing off, the patient is relatively unprotected from VTE. The risk of recurrence during a brief period of warfarin cessation depends upon the timing of the most recent thrombotic event, the duration of anticoagulant cessation, and the intensity of the underlying proclivity to develop thrombosis. In general, for patients with a thrombosis in the preceding month, the average daily recurrence rate is approximately 0.3% to 1.3%.<sup>42–45</sup> This high rate may stem from the likelihood that residual, unstabilized thrombus is still present. Over the next two months, the daily recurrence rate is approximately four- to tenfold lower.<sup>42–44</sup> However, these figures apply to all patients on warfarin for acute VTE, and there is reason to suspect that patients with underlying hypercoagulable states (such as malignancy) may be at higher risk for thrombosis than these figures suggest. Therefore, we recommend that all cancer patients with a thrombotic episode in the preceding three months receive short-acting anticoagulants prior to surgery

starting 2 days after the warfarin is discontinued. If the most recent event occurred in the preceding month, consideration should be given to delaying the procedure or placing an inferior vena cava filter. In patients with more distant thrombosis (> 3 months prior) without evidence of underlying active cancer, it may be reasonable to simply let the warfarin wash out without any preoperative bridging therapy. However, this latter approach should be exercised cautiously in patients with a history of life-threatening, recurrent thromboses and active cancer. Patients with cancer without history of VTE, but who are on warfarin for other conditions (such as atrial fibrillation), may also need bridging therapy. The need for bridging therapy in these cancer patients is summarized in Table 4. As a general rule, patients at very high risk (ie, > 10% annual risk for arterial embolism or > 10% monthly risk for venous thromboembolism) should receive bridging anticoagulation. For patients at low-risk (ie, < 5% annual risk for arterial embolism, or < 5% monthly risk for venous thromboembolism), however, bridging therapy prior to surgery may involve unnecessary risk. The need for bridging in intermediate-risk patients may need to be decided on a case-by-case basis.

If a decision is made that bridging therapy with short-acting anticoagulants is warranted, LMWHs allow for effective outpatient treatment. Unless the thrombosis was very recent (in the preceding 3 months), we believe that prophylactic doses of LMWH are appropriate. It is important to recognize that the doses of LMWH used in the initial treatment of VTE (“full-intensity” treatment) may, in fact, be higher intensity than necessary, with potential risk of bleeding.<sup>45</sup> Although full-intensity treatment with heparin products is clearly indicated for the initial treatment of VTE, lower doses may be reasonable following the first few weeks of therapy. For example, in the CLOT study, which compared dalteparin to oral anticoagulation following cancer-associated VTE,<sup>30</sup> the dose of dalteparin was decreased from full-intensity (200 IU/kg/d) to 75% of the full-intensity (150 IU/kg/d) after the first month of therapy to reduce the risk of bleeding. Despite this dose reduction, there was a > 50% reduction in VTE recurrence in those assigned to dalteparin (compared to oral anticoagulation) and comparable bleeding rates in both groups. This supports the concept that full-dose treatment with LMWH may be excessive and unnecessary beyond the first month of VTE treatment. Observational bridging studies of LMWH in patients who require temporary interruption of warfarin therapy have utilized full doses of LMWH (ie, dalteparin 200 IU/kg SC qd, enoxaparin 1 mg/kg SC q12h or enoxaparin 1.5 mg/kg SC qd).<sup>46</sup> However, the ideal dosing regimen remains to be determined in a randomized

**Table 4** Risk for Thromboembolism

**High risk [annual risk of arterial thromboembolism > 10% or monthly risk of venous thromboembolism > 10% without anticoagulation] (bridging advised)**

Known hypercoagulable state as documented by a thromboembolic event and one of the following: protein C deficiency, protein S deficiency, antithrombin III deficiency, homozygous factor V Leiden mutation or antiphospholipid antibody syndrome

Hypercoagulable state suggested by recurrent (two or more) arterial or idiopathic venous thromboembolic events (not including primary atherosclerotic events, such as stroke or myocardial infarction due to intrinsic cerebrovascular or coronary disease)

Venous or arterial thromboembolism within the preceding 3 months

Rheumatic atrial fibrillation

Acute intracardiac thrombus visualized by echocardiogram

Atrial fibrillation plus mechanical heart valve in any position

Older mechanical valve model (single disk or ball-in-cage) in mitral position

Recently placed mechanical valve (< 3 months)

Atrial fibrillation with history of cardioembolism

**Intermediate risk [annual risk of arterial thromboembolism 5 to 10% or monthly risk of venous thromboembolism 5 to 10% without anticoagulation] (Bridging decision to be made on a case-by-case basis)**

Cerebrovascular disease with multiple (two or more) strokes or TIAs without risk factors for cardiac embolism

Newer mechanical valve model (eg, St. Jude) in mitral position

Older mechanical valve model in aortic position

Atrial fibrillation without a history of cardiac embolism but with multiple risks for cardiac embolism (eg, low ejection fraction (< 40%), diabetes, hypertension, non-rheumatic valvular heart disease, recent (within preceding month) transmural myocardial infarction)

VTE > 3 to 6 months ago

**Low risk [annual risk of arterial thromboembolism < 5% or monthly risk of venous thromboembolism < 5% without anticoagulation] (bridging not advised)**

One remote VTE (> 6 months ago)

Intrinsic cerebrovascular disease (such as carotid atherosclerosis) without recurrent strokes or TIAs

Atrial fibrillation without multiple risks for cardiac embolism

Newer model prosthetic valve in aortic position

clinical trial. In the absence of prospective randomized clinical trials, we believe that established prophylactic doses (eg, 40 mg daily or 30 mg twice daily of enoxaparin, or dalteparin 5,000 IU) are probably appropriate for “bridging” therapy in most patients with a history of cancer-associated

VTE, and that 75% of full-dose treatment can be considered (eg, 1.125 mg/kg daily or 0.75 mg/kg twice daily of enoxaparin, or 150 IU/kg/d of dalteparin) if the thrombosis was recent (1 to 6 months prior). The last dose of LMWH should be approximately 24 hours before surgery if full-dose or 75% of full-dose LMWH is used and at least 12 hours prior to surgery if prophylactic doses of LMWH are used. This is important to prevent unnecessary surgical bleeding and complications related to spinal or epidural anesthesia. In patients with renal insufficiency, subcutaneous UFH or dose-reduced enoxaparin may be appropriate options,<sup>40,47,48</sup> but we discourage the use of intravenous heparin except in patients at extremely high risk (eg, those with thrombosis in the preceding month) since it necessitates hospitalization, and prophylactic dosing regimens are not established for intravenous heparin. In patients with a history of heparin-induced thrombocytopenia, LMWH and UFH should be avoided. Consideration can be given to the off-label use 2.5 mg daily of fondaparinux (a pentasaccharide with no in-vitro cross-reactivity to antibodies against platelet-factor 4).<sup>49,50</sup> In patients with a history of HIT who are at very high risk for recurrence (eg, thrombosis in the preceding month), admission to the hospital for administration of perioperative intravenous direct thrombin inhibitors (such as lepirudin or argatroban) is appropriate.

Following surgery, the daily risk for recurrent VTE is much higher than prior to surgery, since surgery itself is a major risk factor for VTE. However, there is also an increased risk for anticoagulant-mediated bleeding, especially from the surgical site.<sup>50</sup> Major postoperative bleeding is a problem in its own right but also necessitates cessation of anticoagulation, placing patients at high risk for thrombosis. For this reason, it is appropriate to use prophylactic doses of agents with demonstrated efficacy in VTE prevention following major surgery (eg, enoxaparin 40 mg daily or 30 mg twice daily, dalteparin 5,000 IU SC qd or fondaparinux 2.5 mg daily),<sup>50-52</sup> rather than full-intensity anticoagulation. Since the antithrombotic effects of warfarin are delayed, warfarin can be restarted the day of surgery or on the following day. Once the INR approaches therapeutic intensity, the parenteral antithrombotic drugs can be discontinued. Figure 1 outlines a protocol bridging them copy.

## Conclusion

VTE is a common complication in cancer patients especially those undergoing surgery, and patients who develop this complication have a higher rate of dying compared to non-cancer patients with VTE. It is clear that cancer patients undergoing major surgery need both aggressive and extended

**Pre-op Protocol:**

- If pre-op INR 2-3, stop warfarin 5 days before surgery (4 doses).
- If pre-op INR 3-4.5, stop warfarin 6 days before surgery (5 doses).
- Start LMWH\* about 2 days after last warfarin dose.
- Last dose of LMWH\* approximately 24 hours prior to procedure.
- Patient educated in self injection and provided with written instructions
- Discuss plan with Surgeon and Anesthesiologist.
- Check stat INR in am of surgery to ensure <1.5 and in some cases <1.2

**Post-op Protocol:**

- Restart LMWH\* approximately 24 hours post procedure; consider thromboprophylaxis dose of LMWH on post-op if patient is at high risk for bleeding.
- Discuss above with Surgeon.
- Start warfarin at patient's pre-op dose on day of surgery or post-op day 1.
- Daily PT/INR until patient is discharged and periodically thereafter until INR therapeutic.
- Make arrangements for frequent patient contact following hospital discharge to ensure adherence to therapy and no anticoagulant related bleeding
- CBC with platelets at day 3 and day 7 post-op to screen for HIT
- Discontinue LMWH when INR is 2-3 for two consecutive days.

\*Enoxaparin 1mg/kg SC q12h or 1.5mg/kg SC 24hr  
or Dalteparin 120U/kg q12h or Dalteparin 200U/kg SC q24h. and adjusted dose LMWH for patients with CrCl<30ml/min

**INCLUSION CRITERIA:**

- Treating physician thinks patient needs bridge therapy.
- Medically and hemodynamically stable.
- Scheduled for elective procedure or surgery.

**EXCLUSION CRITERIA**

- Allergy to UFH or LMWH.
- Morbid obesity (eg. BMI > 40 kg/m<sup>2</sup>, or weight > 150 kg in a patient of average height)
- Pregnant woman with a mechanical valve .
- History of bleeding disorder or intracranial hemorrhage.
- GI bleeding within the last ten days.
- Major trauma or stroke within the past two weeks.
- History of HIT or severe thrombocytopenia (< 30-50K).
- Language barriers that may interfere with successful drug administration.
- Potential for medication noncompliance.
- Unsuitable home environment to support therapy.
- Severe Liver Disease.

**FIGURE 1** Outlines a bridging protocol for cancer patients on warfarin in head of a surgery requiring short acting parenteral antithrombotic. BMI = body mass index; CBC = complete blood count; CrCl = ; GI = gastrointestinal; HIT = heparin-induced thrombocytopenia; INR = international normalized ratio; K = ; kg = kilograms; LMWH = low-molecular-weight heparin; PT = ; q12h = every 12 hours; q24h = every 24 hours; SC = subcutaneously. \*Enoxaparin 1mg/kg SC q12h or 1.5mg/kg SC 24 hours or dalteparin 100 U/kg q12h or dalteparin 200 U/kg SC q24h and adjusted dose Enoxaparin for patients with CrCl < 30 mL/min.

pharmacologic prophylaxis for up to 28 days postoperatively. At this time, we believe that LMWHs are the agents of choice; however, encouraging data are emerging for newer agents such as fondaparinux. Patients on long-term

warfarin with recent VTE, high-risk atrial fibrillation or mechanical valves may need parenteral bridging therapy with short acting anticoagulants such as LMWHs in preparation for their surgery to decrease the risk of thromboembolism.

# Surgery in the Patient with Endocrine Disease

Gail A. Welsh, MD  
Karen F. Mauck, MD, MSc

Endocrine disorders are common in cancer patients who undergo surgery. Patients may have a chronic endocrine disease, such as diabetes mellitus, in addition to their malignancy. They may have primary or metastatic disease of an endocrine organ, such as the thyroid or adrenal gland. Finally, treatment of their malignancy, whether by surgery, radiation or chemotherapy, may affect endocrine function. This chapter discusses perioperative evaluation and management of cancer patients with diabetes mellitus, thyroid disorders, adrenal dysfunction due to exogenous steroids, and electrolyte abnormalities.

## The Patient with Diabetes Mellitus

### Introduction

Diabetes mellitus is a common medical condition with a prevalence of about 8% in the United States population.<sup>1</sup> Complications from diabetes such as hyperglycemia, ischemic heart disease, peripheral vascular disease and renal insufficiency can contribute to adverse perioperative outcomes that include postoperative infection, myocardial infarction, and acute renal failure.<sup>2</sup> The cancer patient with diabetes may have additional risk factors for complications that must be identified in the perioperative period. Chemotherapy with corticosteroids can worsen insulin resistance and precipitate or maintain hyperglycemia. Immunosuppression from both malignancy and its therapies can add to an increased risk of infection from both hyperglycemia and poor wound perfusion secondary to vascular disease. Anorexia and cachexia from cancer may affect the patient's need for diabetic medications and lead to hypoglycemia. Careful preoperative evaluation and meticulous perioperative management of diabetic cancer patients undergoing surgery can modify risk factors and prevent both medical and surgical complications.

### Preoperative Assessment

Patients with known diabetes should be identified preoperatively, but up to a third of patients with

diabetes may be undiagnosed.<sup>3</sup> Those with risk factors for diabetes, including family history, advanced age, obesity, inactivity, dyslipidemia, polycystic kidney disease or a history of gestational diabetes, and those with symptoms of diabetes, such as polyuria, polydipsia, weight loss or weight gain, should be tested for it before surgery.<sup>1</sup> Nonurgent surgery may need to be postponed in the newly diagnosed diabetic if blood sugars are very high or ketosis is present.

Duration of disease, episodes of diabetic ketosis, complications from previous surgeries, and medications should be documented. An A1C may be helpful in determining how well controlled the patient has been and how effective his or her current medication regimen is. All diabetics should be tested preoperatively for renal disease with electrolytes and a creatinine.

One of the greatest risks for the diabetic undergoing surgery is perioperative ischemia and infarction. Diabetic patients without previous myocardial infarction have the same risk for myocardial infarction as nondiabetic patients with a previous myocardial infarction.<sup>4</sup> The Relative Cardiac Risk Index (RCRI) includes insulin-requiring diabetes mellitus as one of six well-validated independent predictors of major perioperative cardiac complications.<sup>5</sup> Therefore, all diabetics should be screened for heart disease with a pertinent history, cardiac exam and EKG. Early studies suggested that treatment of patients at risk for cardiac complications with beta-blockade could prevent perioperative morbidity and death,<sup>6</sup> but subsequent randomized trials have not demonstrated similar efficacy. Based on the most recent guidelines from the American College of Cardiology (ACC), beta-blockade should be continued in diabetics going to surgery who are already on them for cardiac disease. There is also probable benefit in initiating perioperative beta-blockade in diabetics going for vascular or intermediate surgery who have a history of or newly diagnosed coronary heart disease, or who have a history of heart failure, a history of

cerebrovascular disease or a serum creatinine greater than 2.0 mg/dL.<sup>5</sup> If possible, beta-blockade should be initiated days to weeks prior to the procedure, and the target heart rate should be 70 or less. The ACC guideline is also useful in determining which patients should undergo additional cardiac studies prior to surgery, but invasive studies and interventions may not be warranted in the cancer patient with a poor prognosis who is undergoing palliative rather than curative surgery. Medical treatment for presumptive disease can be used to modify cardiac risk after discussion and agreement with the patient and surgical team.

### Perioperative Management

Type 1 diabetics have an absolute deficiency of insulin due to pancreatic islet cell failure, and always require insulin. Type 2 diabetics have a relative insulin deficiency with peripheral insulin resistance and increased hepatic gluconeogenesis.<sup>1</sup> Management options in them include diet and exercise, oral medications, or insulin, but a patient's usual regimen may need to be modified in the perioperative period. Surgery is a stress that releases counterregulatory hormones such as cortisol, glucagon, catecholamines, and growth hormone that oppose insulin, increase insulin resistance, and exacerbate hyperglycemia.

There is an increasing body of evidence that suggests that hyperglycemia contributes not only to a higher incidence of wound and other postoperative infections, but may predict higher morbidity and mortality in hospitalized patients as well. Additional studies have suggested that closer management of hyperglycemia, usually with insulin infusions, can decrease the risk of postoperative infection, affect long-term outcomes of myocardial infarction, and reduce mortality in intensive care unit (ICU) patients.

In a study that prospectively monitored glucose control in 100 diabetic patients undergoing major surgery at a tertiary care center, a glucose level >220 on postoperative day 1

increased the relative risk of a serious postoperative infection to 5.7 compared to patients with blood sugars less than 220.<sup>7</sup> In another study, the mean of six blood sugars was used to evaluate perioperative glycemic control in the first 36 hours after coronary artery surgery in 411 diabetic patients. Postoperative hyperglycemia greater than 200 was an independent predictor of short term postoperative infectious complications.<sup>8</sup> In a prospective study of 2,467 diabetic patients who underwent open heart surgeries over a period of 10 years, those who were treated with a continuous intravenous insulin infusion to maintain blood sugars less than 200 had a clinically significant decrease in sternal wound infections compared to those who were treated with intermittent subcutaneous insulin injections based on a sliding scale.<sup>9</sup>

Several studies in stroke and myocardial infarction patients have shown that higher blood sugars at admission correlate with poorer outcomes, even in patients without diabetes.<sup>10,11</sup> The hyperglycemia may be an indicator of insulin resistance due to the stress of the illness or a marker for the extent of injury. A retrospective study of 1,826 patients admitted to a single ICU for a wide range of medical and surgical diagnoses showed that hospital mortality increased as glucose levels increased and that the lowest mortality occurred among patients with mean glucose values between 80 and 99 mg/dL.<sup>12</sup> Records of 2,030 consecutive adult patients with and without diabetes admitted to the general wards of a single hospital were reviewed for hyperglycemia. Of the study patients, 38% had either a fasting glucose of 126 or greater or two or more random glucose levels of 200 or more. Newly diagnosed hyperglycemia was associated with a higher in-hospital mortality rate (16%) compared to those patients with known diabetes (3% mortality) and patients with normoglycemia (1.7% mortality).<sup>13</sup>

Some authors argue that close monitoring and modification of hyperglycemia with intravenous insulin infusions can decrease hospital mortality. The Diabetes and Insulin-Glucose Infusion in Acute Myocardial Infarction study showed that long-term mortality was decreased in diabetic patients whose blood sugars were tightly controlled after an acute myocardial infarction.<sup>14</sup> A prospective controlled study randomized 1,548 patients admitted to a surgical ICU on mechanical ventilation either to intensive insulin therapy to maintain blood glucose between 80 and 110 mg/dL or conventional treatment with maintenance of blood glucose between 180 to 200 mg/dL. Intensive insulin therapy reduced mortality during intensive care from 8% with conventional treatment to 4.6% ( $p < .04$ ) with the benefit attributable to its effect on mortality in patients who remained in ICU for more than 5 days. Intensive insulin therapy also reduced overall hospital mortality by 34%, bloodstream

infection by 46%, acute renal failure requiring dialysis by 41%, the median number of red-cell transfusions by 50%, and critical-illness polyneuropathy by 44%.<sup>15</sup> In another study, 800 consecutive patients admitted to a single ICU were placed on a protocol to monitor and maintain blood glucose levels lower than 140 mg/dL. A continuous insulin infusion was begun if a patient had a glucose reading of 200 on two separate occasions. The patients were matched to 800 patients previously admitted prior to initiation of the protocol. The protocol resulted in significantly improved glycemic control and was associated with decreased mortality (29.3% reduction,  $p = .002$ ) and decreased length of ICU stay (10.8% reduction,  $p = .01$ ).<sup>16</sup>

These studies, which assessed the correlation between hyperglycemia and hospital mortality, looked at patients with and without diabetes admitted mainly to ICUs and did not specifically address postoperative diabetic patients. However, a study of 3,554 diabetics undergoing coronary artery bypass grafting compared aggressive treatment of hyperglycemia with subcutaneous insulin (1987 to 1991) versus a continuous insulin infusion (1992 to 2001). Glucose control was significantly better with a continuous infusion ( $177 \pm 30$  mg/dL vs.  $213 \pm 40$  mg/dL). Observed mortality was significantly lower in patients on a continuous insulin infusion (2.5%) compared to those patients on subcutaneous insulin (5.3%,  $p < .0001$ ). Multivariable analysis revealed that continuous insulin infusion added an independently protective effect against death.<sup>17</sup> A smaller study of 141 diabetics undergoing coronary artery bypass grafting prospectively randomized patients to tight glycemic control (serum glucose of 125 to 200 mg/dL) with an intravenous glucose, insulin, and potassium solution versus standard treatment with intermittent subcutaneous insulin and a serum glucose target of less than 250 mg/dL. Patients with tight glycemic control had improved perioperative outcomes, enhanced survival and decreased incidence of both ischemic events and wound complications.<sup>18</sup>

Continuous insulin infusions are labor-intensive, and, so far, there is insufficient evidence to justify a continuous insulin infusion in all diabetics undergoing surgery. However, critically ill surgical patients and those undergoing major surgeries should be considered for this therapy. Perioperative blood sugars less than 200 mg/dL should be a target in all diabetic patients to decrease risk of infections. Postoperative ICU patients should be more tightly controlled with blood sugars between 80 to 110 mg/dL.<sup>15</sup> More studies need to be done to see if tighter glucose control in diabetic patients undergoing noncardiac surgery reduces postoperative ischemia, infarction, and mortality.

The timing, type and duration of surgery will determine perioperative management of oral

hypoglycemics as well as insulin dosing in the diabetic. Oral hypoglycemics should be held the morning of surgery. Insulin may be needed in the patient who is only on oral medication if the patient's diabetes is poorly controlled. Table 1 details preoperative dosing of insulin based on a patient's type and scheduled regimen of insulin as well as the time and duration of surgery. Patients on basal insulin regimens such as glargine or continuous infusion pumps should receive their basal medication during surgery without boluses. Insulin-treated patients undergoing major surgery should be treated with a continuous insulin infusion.<sup>19</sup>

The patient who receives insulin prior to surgery should be given D5 in the intravenous fluids at 100 to 150 cc/hr to prevent hypoglycemia while taking nothing by mouth. All diabetics should have their blood glucose checked preoperatively and then frequently throughout the surgery and in the postoperative period. Postoperative blood sugars can be managed with a continuous insulin infusion or sliding scale subcutaneous insulin with reintroduction of the patient's preoperative regimen when he or she resumes a full diet. An exception is a patient on metformin hydrochloride who receives intravenous contrast during a procedure. The medication should be held for 72 hours after the procedure, and a creatinine should be checked before it is restarted.<sup>19</sup> Metformin should not be resumed in a patient who develops postoperative heart failure, hypotension, renal insufficiency or hepatic dysfunction.<sup>20</sup> Metabolic and hormonal changes can continue up to 4 days after major surgery, but are most pronounced through the first postoperative day.<sup>21</sup> Persistence of hyperglycemia may reflect a perioperative complication such as infection. Providers must be alert throughout the perioperative period for neuropsychiatric symptoms in a diabetic that may be due to hypoglycemia or ketosis.

## The Patient with Hypothyroidism

### Introduction

Hypothyroidism is a common disease with a prevalence of 1 to 2% in the general population, though it is ten times more common in women than men.<sup>22</sup> Genetics, environmental factors, such as dietary iodine deficiency, and autoimmune disease play a role in its development. Medications such as lithium or amiodarone, surgery for benign or malignant thyroid disease, and radiation to the head and neck or to the mediastinum in lymphoma, head and neck, or breast cancer can cause hypothyroidism.<sup>23,24</sup>

Thyroid function affects the physiology of many of the body's organs, and its dysfunction can influence perioperative outcome through myocardial contractility and heart rate, lowered

**Table 1 Perioperative Management of Diabetes Mellitus Insulin Regimens**

<i>Duration and Type of Surgery</i>	<i>Anticipated Meals</i>	<i>Usual Insulin Regimen</i>	<i>Perioperative Management</i>
Short Early am	Breakfast will be eaten	Single or multiple doses Peakless (glargine) Insulin pump	Delay and give after procedure with breakfast Usual am dose Basal rate, bolus with breakfast if needed
Short Late am	Breakfast will be missed Lunch will be eaten	Single am dose 2 or 3 daily doses MDI Peakless (glargine) Insulin pump	2/3 TDD as IAI 1/2 TMD as IAI 1/3 am dose of SAI Usual am dose Basal rate only
Short Afternoon	Breakfast will be missed Lunch will be missed	Single am dose 2 or 3 daily doses MDI	1/2 TDD as IAI 1/3 TMD as IAI 1/3 am, 1/3 lunch doses of SAI
<i>or</i> Uncertain Complex Prolonged	<i>or</i> Uncertain NPO	Peakless (glargine) Insulin pump Any	Usual am dose Basal rate only Continuous IV insulin

Adapted from Jacober SJ and Sowers JR.<sup>19</sup>  
IAI = intermediate-acting insulin; MDI = multiple doses of short-acting insulin; SAI = short-acting insulin; TDD = total daily dose (short plus intermediate-acting insulin); TMD = total morning dose (short plus intermediate-acting insulin).

metabolic rate, hemostasis, gastrointestinal motility, and free water balance.<sup>25</sup> There are case reports of intraoperative hypotension, cardiovascular collapse, and myxedema coma in undiagnosed hypothyroid patients undergoing anesthesia and surgery.<sup>26,27</sup> Yet there are no randomized, prospective studies that compare surgical outcomes in untreated hypothyroid patients versus controls.

However, two studies from the 1980s did evaluate the hypothyroid patient undergoing surgery with retrospective case-matched controls. In one study, anesthetic and surgical outcomes were compared in 59 hypothyroid and 59 paired euthyroid patients. There was no difference in surgical outcome, hospital length of stay, or perioperative complications that included pulmonary or myocardial infarction, sepsis, arrhythmias, need for postoperative ventilatory assistance, fluid and electrolyte imbalances, or bleeding complications. In addition, no differences in outcome were found based on level of thyroxine, although only a few patients in the sample were severely hypothyroid.<sup>28</sup> A second retrospective study looked at perioperative complications in 40 hypothyroid patients matched to 80 euthyroid controls. Hypothyroid patients had more intraoperative hypotension in noncardiac surgery, more heart failure in cardiac surgery, more postoperative gastrointestinal and neuropsychiatric complications and were less likely to mount a fever with infection. However, there were no differences between the two groups in duration of hospitalization, perioperative arrhythmias, delayed anesthetic recovery or death.<sup>29</sup>

### Preoperative Assessment

Despite its prevalence, preoperative screening for thyroid disease is not justified in the general population. Furthermore, assessment of thyroid function is complicated in the hospitalized patient by the euthyroid sick syndrome, which significantly reduces the specificity of the serum thyroid-stimulating hormone.<sup>30</sup> Nevertheless, cancer patients who have undergone radiation to the thorax or head and neck or who have undergone prior thyroidectomy or head and neck surgery should be assessed for hypothyroidism.<sup>31</sup> Increased risks for hypothyroidism were found in post-laryngectomy patients who were female, received preoperative radiation therapy, had invasion of the thyroid gland by tumor, had cervical metastasis, and had postoperative fistula.<sup>32</sup> Studies have shown a higher prevalence of hypothyroidism in patients with cutaneous melanoma,<sup>33</sup> as well as those with autoimmune diseases such as autoimmune pancreatitis, Sjögren's syndrome, polymyalgia rheumatica and giant cell arteritis.<sup>34–36</sup> Hypothyroidism should be considered in any of these patients. In addition, thyroid function should be assessed in all patients with known hypothyroidism prior to surgery.

### Perioperative Management

Clinical and laboratory euthyroidism is the optimal management goal for hypothyroid patients undergoing elective surgery, but patients with mild to moderate hypothyroidism may undergo urgent or emergent surgery without delay. Postoperative complications in subtherapeutic patients such as ileus, delirium, or infection

without fever, should be anticipated and managed. Patients with severe hypothyroidism manifested by heart failure, pericardial effusion, mental status changes, or very low levels of thyroxine should be treated with perioperative intravenous triiodothyronine (T<sub>3</sub>) or thyroxine (T<sub>4</sub>) along with glucocorticoids if they undergo urgent or emergent surgery.

Thyroid replacement therapy can be initiated in the newly diagnosed patient with mild to moderate disease who undergoes noncardiac surgery at the same dose and schedule that would have been initiated in the outpatient setting. Patients already on therapy can take their usual dose of medication the morning of surgery. Levothyroxine (synthetic T<sub>4</sub>) has a half-life of 5 to 9 days and so oral doses can be missed for several days after surgery in a patient who is not eating. Liothyronine (synthetic T<sub>3</sub>) has a shorter half-life of 1.5 days. About 80% of levothyroxine is absorbed enterally in the duodenum and proximal jejunum, and, therefore, patients who are fed with a percutaneous jejunostomy tube may not adequately absorb levothyroxine over a prolonged period of time.<sup>37</sup> In those cases, infusion intravenously or through a nasogastric tube may be warranted. Intravenous levothyroxine should be reduced to 80% of the oral dose.

There is controversy regarding the initiation of thyroid hormone replacement in those patients who undergo cardiac surgery. A common concern is that treatment may provoke or exacerbate ischemia, though a large early study showed that less than 1% of newly diagnosed hypothyroid patients developed angina in the first 6 months of therapy.<sup>38</sup> A small retrospective study showed no difference in outcome in coronary artery bypass graft (CABG) between hypothyroid patients with mild to moderate hypothyroidism compared to those who were euthyroid on replacement.<sup>39</sup> A prospective study showed no difference in outcome from CABG between patients with mild to moderate hypothyroidism and those without the disease.<sup>40</sup> A more recent prospective study evaluated 58 consecutive patients on thyroid replacement in a sample of 3,631 patients who underwent CABG over a 7-year period. Women with hypothyroidism on hormone replacement had an excess 30-day mortality compared to men with hypothyroidism on replacement. Levothyroxine dose and serum thyroxine level were inversely associated with mortality. However, the study was limited in several ways. The number of hypothyroid patients was small, and the prevalence of hypothyroidism in the study sample was likely underestimated because thyroid hormone levels were not checked preoperatively in all patients.<sup>41</sup> Given the conflicting studies, the need for thyroid replacement in newly diagnosed or undertreated hypothyroid patients undergoing cardiac surgery needs to be assessed on an individual basis.

In a case series of 136 post-laryngectomy head and neck cancer patients, wound complications were twice as frequent in those who were hypothyroid.<sup>32</sup> Case reports documented rapid healing of fistulas refractory to conservative therapy in head and neck cancer patients if occult hypothyroidism was treated.<sup>42</sup> Hypothyroidism should be suspected in any postoperative patient who develops unexplained heart failure, prolonged ileus or neuropsychiatric complications. Myxedema coma is rare, but surgery can precipitate it.<sup>43–44</sup> It should be considered in any hypothyroid patient who develops seizures, shock or coma and should be treated in an ICU with intravenous T<sub>3</sub> and T<sub>4</sub> as well as glucocorticoids.<sup>45</sup>

## The Patient with Hyperthyroidism

### Introduction

Thyrotoxicosis carries risk for the perioperative patient. Thyroid hormone exerts direct inotropic and chronotropic effects on cardiac muscle, and it influences the sympathetic nervous system and vasculature. Manifestations of thyrotoxicosis include systolic hypertension with a widened pulse pressure, tachycardia, decreased systemic vascular resistance, and increased cardiac output, all of which can lead to angina, congestive heart failure and arrhythmias.<sup>46–48</sup> Thyroid storm is a rare but life-threatening complication of thyrotoxicosis. It can present with fever, tachycardia, and confusion, and can quickly progress to cardiovascular collapse and death.<sup>49</sup> The stress of surgery can provoke perioperative complications in the undiagnosed or undertreated hyperthyroid patient.

### Preoperative Assessment

Like hypothyroidism, the prevalence of hyperthyroidism is higher in women and increases with age.<sup>50–52</sup> It may also be higher in patients with thyroid cancer. Two European studies showed a prevalence of hyperthyroidism of 9.1% in 217 patients<sup>53</sup> and 14% in 110 patients who underwent thyroidectomies for differentiated cancer.<sup>54</sup> Struma ovarii is a teratoma of the ovaries that contains thyroid tissue. Tumors may be benign or malignant, but in either case, a small percentage of patients can develop ectopic hyperthyroidism from them.<sup>55</sup> Patients with previous radiation therapy for Hodgkin's disease have an elevated risk, not just for hypothyroidism but for Graves' disease.<sup>23</sup> Patients who have undergone past treatment for hyperthyroidism may develop recurrent disease.<sup>56</sup> While screening for hyperthyroidism is not warranted in the general surgical population, patients with previous thyroid surgery or treatment, patients with clinical symptoms suggestive of hyperthyroidism and patients with cancers associated with it should be tested for thyroid function.

## Perioperative Management

Elective surgery in a patient with hyperthyroidism should be postponed until the patient is clinically and biochemically euthyroid. Preoperative treatment should include a combination of therapies directed against the thyroid gland, against peripheral effects of thyroid hormone, and against systemic decompensation (Table 2).<sup>57</sup> The thionamides, propylthiouracil (PTU) and methimazole, block thyroid hormone synthesis but not its release. Though it may take 3 to 8 weeks for the patient to become euthyroid while on them, they are preferred therapy. Methimazole has a longer duration of action and once-daily dosing, while PTU has the advantage of blocking peripheral T<sub>4</sub> to T<sub>3</sub> conversion. Both can cause agranulocytosis in less than 1% of patients.

Iodine can be beneficial in patients who need rapid preparation or combination therapy for severe thyrotoxicosis. It decreases the synthesis

of new hormone,<sup>58</sup> but in hyperthyroid patients it may paradoxically worsen thyrotoxicosis by temporarily providing substrate for more thyroid production.<sup>59</sup> Thus a thionamide should be given at least an hour before its administration. Iodine can be given orally through Lugol's solution, or iopanoic acid, a radiographic contrast agent. It can also be given intravenously or rectally.

All thyrotoxic patients should be treated with beta-blockade unless there are contraindications to its use. At high doses propranolol blocks peripheral conversion of T<sub>4</sub> to T<sub>3</sub>, but other β-blockers have no effect on hormone production. Rather, they treat tachycardia and help prevent cardiac complications such as arrhythmia. Higher and more frequent doses of β-blockers than usual may be necessary because of increased metabolism in the hyperthyroid patient.<sup>60</sup> Heart rate and blood pressure should be used as a guide for dosing. Longer acting β-blockers such as atenolol given the morning of surgery provide longer perioperative blockade.<sup>61</sup> Intravenous propranolol, metoprolol or esmolol can be used for the patient who cannot take oral medication.

Some patients may need rapid preparation for urgent or emergent surgery, and reports have shown this can be done safely in an average of seven days.<sup>62,63</sup> A regimen for this preparation is detailed in Table 3.

All patients should be monitored closely for intraoperative and postoperative cardiac complications, including ischemia, heart failure, and arrhythmia. Thionamides should be continued in the postoperative patient who has not undergone thyroidectomy. These can be given rectally for the patient who cannot take them orally.<sup>64,65</sup> Adrenal reserve may be low in the thyrotoxic patient, and corticosteroid replacement should be considered in the decompensating or critically ill postoperative patient. Corticosteroids treat adrenal insufficiency and may block peripheral conversion of T<sub>4</sub> to T<sub>3</sub>. Thyroid carcinoma, an elevated free thyroxine level and substernal thyroid disease are risk factors for post-thyroidectomy hypocalcemia, and postoperative calcium should be checked in those cases.<sup>66</sup>

Although thyroid storm is now rare, it should be considered in patients with high fever, gastrointestinal symptoms (such as nausea, vomiting, diarrhea or abdominal pain), and cardiac or neuropsychiatric decompensation.<sup>49</sup> Therapy is similar to the patient with severe thyrotoxicosis but is given at higher doses and includes beta-blockade, thionamides, iodinated contrast agents, iodine and corticosteroids. Supportive care in the ICU is essential and should include hydration, nutrition with glucose and vitamins, antipyretics, cooling blankets, and treatment of cardiac decompensation. Acetaminophen should be given for fever because aspirin may increase thyroid hormone concentrations by

bid = twice a day; IM = intramuscularly; IV = intravenously; PO = by mouth; qid = four times a day; q4h = every 4 hours; q6h = every 6 hours; q8h = every 8 hours; T<sub>3</sub> = triiodothyronine; T<sub>4</sub> = thyroxine; tid = three times a day.

interfering with protein binding of T<sub>3</sub> and T<sub>4</sub> (see Table 2).

## The Patient on Exogenous Corticosteroids

### Introduction

Millions of prescriptions for oral corticosteroids are written yearly in the United States for autoimmune and inflammatory diseases such as asthma or rheumatoid arthritis.<sup>67</sup> Corticosteroids are also frequently used in cancer patients in chemotherapy regimens and as treatment for complications of malignancy and chemotherapy, such as nausea or increased intracranial pressure and swelling from primary and metastatic brain tumors.

Adrenal gland production of cortisol is an essential endocrine response to stress and is caused by activation of the hypothalamic-pituitary-adrenal (HPA) axis and increased serum corticotropin (also called ACTH). Cortisol maintains vascular tone, endothelial integrity, and vascular permeability, and also potentiates the vasoconstrictor actions of catecholamines.<sup>68</sup> Destruction of the adrenal glands through infection, infarction, hemorrhage, or autoimmune disease leads to primary adrenal insufficiency. Secondary adrenal insufficiency can be caused by

exogenous corticosteroids that can suppress the normal feedback loop of the HPA axis. Chronic suppression may prevent sufficient innate cortisol production by otherwise normal adrenals during stress. Recovery of adequate adrenal function may be delayed after cessation of exogenous corticosteroids.

The stress of surgery can precipitate adrenal crisis in the cancer patient with underlying adrenal insufficiency and lead to fever, hypotension, shock, and death. Early case reports in the 1950s suggested that acute adrenal insufficiency occurred when patients' chronic corticosteroids were withheld in the perioperative period. In response to those reports, "stress dose" supplemental steroid regimens were devised to give to patients currently or previously on corticosteroids who underwent surgery to ensure adequate cortisol coverage and to prevent adrenal crisis. Patients often received large doses of corticosteroids for several days in the perioperative period. More recent authors have questioned the need for, or the amount of, supplemental perioperative corticosteroids.<sup>69</sup> Some have argued that patients only need to continue on their usual dose of corticosteroids in the surgical period.<sup>70</sup> Although other recent studies have shown that perioperative corticosteroids may carry additional benefits, such as prevention of postoperative nausea and

modulation of inflammatory mediators that may improve surgical outcomes, they can also increase the risk of infection and mask a febrile response to it.<sup>71-73</sup> Corticosteroids can provoke or increase hyperglycemia, affect wound healing, and contribute to gastrointestinal hemorrhage and perforation.<sup>74-77</sup> Management of patients on chronic corticosteroids must balance the risk of adrenal crisis from insufficient corticosteroid supplementation against the risk of complications from excessive corticosteroid supplementation.

The dose and duration of exogenous corticosteroids that cause suppression of the HPA axis are highly variable among individuals. It seems clear that doses equivalent to less than 5 mg of morning prednisone or prednisone given on an every-other-day regimen do not cause HPA axis suppression no matter how long they are given.<sup>78,79</sup> Long-acting corticosteroids such as dexamethasone, which are frequently given to cancer patients, may cause HPA suppression sooner than those with shorter half-lives. A number of small studies showed that patients recover HPA function quickly (within one to two weeks) after given high doses of corticosteroids for 5 to 30 days, but a few patients may remain suppressed for much longer.<sup>80,81</sup> There are studies that show biochemical evidence of HPA axis suppression in patients on chronic, high-dose, inhaled or potent topical steroids, and case reports of adrenal insufficiency with stress in patients, especially children, on those medications.<sup>82,83</sup> There are only a few older, poorly designed studies that look at how long it takes for the HPA axis to recover after a course of prolonged corticosteroids.

Some have argued that the corticotropin stimulation test should be used to assess patients preoperatively for HPA axis suppression so that only those who need supplemental corticosteroids receive them. Though it is a very sensitive test for primary adrenal insufficiency, its sensitivity is less for secondary adrenal insufficiency.<sup>84</sup> Furthermore, there may not be time for the patient to undergo the test prior to surgery. In addition, a few small studies showed that even those patients who have documented HPA axis suppression from exogenous corticosteroids do not develop adrenal insufficiency—even when they go to surgery without corticosteroid coverage.<sup>70,85,86</sup> Laboratory evidence of HPA axis suppression does not always correlate with clinical adrenal insufficiency.

Without a sufficient number of well-designed studies to provide reliable evidence for decisions on which patients on chronic corticosteroids need perioperative supplementation, the consultant must rely on consensus. The likelihood of adrenal crisis in a surgical patient on chronic corticosteroids is low, but the morbidity and mortality from untreated adrenal crisis is high, and, therefore, it must be prevented. A conservative approach is to

consider any patient who has been on greater than 5 mg of prednisone for more than a week as possibly suppressed. Though there is still disagreement among experts on what dose and duration to use as a cut-off for presumed HPA axis suppression, there is more agreement on what amount of corticosteroid needs to be given for specific types of procedures.

Cortisol levels peak postoperatively in the early recovery period, probably in response to pain, but usually return to normal 24 hours after surgery.<sup>87,88</sup> The average corticosteroid requirement for minor surgery is 25 mg/d of hydrocortisone; for moderate stress surgery, it is 50 to 75 mg/d; and for major surgery, 100 to 150 mg/d.<sup>69</sup> Though the response to severe stress or critical illness can be 200 to 500 mg of cortisol per day, responses of more than 200 mg/d in the first 24 hours after surgery are rare. Therefore, many patients on corticosteroids will only need to take their usual dose for minor or moderate stress surgery to meet the hydrocortisone needs of the procedure. For example, patients on 7.5 mg daily of prednisone who undergo a minor procedure, such as an inguinal hernia repair, are already on the equivalent of more than 25 mg of hydrocortisone. They should take the usual dose the morning of surgery and do not need supplementation with additional corticosteroids (Table 4).

### Preoperative Assessment

A patient's type and dose of corticosteroid and duration of use should be documented. Use in the 6 months to a year before surgery should be investigated, especially in patients with underlying diseases that are treated with corticosteroids. Previous complications from corticosteroids, such as osteoporosis or infections, should be noted. The decision to continue with the usual corticosteroid dose or to add a supplemental dose needs to be communicated to the patient and the anesthesiologist. The consultant must be familiar with corticosteroid equivalencies in order to choose dosing compatible with the patient's corticosteroid regimen and the stress of the anticipated surgery (Table 5).

**Table 5 Supplemental Corticosteroid Regimen**

Type of surgical procedure	Corticosteroid supplementation
Minor	If currently taking corticosteroids take usual dose in am, no supplementation needed If not currently on corticosteroids, take the equivalent of 25 mg of hydrocortisone
Moderate	50 to 75mg hydrocortisone equivalent over the day of surgery Resume usual dose POD 1
Major	100 to 150 mg of hydrocortisone equivalent over day of surgery Taper by 1/2 to usual dose over 24-48 hours
Critical Illness	50 to 100 mg hydrocortisone IV q6 to 8 or .18 mg/kg/h continuous infusion plus 50ug fludrocortisone until shock resolved.

Reproduced with permission from.

### Perioperative Management

Usual and supplemental oral corticosteroids can be given the morning of surgery if it is minor or of short duration. Supplemental corticosteroids given in addition to the patient's usual oral dose should be given intravenously prior to intubation for prolonged or complex procedures. Additional doses may need to be given intraoperatively or in recovery depending on the length and stress of surgery and half-life of the corticosteroid used. Corticosteroids with longer half-lives such as dexamethasone may be preferred over ones with shorter half-lives, such as hydrocortisone, to achieve longer lasting coverage and less fluctuation in cortisol levels in the surgical period. Supplemental corticosteroids do not need to be given to patients on high-dose inhaled or topical

corticosteroids unless they have documented HPA axis suppression. However, if they develop perioperative hypotension or other signs of adrenal insufficiency, they should be assessed and treated promptly.

In the absence of complications such as bleeding, ischemia, or infection, the patient can resume his or her usual corticosteroid dose the day after minor or moderate stress surgery. Patients who undergo major surgery should probably be tapered over 24 to 48 hours to their usual dose.

Adrenal insufficiency should be suspected in any patient who develops fever, hypotension, or shock, postoperatively. Confusion, hyperkalemia, and hyponatremia may also be indications of adrenal insufficiency. Though acute primary adrenal insufficiency is uncommon in the surgical period, it can occur in response to prolonged hypotension or overwhelming infection or hemorrhage involving both adrenals.

The surgical patient in the ICU may need special evaluation of adrenal function. In critical illness, and in particular septic shock, inflammatory mediators may suppress the HPA axis. Tissues and receptors may become resistant to corticosteroids, and, despite normal or even high levels of cortisol, a relative adrenal insufficiency may develop. Some studies have shown that, in these patients, supplemental corticosteroids may decrease mortality.<sup>89,90</sup> Therefore, surgical patients with septic shock resistant to vasopressors should have a random cortisol level checked. If it is less than 20, they should be treated with corticosteroids. If the level is 20 to 34, an ACTH stimulation test should be done. If the rise in cortisol in response to the test is less than 9, corticosteroids should be given (see Table 5).

## The Patient with Electrolyte Abnormalities

### Hypercalcemia

#### General Overview

Malignancy associated hypercalcemia is a life-threatening disorder with high morbidity and mortality. Approximately one-third of all outpatients who present with hypercalcemia and half of all hospitalized patients with hypercalcemia have a malignancy-related etiology.<sup>91</sup> It is the most common life-threatening metabolic disorder associated with cancer.<sup>92</sup> Hypercalcemia is estimated to occur in 10% to 20% of cancer patients during the course of their disease, but the symptoms are often overlooked because they are nonspecific and are dismissed as being due to the underlying malignant process or its therapy.<sup>93,94</sup>

Various types of malignancies have been associated with hypercalcemia. However, over half of the patients with malignancy-associated hypercalcemia have a lung or breast carcinoma.

**Table 4 Corticosteroid Equivalents**

Corticosteroid	Relative Potency	Equivalent Dose (mg)	Biological Half-life (hr)
Hydrocortisone (cortisol)	1	20	8 to 12
Cortisone	.8	25	8 to 12
Prednisone	4	5	18 to 36
Prednisolone	4	5	18 to 36
Methylprednisolone	5	4	18 to 36
Triamcinolone	5	4	18 to 36
Dexamethasone	25 to 50	.5	35 to 54

Adapted from Krasner AS. Glucocorticoid-induced adrenal insufficiency. JAMA 1999;282:671-6.

Other malignancies frequently associated with hypercalcemia include multiple myeloma, squamous carcinomas of the head and neck, and carcinomas of the kidney and ovary.<sup>95</sup> The relative frequency of the type of malignancies associated with hypercalcemia is outlined in Table 6.

Malignancy-associated hypercalcemia is predominantly due to increased mobilization of calcium from bone, and to a minor degree from increased renal tubular calcium reabsorption. There are three major mechanisms by which this occurs: tumor cell release of parathyroid-hormone-related peptide, induction of local osteolysis by tumor cell mediators, and increased production of calcitriol (1, 25 hydroxy-vitamin D<sub>3</sub>) by tumor cells.<sup>96</sup>

#### Preoperative Assessment

Free intracellular calcium initiates or regulates muscle contraction, neurotransmitter release, hormone secretion, enzyme action, and energy metabolism. Thus, symptoms of hypercalcemia are due to the various end-organ abnormalities associated with these functions.<sup>97</sup> The degree of symptomatology is linked more to the rate of increase in serum calcium than to that of the absolute serum calcium level.<sup>98</sup> Mild to moderate hypercalcemia is often asymptomatic, but symptoms could include anorexia, nausea, vomiting, constipation, polydipsia and polyuria, muscle weakness, and fatigue. When the hypercalcemia is more severe (corrected serum calcium of more than 14.0 mg/dL), the patient will often develop mental status changes such as lethargy, headache, confusion or obtundation. Cardiac abnormalities are also common and include shortened QT intervals, bradycardia, ST-T wave abnormalities and arrhythmias. Peptic ulcer disease is more prevalent in hypercalcemic patients because the production of gastrin and gastric acid is increased. Approximately one-third of all hypercalcemic patients are hypertensive; the hypertension usually resolves with successful treatment of the primary disease.

**Table 6 Malignancies Associated with Hypercalcemia**

	No. of Patients	Percent of Total
Breast	40	36
Lung	26	23
Myeloma	15	14
Head and Neck	9	8
Kidney	9	8
Gastrointestinal	6	5
Bladder	3	3
Undifferentiated	3	3
Total	111	100

Reproduced with permission from Adami S and Rossini M.<sup>95</sup>

It is important to check calcium levels in the perioperative assessment of patients with malignancy—regardless of symptomatology. In this population, ionized calcium levels are a better alternative than total serum calcium levels. Because half of the total extracellular calcium is protein-bound (mainly albumin) or complexed with anions, decreased serum albumin levels can markedly affect the result of the measured total serum calcium. In a patient with abnormal albumin levels, the total serum calcium needs to be corrected; every change in total serum albumin of 1 g/dL is associated with a 0.8 mg/dL change in total serum calcium. This is important to keep in mind because of the high prevalence of low serum albumin in this population. Alternatively, plasma concentrations of ionized calcium represent the hormone-regulated and biologically active form of calcium and do not need to be corrected for albumin. Ionized calcium levels are therefore a better alternative for calcium measurement in the cancer patient.

The acute treatment of hypercalcemia is hydration with normal saline. The benefit of hydration is twofold. Hydration lowers serum calcium concentrations by dilution and sodium acts to inhibit renal tubular absorption of calcium. Once the patient is volume-expanded, furosemide-induced diuresis will facilitate renal elimination of calcium. Complications of these interventions include hypomagnesemia and hypokalemia, and, thus, magnesium and potassium need to be followed closely and replaced as necessary. Phosphate levels should be monitored and replaced because hypophosphatemia decreases calcium uptake into bone, increases calcium, and stimulates breakdown of bone. Hydration and diuresis, accompanied by phosphate repletion, suffice for the acute management of most hypercalcemic patients.

#### Intraoperative Management (Communication with Anesthesia)

Patients with mild or moderate hypercalcemia (12 to 14 mg/dL) who have normal renal and cardiovascular function present no special preoperative problems. Because severe hypercalcemia (> 14 mg/dL) can result in hypovolemia, normal intravascular volume and electrolyte status should be restored before anesthesia and surgery are begun. However, asymptomatic hypercalcemia is associated with minimal risk in the euvolemic patient if the corrected calcium concentration is less than 12 mg/dL. The anesthetic management of a patient with hypercalcemia should involve maintenance of hydration and urine output with sodium-containing fluids.<sup>97</sup>

Intraoperative monitoring of the electrocardiogram is useful to detect cardiac conduction defects with prolonged PR or QT intervals and/or

widening of the QRS complex. Hypercalcemic patients who have skeletal muscle weakness may have decreased requirements for muscle relaxants, whereas hypercalcemia might also antagonize the effects of nondepolarizing muscle relaxants. In view of this unpredictable response to muscle relaxants, many anesthesiologists will decrease the initial dose of these drugs and monitor the patient's response with a peripheral nerve stimulator.<sup>99</sup>

#### Postoperative Management

Postoperative management of hypercalcemia in this population should include more definitive treatment of the hypercalcemia. The most effective way to control the hypercalcemia of malignant disease is by expedited therapy (chemotherapy, radiation therapy or surgical therapy) aimed at eradicating or reducing the tumor burden.<sup>94</sup> To control the serum calcium level in the interim, an antihypercalcemic drug can be used.

There have been several antihypercalcemic therapies used in the past, but bisphosphonates have become the drug of choice because they inhibit osteoclast function—which is the final common pathway for bone resorption in both humoral and local osteolytic hypercalcemia (bone resorption is increased in the majority of patients with malignancy-induced hypercalcemia).<sup>100</sup> An infusion of either intravenous zoledronic acid or pamidronate is most commonly used. In the presence of more severe or symptomatic hypercalcemia, intramuscular calcitonin can be used in conjunction with the bisphosphonate.<sup>94</sup> The serum calcium will usually reach a nadir at 5 to 7 days. The duration of normocalcemia is variable, depending on the tumor type, tumor burden, and patient differences. Calcium concentrations should be monitored on a weekly basis and repeat treatment with zoledronic acid or pamidronate at 2- to 3-week intervals is recommended until the patient has definitive treatment of the malignancy and the hypercalcemia has resolved. Unfortunately, the malignant process is often quite advanced when hypercalcemia occurs and the patient usually dies within a few weeks.

#### Hyponatremia

##### General Overview

Hyponatremia is defined as a decrease in serum sodium concentration below 136 milliequivalents per liter (mEq/L).<sup>101</sup> It is one of the most common electrolyte disorders in the general population, occurring in 1 to 20% of all hospitalizations.<sup>102–107</sup> Similarly, hyponatremia has been reported in about 4% of cancer patient hospitalizations.<sup>108</sup>

Many malignancies have been associated with hyponatremia. However, more than 50%

of patients with malignancy-associated hyponatremia have lung (both non-squamous cell and squamous cell), breast and head/neck carcinomas. Other malignancies that are occasionally associated with hyponatremia are gastrointestinal neoplasms, acute leukemias, non-Hodgkin lymphomas and other hematological malignancies.<sup>108</sup>

Hyponatremia in the setting of malignancy has several potential etiologies. The most common causes are syndrome of inappropriate antidiuretic hormone (SIADH) secretion and depletion (gastrointestinal, renal losses or poor oral [PO] intake) states, occurring in 35% and 33%, respectively, of hospitalized cancer patients.<sup>108</sup> Of course, hyponatremia in this population can also be secondary to certain antineoplastic drugs, by iatrogenic causes, and by other comorbid conditions. Table 7 outlines the common causes of hyponatremia in cancer patients categorized into one of three categories: 1) related to tumor or metastasis, 2) related to therapy, or 3) related to secondary complications.<sup>109</sup>

#### Preoperative Assessment

The symptoms of hyponatremia are primarily neurologic, and the severity is dependent on the rapidity of onset and absolute decrease in plasma sodium. Early on, patients may be asymptomatic or may complain of nausea and malaise. As the plasma sodium falls, the symptoms progress to include headache, lethargy, confusion, and obtundation. Stupor, seizures, and coma do not usually occur unless the plasma sodium falls acutely

below 120 mEq/L.<sup>110</sup> Cardiac symptoms (ventricular tachycardia and fibrillation) usually occur late, at levels of 110 mEq/L or lower.<sup>97</sup> However, electrocardiogram (ECG) changes (widened QRS and elevated ST segment) are noted at levels of 115 mEq/L.<sup>99</sup> In chronic hyponatremia, adaptive mechanisms designed to preserve cell volume occur and tend to minimize the increase in intracellular fluid volume, and, thus, patients are less symptomatic at lower sodium levels.<sup>110</sup> Since serum sodium concentrations of less than 130 mEq/L have been associated with a 60-fold increase in mortality, early recognition and appropriate therapy are important.<sup>109</sup>

A careful history and physical examination is important to help identify the etiology of the hyponatremia. An assessment of fluid intake and output should include oral and parenteral intake, as well as extracellular volume losses from gastrointestinal sources, from skin and from urine. The physical exam should focus on volume status. Postural hypotension, dry mucous membranes, and poor skin turgor suggest decreased extracellular fluid volume. Peripheral edema and jugular venous distention suggest increased extracellular fluid volume. However, commonly, the patient is euvoletic, and none of these findings are present.

Laboratory evaluation should include plasma osmolality, electrolytes, blood urea nitrogen and creatinine, glucose, urine sodium and urine osmolality. The results of the history, physical examination findings, and the laboratory evaluation should help to narrow down the etiology of the hyponatremia, which is crucial to implementing an appropriate treatment plan aimed at normalizing the serum sodium levels.

Acute treatment of hyponatremia and the urgency of sodium correction depend on the presence and severity of the symptoms and the rapidity in which the hyponatremia has developed. The treatment of hyponatremia is directed by the presumed etiology and by the extracellular fluid volume status. For patients with hypovolemic hyponatremia, treatment should involve replacing the extracellular fluid volume with isotonic saline, which will restore normal intrarenal hemodynamics and suppress vasopressin release. For patients with hypervolemic hyponatremia, the mainstay of treatment consists of sodium and water restriction, often with the use of loop diuretics to facilitate free water excretion. Those patients with euvoletic hyponatremia are the most common and, perhaps, the most difficult to treat in that patients usually have to adhere to strict water restriction.

In any patient with severe, symptomatic hyponatremia, a concentrated solution of saline can be used cautiously to replace the serum sodium up to 125 mEq/L, and then less aggressive measures can be instituted. If hypertonic saline

is necessary, the patient should be closely monitored in an intensive care setting where sodium levels and urine output can be monitored on an hourly basis. The rate of correction of the serum sodium concentration has been the subject of debate. A good rule of thumb is to correct the serum sodium at the rate in which the hyponatremia developed. If the patient developed hyponatremia and symptoms within 48 hours, a more rapid correction is safe. If the timeline of onset is unknown or greater than 48 hours, it is best to replace the serum sodium more slowly (10 to 12 mEq/L per day) to prevent delayed neurologic complications.<sup>109</sup>

#### Intraoperative Management

Asymptomatic hyponatremia is not associated with increased perioperative risk, provided that normal extracellular fluid volume is normalized.<sup>111</sup> Patients with symptomatic hyponatremia, however, need to be treated urgently and should not undergo any surgical procedure until the symptoms resolve.

Due to the decreased excitability of cells as a result of the hyponatremia, patients may have poor myocardial contractility and increased sensitivity to nondepolarizing muscle relaxants. Patients with hyponatremia may also develop unexpected hypotension in response to cardiac depressant anesthetic drugs due to the hyponatremic effect on myocardial function.<sup>99</sup>

Preventive measures, such as preference for the use of isotonic saline for intraoperative fluid replacement in patients who are “at risk” for hyponatremia are also important. Those felt to be “at risk” are patients with malignancies known to be associated with SIADH, patients with CNS lesions, patients on positive pressure ventilation, and patients who are currently on chemotherapy. For these patients, it is important to monitor sodium levels closely and to avoid the use of hypotonic fluid replacement if at all possible.

#### Postoperative Management

The sodium levels need to be monitored closely in the postoperative period, as well, because pain, stress, and opiate use can also stimulate ADH secretion. In addition, postoperative oral intake is usually reduced, and fluid replacement can often be excessive. All these factors can worsen hyponatremia.

The postoperative management of patients with malignancy-associated hyponatremia should be directed at treating the underlying neoplasm or correcting the underlying disorder felt to be contributing to the hyponatremia. The cornerstone of hyponatremia treatment is fluid management. However, for patients who are unresponsive or noncompliant with water restriction, there are pharmacologic agents that interfere with

**Table 7 Major Causes of Hyponatremia in Cancer Patients**

#### *Related to Tumor or Metastasis*

Syndrome of inappropriate antidiuretic hormone (SIADH) secretion  
Adrenal insufficiency

vasopressin action—the most common of which is demeclocycline. Demeclocycline interferes with the effect of antidiuretic hormone at the level of the collecting tubule and is most effective for patients with hyponatremia due to SIADH, but can also be used for patients with other causes of hyponatremia in whom loop diuretics are either contraindicated or ineffective.<sup>112</sup>

# Perioperative Cardiopulmonary Complications and Consideration in the Cancer Patient

Valerie Seabaugh, MD

Cancer patients are prone to many cardiothoracic complications, even if their primary tumor site is distant from the chest. Complications, such as pleural effusions, pulmonary embolism (PE), and cardiac compromise (from a variety of mechanisms), are commonly encountered in the oncology patient. These cardiothoracic complications can be particularly devastating—if not lethal—to this already physiologically compromised patient population. In fact, oncology patients admitted to the intensive care unit (ICU) with a complication requiring mechanical ventilation have a 65 to 75% mortality rate.<sup>1,2</sup> Needless to say, in patients at increased risk for cardiothoracic complications, it is not surprising that there are unique considerations for cancer patients in the perioperative phase of their treatment. This chapter will focus on these special considerations, as well as the frequent and infrequent complications encountered in thoracic surgery for cancer patients.

## Pre-Operative Considerations

Lung cancer consistently remains one of the leading causes of cancer death in the United States.<sup>3</sup> The 5-year mortality of nonoperative treatment for stage one lung cancer is almost 83%.<sup>4</sup> In contrast, mortality from lung resection surgery is about 3 to 4%.<sup>5</sup> Because resection remains the only hope for cure, every patient presenting with a lung tumor deserves careful consideration for surgery.

In evaluating patients preoperatively for pulmonary resection, a balance must be struck between the patient's mortality risk of nonoperative treatment versus the mortality risk of surgical lung resection. Because many of the patients presenting for lung resection have a smoking history, the concurrence of chronic obstructive pulmonary disease (COPD) with lung cancer is quite high. The challenge becomes predicting which patient with already compromised

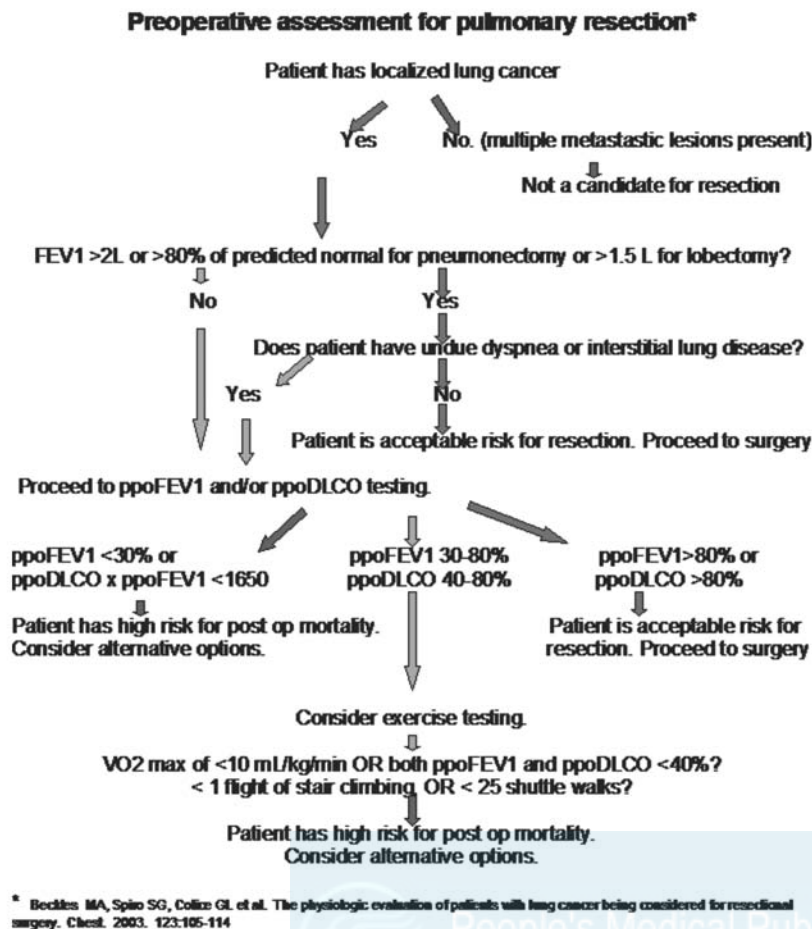

pulmonary function will tolerate loss of lung tissue (Figure 1).

Forced expiratory volume in one second (FEV1) is a commonly used spirometry study that has been shown to be a predictor of postoperative complications.<sup>6</sup> Although this test is effort-dependent, it does help quantify the extent of disease in COPD patients. In the patient being considered for pneumonectomy, an FEV1 greater than 2 L indicates the patient is in a lower risk category and can proceed to surgery. Alternatively, in the case of smaller adults, an FEV1 greater than 80% of predicted suggests the patient will tolerate pneumonectomy. If the FEV1 is greater than 1.5 L the patient is a suitable candidate for lobectomy. Additionally, each patient must be assessed for radiographic evidence of interstitial disease and queried about level of dyspnea during exercise. If there is interstitial disease or a history of undue dyspnea on exertion, the diffusing capacity of carbon monoxide (DLCO) should also be measured. A predicted postoperative DLCO (ppoDLCO) of greater than 80% has been shown to have a very low postoperative mortality. A ppoDLCO value less than 40% of predicted is very sensitive as an indicator of a high postoperative mortality risk, and a ppoDLCO less than 80% is indicative of a threefold increased risk of pulmonary complications.<sup>7</sup> Therefore, patients with a ppoDLCO greater than 80% may proceed to surgery without further testing. For patients with ppoDLCO less than 40%, the product of the ppoDLCO and ppoFEV1 has been shown to be a sensitive predictor of surgical outcome. If the ppoDLCO × ppoFEV1 is less than 1,650, there is a high risk of mortality, and other options should be considered.<sup>8</sup> For patients where the ppoFEV1 is 30 to 80% and the ppoDLCO is 40 to 80%, additional exercise testing is recommended.

The maximal oxygen consumption ( $\text{VO}_2$  max) is calculated from measuring exhaled gases

during exercise. During exercise, oxygen uptake increases incrementally up to a maximum amount. Beyond this level of activity, there is no increase in oxygen entering the circulation from the lungs. This peak uptake is the  $\text{VO}_2$  max and is thought to be a reflection of a patient's pulmonary reserve. A  $\text{VO}_2$  max less than 10 mL/kg/min portends an unacceptably high risk for postoperative complications and death. If the  $\text{VO}_2$  max is greater than 20 mL/kg/min, the risk is acceptable for surgery. If the  $\text{VO}_2$  is less than 15 mL/kg/min and the ppoFEV1 and DLCO are both less than 40%, the danger of death is too high for surgical treatment.<sup>8</sup> For patients testing between 10 to 20 mL/kg/min, decision-making should be based on overall clinical picture and additional testing. Additional exercise testing to consider is the patient's ability to climb a flight of stairs or to walk at a progressively faster pace. Stair climbing is a rather simple form of exercise testing that was used to evaluate lung resection candidates prior to the availability of pulmonary function testing. A patient unable to climb one flight of stairs has been shown in several studies to be in danger of serious postoperative complications.<sup>9-12</sup> Shuttle walking is a test that estimates pulmonary reserve based on walking between two points that are 10 m apart. Each trip between the markers is timed by an audio signal that is shorter for each repetition, forcing the patient to walk at an escalating pace. The number of completed trips between the markers before the patient must stop due to dyspnea is their shuttle-walking score. Inability to complete at least 25 shuttles during two tests correlates with a high mortality risk and approximates a  $\text{VO}_2$  less than 10 mL/kg/min.<sup>9-12</sup>

For patients with conflicting test results or on the borderline of acceptability for surgical treatment, a broader approach must be used to consider their surgical candidacy. Age should not be used as a selection criteria since there is suggestion that elderly patients with adequate

**FIGURE 1** Preoperative assessment for pulmonary resection.

pulmonary reserve can tolerate resection.<sup>13</sup> Rather, patients need to be presented with the options and known risks based on their cardiopulmonary function profile and allowed to weigh the risks versus the potential benefits for themselves.

## Pulmonary Complications

### Pleural Effusions

Pleural effusions are a common and troublesome complication in oncology patients in both the acute inpatient and the chronic office-based setting. Because of their frequent presence in patients with all types of neoplasms, a discussion of the physiology of the pleura and the mechanism of fluid accumulation is necessary to understand their treatment.

### Physiology of the Pleura

The pleura is a membranous surface covering the lungs, mediastinum, diaphragm, and intrathoracic chest wall. This surface comprises the parietal and visceral pleura. The visceral pleura covers the lung parenchyma, including the intralobar fissures. The parietal pleura provides coverage to the thoracic wall. The parietal pleura is made of loose, irregular connective tissue over which lies a single layer of mesothelial cells. Vessels and initial lymphatics are within this irregular connective tissue matrix. The connective tissue within the visceral pleura contains collagenous fibers (woven in a pleated fashion) which have two discrete functions in lung physiology. This woven layer helps create the elastic recoil of the lung allowing for passing exhalation.

Additionally it provides the lung with resistance to overinflation.<sup>14</sup>

### Physiology of Pleural Fluid Accumulation

There are two main pathophysiologic perturbations which lead to the formation of pleural fluid accumulation. Either the rate of pleural fluid accumulation has exceeded the rate of maximal fluid absorption, or the pleural space's ability to absorb the fluid has decreased. Of course, a combination of these two variables can also lead to fluid accumulation.

Ordinarily, there is a balance between the oncotic and hydrostatic pressure gradients, so that the net accumulation of fluid in the pleural space is zero. Under normal conditions, the hydrostatic fluid tension favoring movement from the capillaries to the pleural space is about 35 cm H<sub>2</sub>O. This number reflects about 5 cm H<sub>2</sub>O of negative pleural pressure pulling across the capillary, as well as 30 cm of H<sub>2</sub>O in capillary hydrostatic pressure within the vessel wall. Opposing this force out of the capillaries is the oncotic pressure exerted by protein and solute within the plasma of the capillary, which totals about 34 cm H<sub>2</sub>O. However, there is an oncotic pressure from the normal pleural fluid protein found within the space. This small amount of fluid contains some protein, even at baseline conditions. This protein opposes the capillary oncotic pressure by about 5 cm H<sub>2</sub>O. Therefore, the net oncotic pressure working against the hydrostatic pressure totals 29 cm H<sub>2</sub>O.<sup>14</sup>

As demonstrated in Figure 2, there is a 6 cm H<sub>2</sub>O pressure gradient favoring movement of fluid from the capillaries to the pleural space (35 cm H<sub>2</sub>O – 29 cm H<sub>2</sub>O = 6 cm H<sub>2</sub>O). In animal models, the rate of pleural fluid formation is 0.01 mL/kg/h.<sup>15</sup> The mechanism to clear this constantly forming pleural fluid is the lymphatic system. When challenged with increasing pleural fluid formation, the lymphatic system has the ability to absorb between 0.22 to 0.40 mL/kg/h.<sup>16,17</sup> Therefore, a 70-kg human can clear over 670 mL of pleural fluid in a 24-hour period (or 28 mL per hour).

With the physiologic and respiratory changes that accompany surgery, formation of pleural effusions is unfortunately common. In the setting of surgery (in the cancer patient, in particular), there are additional causative factors for the formation of pleural effusions.

In the setting of a gastrointestinal/abdominal tumor, cancer patients are at increased risk of malnutrition and, consequently, hypoproteinemia. Hypoproteinemia can decrease plasma oncotic pressure and, therefore, contribute to net movement of fluid out of the pleural capillary. Up to 8% of effusions may be associated with

**FIGURE 2** Summary of pleural fluid forces.

hypoproteinemia/hypoalbuminemia.<sup>18</sup> Hypoalbuminemia as the sole cause of pleural effusion, however, is controversial. In studies of four patient groups (divided into four discrete groups with serum proteins above 3.5 g/dL, from 2.1 to 3.5 g/dL, from 1.0 to 2.0 g/dL, and less than 1.0 g/dL), the incidence of an effusion was comparable among all the groups. In each patient in the group with serum albumin less than 1.0 g/dL, there was an additional causative factor for the effusion.<sup>19</sup> Hypoproteinemia may be a contributing factor more than a causative factor in the formation of pleural effusion.

Patients with abdominal neoplasms also frequently develop paradoxical pleural effusions. The mechanism for this fluid accumulation may be due to anatomic defects in the diaphragm. Porous openings in the diaphragm, as well as defects around the esophageal junction, which allow ascitic fluid to freely flow into the thoracic cavity, have been described.<sup>20</sup>

Obviously, cancer patients with metastatic disease many times have obstructed lymphatic channels, as well as plugged porous end-openings, and may not have the ability to accommodate even the normal rate of pleural fluid formation leading to fluid collection. Local tumor growth may also block the thoracic duct and create an effusion comprised of chyle (chylothorax). Cancer (specifically lymphoma) is responsible for about 75% of non-traumatic chylothoraces.<sup>14</sup>

Any perturbation that increases the rate of formation has the potential to create a large effusion. Compounding the inability to reabsorb normal pleural fluid, is the additional risk factor for congestive heart failure from prior cancer treatments. Chest radiation and chemotherapy can both contribute to the development of heart failure as well as edematous tissues with leaky capillary beds. In these patients, as pulmonary capillary pressure increases, fluid begins to leak out of the vessel wall and into the interstitium. This edema in the interstitium elevates the interstitial pressure and drives fluid across the visceral pleura into the pleural space.<sup>21,22</sup>

In the critically ill patient, the systemic inflammatory response (SIR) and sepsis (which can both be seen frequently in the postoperative

oncology patient) also cause capillary leak. Both the sepsis and SIR syndromes similarly result in effusion formation. Both syndromes are associated with the release of mediators that affect capillary permeability and create leaky vessels.

### Indications for Drainage of Effusions

Simply stated, there are three indications for drainage of pleural fluid. If the patient has a parapneumonic effusion or empyema, drainage of the infected fluid is indicated to clear the infection. Secondly, if the fluid is of unknown origin, drainage for diagnostic purposes is a reasonable approach. Thirdly, effusions can be drained for symptomatic relief in patients who have chronic or acute accumulations of a known origin.

Whether the effusion is of lung, pleural, or paramalignant origin the approach to management is similar. When constructing therapy plans for cancer patients with pleural effusions, symptomatology must first be assessed. Complaints of dyspnea and fatigue are not only associated with pleural effusions, but also concurrent cardiopulmonary disease, respiratory complications (such as PE & infection), and complications of chemotherapy or radiation therapy. If a symptomatic patient with a pleural effusion reports relief of dyspnea with thoracentesis and the post-procedure chest x-ray shows lung re-expansion, there are several options for long-term management. In patients deemed to have only a few months expected survival, periodic therapeutic thoracentesis is a reasonable approach to palliate symptoms. In patients with longer expected survival, chemical pleurodesis by chest tube or thoroscopic technique can be considered. Pleuroperitoneal shunting, permanent pleural drainage catheters, pleurectomy/pleural abrasion and systemic therapy are additional options. In patients with non-small cell lung cancer, recurrent effusion, and improvement with thoracentesis, pleurodesis is recommended.<sup>23</sup> In patients with small cell lung cancer, systemic chemotherapy is recommended. There is also data to suggest that effusions from other types of cancer, such as breast, lymphoma, prostate, ovarian, thyroid, and germ cell neoplasms, may respond to systemic chemotherapy.<sup>24</sup>

### Preoperative Pleural Fluid Drainage

In a symptomatic patient being considered for surgery or a general anesthetic, drainage of a large effusion may be indicated for the potential benefit of increasing lung expansion and facilitating ventilation.<sup>25</sup> However, in the surgical candidate without symptoms of dyspnea, preoperative drainage is not necessary given the continued ability to effectively ventilate and oxygenate the patient.<sup>26</sup>

### Postoperative Pleural Fluid Drainage

In the immediate postoperative setting, pleural effusion drainage may be indicated if there is difficulty in ventilator weaning or if a pleural effusion is felt to be the source of dyspnea threatening a patient to be reintubated. If there is any suspicion of an effusion becoming contaminated and developing into an empyema, then surgical intervention is absolutely necessary for drainage and decortication of the infected material.

### Perioperative Pulmonary Embolism

The association between pulmonary thromboembolism and malignancy has been known since 1865. Malignancy along with stroke, immobilization, recent surgery, and a history of previous thromboembolism are the five most common risk factors for developing pulmonary embolism.<sup>27</sup> In one study, 17% of patients initially presenting with pulmonary embolism or deep venous thrombosis (DVT) had a known cancer diagnosis.<sup>28</sup> Another 5% of these patients went on to have a malignancy diagnosed either at presentation or within one-year follow up. Patients receiving certain chemotherapy regimens, such as asparaginase for acute lymphoblastic leukemia (ALL), tamoxifen combined with chemotherapy for breast cancer, and docetaxel with thalidomide for prostate cancer, have all been reported to have increased rates of thromboembolism.<sup>29-31</sup> It is well established that oncology patients are at increased risk for thromboembolism, but the additional risk factor of surgery can double their likelihood for pulmonary embolism.<sup>32</sup>

Most pulmonary embolisms arise from the venous system of the lower extremities. Having a high index of suspicion for DVT and pulmonary embolism is necessary due to the vague and unreliable symptomatology associated with both PE and DVT. Patients with symptomatic DVT have been shown to have asymptomatic pulmonary embolisms, and patients with pulmonary embolisms do not necessarily have any preexisting symptomatology of a DVT.<sup>33-37</sup> The most frequent symptoms of PE are dyspnea, pleuritic pain, cough, and hemoptysis. The most common signs of acute PE are tachypnea, rales, tachycardia, a fourth heart sound, and an accentuated pulmonary component of the second heart sound.<sup>34</sup> Fever is associated with PE in 14% of patients.<sup>38</sup>

**FIGURE 3** Chest computed tomography scan demonstrating bilateral pulmonary artery filling defects consistent with massive pulmonary embolism.

#### Diagnostic Modalities for PE

Diagnosing acute PE can be challenging, and a variety of diagnostic studies are available to the clinician. Simple studies such as EKG, chest radiography, and arterial blood gas can be completed rapidly at the bedside, but are nonspecific for diagnosing pulmonary embolism. Generally, these studies are useful to rule out other conditions that may be mimicking a suspected PE.

Pulmonary venography is the gold standard for diagnosing PE. It is performed by injecting contrast (usually by a transfemoral approach) into a pulmonary artery branch under fluoroscopy. The drawback to pulmonary angiography is that it is an invasive study that requires a skilled clinician, who may not always be available to perform the study.<sup>39</sup>

Pooled data suggests that contrast-enhanced spiral CT has a 70% sensitivity and an 88% specificity with a 76% positive predictive value and an 84% negative predictive value.<sup>40</sup> It has the advantage of being fairly expeditious to perform and readily available. Another advantage is the benefit of imaging the chest to rule out other possible intrathoracic pathology. Advances in computed tomography (CT) have now made it possible to scan with 1 mm resolution in a single 10-second breathhold for the patient. Although some studies have shown a sensitivity of only 70% for standard CT angiography,<sup>41</sup> with multidetector row CT, the improved resolution appears to have the ability to detect PE in sixth-order branches of the pulmonary vasculature and is recommended as a first-line imaging modality by Schoepf and Costello.<sup>42</sup>

Magnetic resonance imaging (MRI) is an evolving area in the diagnosis of PE. It has a

sensitivity of 88% and a specificity of 90% in diagnosing central pulmonary emboli.<sup>43</sup> MRI has the advantage of being minimally invasive without the need for nephrotoxic contrast administration. However, many patients have contraindications to MRI and it does not appear to be as sensitive for segmental pulmonary emboli.<sup>40</sup>

Transesophageal echocardiography can be utilized in diagnosing a central PE with a specificity of 100% but a sensitivity of 76%.<sup>44</sup> It has severe limitations in diagnosing segmental pulmonary emboli and can be poorly tolerated in nonintubated patients already experiencing respiratory compromise from a suspected PE.

D-dimer blood assays quantify the cross-linked fibrin degradation products in the circulation. They are not only elevated in the setting of PE, but trauma, surgery, disseminated intravascular coagulation, inflammatory states, and malignancy have been known to elevate D-dimer levels as well. The D-dimer assay has a high negative predictive value and is useful in excluding the diagnosis of PE together with the clinical presentation.<sup>45,46</sup>

Lung scintigraphy or a ventilation/perfusion scan will study the consequence of a PE occluding flow within the pulmonary artery(s). Comparison of blood flow to air flow is used to predict the presence of a PE. This comparison of the ventilation to perfusion (V/Q scan) has the ability to predict the presence of a PE when the scan is interpreted as high probability. In high probability scans, the prevalence of PE is about 85% (however, this does leave 15% of patients receiving anticoagulation unnecessarily). In low probability to intermediate probability studies, the prevalence of PE is 25%. However, in the setting of a patient with a low probability scan but high clinical likelihood, the prevalence of PE can

**FIGURE 4** Chest computed tomography scan demonstrating large anterior and posterior pericardial effusion. Image courtesy of Mylen Truong, MD, The University of Texas M. D. Anderson Cancer Center.

be as high as 40%.<sup>27</sup> The disadvantage of the V/Q scan for clinicians lies in the difficulty of formulating the best treatment course for a patient when 73% of V/Q scans are reported as intermediate probability.<sup>27</sup>

Lower extremity venous ultrasonography is another option available to diagnose DVT. Lower extremity ultrasonography has limitations in the availability of staff to perform the study; and the presence of casts, dressings, or other lower extremity fixation devices can prevent the performance of complete studies. Most importantly, a normal venous sonogram does not exclude the possibility of a pulmonary embolism already occurring. In patients with objective evidence of a PE, lower extremity ultrasonography is only able to diagnose a DVT in 50% of cases.<sup>47</sup> This may be due to the possibility that the entire thrombus has already embolized out of the lower extremity venous system or that the PE originated from another source, such as the pelvis. Therefore ultrasonography is probably most useful to the clinician in surveillance of DVT formation and prevention of the occurrence of PE.<sup>47</sup>

#### Treatment of PE and DVT

Recent treatment guidelines were developed by the American College of Chest Physicians concerning the treatment of both DVT and PE.<sup>48</sup> The following discussion provides a summary specific to cancer patients.

When there is objective evidence of DVT, anticoagulation with unfractionated heparin or low-molecular-weight heparin (LMWH) is recommended. If unfractionated heparin is used intravenously (IV), the initial loading dose can be

**FIGURE 5** Chest radiograph demonstrating contrast leaking from esophageal anastomosis.

either 5,000 units or weight-adjusted to 80 units per kilogram of body weight. This dose is followed by 30,000 units over the first 24 hours or 18 units/kg/h by continuous infusion. Although activated partial thromboplastin time (aPTT) is most commonly used to titrate the heparin infusion, it is important to realize that the PTT study is a global coagulation test that does not always correlate to the antithrombotic activity of heparin or its concentration in the plasma. Laboratories should therefore standardize the aPTT assay to correspond with plasma heparin levels between 0.3 to 0.7 IU/mL anti-Xa activity by the amidolytic assay.<sup>49</sup> Subcutaneous administration is as effective and safe as IV administration.<sup>50</sup> If the subcutaneous route is utilized, 5,000 units should be given IV followed by 17,500 units subcutaneously twice on the first day. The dose is then adjusted to achieve 1.5 to 2.5 prolongation based on an aPTT drawn 6 hours after the morning administration.

LMWH is another treatment option for DVT. Recent meta-analysis failed to show any benefit in bleeding risk or recurrence of embolus with LMWH compared to unfractionated heparin.<sup>51</sup> However, other studies have shown the benefit of decreased hospital time with home use of LMWH in the treatment of DVT and that it can be administered in once- or twice-daily dosing.<sup>52,53</sup>

If the patient has reversible risk factors for DVT (such as surgery within the last 3 months) it is recommended that treatment be initiated with several days of LMWH or unfractionated heparin followed by 3 months of vitamin K antagonist therapy. However, in a patient with non-reversible risk factors such as cancer, treatment with LMWH for a minimum of 6 months is recommended (dalteparin 200 IU/kg body weight subcutaneously daily for one month followed by 150 IU/kg, or tinzaparin sodium 175 IU/kg body weight subcutaneously daily). Discontinuation after 6 months can be considered if the cancer is felt to be resolved. In the case of patients with ongoing presence of malignancy, indefinite anticoagulant therapy is appropriate.

Since PE and DVT are different manifestations of the same disease process, recommendations for the treatment of pulmonary embolism are similar to the treatment of DVT. The exception is that anticoagulant therapy should be initiated prior to definitive diagnostic testing in the setting where there is a high clinical suspicion of PE. Again, unfractionated heparin and low-molecular-weight heparin are both options. LMWH allows for earlier discharge in some cases. In the cancer patient, LMWH is preferable to unfractionated heparin. Duration of therapy for PE is identical to the recommendations for DVT treatment. Several days of unfractionated heparin or LMWH should be followed by long-term

anticoagulation. For patients with malignancy still present, LMWH is superior to vitamin K antagonists unless the cancer is felt to be resolved. In the case where anticoagulation is contraindicated or there is recurrent DVT or PE despite adequate therapy, a vena caval filter is indicated.

## Cardiac Complications

### Pericardial Effusion

The pericardium and heart can be a common site for metastatic disease as opposed to primary neoplasia. Up to one in five post mortem exams of cancer patients showed evidence of metastatic disease to the heart or pericardium.<sup>54</sup> Adenocarcinoma of the esophagus, breast, and lung are the most common malignancies known to metastasize to this area, but it is possible for nearly any cancer type.<sup>55,56</sup> It is therefore not surprising to be faced with the issue of pericardial effusion in the perioperative period either from neoplastic origin or as a secondary sequelae of the patient's systemic disease state (chemotherapy, chest radiation, myocardial infarction, uremia, hypothyroidism, trauma to pericardium such as cardiac surgery, tuberculosis, viral/bacterial/fungal pericarditis). Although low voltage changes and tachycardia are nonspecific electrocardiogram findings, pericardial effusion is best evaluated by echocardiography.<sup>57</sup>

Treatment decisions are best made on an individual basis, taking into consideration the patient's symptoms, the effusion etiology, if the patient is being evaluated preoperatively, and the patient's prognosis. If an effusion within the pericardial sac is creating pressure that impairs cardiac function, then by definition a cardiac tamponade exists. Tamponade can be either acute or chronic. Accumulation of a very small amount of fluid in a short amount of time can lead to serious tamponade symptomatology. Conversely, if given time to expand, the pericardium can hold a surprising amount of fluid while a patient remains asymptomatic. In the acute situation, as pressure begins to equalize in the chambers of the heart due to the extrinsic pericardial pressure, filling of the heart is severely compromised. As the right-sided pressure approaches 20, emergent evacuation of the fluid is indicated by the most expeditious method. Usually, this is accomplished with percutaneous drainage through a subxiphoid approach. If the etiology of the accumulation is known, a catheter may be left in place for future sclerosis.

Other treatment options include creation of a pericardial window or pericardioperitoneal shunt.<sup>58</sup> Large effusions or those with any evidence of hemodynamic compromise should be drained.<sup>59</sup> Because of the hemodynamic lability associated with general anesthesia and even the regional anesthetic techniques (spinal/epidural)

preoperative drainage of significant pericardial effusions should be strongly considered.

## Perioperative Thoracic Mechanical Complications

### Lobar Lung Collapse and Torsion

Lobar torsion is a recognized but rare complication of pulmonary resection. However, undiagnosed lobar torsion can have serious sequelae. The incidence of lobar torsion is between 0.3 to 0.089%.<sup>60,61</sup> The presentation of lobar torsion is nonspecific and includes fever, tachycardia, loss of breath sounds over the affected field, and sudden cessation of air leak. On chest radiography, there may be rapid opacification of the affected lobe. A high index of suspicion is required to make the diagnosis. In the clinical setting of lobar opacification on chest radiography, it is prudent to proceed with a bronchoscopic evaluation. On bronchoscopy, complete or partial airway occlusion can usually be seen. If the diagnosis is not clear, follow-up CT can be a useful adjunct. Treatment for torsion is thoracotomy to detorse the lobe and resect any infarcted tissue.<sup>61</sup>

Lobar collapse is a much more common complication in postsurgical patients, particularly post-thoracotomy patients. The incidence of lobar collapse in a surgical ICU setting has been stated to be as high as 8.5%.<sup>62</sup> Lobar collapse can result from mucous plugging a bronchus. Inflammation of bronchial mucosa can also create an elliptically shaped channel that decreases air flow and mucous clearing, resulting in collapse.<sup>63</sup> In the setting of an upper lobectomy, the pulmonary anatomy is altered such that the remaining lung is shifted upward in the chest creating a partial torsion or narrowing of the bronchi to the lower lobes (23).<sup>64</sup> Treatment includes bronchoscopy (to rule out torsion as well as to clear retained secretions) and supportive pulmonary physiotherapy.

### Post-pneumonectomy Syndrome

Pneumonectomy creates an empty pleural cavity, which can be associated with anatomic changes creating the post-pneumonectomy syndrome. As the remaining lung overinflates, the entire mediastinum can shift into the empty thorax, creating a torsion-type compression of the trachea and bronchus. The shifting of the mediastinum can be evident on a plain chest film, but is also diagnosed on chest CT and bronchoscopy. This complication can occur anywhere from 6 months to many years postoperatively. Patients who develop this syndrome present with cough, recurrent pneumonia, and stridor.<sup>65</sup> Treatment is a surgical procedure to reposition the mediastinum and fill the empty cavity with a nonabsorbable material such as saline breast implants, thereby shifting

the mediastinum back to the original anatomic position.<sup>66</sup>

### Bronchopleural Fistula

Bronchopleural fistulas can develop as a complication of pneumonectomy and carry anywhere from a 30 to 80% mortality rate. Patients with a large (> 25 mm) bronchial stump are at risk.<sup>67</sup> Other risk factors include right-sided surgery and age above 60 years. Unresolved tumor which requires chemotherapy or radiation also places patients at additional risk.

The possible sequela of a postoperative bronchopleural fistula is the development of an empyema. Early development of an air leak in the chest tube of the operative side may herald fistula formation. In the first postoperative week, empyema is not as large of a concern as it is in the 2 to 3 weeks following surgery.

Treatment includes draining the empyema and systemic antibiotics. When the acute infection is resolved, surgical repair of the fistula is required.

### Chylothorax

Chylothorax usually develops within the first 1 to 3 postoperative days after thoracotomy and has an incidence of 1 to 2% in post-thoracotomy patients.<sup>68</sup> It presents as rapid filling of the empty thoracic cavity after pneumonectomy and/or chylous drainage from chest tubes. Although it more commonly occurs after procedures involving lymph node resection and dissection near the thoracic duct in the mediastinum, it can occur with any cardiovascular or pulmonary surgery.<sup>69</sup> Diagnosis is confirmed by the presence of triglycerides (> 110 mg/dL) as well as chylomicrons in the drainage fluid.<sup>70</sup> Conservative treatment has a 70 to 80% success rate and consists of a nothing-by-mouth (NPO) diet with total parenteral nutrition support.<sup>68,71</sup> Reoperation with thoracic duct ligation should be considered if chest tube drainage does not decrease to less than 1,500 mL/day for 5 days, if drainage does not considerably decrease over 2 weeks of treatment, or if the patient's nutrition status is impaired by treatment.<sup>72</sup>

### Cardiac Herniation

Although cardiac herniation is a rare complication following pneumonectomy in cancer patients, it merits discussion because missing this diagnosis can be lethal to the patient. With either right or left pneumonectomy, the heart can herniate through a defect in the pericardium and into the empty pleural space. It is most common within 3 days of surgery, although it has been reported as far as 6 months postoperatively.<sup>73</sup> The presentation can mimic many other acute catastrophic cardiopulmonary events such as pulmonary

embolism, massive myocardial infarction, and great-vessel rupture. Patients have a sudden onset of hypotension, chest pain, cyanosis, elevated central venous pressure, and shock, which can quickly progress to cardiovascular collapse. Chest radiography can be useful in diagnosis by showing a shift of the heart shadow out of the thoracic cavity with the remaining lung and into the empty pleural space. Treatment is emergent thoracotomy to reposition the heart and repair the defect.<sup>74</sup>

### Esophageal Leak

In experienced centers, postoperative mortality from esophagectomy is 5%, with about a 35% five-year survival.<sup>75</sup> Although there is no uniformity in the definition of anastomotic leak, some authors report a post-esophagectomy leak rate as high as 53%.<sup>76</sup> Lerut and colleagues suggest dividing anastomotic leaks into four categories.<sup>77</sup> Small leaks lacking major symptomatology, but visualized with a radiographic contrast study, may be managed conservatively with a nothing-by-mouth regimen for several days. In leaks of a cervical anastomosis with wound inflammation and containment on contrast study, wound drainage, antibiotics, and NPO are recommended. Somatostatin (to decrease gastric secretion) and proton pump inhibitors (to neutralize gastric secretion) can also be of additional benefit in these cases. In clinically major leaks, with patients showing signs of sepsis and severe anastomotic disruption on endoscopy, CT-guided drainage is indicated for well-contained fluid collections. Reoperation for débridement and temporary esophagostomy and feeding jejunostomy are recommended in the case of a poorly contained thoracic leak with a large anastomotic defect on endoscopy. Otherwise, conservative treatment is favored. At the fourth level of anastomotic leak, there is evidence of tissue necrosis on endoscopy. These cases also require reoperation with débridement, esophagostomy, and feeding jejunostomy.

### Tumor Embolization

Dyspnea in a cancer patient can have a variety of etiologies and presents a challenge to clinicians. There are a host of reasons for oncology patients to complain of shortness of breath. Infection, thromboembolism, cardiopulmonary disease (induced by prior chemotherapy or radiation therapy), baseline cardiopulmonary disease (from COPD and coronary artery disease), metastases, and effusions are all common occurrences in patients with cancer. However, embolization of solid tumor cells is probably underdiagnosed. Autopsy series estimate the incidence of tumor embolization in patients with solid tumors to be anywhere from 3 to 26%.<sup>78-80</sup> Tumor embolization is not necessarily the same entity as

tumor metastasis to the lung. Tumor emboli can occur in large proximal vessels (similar to thromboembolism), in the microvasculature, in the lymphatic system, or a combination of these.<sup>78</sup> Although tumor cells have broken away from the primary site and traveled through the venous system to lung vasculature, the cells ability to grow in a distant site depends on interactions with local inflammatory mediators and signaling pathways.

Tumor emboli are more tenacious compared to thromboemboli owing to the inability of tumor cells to be reorganized. If a patient survives a thromboembolic event, symptomatology will eventually improve due to the reorganization of the clot and recannulation of the vessel. In contrast, tumor emboli lack this reorganizational capability and their presence represents a continued problem for the patient.

The most common presenting complaint is dyspnea, but patients may also experience cough, chest pain, and abdominal pain.<sup>12</sup> Patients can develop cor pulmonale symptomatology over weeks to months. Presenting examination findings include peripheral edema, ascites, jugular venous distention, and an augmented second heart sound. Patients may be hypoxic with a respiratory alkalosis on arterial blood gas sampling. Echocardiogram can show a dilated right heart. Definitive diagnosis is difficult with conventional imaging modalities. Chest radiography may only show prominent pulmonary vasculature or an enlarged cardiac silhouette. Because the emboli are most commonly found in the microvasculature, CT angiography is usually normal. Pulmonary angiography is considered the definitive diagnostic modality for thromboembolism, but it is insensitive to tumor emboli.<sup>81</sup> Ventilation perfusion scanning may be the only abnormal radiologic exam in the tumor embolism patient. Small, peripheral, subsegmental perfusion defects may appear concomitantly with a normal ventilation scan.<sup>82,83</sup>

Pulmonary artery wedge aspiration cytology is possibly the most definitive test for diagnosis of tumor embolus (although negative cytology does not rule out the diagnosis). After a pulmonary artery catheter is inserted, the catheter is wedged with the balloon inflated as if to measure a wedge pressure. The first 10 to 15 mL of aspirated blood is discarded. The next 10 mL are sent in a heparinized tube for cytologic analysis. In order to avoid misinterpretation of normal megakaryocytes as tumor cells, an experienced pathologist should review the cytology.<sup>84</sup>

Treatment of tumor emboli is directed toward treatment of the underlying tumor. If the patient has a larger central embolus, it may be worthwhile to consider a vena caval filter, or even embolectomy. However, most emboli will not be amenable to this type of therapy, and the best response will probably be gained from

eradication of the presenting mass with conventional methods.

## Summary

Cancer patients frequently experience cardiopulmonary complications. Patients with primary pulmonary tumors require careful testing to evaluate their suitability for lung resection. Pleural effusions are a troublesome and common occurrence in patients in the perioperative setting. An understanding of the physiology of the pleura as well as the patients expected disease course is paramount in the consideration of the treatment of pleural effusion. Cancer patients are well known to be at increased risk for thromboembolism. Thromboembolism may require an indefinite therapeutic time period as long as tumor is still present. Pericardial effusion and tamponade can occur secondary to tumor metastasis to the pericardium and must be ruled out in any oncology patient. Although rare, lobar torsion and cardiac herniation can be deadly post-lobectomy and post-pneumonectomy complications. Elderly, right-sided pneumonectomy patients with larger bronchial stumps are at greatest risk of developing bronchopleural fistula. Bronchopleural fistula is associated with empyema. A rapidly developing effusion after thoracotomy may represent chylothorax and must be investigated. Esophageal leaks after esophagectomy may develop relatively well-contained cavities with mild symptomatology or cause life-threatening septic shock, depending on their location and size. Tumor embolus is probably underdiagnosed and can cause symptoms of cor pulmonale.

# Psychosocial Issues

Kathleen Young Bellamy, MSW, LISW  
Harrison G. Weed, MD, MS, FACP

## The Importance of Social Support

Treatment plans can be undermined by a lack of consideration of the patient's social context, including the patient's financial and emotional needs, the patient's family concerns and the patient's belief systems (Table 1). Addressing a patient's psychosocial needs is an essential aspect of good perioperative patient care; however, doing so can be difficult and time-consuming.<sup>1,2</sup> Furthermore, patients are sometimes embarrassed to bring social issues, such as finances, to a physician's attention. Other professionals can help to address these issues, including social workers, psychologists, psychiatrists and chaplains (Table 2). Two critical tasks for the physician are, (1) to recognize the importance of social issues in successfully implementing a treatment plan, and (2) to communicate early and often with the other professionals who can help to address the social issues. Before surgery, it is important to establish the kinds of support that the patient will need after the procedure. As we have reduced the length of the perioperative hospital stay, we have placed more responsibility

**Table 1 Psychosocial Issues for Cancer Patients in the Perioperative Period**

### *Financial Needs*

Paying for treatment  
Communication with insurers  
Time off from work  
Obtaining needed medical equipment

### *Emotional Needs*

Impact—response to diagnosis of cancer  
Depression: diagnosis and treatment including counseling

### *Family Concerns*

Care for a child, spouse, pet or other family member  
Keeping family members informed

### *Belief System*

Treatment proscriptions (eg prohibition of blood transfusion)  
Disposition of removed body parts  
Rituals, including those in case of death

**Table 2 Professionals Who Provide Psychosocial Support**

### *Social Worker*

Financial  
Communicating with Insurers, eg reimbursement  
Communicating with Employer, eg time off of work  
Obtaining resources, eg tube feeds, medical equipment  
Helping to navigate disability application process  
Completing forms for physician/patient  
Counseling of patient/family, less-intimidating source of information  
Discharge planning and arrangements  
Placement—Aftercare Needs

### *Psychologist and Psychiatrist*

Counseling of patient and family  
Recommendations on approach to patient and family

### *Psychiatrist*

Prescription of treatment for psychiatric illness

### *Chaplain*

Counseling of patient and family  
Advice on ritual needs and religious proscriptions

### *Hospice*

Palliative therapies

outside of the hospital on patients and families to prepare for, and to recover from, surgery. Having the appropriate support available at home can sometimes enable a patient to recover from surgery at home instead of at an extended care facility (nursing home). Furthermore, patients with adequate social support are less likely to have complications than clinically similar patients without social support.<sup>3,4</sup> Note that the patient's family might also require psychosocial support. For example, the patient might be the primary care provider for a family member, such as a child, spouse or parent, and alternate sources of care will be needed to enable the patient to have surgery and recover. Usually, the sooner these needs are discovered, the easier it is to address them. Therefore, a thorough preoperative evaluation should include an assessment of the patient's

psychosocial needs and referral to appropriate professional help.

## Procedure-Specific Issues

Different surgical procedures may bring up different psychosocial issues. For example, although sexuality can be an issue with any serious illness, it is even more likely to be an issue for patients with breast and genital cancers. Therefore, providing these patients with information, and, if needed, referral to a counselor can be important to postoperative recovery. Perioperative patient education and supplies must be tailored to the surgery and to the patient. For example, patients with cancers involving the airway are likely to require information (and even training) about keeping the airway patent, and are likely to need suction equipment if they will go home with a tracheotomy. Failure to plan for these considerations can not only delay hospital discharge, but can be fatal. As another example, patients with oropharyngeal and gastrointestinal cancers, and their families often have questions about foods and diets. Patients with oropharyngeal cancers usually have difficulty chewing and swallowing, and may even have difficulty speaking, before and/or after surgery. Patients, and the families of patients with cancers of the face, neck, and breast are often concerned about how they will appear after surgery and what cosmetic and prosthetic options are available. If these issues are not adequately addressed prior to surgery, then the patients and their families can suffer unnecessary shock and consternation, and have a negative perception of a surgery that was technically successful.

## Write a List of Psychosocial Issues

In the same way that physicians keep a medical "problems list," it is useful to write out a psychosocial problems list for patients with cancer who are anticipating surgery. This list should include tests and treatments that might be unusual or experimental, and therefore not reimbursed. A social worker can often help to generate this list, and to garner the necessary resources. The list

should also include special needs during hospitalization, such as diet or visitation, and the patient's anticipated needs for postoperative rehabilitation or placement. There are many government and private programs to help patients with cancer. The two keys to obtaining assistance from these programs are (1) learning about them, and (2) applying for them early in the clinical course. Therefore, the earlier a social worker or other qualified person is engaged in this task, the more likely the patient is to obtain needed resources. The patient will not receive the care, no matter how medically necessary, if it is not both feasible and paid for. Therefore, sometimes the care plan must be modified to accommodate social realities, including transportation, religious proscriptions, and reimbursement limitations.

### Resources for the Primary Care Physician

A primary care physician whose patient is undergoing cancer surgery may not have the resources to address the patient's many psychosocial issues. Hospitals often have professional social work staff that can be a useful resource for the primary care physician. Clerical staff and nurses in oncologists' and surgeons' offices are another useful resource because they usually have experience working with similar patients and addressing cancer-specific psychosocial issues. They can often refer the patient to additional financial and counseling services. Written, faxed, or phoned communication with the oncologist's or the surgeon's office as soon as an issue is identified can often speed resolution of the problem.

### Psychosocial Issues for Children of Parents undergoing Cancer Surgery

The young children of a cancer patient can present additional psychosocial issues. These issues include relatively straightforward problems, such as obtaining childcare, to more subtle problems, such as a child's magical thinking (blaming him- or herself for the parent's illness). Additional issues can include helping young children cope with separation from a hospitalized parent (for example, by arranging for hospital visits). Teenage children are often dealing with issues of separation and independence that can be complicated by the parent's cancer and hospitalizations. The American Cancer Society has information, pamphlets, and videotapes in a "Kids Can Cope with Cancer" program that can be accessed via their Web site ([www.cancer.org](http://www.cancer.org)) or through the local society.

### Working with the Patient's Belief System

The patient's religious/spiritual belief system can determine which treatments are acceptable.<sup>5</sup> The classic perioperative example is the proscription against blood transfusions by some religions. Another consideration is the disposition of any removed body parts. This information must be ascertained and communicated to the surgeon prior to surgery. Although the surgeon is ultimately responsible, the internist and the primary case physician are often in a good position to know such information and to work closely with the patient and family. Information on the patient's religious beliefs is usually collected on nursing intake forms, but must be explicitly reviewed and addressed to avoid inconvenience and religious transgression. When faced with the diagnosis of cancer, and with the need for surgery, many patients are overwhelmed with issues of mortality.<sup>6</sup> This can complicate their care and can lead to avoidance and even refusal of therapeutically indicated procedures. Unless these issues are addressed, they can continue to plague the patient and interfere with care. A physician can make significant progress in addressing these issues simply by acknowledging them.<sup>5</sup> In the inpatient setting, the hospital chaplain can also often provide substantial comfort and reassurance to patients and families.

### Complementary and Alternative Therapies in the Perioperative Period

Most studies find that complementary and alternative therapies are used by about half of cancer patients, and find that, about half the time, the patient's doctors' are unaware of them.<sup>7</sup> Some alternative therapies are being actively investigated for their potential benefits; however, they can also directly interfere with surgery. The Society for Integrative Oncology (<http://www.inegativeon.org>) is a useful source of current knowledge. In the perioperative period, some relatively noninvasive treatments, such as massage, can help to relieve anxiety and discomfort without adverse effects.<sup>8,9</sup> Other complementary treatments (such as herbal medicines) can have adverse effects. For example, ginseng, garlic, and ginkgo biloba can increase perioperative bleeding. It is generally recommended that all herbal medications be discontinued two weeks prior to surgery.<sup>10</sup> The physician must recognize that alternative therapies are often an important part of the patient's belief system, and that the patient's

belief in the alternative therapy can be stronger than the patient's belief in conventional medicine. Compassionate and open communication is critical to developing a care plan that is agreeable to the patient and concordant with our best current understanding of pathophysiology and therapeutics.

### Additional Psychosocial Issues for an Inpatient

One key to effective inpatient management is keeping the hospital social worker or discharge planner updated on the treatment plan. It is a useful practice to include an estimate of the discharge date and a summary list of the patient's discharge needs (including any placement issues) in the patient's daily progress note. This note is usually written by a social worker or discharge planner, but must be reviewed and updated by the physician to ensure good communication.

### Billing for Psychosocial Care

Payment for psychosocial support is often considered to be "bundled" with the perioperative care; but specific interventions, such as counseling, can be appropriately billed and are covered by some health plans. To be reimbursed, both the medical diagnosis and the time spent counseling must be documented in the patient's medical record.

# Emergency Care: Special Considerations in Cancer Patients

Margaret B. Row, MD, MBA  
Sai-Ching Jim Yeung, MD, PhD

The emergency care of patients with cancer presents many challenges. To formulate an appropriate treatment plan, clinicians providing emergency care for cancer patients (newly diagnosed patients, patients currently receiving cancer treatments, patients with stable disease, patients in remission, and patients dying from cancer) must not only be guided by the standard emergency protocols but also by the prognosis, the quality of life, and the patient's and family's wishes.

There are few emergency centers that provide care to large numbers of cancer patients. Each year at The University of Texas M. D. Anderson Cancer Center, approximately 18,000 patients with acute care issues are evaluated in the emergency center. About 40% of those patients require hospitalization, and about one quarter of these require critical care. Patients with cancer present to emergency centers with medical complaints related to the malignancy, related to treatments for the malignancy, or completely unrelated to the malignancy. The emergency physician must determine quickly and methodically whether the patient's presenting complaint is a true oncologic emergency or just an unscheduled consultation for a non-emergency condition. The key to accurate diagnosis is being able to identify common complaints associated with various cancer types at different stages of the natural history or treatment. Medical problems unrelated to the malignancy must always be considered in the differential diagnosis of the presenting complaint.

The goal of this chapter is to share our experience and discuss selected issues in the emergency care of cancer patients. Rather than discussing a laundry list of topics traditionally considered oncologic emergencies—such a discussion could fill volumes<sup>1,2</sup>—we shall address the major presenting complaints seen among patients at our emergency center. The major topics we will cover are cardiopulmonary emergencies, thromboembolic disease, hemostatic disorders,

central nervous system emergencies, tumor lysis syndrome, and infection.

## Cardiopulmonary Emergencies

### Sudden Cardiopulmonary Arrest

When a cancer patient is brought to an emergency center in full or impending cardiopulmonary arrest, the emergency care provider may never have met the patient before, which makes assessing prognosis difficult. The success rate of cardiopulmonary resuscitation and the hospital discharge rate of resuscitated patients are similar for cancer patients and non-cancer patients.<sup>3</sup> If a cancer patient has good performance status and is not expected to die soon, the patient should be resuscitated with the same vigorous effort as non-cancer patients. However, when cardiopulmonary arrest comes as the last events in the disintegration of bodily functions caused by cancer, resuscitation will generally be futile.

The emergency care provider faces the major decision on whether to initiate or continue resuscitative efforts or stop because of futility. The decision is based on the patient's physical status, the events leading to the cardiopulmonary arrest, duration of arrest, initial cardiac rhythm; presence of rigor mortis or algor mortis, the stage and prognosis of cancer, prospects for cancer treatment success, directives of the patient or family, comorbid conditions, performance status, nutritional status, advanced age, and potential quality of life if the patient survives.

Resuscitation generally follows the algorithms outlined in the advanced cardiac life support protocols.<sup>4</sup> However, if the specific causes of cardiopulmonary arrest are identified, the clinician may be able to tailor resuscitative efforts accordingly. For example, prior knowledge of the presence of pericardial effusion would help the physician tailor the resuscitative effort. Emergent pericardiocentesis will relieve the pressure on the cardiac chambers and rapidly restore cardiac output in pulseless electrical activity due to

cardiac tamponade. Acute carcinoid syndrome is another example of a treatable cause of cardiopulmonary arrest in cancer patients. Anesthesia, chemotherapy, adrenergic drugs (eg, dopamine and epinephrine), biopsy, or surgery may precipitate a carcinoid crisis in carcinoid tumor patients. Hypotension, arrhythmias, and bronchospasm due to massive release of serotonin and other vasoactive humors from the tumor can be treated effectively with a somatostatin analogue (octreotide acetate 150 to 500 µg intravenously).<sup>5</sup>

### Arrhythmia

Arrhythmia is a common presenting problem of cancer patients in emergency centers. Arrhythmia may be related to cancer, cancer treatment, or unrelated medical problems. Signs and symptoms of arrhythmia can be subtle and intermittent, and may include isolated or recurrent syncope, lightheadedness, dizziness, dyspnea (Table 1), hypotension (Table 2), palpitation, chest pain, transient or persistent neurologic deficits of acute onset, and peripheral vascular embolization.

Sustained arrhythmia can be diagnosed easily by electrocardiography. However, transient or intermittent arrhythmia, which is common, may present a diagnostic challenge. Normal findings on a brief period of continuous monitoring do not exclude the presence of an intermittent or latent, but potentially life-threatening, rhythm disturbance. If the symptoms suggest arrhythmia, Holter monitoring for 24 to 48 hours is warranted. Cardiac rhythm analysis can be challenging in cancer patients because exaggerated respiratory variations of the electrical axis and changes in mean QRS voltage due to pleural or pericardial effusions, pulmonary surgery or radiation-induced lung damage may be confused with heart rhythm irregularity.

Primary arrhythmia is caused by focal or diffuse abnormalities in cardiac and pericardial structures. Common causes of primary

**Table 1** Differential Diagnosis of Dyspnea in a Cancer Patient**Cardiac**

Congestive heart failure (comorbid heart diseases, chemotherapy-induced cardiomyopathy, amyloidosis, ... etc.)  
 Cardiac arrhythmia (comorbid heart diseases, cancer treatment-induced arrhythmia, arrhythmia secondary to electrolyte abnormalities, ... etc.)  
 Valvular heart disease (carcinoid cardiac disease, comorbid valvular diseases)

 Anemia

arrhythmia in cancer patients include increased intracardiac pressure and wall stress; ischemic heart disease; hypertrophic, congestive and infiltrative cardiomyopathy; and fibrosis related to aging. The major cancer-related causes of primary arrhythmia are intracardiac tumors (primary or metastatic),<sup>6</sup> amyloid infiltration,<sup>7</sup> myocarditis,<sup>8</sup> pericarditis,<sup>9</sup> and chemotherapy-induced cardiomyopathy (especially anthracyclines).<sup>10</sup>

Secondary arrhythmia arises from abnormal electrolyte concentrations, toxic reactions to drugs, thyroid disorders, vasoactive mediator release (by pheochromocytomas and carcinoid tumors), and radiation-induced heart damage. Arrhythmogenic cancer drugs include anthracyclines,<sup>11</sup> arsenic trioxide,<sup>12</sup> 5-fluorouracil,<sup>13</sup> irinotecan,<sup>14</sup> gemcitabine,<sup>15</sup> and interferon.<sup>16</sup>

 Valvular dysfunction

**Infection**

Sepsis  
 Endocarditis

**Treatment of Arrhythmia**

The urgency and etiology of arrhythmia guide the therapy. Specific treatment aimed at reversing the causative factor is preferred.

Treatment of stable secondary arrhythmia usually involves restoring metabolic homeostasis (particularly glucose, potassium, calcium, and magnesium) and removal of offending drugs or substances. When antiarrhythmic treatment is necessary, standard guidelines for arrhythmia management may be followed.<sup>4</sup> Except for beta-adrenergic blockers, many antiarrhythmic agents are potentially proarrhythmic,<sup>17</sup> and the cardiac rhythm should be monitored during the initiation of therapy.

Supraventricular tachycardia is the most common arrhythmia in cancer patients. Paroxysmal supraventricular tachycardia can be aborted by vagus-stimulating maneuvers such as carotid sinus massage. Adenosine administered as one or two rapid intravenous boluses is frequently effective in restoring normal sinus rhythm. When the mechanism of supraventricular tachycardia is unclear on electrocardiographic monitor strips, adenosine is sometimes used to help determine the mechanism. However, adenosine for diagnostic purpose is usually unnecessary with careful analysis of standard electrocardiograms. In cancer patients, sustained supraventricular tachycardia often cannot be terminated by drug therapy. While drugs are used to regulate the excessive pulse rate, elective synchronized cardioversion should be considered and planned soon after diagnosis. Anticoagulation therapy may be avoided if supraventricular tachycardia can be terminated within 48 hours of the onset. In the absence of a reliable time of arrhythmia onset, anticoagulation therapy is needed, and transesophageal echocardiography may be

performed to exclude the presence of intracardiac thrombi prior to elective cardioversion.

Arrhythmias due to structural cardiac abnormalities are likely to persist and progress to life-threatening arrhythmias. In the emergency setting, the treatment goals are stabilization of blood pressure and oxygenation, diagnosis of correctable causes, and symptom control. Emergent consultation with cardiologists, cardiothoracic surgeons may be required to arrange for emergent diagnostic or interventional procedures to address the root cause of arrhythmias.

In the absence of do-not-resuscitate (DNR) orders, cancer patients with unstable arrhythmia should be treated with pharmacologic or electrical interventions according to the current standard of care, such as the guidelines recommended by the American Heart Association.<sup>18</sup> These interventions include administration of a vasopressor, (vasopressin or epinephrine), administration of antiarrhythmic drugs (amiodarone, lidocaine, or procainamide), electrical cardioversion or defibrillation, intravenous infusion of crystalloid fluid, airway management and ventilation with oxygen, and chest compression. Torsades de pointes may be treated by intravenous magnesium, electrical overdrive pacing or pharmacologic overdrive with isoproterenol, and antiarrhythmic agents such as phenytoin or lidocaine. As for emergent synchronized cardioversion, the initial energy level for atrial fibrillation may be 200 joules,<sup>19</sup> although higher energy levels for cardioversion are appropriate when cancer patients are significantly overweight or have concomitant effusions. Lower initial energy levels (ie, 50 to 100 joules) should be used to for atrial flutter.

**Pericardial Tamponade**

Pericardial tamponade occurs when hemodynamics is impaired by accumulation of fluid in the pericardial cavity. Not including hemopericardium, the etiology of pericardial tamponade is usually either malignant or infectious. Infectious causes of pericardial tamponade include pericardial abscess<sup>20</sup> and *Candida* pericarditis.<sup>21</sup> Excess pericardial fluid accumulation due to malignancy can be caused by (1) obstruction of lymphatic drainage and (2) tumor nodules on pericardial surfaces secreting excess fluid. Pericardial fluid cytologic tests have a 70 to 80% diagnostic yield for malignant pericardial effusion.

Pericardial tamponade can be caused by a number of cancers. The most common malignancy that actually arises from the pericardium is mesothelioma. Cancers in the chest, such as carcinoma of the lung and malignant thymoma, may extend directly into the pericardium. Yet the most frequent routes of spread to the pericardium by cancer are by retrograde lymphangitic spread

or hematogenous dissemination, which occur frequently in cancers arising in the chest (eg, breast and lung carcinomas). Malignant melanoma is the most likely cancer to metastasize to the heart. Leukemias and lymphomas (both Hodgkin's and non-Hodgkin's) may cause pericardial effusions as well<sup>22</sup>.

Usually pericardial effusion is a late complication in patients with known metastatic disease although it may occasionally be the first clinical manifestation of malignancy. Less than one third of patients with malignant pericardial effusion are symptomatic. The most common complaints are shortness of breath, dyspnea on exertion, orthopnea, pleuritic chest pain and general weakness. Physical findings may range from normal to hemodynamic collapse. Signs of compromised cardiac output include tachypnea, hypotension, tachycardia, jugular venous distention and peripheral edema. The severity of hemodynamic impairment is determined by both the amount of pericardial fluid and the rate of fluid accumulation. Exaggerated decrease in systolic blood pressure with inspiration (pulsus paradoxus) is a classic finding of cardiac tamponade, but it is nonspecific because it can also be present in patients with significant lung disease, or cor pulmonale.

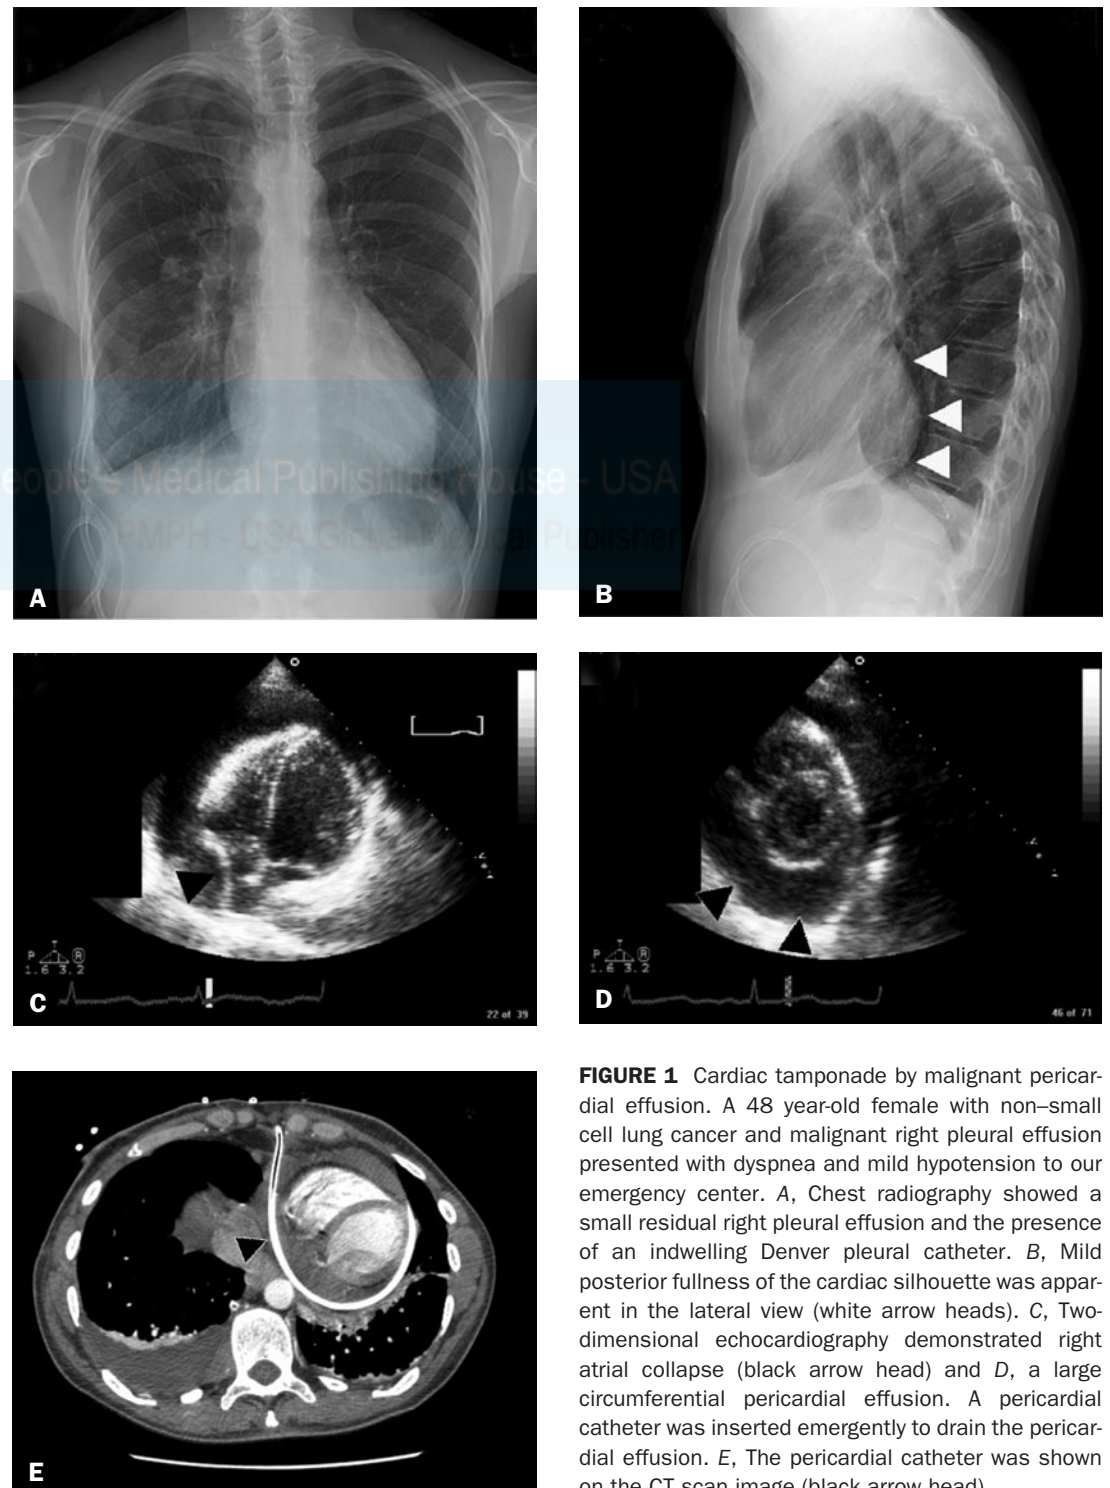

In the course of investigating the signs and symptoms of cancer patients with pericardial tamponade, electrical alternans in electrocardiographs or widening of the cardiac silhouette on plain chest radiographs are very helpful findings when present. (Figure 1.) Computed tomography (CT) or magnetic resonance imaging (MRI) studies provide information on the size, location, and presence of loculation of pericardial effusions but do not provide adequate assessment of the hemodynamic significance of the effusions. In contrast, two-dimensional echocardiography can not only diagnose pericardial effusion but can also evaluate its hemodynamic significance (ie, determine whether there is cardiac tamponade). Compression of the right atrium, diastolic collapse of the right ventricle, and a side-to-side or front-to-back movement of the heart (cardiac rocking) are common echocardiographic signs of pericardial tamponade. Doppler study of respiration-induced alterations in the blood flow across the mitral valve is also helpful in evaluating the hemodynamic significance of pericardial effusions.

Initial management of a malignant pericardial effusion depends on its hemodynamic significance. In patients with severe symptoms and compromise in cardiac output, echocardiography-guided pericardiocentesis may be performed in the emergency center or intensive care unit. Placement of a drainage catheter into the pericardial space may be required to prevent rapid recurrence of tamponade. The catheter

can remain in place until the pericardial fluid drainage is <50 mL over 24 hours.

Long-term management aims at preventing reaccumulation of pericardial fluid, which occurs in >50% of patients with malignant effusions. In patients with rapidly reaccumulating effusion with significant hemodynamic compromise, creating a pleuropericardial window using one of a variety of approaches can help the patient to avoid repeated pericardiocentesis. The pleuropericardial window procedure is usually performed in an operating room, but can also

be performed at the intensive care unit using local anesthesia (eg, the use of a percutaneous intrapericardial balloon catheter to create a pleuropericardial window).<sup>23</sup> Creating a pericardioperitoneal shunt through a laparoscopic transdiaphragmatic approach is another treatment option.<sup>24</sup> In hemodynamically stable patients, pericardial radioactive colloid, systemic chemotherapy or external-beam irradiation may be used for tumors that are sensitive to these treatments. Instillation of chemotherapeutic agents or sclerosing agents into the pericardial cavity can

**FIGURE 1** Cardiac tamponade by malignant pericardial effusion. A 48 year-old female with non-small cell lung cancer and malignant right pleural effusion presented with dyspnea and mild hypotension to our emergency center. A, Chest radiography showed a small residual right pleural effusion and the presence of an indwelling Denver pleural catheter. B, Mild posterior fullness of the cardiac silhouette was apparent in the lateral view (white arrow heads). C, Two-dimensional echocardiography demonstrated right atrial collapse (black arrow head) and D, a large circumferential pericardial effusion. A pericardial catheter was inserted emergently to drain the pericardial effusion. E, The pericardial catheter was shown on the CT scan image (black arrow head).

also prevent reaccumulation of pericardial fluid in many patients.<sup>25</sup>

### Acute Airway Obstruction

Acute airway obstruction usually involves the upper airway. Nonmalignant causes of upper airway obstruction in cancer patients include foreign body or food aspiration, severe tracheomalacia, tracheal stenosis, airway edema, and fungal, viral, or bacterial infections. Upper airway obstruction due to angioedema can occur in 2 to 3% of patients receiving paclitaxel.<sup>26</sup> Causes of airway obstruction related to cancer include tumor encroachment, tumor-associated airway edema, or hemorrhage. Primary tumors of the head and neck (base of tongue, larynx, hypopharynx, thyroid, or trachea) and lung can directly extend to the upper airway and cause obstruction. Metastatic spread of cancers to the neck or mediastinum can also cause obstruction of the upper airway.

For the lower airway, the most common cause of obstruction is primary bronchogenic carcinoma. Other, less common causes are metastases from cancers of the colon, breast, thyroid, or kidney; melanoma; lymphoma; or sarcoma. Severe bronchospasm due to release of hormone mediators is a major component of the acute carcinoid syndrome.

Dyspnea is the primary symptom of airway obstruction. As the airway diameter narrows, dyspnea on exertion will progress to dyspnea at rest. Further progression of obstruction will lead to wheezing, orthopnea, tachycardia, diaphoresis, stridor, and respiratory distress. Stridor is an ominous sign that can rapidly be followed by bradycardia, obtundation, and death.

The oral cavity should be quickly inspected to exclude the presence of foreign body or food. Clinical diagnosis of upper airway obstruction is often confirmed by direct visualization with either a laryngoscope or bronchoscope. Endotracheal intubation may be difficult, and laryngoscopy or bronchoscopy may be necessary to guide the endotracheal tube. Severe upper airway obstruction that is immediately reversible may require tracheotomy. Other supportive therapies include corticosteroids, bronchodilators, and helium-oxygen mixtures.

For patients with lower airway obstruction, chest radiographs identify the obstruction in 75% of cases. In other cases, CT scan of the chest can usually reveal the diagnosis. (Figure 2.) Interventional pulmonary treatments using rigid or flexible bronchoscopes and may involve balloon bronchoplasty,<sup>27</sup> placement of stents,<sup>28,29</sup> laser bronchoplasty,<sup>29,30</sup> cryosurgery,<sup>31</sup> and brachytherapy.<sup>32</sup> Other surgical interventions may be considered as appropriate for the patient's cancer prognosis, functional performance status, and comorbid conditions.

**FIGURE 2** Carinal mass obstructing right main stem bronchus. A 65 year-old man with adenocarcinoma of the lower esophagus presented with subacute onset of dyspnea on exertion. Computed tomography of the chest revealed a subcarinal mass encasing the right main stem bronchus with endobronchial extension (white arrow heads) that caused obstruction of right main stem bronchus.

### Pneumothorax

In cancer patients, procedures often associated with iatrogenic pneumothorax include percutaneous lung biopsy, transbronchial biopsy, and insertion of central venous lines. Even nasogastric tube placement may occasionally result in pneumothorax. Secondary Spontaneous pneumothorax is most often due to chronic obstructive pulmonary diseases, and may be common among smokers with lung cancers and head-and-neck cancers. Primary and metastatic pulmonary neoplasms may also lead to spontaneous pneumothorax. Pneumothorax has been reported in chemotherapy with bleomycin,<sup>33</sup> carmustine,<sup>34</sup> and lomustine. Rupture of mycetoma (aspergillosis, coccidioidomycosis, cryptococcosis, and mucormycosis) into the pleural space may result in pneumothorax. Other infectious agents associated with pneumothorax include *Klebsiella*, *Staphylococcus*, and *Pseudomonas* species, jiroveci (formerly *Pneumocystis carinii*), and *Mycobacterium* species.

Patients with underlying lung disease often cannot tolerate decreases in vital capacity and have a higher risk for respiratory failure when pneumothorax occurs. Dyspnea and chest pain are invariably present in a significant pneumothorax. Other symptoms, such as cough, hemoptysis, or orthopnea, are less common. Small pneumothoraces (<20% of lung volume) are undetectable on physical examination. In a large pneumothorax, examination usually reveals absent or decreased breath sounds on auscultation, absent tactile fremitus, and hyperresonance of the affected side of the chest. Deviation of the trachea to the side contralateral to the affected lung and decreased movement of the affected hemithorax may also be present. In a tension pneumothorax, increased central venous and intrapleural pressures may manifest as jugular venous distension. When venous return and

cardiac output are impeded by the tension pneumothorax, hypotension, severe hypoxemia, and respiratory acidosis will occur.

Chest radiographs are the most valuable diagnostic tools for pneumothorax. Pneumothorax is diagnosed when a chest radiograph reveals a visceral pleural line beyond which there are no lung markings. About one-third of pneumothoraces are undetected on semi-erect and supine chest radiographs.<sup>35</sup> In a small pneumothorax, the pleural line may be difficult to see. Therefore, a good-quality upright chest radiograph and a bright light for viewing are needed, and in some cases, expiratory films may be helpful. Recently, digital processing of digitized chest radiographs to enhance edges are becoming popular to help to detect visceral pleural lines.

For small pneumothoraces without significant symptoms, close observation will suffice. Serial chest radiographs should be obtained several hours after the initial radiograph to rule out further expansion of the pneumothorax. If the small pneumothorax is stable in size, the patient may be discharged with appropriate instructions and follow-up arrangement, and scheduled for repeat chest radiographs in 12 to 48 hours.<sup>36</sup>

Intrapleural catheter aspiration may be performed for symptomatic pneumothoraces, rapidly expanding pneumothoraces, and pneumothoraces of more than 15% of the ipsilateral pleural space (Figure 3). A pneumothorax

**FIGURE 3** Pneumothorax. A 38 year-old female suffered pneumothorax during attempts for central venous catheter insertion. A small residual pneumothorax persisted despite placement of a pig-tail catheter into the pleural cavity connected to a Heimlich valve (enlarged inset: the pleural line indicated by the arrow heads). The left lung became fully expanded after repositioning of the pig-tail catheter (full chest radiograph).

that fails to reexpand or recurs after catheter aspiration requires tube thoracostomy. Heimlich valves are often used. Initial treatment with tube thoracostomy is indicated for a traumatic pneumothorax and hemothorax, a pneumothorax occupying more than 15% of the ipsilateral pleural space with retained secretions or lung infections on the affected side, or a pneumothorax that developed while on mechanical ventilation. Thoracotomy or thoracoscopic surgical repair may be considered for patients with only partial lung expansion 5 to 7 days after a tube thoracostomy and for patients with a persistent air leak due to bronchopleural fistula. Thoracoscopic pleurodesis with talc or other drugs, thoracoscopic pleurectomy, thoracoscopic pleural abrasion, or chest tube pleurodesis may be considered to prevent recurrence.<sup>37</sup>

## Thromboembolic Diseases

### Venous Thromboembolism

The association between malignancy and venous thromboembolism (VTE) is well established; numerous studies have demonstrated that almost all types of cancer may be associated with an increased risk for thromboembolic disease. VTE is the second leading cause of death in patients with cancer. VTE comprises two related conditions: deep venous thrombosis (DVT) and pulmonary embolism (PE). DVT is often a precursor of PE. Unfortunately, even one and a half centuries after Armand Trousseau reported the association between VTE and malignancy in 1865, the pathophysiology of VTE remains poorly understood.

Compared with non-cancer patients, cancer patients have higher rates of initial thrombosis, recurrence of thrombosis, and fatal PE.<sup>38</sup> Patients with malignancy and no underlying comorbid condition have a 15 to 20% risk of developing thromboembolic disease. Compared with patients without cancer undergoing similar procedures, cancer patients undergoing surgery have two to three times the risk of developing postoperative VTE.<sup>39</sup> The most common cancers associated with VTE include prostate, colon, lung, and brain cancer (in men), and breast, lung, and ovarian cancer (in women).<sup>40,41</sup> In one retrospective analysis, pancreatic cancer was also associated with a high incidence of VTE and a 12.1% per-hospitalization risk of VTE.<sup>42</sup> In another study, genitourinary and gynecologic malignancies were commonly associated with VTE.<sup>43</sup> The incidence of DVT after surgery for brain tumors has been reported to be 1.6 to 4%. PE occurs in as many as 5% of patients after neurosurgery, and the associated mortality rate is 9 to 50%.<sup>44,45</sup>

Extrinsic factors play an important role in cancer patients' predisposition to VTE. These include cytotoxic chemotherapeutic agents which

increase the risk 6.5-fold<sup>54</sup> hormonal treatments (estrogens and anti-estrogens), radiotherapy, and central venous catheters. Radiotherapy causes endothelial damage, making a nidus for the formation of platelet clumping.

The presence of a central venous catheter, commonly used in cancer patients to facilitate chemotherapy administration and blood draws, is an independent risk factor for VTE and carries the same weight as other risk factors, such as malignancy, chemotherapy, and oral contraceptive therapy.<sup>46</sup> Approximately 13 to 35% of patients with subclavian venous catheters develop axillary-subclavian vein thrombosis, with catheterization estimated to account for 39% of all subclavian vein thromboses.<sup>47</sup> The question of whether cancer patients with central venous catheters should receive prophylaxis with warfarin is controversial, and a need for more randomized studies is recognized.<sup>48</sup>

Patients with a prior episode of VTE are at increased risk for recurrence, especially if other risk factors are present. In a case-control study, patients with prior VTE had eight times the risk of a subsequent episode compared to patients without prior VTE.<sup>49</sup>

### Diagnostic Strategies in the Emergency Setting

In the emergency room, the diagnostic evaluation of patients with suspected VTE should include history and complete physical examination, radiologic imaging, and, as more recent evidence suggests, laboratory studies. The clinician needs to be astute to elicit additional risk factors that would predispose the cancer patient to VTE, as discussed previously.

In the case of DVT, the patient may be asymptomatic or have complaints such as pain or swelling in the involved extremity. It is difficult to diagnose PE in cancer patients because the signs and symptoms are vague and difficult to differentiate from those related to the malignancy process or side effects of cancer treatments. The most common presenting symptoms of PE are dyspnea, tachypnea, and pleuritic chest pain.<sup>50,51</sup> Sometimes, fever and a pleural rub may be detected. When massive PE occurs, increase in pulmonary vascular resistance and right ventricular afterload causes right ventricular failure. The patient may have angina due to right ventricle ischemia. Cardiovascular collapse and death may ultimately occur following development of ischemia, right ventricular dysfunction, tricuspid regurgitation, and forward flow failure. Hemoptysis is rare and is associated with pulmonary infarction, a complication happening 12 to 36 hours after PE.

Although DVT in the lower extremities occurs in fewer than half of all patients with PE,<sup>52</sup> the lower extremities should be examined for evidence of thrombosis. Assessment of oxygen

saturation by pulse oximetry or arterial blood gas measurements and calculation of alveolar-arterial oxygen gradient can be helpful. A chest radiograph is needed to exclude causes of pulmonary symptoms other than PE. An electrocardiogram commonly shows sinus tachycardia, inverted T waves, or nonspecific ST-T wave abnormalities, but the S<sub>1</sub>-Q<sub>3</sub>-T<sub>3</sub> pattern classical for PE is uncommon. Other electrocardiographic changes associated with right ventricular abnormalities such as right axis deviation, atrial arrhythmia, P-pulmonale, and right bundle branch block may occur. Electrocardiography, chest radiography, and measurement of arterial blood gases, although routinely performed in patients with clinically suspected PE, may not be of value in confirming the diagnosis.<sup>53</sup>

D-dimer, a marker of endogenous fibrinolysis, has been studied in a variety of settings to determine whether it can be used alone or in combination with radiologic studies to exclude the diagnosis of VTE. Elevated D-dimer levels usually occur in patients with VTE but may also be elevated in other conditions, including infection, trauma, and malignancy. Several studies in the 1990s showed that the D-dimer has a high negative predictive value and is a sensitive but nonspecific marker of VTE. In a meta-analysis of studies from 1983 to 2003 comparing results of different D-dimer assays with findings on objective tests for VTE (compression ultrasonography, venography, and lung scanning) in patients with suspected DVT or PE, Stein and colleagues concluded that the D-dimer enzyme-linked immunosorbent assay (ELISA) had 95% sensitivity and negative likelihood ratios (about 0.1) for excluding DVT and PE.<sup>54</sup>

The usefulness of a D-dimer test coupled with clinical suspicion of DVT was tested in a study of 1,096 outpatients.<sup>55</sup> The patients were divided into two groups by using the "Clinical Model for Predicting the Pretest Probability of Deep-Vein Thrombosis."<sup>56</sup> Completely normal findings on D-dimer testing may exclude the possibility of VTE in a low-risk population. Recent data suggest that D-dimer testing may be also be used to determine if a patient has a recurrent DVT. Plasma D-dimer measurement seems to provide a simple method for excluding acute recurrent DVT in symptomatic patients.<sup>57</sup>

Venous compression ultrasonography is the radiologic diagnostic test of choice for suspected DVT.<sup>58</sup> Normally, the veins are compressible. In the presence of a DVT, the vein is non-compressible.<sup>59</sup> Contrast venography remains the reference standard for diagnosis of DVT, but is rarely used because it is invasive, expensive, and not readily available.<sup>53</sup>

The degree of clinical suspicion should guide the clinician in the diagnostic work-up of VTE, especially PE. A patient with a high clinical

suspicion of PE should undergo imaging testing immediately. D-dimer is not the diagnostic test of choice when there is a high clinical suspicion of PE but may be useful if the clinical probability is low.<sup>60,61</sup>

The radionuclide ventilation-perfusion (V/Q) scan is a common initial test for diagnosing PE. When V/Q scans are interpreted as having an “intermediate probability” of PE, other tests such as spiral CT, MRI, and pulmonary angiography may be indicated to further investigate the diagnosis of PE. Spiral CT and MRI are relatively new diagnostic modalities with sensitivities and specificities of about 80% and 90%, respectively.<sup>62,63</sup> Despite those rates, PE in the distal pulmonary vasculature is not reliably detected with these modalities<sup>64</sup>; the negative predictive value of spiral CT angiography for PE is 98% (Figure 4).<sup>65</sup> Spiral CT is increasingly becoming the diagnostic method of choice for acute PE at many institutions. Moores and colleagues performed a meta-analysis of the literature from 1966 through 2004, assessing the safety of withholding anticoagulation in patients with suspected PE and negative results on spiral CT, and concluded that it was safe to withhold anticoagulation after negative spiral CT results since the rate of subsequent VTE was the same as that seen after negative results on conventional pulmonary angiography.<sup>66</sup> Nevertheless, the gold standard for the diagnosis of PE is pulmonary angiography, which should be considered in patients with strong clinical suspicion of PE and negative initial diagnostic tests.<sup>67</sup>

**FIGURE 4** Bilateral pulmonary embolism. A CT chest angiogram demonstrated multiple filling defects in the lumen of pulmonary vasculature on both sides (arrow heads) in a pancreatic cancer patient with chest pain and dyspnea.

### Treatment Options in the Emergency Setting

In cases of massive PE, hemodynamic instability and hypoxia must be treated emergently with intravenous crystalloid fluids, inotropic agents, and oxygen administration by mask or endotracheal tube. For patients in whom PE is strongly suspected, heparin or low-molecular-weight heparin (LMWH) should be administered unless clinically contraindicated. Unfractionated heparin is administered in a bolus injection of 80 U/kg, and then a continuous intravenous infusion of 18 U/kg/h is used, adjusted to maintain the activated partial thromboplastin time at 1.5 to 2.0 times the baseline control value.<sup>68</sup> LMWHs are alternatives for unfractionated heparin<sup>69</sup> with the same or lower risk of bleeding complications as unfractionated heparin,<sup>70</sup> and have the advantage of not requiring intravenous access and partial thromboplastin time monitoring. Thrombolysis is generally considered in patients with massive PE and hemodynamic instability.<sup>71</sup> Criteria for thrombolytic therapy are emboli occlusion of more than 40% of the pulmonary vasculature,<sup>72</sup> echocardiographic evidence of right ventricular dysfunction, and severe hypoxemia.<sup>73</sup> Compared to anticoagulation alone, thrombolytic therapy doubles the rate of major complications, including intracranial hemorrhage.<sup>74</sup> Although thrombolysis accelerates fibrinolysis and clot dissolution and improves cardiopulmonary function, a definite beneficial effect on mortality remains to be demonstrated by large-scale studies.<sup>75</sup> Surgical and catheter embolectomy is reserved for patients in whom the usual treatment approaches fail.

In hemodynamically stable patients with VTE, treatment should begin with administration of unfractionated heparin or LMWHs to prevent thromboembolic recurrence. The therapy should begin immediately after the diagnosis is established. Studies comparing the LMWHs and unfractionated heparin have found that they are equally effective, but LMWHs have the advantage of potential outpatient administration and no need for coagulation laboratory monitoring.<sup>40,76,77</sup> For cancer patients, anticoagulation therapy should be continued until the malignancy is no longer active,<sup>78</sup> and LMWHs may be superior to warfarin in the prevention of recurrent VTE.<sup>79</sup> The high drug cost of LMWHs may be offset by the cost of coagulation laboratory monitoring required for warfarin therapy.

Outpatient treatment of DVT with LMWHs and close monitoring has become standard practice. Patients treated on an outpatient basis need to have follow-up with their primary physicians within 3 to 5 days for monitoring of the platelet count and coagulation parameters and decide whether or not to transition to oral anticoagulation.<sup>80</sup> Outpatient treatment of PE has been investigated in a limited number of studies of the general patient population. Patients with low

risk according to a quantitative risk score were treated successfully in the outpatient setting with LMWH.<sup>81</sup> Another prospective cohort study showed that outpatient LMWH treatment was feasible and safe for patients with non-massive PE.<sup>82</sup> Outpatient treatment of PE needs to be investigated further in cancer patients. Exclusion criteria for the outpatient treatment of VTE with LMWH should include the need for hospitalization (because of the severity of the disease and comorbidities), active bleeding, and severe coagulopathy.

Patients with VTE who are severely thrombocytopenic, who are at risk of serious bleeding, who are actively bleeding, or who are allergic to heparin products present a therapeutic challenge to the emergency center physician. The accepted indications for the placement of an inferior vena caval filter include active bleeding, risk of serious bleeding that precludes the use of anticoagulant therapy, and failure of anticoagulant therapy. However, the use of inferior vena caval filters is associated with an increased long-term risk of recurrent DVT despite concurrent oral anticoagulant therapy.<sup>83</sup>

### Hemostatic Disorders and Acute Hemorrhage

After organ failure due to tumor invasion and infection, bleeding is the third most common cause of death in patients with metastatic cancer and the second most common cause of death in patients with hematologic malignancies.<sup>84,85</sup> Causes of hemorrhage in cancer patients include coagulopathies due to the malignancy or its treatment, tumor invasion of vascular structures, and bleeding from the tumor itself.

In the hemorrhaging cancer patient, no matter where the bleeding site is, the immediate treatment goal is to achieve hemostasis, establish hemodynamic stability, determine the cause, and correct any coagulopathy. Prompt action on the part of the emergency physician will limit morbidity and mortality.

In the emergency setting, direct compression of the bleeding vessel or site should be applied whenever feasible while the cardiopulmonary status is rapidly assessed. Intravenous fluid resuscitation is vital to maintain intravascular volume, cardiac output, and adequate vital organ perfusion. Isotonic crystalloid fluids (lactated Ringer's solution, normal saline, etc.) are the appropriate first-line agents because colloids (eg, hetastarch) have not been proven to improve survival compared with crystalloids.<sup>86</sup> Coagulopathy and thrombocytopenia should be corrected by transfusion of blood products as quickly as possible. Whether to transfuse red blood cells depends on hemodynamic stability, estimated blood loss,

persistence of hemorrhage, and comorbid conditions (eg, ischemic heart disease and cerebrovascular disease). Typed and cross-matched red blood cells are preferred, but in the case of massive life-threatening hemorrhage, non-cross-matched type-specific blood or type-O blood may have to be administered during emergent resuscitation. Specific procedures to control bleeding, such as balloon tamponade, embolization, or surgical ligation of bleeding vessels, should be performed rapidly.

### Massive Hemoptysis

Massive hemoptysis can be defined as expectoration of 100 mL of blood in a single episode or more than 600 mL of blood over a 24-hour period.<sup>87,88</sup> Mortality increases with increased bleeding. Nearly a third of patients with massive hemoptysis have a fatal hemorrhage.<sup>89</sup> Death results from asphyxiation rather than exsanguination.

Patients at greatest risk for massive hemoptysis are those with tumors involving the airway (eg, endobronchial tumor or tumor invading the pulmonary or bronchial vessels). Other causes of massive hemoptysis include infection (eg, necrotizing pneumonia or lung abscess due to various organisms, including mycobacteria and fungi), PE with infarction, and bronchiectasis. Hemostatic abnormalities, such as severe thrombocytopenia and coagulopathy, may result from malignancy or its treatment, and impaired hemostasis will worsen pulmonary hemorrhage. Hemoptysis may be the presenting symptom of malignancy, especially in patients with lung cancer. Metastatic disease from breast cancer, melanoma, laryngeal cancer, sarcoma, or lymphoma may also lead to massive hemoptysis.<sup>90</sup>

The airway should be protected. Intubation is recommended for patients with rapid bleeding, hemodynamic instability, severe dyspnea, ventilatory impairment, or hypoxia.<sup>87</sup> Patients with hemodynamic instability also require volume resuscitation, administration of supplemental oxygen, correction of underlying coagulopathies, and cough suppressants. Attempts should be made to localize the site of bleeding, and the patient should be positioned bleeding side down to prevent aspiration of blood into the unaffected lung. Maintenance of the airway is important, and the patient should be intubated in preparation for bronchoscopy. If the bleeding can be localized, unilateral intubation should be done to protect the non-bleeding lung.<sup>91</sup> A balloon occlusion (Fogarty) catheter may be used temporarily to tamponade the bleeding. Emergency thoracic surgery and pulmonary medicine consultations should be arranged.<sup>92</sup> Nonsurgical options include arterial embolization of bronchial arteries,<sup>93</sup> bronchoscopic laser photocoagulation and electrocautery,<sup>29,94–96</sup> or radiation treatment.<sup>93,97,98</sup>

### Carotid Artery Rupture

Rupture of the carotid artery (or “carotid blowout”) is one of the most devastating complications of head and neck cancer and its treatment and is now considered a syndrome. Carotid blowout syndrome (CBS) is defined as the rupture of the extracranial carotid arteries or their major branches. It is most commonly seen in squamous cell carcinoma of the head and neck. Additional risk factors include previous neck dissection, irradiation, previous CBS with stent placement, and wound infection.<sup>99–102</sup>

Carotid artery rupture often occurs as a sudden and massive arterial spurting. Occasionally, ominous minor and transient sentinel bleeding episodes herald the massive carotid blowout. In some cases, bleeding through a fistula into the esophagus, trachea, hypopharynx or pharynx may masquerade as massive hematemesis or hemoptysis. Even with prompt management, many such patients will rapidly deteriorate with hypotension, hypovolemic shock, and loss of consciousness, ending in death.

Prompt control of the bleeding site is key in reducing mortality. Firm, constant pressure with a gauze bandage at the site of bleeding is mandatory until the patient arrives in the operating room or interventional radiology suite. Initial management should also include airway management and aggressive fluid resuscitation. Large-bore intravenous access with crystalloid infusion should be immediate. Transfusion of packed red blood cells should be started promptly. Vasopressor agents may be necessary for hemodynamic support until the bleeding can be stopped. The bleeding very rarely stops spontaneously. With emergent operative ligation of the common carotid artery or internal carotid artery, a mortality rate of 40% and a neurologic morbidity rate of 60% have been reported.<sup>103–105</sup> More recently, management of carotid blowout syndrome with intraluminal balloon occlusion and endovascular stenting has shown promising results: reported morbidity and mortality rates are less than 10%.<sup>106–108</sup>

### Splenic Rupture

Acute leukemia, chronic myelogenous leukemia and non-Hodgkin’s lymphoma are malignancies commonly associated with spontaneous splenic rupture. Other associated malignancies include hairy cell leukemia, Hodgkin’s lymphoma, gastric cancer, prostate cancer, and lung cancer. The mechanism of spontaneous splenic rupture is not clear but may involve minor trauma to the spleen, infiltration of the splenic capsule by malignant cells, severe splenomegaly, splenic infarction, thrombocytopenia, and coagulopathy.

Pain in the left shoulder or abdomen (left upper quadrant), tachycardia, and hypotension are typical signs and symptoms of splenic

rupture, the severity of which depends on the extent of bleeding. Diagnostic peritoneal lavage is rarely used in non-trauma cases. Imaging studies often can provide a definitive diagnosis of splenic rupture. The diagnostic study of choice is CT, which is noninvasive and can provide detailed information about the severity of retroperitoneal or intraperitoneal hemorrhage. Splenic rupture can also be diagnosed by ultrasonography,<sup>109</sup> the portability of which allows bedside evaluation for hemodynamically unstable patients.

Prompt splenectomy is indicated for patients with hematologic malignancies having splenic rupture because the mortality rate is high without surgery. In selected patients with contraindications to surgery, selective arterial embolization or external-beam irradiation of the ruptured site may control bleeding.<sup>110</sup> Patients who are not surgical candidates should be supported with intravenous crystalloid fluid, supplemental oxygen, pain medications, and blood products.

### Gastrointestinal Hemorrhage

Upper gastrointestinal bleeding is a common problem, both in the general patient population and in cancer patients. Fewer than 20% of cases of upper gastrointestinal bleeding can be attributed to cancer<sup>111–113</sup>; most cases of upper gastrointestinal bleeding are due to non-cancer causes, such as hemorrhagic gastritis and peptic ulcer disease, esophagitis, esophageal varices, and Mallory-Weiss tears. When cancer is the cause, the malignancies most commonly implicated include adenocarcinoma, lymphoma or sarcoma of the gastrointestinal tract, and metastatic tumors.

Treatment of upper gastrointestinal bleeding in cancer patients should address the cause. Fluid resuscitation and blood transfusions are warranted to maintain hemodynamic stability. Correction of coagulopathy is necessary, and, if the patient is actively bleeding, platelet transfusions should be given to maintain the platelet count above 50,000 per microliter. H<sub>2</sub>-antagonists or proton-pump inhibitors are routinely given to reduce or neutralize gastric acid, but this has not been shown to stop active bleeding or prevent rebleeding.<sup>114</sup> Endoscopic therapies such as epinephrine injections, bicap electrocoagulation, heater probe, and the argon plasma laser coagulator may be used to achieve hemostasis.

### Retroperitoneal Hemorrhage

Any damage to retroperitoneal organs (eg, the kidneys, adrenal glands, pancreas, duodenum, major blood vessels) may cause retroperitoneal hemorrhage. Retroperitoneal or intraperitoneal invasive procedures (including radiofrequency coagulation for treatment of liver tumors<sup>115</sup>) and placement of a central venous catheter through a femoral vessel can also cause severe retroperitoneal hemorrhage. Malignancies rarely cause spontaneous retroperitoneal hemorrhage; cases

involving renal cell carcinoma (primary or metastatic),<sup>116</sup> angioliipoma,<sup>117</sup> or adrenal-gland tumors<sup>118</sup> have been reported. Hemostatic abnormalities are predisposing factors for spontaneous retroperitoneal hemorrhage.

Retroperitoneal hemorrhage causes nonspecific signs and symptoms that may vary according to the rate of, and the site of, bleeding. Patients may present with abdominal pain, a tender mass in the flank, tachycardia, and hypotension. Some may have hematuria or hematochezia if the blood somehow finds its way into the ureter or gastrointestinal tract. Diagnosis of retroperitoneal hemorrhage is difficult on the basis of clinical findings, and a high level of clinical suspicion and early imaging studies are keys to successful diagnosis and treatment. CT of the abdomen and pelvis is the noninvasive study most commonly used to diagnose retroperitoneal bleeding. (Figure 5.) Ultrasonography can be performed at the bedside for rapid diagnosis of unstable patients.

In the emergency center, stabilizing treatments for acute retroperitoneal hemorrhage—such as intravenous crystalloid fluid, blood transfusion, and correction of coagulopathy and thrombocytopenia—should be started immediately. The patient should be monitored closely for hemodynamic stability. In life-threatening cases of acute retroperitoneal hemorrhage, most patients require emergent laparotomy and surgical removal of the bleeding tumor or organ. Selective arterial embolization may control the bleeding of a renal lesion since renal cell carcinomas are often hypervascular. Preoperative embolization may also help minimize intraoperative blood loss. In hemodynamically stable patients with subacute bleeding, external-beam irradiation of the bleeding tumor may be performed.<sup>119</sup>

## Epistaxis

Epistaxis is common in patients with malignancies, especially in those who are thrombocytopenic or coagulopathic. Epistaxis is the most frequent otolaryngologic complication in patients undergoing leukemia treatment or bone marrow transplantation.<sup>120</sup> Most minor episodes of epistaxis result from drying of the nasal mucosa and local trauma to the anterior nasal vessels.<sup>121</sup> Epistaxis in cancer patients is usually not life-threatening. The physician's approach should be to maintain an adequate airway while reassuring the patient. If blood is aspirated and then expectorated or swallowed and then vomited, epistaxis may mimic hemoptysis or hematemesis, respectively. Maneuvers to control the bleeding may include pinching the nose, applying an ice pack to the face and nose, and applying pressure to the gingival buccal junction above the maxillary incisors to compress the anterior nasal artery. In cases of more severe bleeding, topical vasoconstrictors/decongestants [eg, phenylephrine hydrochloride, oxymetazoline] can be used to constrict the mucosal vessels to stop the bleeding. Electrocautery may also be used if the bleeding site can be identified. Nasal packing may be used for anterior bleeds. Posterior artery bleeding necessitates posterior packing and endoscopic evaluation. Correction of thrombocytopenia and coagulopathy by transfusion of blood products is essential to control the bleeding.

## Urinary Tract Hemorrhage

Hematuria is common in patients with cancer, and it may be massive and life-threatening, requiring aggressive management. Causes include tumor involving the bladder, chemotherapy, radiation-induced or viral hemorrhagic cystitis,

and severe coagulopathy. Bladder and prostate carcinomas are the tumors that most often cause massive hematuria. Cervical and rectal carcinomas may also cause bleeding if they invade the bladder.<sup>122</sup> The oxazaphosphorine drugs (cyclophosphamide, ifosfamide, and busulfan) are the chemotherapy agents most commonly associated with hemorrhagic cystitis.<sup>123,124</sup> Prophylactic measures aimed at minimizing the formation of the offending metabolite and its contact with the bladder epithelium include aggressive hydration to encourage frequent urination, continuous bladder irrigation, and administration of the uroprotective agent 2-mercaptoethane sulfonate.<sup>122</sup> Patients who have undergone bone marrow transplantation may develop severe hemorrhagic cystitis associated with adenovirus and parvovirus infections.<sup>125,126</sup> Pelvic irradiation may result in bladder complications, including massive hematuria; the tumors most commonly associated with this finding include bladder, rectal, cervical, and prostate carcinoma.

Massive hematuria may lead to intravesicular clot formation and urinary retention. In such cases, after a urology consultation, the bladder should be lavaged to evacuate clots via a three-way Foley catheter, and continuous bladder irrigation with normal saline should be continued until bleeding subsides. Aggressive volume resuscitation with crystalloid intravenous fluid and packed red blood cell transfusion may be necessary. Any coagulation abnormalities must be promptly addressed. If hemorrhage persists, formalin, alum, prostaglandins, phenol, iced saline, or silver nitrate may be instilled in the bladder in an attempt to stop the bleeding. Should conservative measures fail, surgical measures may be required to control bleeding.<sup>127</sup>

## Central Nervous System Emergencies

### Altered Mental Status

“Altered mental status” is a general phrase describing reduced levels of mentation, including impaired cognition, diminished attention, altered level of consciousness, and/or reduced awareness, and may range from intermittent mild disturbance to coma. Altered mental status is a common chief complaint in emergency departments, accounting for 4 to 10% of emergency visits in the general population, and may be a confounding complaint with other clinical presentations (Table 3). Elderly patients are more likely (up to 30%) to present with altered mental status for emergency care than are younger patients.<sup>128</sup>

The evaluation of altered mental status in an emergency setting requires complete evaluation of the patient. A reliable history is often not attainable from the patient, and family members and/or bystanders offer important components

**FIGURE 5** Retroperitoneal bleeding from left iliac artery with hemoperitoneum. A 44 year-old male with retroperitoneal malignant fibrous histiocytoma had surgical resection of the cancer 6 weeks prior to presentation at the emergency center with mild abdominal pain and hypotension. CT scan of the abdomen demonstrated hemoperitoneum (left panel: arrow heads) and extravasation of intravenous contrast from the left iliac artery (right panel: arrow head).

**Table 3** Differential Diagnosis of Altered Mental Status in a Cancer Patient

Hypoxia
Hypoglycemia or hyperglycemia
Thiamine deficiency
Hypothermia or hyperthermia
Seizures
Toxins (medications, illicit drugs, alcohol)
Electrolyte abnormalities
Infectious causes (meningitis, encephalitis, abscess)
Stroke
Subarachnoid hemorrhage
Intracerebral hemorrhage
Tumors
Metabolic encephalopathy/encephalopathy (hepatic, uremic, sepsis, etc.)
Hypercapnia
Vasculitis

of the history. Underlying medical conditions—including diabetes mellitus, hypertension, coronary artery disease, chronic obstructive pulmonary disease, and alcohol abuse—may point to a possible cause (Table 3).<sup>129</sup>

Patients with altered mental status should be examined to ensure that their vital signs are sufficient to support brain function. The “ABCs”—airway, breathing, and circulation—are of utmost importance. Blood pressure, respiration rate, and oxygen saturation must be checked, and testing must be done to ensure that the patient is not hypoglycemic. Once these basic functions are examined, a complete physical examination, including a complete neurologic examination, should be completed. Essential laboratory studies should be ordered, including a complete blood cell count, prothrombin time, partial thromboplastin time, chemistry panel, toxicologic screen, and blood cultures.<sup>130</sup> Arrhythmias and acute myocardial infarction should be ruled out by obtaining an electrocardiogram and measuring appropriate cardiac enzymes. Arterial blood gas values should be obtained if hypoxemia, hypercapnia, drug intoxications, or metabolic encephalopathies are being considered. A head CT scan or a lumbar puncture should be emergently obtained if intracranial pressure or meningitis is considered in the differential diagnosis.

In all patients with coma, a 100 mg intravenous dose of thiamine, an important cofactor for several enzymes, should be replaced since its depletion can lead to Wernicke’s encephalopathy. If opiate overdose is a possible cause, intravenous naloxone, 0.4 to 2.0 mg, should be given. Flumazenil, a specific benzodiazepine receptor blocker, can reverse benzodiazepine-induced coma. However, the benefits of reversing coma induced

by benzodiazepine must be weighed against the risk of flumazenil-induced seizures or cardiac arrhythmias.<sup>131</sup>

### Spinal Cord Compression

About 1 to 5% of cancer patients may develop spinal cord compression, and they should be treated emergently because delays may result in permanent neurologic deficits.<sup>132</sup> Spinal cord compression due to cancer most commonly involves the thoracic spine: 70% of cases involve the thoracic spine; 20%, the lumbosacral spine; and 10%, the cervical spine. Spinal cord compression may be the initial presentation of lung cancer, breast cancer, prostate cancer, multiple myeloma, lymphoma, renal cell cancer, or sarcoma.

Either direct compression or interruption of the vascular supply causes injury to the spinal cord by the tumor. Pain is the most prevailing presenting symptom—present in over 90% of patients. Unlike the pain in degenerative intervertebral disc disease, the pain in spinal cord compression tends to worsen when the patient is supine, moving the back, coughing, or sneezing. Pain (radicular or local, constant or intermittent) may be present for days or months before the emergence of other neurologic deficits. Associated neurologic symptoms may include motor and sensory deficits in the spinal cord levels below the highest point of compression, and autonomic dysfunction (bowel or bladder dysfunction). Physical examination may reveal bone tenderness over the involved area, sensory loss, ataxic gait, or muscle paralysis. Paraplegia with difficulty in ambulation is present at diagnosis in almost three-quarters of patients with spinal cord compression.<sup>133</sup> Dense paralysis and urinary retention before treatment are predictors of a poor neurologic outcome.

The differential diagnosis includes intramedullary metastasis, disc herniation, vertebral body fracture with retropulsion of bone fragment, epidural abscesses, and hematoma. Plain radiographs of the spine may demonstrate bony abnormalities but offer no information on soft tissue lesions. The diagnostic test of choice is MRI of the spine with gadolinium enhancement (Figure 6).<sup>134</sup>

Prompt adequate analgesic therapy will facilitate patient cooperation for physical examination and diagnostic imaging studies. High-dose corticosteroids should be started when the spinal cord compression by tumor is clinically suspected. There is no clear clinical study data to support the superiority of one particular corticosteroid dosing regimen over others. The initial dose of dexamethasone varies from 10 to 100 mg in common clinical practice, and this is usually followed by 4 to 10 mg every 4 to 6 hours.<sup>135</sup> An emergent neurosurgical consultation should be sought to

**FIGURE 6** Thoracic spinal cord compression. A 43 year-old male with adenocarcinoma of the left lacrimal gland presented with severe back pain between his scapulae plus bilateral chest pain. Magnetic resonance imaging of the spine demonstrated tumor replacement of T6 thoracic vertebral body with complete collapse of the vertebral body and epidural extension of the tumor compressing the spinal cord. The patient was treated by emergent T6 discectomy, corpectomy and stabilization, and postoperative radiotherapy.

determine if surgery is indicated. If surgical intervention is not warranted, radiotherapy at the level of the compression should be initiated, although prior radiotherapy to the involved anatomic region must also be taken into consideration.

### Increased Intracranial Pressure with Brain Herniation

Increased intracranial pressure may be caused by primary brain tumors, brain metastases, intracranial hemorrhage, infection, or trauma. Cancers that most frequently metastasize to the brain include lung cancer, breast cancer, and melanoma. Depending on the underlying process, the presentation may be acute or subacute. Processes that develop gradually usually allow early diagnosis and treatment in the clinic setting before herniation develops. Acute processes (eg, hemorrhage) may cause rapid deterioration of neurologic function and require emergency intervention. Patients with hematologic malignancies are likely to have prolonged thrombocytopenia, which increases the risk of intracranial hemorrhage.

The patient with elevated intracranial pressure and brain herniation is often unconscious on arrival at the emergency department. The examination must focus on signs of brain herniation, including level of consciousness, presence of papilledema, papillary size and light responses, whether the patient is exhibiting decerebrate or decorticate posturing, and the presence of nuchal

rigidity or opisthotonos. Uncal herniation, and central transtentorial herniation produce characteristic clinical syndromes, but foraminal or tonsillar cerebellar herniation and transfalcial (cingulated) herniation are difficult to recognize due to the lack of specific features. Cushing reflex (systemic hypertension and bradycardia) is a late finding in elevated intracranial pressure.<sup>136</sup>

If clinical findings suggest increased intracranial pressure or brain herniation and the patient is neurologically unstable, treatment to decrease intracranial pressure should be instituted immediately, even before brain imaging studies. Emergent treatments for brain herniation are hyperventilation, mannitol, and corticosteroids. Hyperventilation is the fastest way to decrease intracranial pressure, but the effects generally last only a few hours. After endotracheal intubation, the ventilator is set to hyperventilate, targeting a PCO<sub>2</sub> of 25 to 30 mm Hg. Hypocapnia causes cerebral vasoconstriction, decreases cerebral blood volume, and, consequently, decreases intracranial pressure. Mannitol, a hyperosmotic agent, also has fast onset but short-lived effects. Solutions of 20 to 25% mannitol are infused intravenously (IV) at 0.5 to 2 g/kg over 20 to 30 minutes. Additional doses may be given if the patient's clinical condition continues to deteriorate. Corticosteroids may be helpful, especially when vasogenic edema is present. Dexamethasone is most often used, and is usually administered IV as an initial bolus of 40 to 100 mg, followed by 40 to 100 mg IV per day in divided doses. Immediate neurosurgical consultation should be sought in the emergency department to determine whether surgical intervention is indicated. Once the patient is stabilized, treatment should be directed at the underlying cause.

### Status Epilepticus

Seizures in cancer patients may be due to metabolic, infectious, structural, and cancer-treatment-related causes, but the majority of cancer patients presenting to an emergency center with seizures are due to brain lesions.<sup>137</sup> Status epilepticus is defined as continuous seizure activity or successive seizures without full recovery between seizures for more than 30 minutes. It can lead to devastating neurologic damage from neuronal injury and cell death, as well as serious systemic complications (eg, neurogenic pulmonary edema and rhabdomyolysis with renal failure).

After seizure activity, physical examination may show bruises, bitten tongue, and signs of urinary or fecal incontinence. Patients may have focal neurologic deficits and altered mental status (confused or unresponsive) in a postictal phase, which may last for up to 24 hours. Laboratory findings may reveal increases in lactic acid and

muscle enzyme levels. The status of the malignancy, cancer treatment history, seizure history, and current medications should also be reviewed.

When a cancer patient presents with status epilepticus, airway, breathing, and circulation should be quickly assessed, and then anticonvulsant therapy with a benzodiazepine (lorazepam or diazepam) should be administered parenterally. Phenytoin (or given as the prodrug fosphenytoin sodium) and phenobarbital are second-line and third-line agents, respectively. After a seizure, the unconscious patient should be placed lying on his or her side in the recovery position to prevent aspiration. Supplemental oxygen and airway suctioning may be needed. For patients with continuing seizure activity refractory to anticonvulsants, combination anticonvulsant therapy with complete sedation or anesthesia is required in the intensive care unit with endotracheal intubation, mechanical ventilation, and monitoring with electroencephalography.

The precipitating factor in provoked seizures needs to be identified by measurement of electrolytes, serum glucose, calcium and magnesium, and hepatic and renal function testing. A complete blood cell count, blood cultures, arterial blood gases, drug screens and electrocardiography may be appropriate. Lumbar puncture may also be needed, depending on the suspected precipitating factor, the patient's condition, and findings on brain imaging by CT or MRI.<sup>138</sup>

### Tumor Lysis Syndrome

Tumor lysis syndrome (TLS) is caused by the death of a large number of cancer cells,<sup>139</sup> and is characterized by hyperuricemia, hyperkalemia, azotemia, hyperphosphatemia, hypocalcemia, and metabolic acidosis out of proportion to the degree of renal insufficiency. TLS usually occurs after chemotherapy (including corticosteroid alone in sensitive lymphomas),<sup>140</sup> immunotherapy,<sup>141</sup> or radiotherapy,<sup>142</sup> but can also occur spontaneously. Historically, TLS has usually occurred less than 72 hours after chemotherapy in patients with leukemia and lymphoma. New effective treatments have caused TLS in patients with chronic lymphocytic leukemia, which is an indolent and chronic disease.<sup>141</sup> TLS also has been reported in patients with solid tumors, including small-cell carcinomas,<sup>143</sup> breast cancer,<sup>144</sup> non-small-cell lung cancer,<sup>145</sup> and ovarian cancer.<sup>146</sup> The dreaded consequences of TLS are life-threatening arrhythmia secondary to the severe electrolyte abnormalities (especially hyperkalemia) and renal failure. Early recognition of metabolic abnormalities in TLS and prompt treatment can minimize morbidity and avoid mortality.

Common symptoms of TLS include nausea, vomiting, weakness, fatigue, cloudy urine, muscle

cramps, and arthralgia. Physical signs include neuromuscular irritability, seizures, muscle weakness, and arrhythmias. Hyperphosphatemia, hyperkalemia, and hypocalcemia may lead to cardiac arrhythmia or tetany. Arrhythmia in TLS may cause sudden death.<sup>147</sup> Precipitation of uric acid or calcium phosphate in the renal tubules may lead to acute renal failure.

Factors associated with high risk of TLS include the type of malignancy (eg, the risk is high in patients with Burkitt's lymphoma), responsiveness of the malignancy to treatment, rapid cell cycle turnover, and large tumor burden. Other risk factors are acute renal failure developing shortly after chemotherapy, preexisting renal insufficiency, and poor response to hydration. Pretreatment lactate dehydrogenase levels, which correlate with tumor bulk in patients with stage C or D lymphoma, can predict the development of azotemia after chemotherapy, but pretreatment uric acid levels are not predictive. Preventive measures in patients at risk for TLS include aggressive hydration with intravenous crystalloid fluid up to 3 L/m<sup>2</sup>/d to maintain a urine output of >100 mL/h with or without loop or osmotic diuretics, and the xanthine oxidase inhibitor allopurinol (100 to 300 mg orally per day).

There are few or no signs or symptoms in early TLS, and the diagnosis requires a high level of suspicion. In cancer patients with risk factors for TLS, routine uric acid and electrolyte screening (including calcium and phosphorus levels) is indicated. Once diagnosed, patients with severe TLS should have intravenous fluid hydration coupled with diuresis by loop diuretics (eg, furosemide 20 to 200 mg IV every 4 to 6 hours), acetazolamide (250 to 500 mg IV daily) and mannitol. If aciduria is present, sodium bicarbonate or sodium acetate infusion may be used to alkalinize the urine between pH 7.1 and 7.5. To treat hyperuricemia, allopurinol may be increased up to 900 mg/d. Recombinant urate oxidase (uricozyme or rasburicase, an enzyme that oxidizes uric acid to allantoin) (200 µg/kg IV daily) may be used to prevent or treat urate nephropathy.<sup>148</sup> The high potassium level can be lowered rapidly by shifting potassium into cells with IV administration of insulin plus dextrose, IV sodium bicarbonate, and beta-adrenergic stimulation. To remove potassium from the body, loop diuretics, oral potassium ion-exchange resins (sodium polystyrene sulfonate), and dialysis may be used. Intravenous calcium infusion can stabilize excitable membranes and decrease the risk of arrhythmia and tetany in hyperkalemia. In hyperphosphatemic patients with hypocalcemia, oral calcium-based phosphate-binding compounds (eg, calcium acetate or calcium carbonate) will reduce phosphate absorption and increase calcium absorption. Intravenous calcium administration can potentially cause

precipitation of calcium phosphate in severe hyperphosphatemia, and should be used cautiously.

Indications for dialysis in patients with TLS include: (1) symptomatic hypocalcemia and a serum phosphorus level greater than 3.3 mmol/L (>10.2 mg/dL), (2) severe azotemia and renal failure (creatinine >10 mg/dL), (3) persistent hyperkalemia (>6 mEq/L), (4) severe hyperuricemia (>10 mg/dL), (5) oliguria or anuria despite diuretic use, (6) refractory acidemia, and (7) volume overload. Hemodialysis is commonly performed intermittently; continuous venovenous hemofiltration and continuous arteriovenous hemodialysis with a high dialysate flow rate are also effective.

## Infection

### Febrile Neutropenia

The most common reason for a visit to the emergency center at M. D. Anderson Cancer Center is fever. Infection remains the leading cause of morbidity and mortality in cancer patients with neutropenia.<sup>149</sup> A clinically evident source of infection will guide antibiotic therapy. In addition, a variety of factors in cancer patients will influence antibiotic therapy: immune compromise, the presence of vascular access devices, breach of host-defense barriers, and the probability of exposure to multi-drug-resistant microbes. Neutropenic fever is a true medical emergency, in which the timely administration of antibiotics may prevent sepsis or death. Neutropenia is defined as an absolute neutrophil count <500/ $\mu$ l or <1000/ $\mu$ l, depending on the reference cited.<sup>150,151</sup> A patient who is neutropenic for weeks is at greater risk for developing life-threatening infections than one who is neutropenic for less than one week.<sup>150,151</sup>

In a general emergency department review of the treatment of patients with neutropenia and fever, less than 50% of these patients had an identifiable source of infection.<sup>152</sup> The type of infection with prolonged or profound neutropenia can also be different than that seen in an immunocompetent host. Invasive fungal infections (*Candida*, *Aspergillus*), viral infections (cytomegalovirus), and life-threatening bacteremia (gram-negative rods) are seen with greater frequency in patients with prolonged neutropenia. In addition, patients who have been hospitalized are at risk for nosocomial infection with multi-drug-resistant organisms such as *Escherichia coli* with extended-spectrum  $\beta$ -lactamase and vancomycin-resistant enterococcus. Patients receiving prophylactic antibiotics may also have infection with organisms resistant to these antibiotics.<sup>153</sup>

During neutropenia, the mucosa of the alimentary tract may be altered, and mucositis

and stomatitis may give bacteria an entryway into the bloodstream, resulting in both gram-positive and gram-negative bacteremia. Perirectal and perineal infections may also occur and must be considered.

Guidelines have been published for the treatment of cancer patients with febrile neutropenia.<sup>154</sup> Low-risk patients with solid tumors (ie, patients with no evidence of infection, able to tolerate oral antibiotics, and able to return for close follow-up) may be treated with oral antibiotics on an outpatient basis.<sup>155,156</sup> These patients can be treated with a combination of oral amoxicillin/clavulanate 500 mg three times a day and ciprofloxacin 500 mg three times a day for a total of 7 days. Patients with solid tumors who have evidence of sepsis, soft tissue infection, or pneumonia, and who are unable to return for close follow-up in the case of a change in status, should be admitted to the hospital and receive intravenous antibiotics.

Most cancer patients with neutropenic fever require hospitalization and intravenous antibiotics—especially leukemia patients and bone marrow transplant recipients. Patients with no obvious infectious source can be treated with monotherapy. Other patients should receive combination therapy with a glycopeptide if there is a suspected gram-positive source of infection and/or receive combination therapy with an aminoglycoside if a gram-negative etiology is possible. Agents that have been studied for monotherapy include the broad-spectrum antibiotics, such as cefepime, carbapenems, and piperacillin/tazobactam.<sup>154,157–163</sup>

Other causes of fever in neutropenic cancer patients are medications used to treat the malignancy, such as monoclonal antibodies, other chemotherapeutic agents (eg, cytarabine), and granulocytic growth factors. Patients may also develop fever while receiving blood transfusions. Drug-induced fever from antibiotics has also been reported; the agents most commonly involved include ciprofloxacin, rifampin, and trimethoprim/sulfamethoxazole.<sup>164–166</sup>

Prophylactic antibiotics should be considered for neutropenic patients who are undergoing emergency invasive procedures because the invasive procedure may lead to bacteremia. Examples include rectal introduction of contrast material for a CT scan in a patient with potential neutropenic colitis and emergent endoscopy in a neutropenic patient.

In formulating an antibiotic regimen, the emergency physician must follow the hospital's antibiogram and be aware of the presence of antibiotic-resistant organisms in the institution and community. In addition, the patient's past culture results and sensitivities must be taken into account. Recent cultures revealing vancomycin-resistance enterococcus should alert the clinician to the risk of failure of empiric therapy using

vancomycin to cover gram-positive organisms. Linezolid or daptomycin should be considered as alternative therapy.<sup>167</sup> The current local *Pseudomonas* resistance patterns should alert the clinicians to the need for double empiric antibiotic coverage for *Pseudomonas*.

### Sepsis

The goal of treatment in patients with sepsis or septic shock is to decrease mortality by rapidly instituting appropriate therapy. With in-hospital mortality approaching 50% in some studies, prompt identification of the septic patient and initiation of therapy are key factors in improving clinical outcomes.<sup>168</sup> In 2003, experts in critical care and infectious diseases from 11 international organizations developed guidelines for managing severe sepsis and septic shock. The Surviving Sepsis Campaign, a worldwide effort, has increased awareness and improved clinical outcomes in sepsis.<sup>169</sup> Many hospitals have instituted "severe sepsis bundles" (a "bundle" being defined as a group of synergistic interventions) to facilitate organized, evidence-based health care in the critical care setting, and emergency departments have started to adopt the Surviving Sepsis Campaign guidelines. A major recommendation by the Surviving Sepsis Campaign is early goal-directed therapy, which is reported to reduce absolute mortality by 16%.<sup>170</sup> In the emergency center, therapy for sepsis must start early and continue throughout the hospital course.

Once a patient with signs and symptoms suggestive of sepsis is identified, the components of the "severe sepsis bundle" should be implemented within 6 hours. Diagnostic studies aimed to identify the infectious process and organisms should include blood cultures from two separate sites, appropriate cultures of body fluid and sites, and radiologic studies. Undisputedly, early appropriate empiric antibiotic therapy is the cornerstone of treating sepsis. Broad-spectrum antibiotics should be administered as soon as possible, preferably within 1 hour of diagnosis. Empiric antibiotic therapy should be chosen on the basis of the current bacterial susceptibility patterns in the hospital and community. Crystalloid and colloid volume resuscitation should begin immediately. Urine output, mental status, and changes in blood pressure should guide treatment. A septic patient may require as much as 6 L of intravenous fluid during the first 24 hours of treatment. Vasopressor support may include norepinephrine and dopamine (pressor doses of >5  $\mu$ g/kg/min) as first-line choices. Glucocorticoid supplementation in adrenal insufficiency produced a 10% benefit.<sup>170,171</sup> Stress dose steroids (eg, hydrocortisone 200 to 300 mg/d) may be necessary if adrenal insufficiency is suspected. Packed red blood cells should be replaced as necessary to maintain a hemoglobin level of 7 to

9 g/dL.<sup>172</sup> Other therapies such as recombinant activated protein C, tight glucose control, and low-tidal-volume ventilation strategies have also led to improved survival.<sup>170</sup>

# Geriatric Considerations in the Care of Cancer Patients

Claudia Beghe, MD  
Lodovico Balducci, MD

A reduction of cancer-related morbidity and mortality in older individuals is essential for cancer control for at least two reasons. First, cancer already affects more persons aged 65 and older than those younger, and this difference is going to widen with the aging of the population (Figure 1).<sup>1</sup> Second, cancer-related mortality has decreased for people younger than 65 but has increased for those older, during the past 50 years.<sup>2</sup> The management of cancer in the older aged person involves an answer to new questions germane to the aging of the population:

1. Why do incidence and prevalence of cancer increase with age?
2. Is cancer equally lethal and morbid in both younger and older individuals?
3. Which older persons may benefit from cancer prevention and cancer treatment (that is, which ones have a life expectancy long enough to die of cancer or to suffer the complications of cancer)? Which ones are able to tolerate cancer treatment?
4. What type of clinical trials are necessary to assess benefits and risks of cancer prevention and cancer treatment in older persons? How can we increase the participation of older individuals in clinical trials?
5. What is the role of the primary care physician in cancer control?

These questions will be addressed after reviewing the extent of the problem (that is, the epidemiology of cancer and aging).

## Epidemiology of Cancer and Aging.

At the beginning of the past century, the age-weighted profile of the population appeared as a pyramid, with a wide base of individuals younger than 20 and a small tip representing those over 85. Today the pyramid has become closer to a square (what epidemiologists like to call the squaring of the pyramid), due to a prolongation of the average life expectancy and a reduction in fatality

**FIGURE 1** Cancer burden of people aged 65+ in 2000 and 2030.

rate.<sup>3</sup> Of interest, the segment of the population undergoing the most rapid expansion in the United States and in the developed world is that aged 85 and over!

The aging of the population has been associated with an increased incidence and prevalence of chronic disease, among which cancer is prominent (Figure 2) since the incidence of most common cancers increases with age. While the mortality rate of cardiovascular disease is decreasing, that of cancer is increasing,<sup>4</sup> and, in a non-distant future, cancer may become the number one cause of mortality for older individuals.

Six epidemiologic observations are highlighted, as they may have clinical implications.

First, Figure 2 indicates that the incidence of most cancers increases until age 65 and levels

off, or even declines, thereafter. Autopsy studies indicate that the incidence of cancer—even occult cancers—declines after age 95, and cancer is only a minor cause of mortality after this age.<sup>5,6</sup> So, when discussing cancer in the elderly, one refers to cancers occurring in the age window of 65 to 95.

Second, some neoplasms (including breast and colorectal cancer) tend to present at a more advanced stage in older rather than younger patients.<sup>7</sup> This suggests a number of remediable causes, including the fact that older individuals may not be utilizing optimal cancer screening<sup>8</sup> and may not be as attentive as the younger ones to early symptoms of cancer. Cognitive decline, increased threshold for visceral pain,<sup>9</sup> symptoms of previous conditions that may mask the symptoms of cancer, and the prejudice that pain is a natural result of aging, may lessen one's alertness to cancer presentation.<sup>10</sup>

Third, in the past two decades the incidence of two neoplasms, non-Hodgkin's lymphomas and malignant brain tumors, has increased unexpectedly among the elderly.<sup>1,2</sup> This phenomenon may be accounted for by the fact that older tissues are more susceptible to environmental carcinogens than younger tissues. In other words, older individuals may represent a natural monitor system for new environmental carcinogens, because an epidemic of cancer in older individuals may predict the same epidemics, to come years later, among the younger ones. Another important clinical implication is that the epidemiology of neoplastic diseases is evolving, and the clinician should be alerted to the possibility that previously rare diseases are becoming more common among the elderly.

Fourth, in the past two decades, there has been an age-related shift in mortality for some cancers, most notably lung cancer. Whereas the mortality has declined for individuals under 60, it has increased for those over 75.<sup>2</sup> In the meantime, a large portion of lung cancers, if not

**FIGURE 2** Incidence of different cancer and age. Reproduced with permission from Berlin NI.<sup>4</sup>

the majority, develop in ex-smokers, are better differentiated, and have a much more indolent clinical course.<sup>11,12</sup> This finding is a direct result of smoking cessation that has resulted in prolongation of survival, decreased incidence of coronary death and chronic obstructive lung disease, and in more indolent forms of lung cancer.

Fifth, the incidence and prevalence of multiple cancers increases with age.<sup>13</sup> In part, this may be due to “field carcinogenesis” and, in part, to the fact that aging is a risk factor for multiple, different cancers. Field carcinogenesis implies that all cells of susceptible tissues have been exposed to the same dose of the same carcinogens during a lifetime, and persons with history of cancer are at increased risk for a second cancer in the same

organ and system (breast cancer, colorectal cancer, etc.). As smoking is a carcinogen for different tissues, it is not unusual to see in the same smoker a primary cancer of the lung, the upper airways, the esophagus, the bladder, or the pancreas. The suspicion for two simultaneous cancers should be high, when older patients present with lesions in different organs. While metastatic cancer is rarely curable, two primary cancers may both be curable. In addition, older individuals may harbor indolent metastatic neoplasms, with a median survival of several years. These include prostate cancer, breast cancer metastatic to the bones and soft tissues, and low-grade lymphomas. The presence of such neoplasms should not preclude the investigation and treatment of more

aggressive tumors that may shorten a patient’s survival.

Sixth, cancer affects preferentially older individuals in good general conditions. Repetto and colleagues and Ferrucci and colleagues established in Italy that older individuals with cancer had a lower prevalence of comorbidity and of functional dependence than individuals of the same age without cancer.<sup>14,15</sup> In an analysis of the Surveillance, Epidemiology and End-Result (SEER) data, Diab and colleagues found that women who developed breast cancer at age 80 and older had a more prolonged life expectancy than women of the same age without breast cancer.<sup>16</sup> These findings support aggressive investigation and treatment of cancer in older individuals since, in the majority of cases, cancer is the cause of death.

### Biologic Interactions of Cancer and Age

Aging involves a progressive reduction of the functional reserve of multiple organs and systems, increased prevalence of diseases, appearance of a number of pathologic conditions that are called geriatric syndromes and restriction in personal and social resources. The final result is a progressive reduction in life expectancy and tolerance of stress, and increased prevalence and degree of functional dependence. An elegant way to summarize the different dimensions of aging is loss of entropy,<sup>17</sup> which is a loss of energy available, a decline in the amount of energy that can be wasted, and the need to economize energy.

A number of molecular cellular and physiologic changes underlie aging and have been partly identified. At the molecular level, aging cells in vitro accumulate genomic abnormalities that make them more susceptible to environmental toxins, including environmental carcinogens.<sup>18</sup> In addition, aging cells may lose the self-replicative ability (proliferative senescence).<sup>19</sup> At a physiologic level, aging is seen as a chronic and progressive inflammation that leads to accumulation of catabolic cytokines in the circulation.<sup>20,21</sup> These substances may be responsible to some extent for many age-related changes, including sarcopenia, fatigue, osteoporosis, cognitive decline, immune senescence, and reduced hemopoiesis.<sup>22,23</sup> Other important physiologic aspects of aging include endocrine senescence, with reduced production of sexual hormones and growth hormone.

### Age and Carcinogenesis

At least three mechanisms may account for the association of aging and cancer. The first is duration of carcinogenesis. As carcinogenesis is a multistep process that may take several years, it is reasonable to expect a linear increase in the incidence of cancer with age.<sup>18</sup> The second involves

increased susceptibility of aging cells to environmental carcinogens. Both experimental and epidemiologic findings support this possibility. In rodents, cutaneous, hepatic, lymphatic, and nervous tissues are more likely to develop cancer after exposure to carcinogens if they are obtained from older animals.<sup>18</sup> In humans, the incidence of some neoplasms, including non-melanomatous skin and prostate cancer, increases logarithmically with age, suggesting that carcinogenesis is enhanced.<sup>24</sup> Increased susceptibility to environmental carcinogens may also explain the increased incidence of non-Hodgkin's lymphomas, anaplastic astrocytomas and glioblastoma multiforme in older individuals during the past 30 years.

Age-related increased susceptibility to environmental carcinogens suggests that cancer prevention strategies may be effective in older individuals. These include elimination of the carcinogen, or blockage and reversal of carcinogenesis via chemoprevention.

Third, proliferative senescence, paradoxically, may enhance the risk of cancer. Senescent cells lose the ability to undergo apoptosis, may become immortal, and give origin to slowly growing tumors, such as follicular lymphoma.<sup>19</sup>

### Aging and Tumor Growth

Aging may influence tumor growth by two mechanisms. First, the tumor cell may have different biologic characteristics in the younger and in the older person. Second, the older tumor host may modulate the tumor growth in a different way.

It is reasonable to expect a concentration of more indolent tumors among older individuals (Figure 3) by a process of natural selection. This is certainly the case with breast cancer, as the prevalence of well-differentiated, hormone-receptor-rich tumors increases with age.<sup>25,26</sup> The influence of the tumor host on cancer growth was

demonstrated in a now classical experiment by Ershler and colleagues, who demonstrated the same load of Lewis lung carcinoma and B16 melanoma were associated with shorter survival and higher incidence of metastasis in younger animals.<sup>27</sup> In successive studies, these authors demonstrated that the tumor growth rate seemed to decrease for poorly immunogenic—and increase for highly immunogenic—tumors, highlighting the influence of immune senescence on tumor growth. In humans, Kurtz, and colleagues, demonstrated a reduction in the growth rate of primary breast cancer among older women directly related to the degree of mononuclear cell reactions.<sup>28</sup> This observation suggested that immune senescence may mitigate tumor growth in poorly immunogenic tumors. In addition to immune senescence, endocrine and proliferative senescence may play a role in modulating tumor growth. Clearly, decline in sexual hormone production may affect the growth of hormone-dependent tumors, such as breast, prostate, and endometrial cancer. In addition, a decline in growth hormone may deprive tumor cells of insulin-like growth factor 1, one of the most powerful tumor growth factors. Proliferative senescence of stromal cells is associated with increased production of heregulin, a powerful tumor growth factor, and of metalloproteinases, enzymes that facilitate tumor metastasis with the dissolution of collagen.<sup>19</sup>

Age-related changes in tumor behavior have clinical relevance (Table 1). Table 1 contains two important messages. The first is that both the biology of the tumor cells and the influence of the tumor host may change with the age of the patient. The second is that tumors may become more aggressive and more lethal (as well as more indolent) with the age of the patient. This information is contrary to common wisdom holding that age is always associated with less aggressive and less lethal neoplasms.

At this point, one should emphasize that age by itself cannot be considered prognostic. While 80% of breast cancers in women aged 70 and older are rich in hormone receptor, 20% of these cancers are poor in hormone receptor and may need cytotoxic chemotherapy. While 67% of patients aged 60 and over with acute myeloid leukemia express Multidrug resistance 1 gene, 33% do not and have a disease responsive to chemotherapy.

Irrespective of age, each case should be treated on its own merits based on an estimate of risks and benefits.

### Biology of Age and Decisions Related to Cancer Prevention and Cancer Treatment

Age may lessen the benefits and increase the risk of cancer prevention and cancer treatment, owing to a reduction in both life expectancy and tolerance of therapy. Prior to involving an older individual in a preventative or therapeutic program, it is important to assess risk and benefit based on individual life expectancy and functional reserve, as well as on the aggressiveness of the tumor. Since aging is highly individualized, chronologic age is not a good predictor of the risk-to-benefit ratio in individual situations. To provide this judgment, the patient's primary care physician and the oncologist need to work together, to share information and to participate in the treatment plan.

### Clinical Evaluation of the Older Patient

A comprehensive geriatric assessment (CGA) reflecting the multidimensional nature of aging is the backbone of any geriatric practice (Table 2). In addition to the medical condition and the function of the patient, the CGA examines the personal and social resources that may compensate for the loss in functional reserve.

In general geriatrics, the CGA has achieved important goals, including reduced rate of functional dependence and of admission to hospital and adult living facilities.<sup>29–32</sup> According to some studies, the CGA has also improved the life expectancy of older individuals.

In geriatric oncology the CGA has succeeded in the following:

- Discovering conditions that may compromise cancer treatment, including unsuspected comorbidity, early cognitive decline, sub-clinical depression, functional limitations, malnutrition, polypharmacy, and adequacy of the caregiver.<sup>14,33–35</sup> In a pilot study involving 15 women aged 70 and older with early breast cancer, the performance of the CGA resulted in additional 17.2 interventions per patient.<sup>35</sup>

**FIGURE 3** The prevalence of more indolent tumors may increase with age for a process of natural selection. In the figure, two persons start developing cancer at the same age of 35. A, One cancer is very aggressive, and will become manifest at age 37 and cause death at age 39. B, The other is very indolent and won't become manifest until age 65 and cause patient's death until age 75. For a process of natural selection, due to the deaths of the bearers of more-aggressive tumors, one can expect to find a higher prevalence of indolent tumors among older individuals.

Table 1 Age and Changes in Cancer Prognosis

Neoplasm	Age-Related Changes in Prognosis	Mechanism(s)
Acute myelogenous leukemia <sup>111</sup>	Worse: Increased resistance to chemotherapy Increased mortality during induction	Increased prevalence of MDR1 expressing cells; Increased prevalence of stem-cell leukemia
Non-Hodgkin's lymphoma <sup>112-114</sup>	Worse: Decreased duration of complete remission	Increased circulating concentration of interleukin 6
Breast cancer <sup>26-28</sup>	More indolent disease	Increased prevalence of hormone receptor-rich well-differentiated tumors Decreased production of sexual hormones Immune senescence
Coelomic ovarian cancer <sup>115</sup>	Worse: Decreased remission duration Decreased survival	Unknown
Non-small cell lung cancer <sup>7</sup>	Better prognosis Presentation at an earlier stage	Unknown
MDR1 = ;

- Providing an estimate of life expectancy and tolerance of treatment. Life-expectancy declines with the degree of functional dependence and with the seriousness of both comorbidity and geriatric syndromes.<sup>36-38</sup> Two recent studies demonstrated that the risk of chemotherapy-induced myelosuppression increased for patients who were dependent in some instrumental activities of daily living (IADLs).<sup>39</sup>
- Instituting a common language for the classification of older individuals undergoing cancer treatment or participating in clinical trials. The subdivision of age into four different functional states proposed by Hamerman has been the frame of reference for this classification (Table 3).<sup>40</sup> Originally, Hamerman called the secondary state frailty, but this term may give rise to some confusion because, in newer classifications achieving widespread

acceptance, frailty is more germane to the intermediate state and is intended as a condition of increased vulnerability to environmental stress, rather than a condition of functional reserve exhaustion.

In the following discussion, the aspects of the geriatric assessment<sup>41</sup> with special interest for the oncologist are highlighted.

## Function

Function is assessed by examining performance status (PS), activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs include transferring, bathing, dressing, eating, toileting, and continence; dependence in one or more of these activities, with the exception of incontinence, assigns an individual to the secondary state defined by Hamerman, and is associated with a two-year mortality rate of 27%. ADL dependence may prompt admission to an assisted living facility.<sup>36,42,43</sup> IADLs are activities necessary to maintain an independent life; they include use of transportation, shopping, the ability to take medications independently, to provide to one's own meals, to use the telephone, and to manage finances. Dependence in one or more IADLs is associated with a 16% two-year mortality rate, a 50% risk of dementia,<sup>36,42-44</sup> and increased risk of neutropenia from cytotoxic chemotherapy.<sup>39</sup> Two studies found a poor correlation between functional dependence and PS, and recommended that both be evaluated.<sup>34,35</sup> Although they are not part of the CGA, advanced activities of daily living (AADLs) are generating increasing interest. AADLs are those that make life pleasurable and include leisure activity as well as professional and other working activities.<sup>41</sup> Assessing AADLs may be considered an indirect measurement of quality of life as well as of psychological health and motivation to undergo treatment.

## Comorbidity

Comorbidity is important for at least three reasons. First, comorbidity is an independent cause of mortality.<sup>45-46</sup> In women aged 65 and older, with early breast cancer, Satariano and Regland showed that comorbidity was associated with reduced survival and reduced cancer-related mortality.<sup>45</sup> In patients with cancer of the upper airways, Piccirillo and colleagues found that comorbidity was associated with increased risk of mortality.<sup>46</sup> Second, comorbidity may reduce the patient's tolerance of cancer treatment. The presence of cardiac diseases may contraindicate the use of anthracyclines; multiple chronic diseases may be associated with increased circulating levels of catabolic cytokines, sarcopenia that compromises hemopoiesis, the main target of cytotoxic chemotherapy, and, in general, may delay or prevent recovery from treatment. (The multiple

Table 3 Taxonomy of Age

Group	Characteristics	Treatment Implications
Primary	No functional dependence Negligible comorbidity	Standard treatment
Intermediate (Functional reserve substantially reduced; some degree of reversibility)	Dependence in one or more IADLs Stable comorbidity (for example, stable angina, chronic renal insufficiency, etc.)	Attempt to rehabilitation and correction of reversible conditions Special precautions such as provision of caregiver and reduction of initial chemotherapy dose
Secondary or frailty (negligible functional reserve, no reversibility; rehabilitation directed only to prevent further deterioration)	One of the following criteria: <ul style="list-style-type: none"> <li>• Dependence in one or more ADLs</li> <li>• Three or more comorbid conditions or one poorly controlled comorbid conditions</li> <li>• One or more geriatric syndrome</li> </ul> Alternative definition: at least three of the following: <ul style="list-style-type: none"> <li>• Involuntary weight loss (<math>\geq 10\%</math> original weight over one year)</li> <li>• Steady fatigue</li> <li>• Difficulty in initiating movements</li> <li>• Slow movements</li> <li>• Reduced grip strength</li> </ul>	Symptom management, that may include chemotherapy at low doses, is the main goal of treatment
Near death (irreversible decline toward death)		Terminal care

Adapted from Hamerman D.<sup>40</sup>  
ADLs = activities of daily living; IADLs = instrumental activities of daily living;

drugs associated with comorbidity may also suppress hemopoiesis).<sup>22,23,47,48</sup> Third, comorbidity may alter the prognosis of cancer. Meyerhardt and colleagues reported that patients with colonic cancer and diabetes experienced higher cancer recurrence rate than those without diabetes.<sup>48</sup> Polypharmacy resulting from comorbidity may alter the metabolism of antineoplastic agents. This possibility has been well established in children with acute lymphatic leukemia, in whom the use of antiepileptic drugs was associated with decreased time to progression and overall survival.<sup>49</sup> Polypharmacy may also have some beneficial effect on cancer. Recent studies showed that chronic use of nonsteroidal anti-inflammatory drugs was associated with lower risk of death from cancer of the large bowel,<sup>50–52</sup> and use of statins was associated with decreased risk of both colorectal and breast cancer.<sup>53</sup> The assessment of comorbidity is controversial.<sup>54</sup> Satariano and Ragland identified seven conditions associated with reduced life expectancy and demonstrated that the risk of mortality increased with the number of comorbid conditions. Other authors devised comorbidity scales, accounting for the degree of severity of each condition. Of these, the Cumulative Index of Related Symptoms-Geriatrics (CIRS-G) proved in some studies as the most sensitive.<sup>54</sup> Another advantage of the CIRS-G is that its final score may be translated into the score of another scale of common use in epidemiologic studies: Charlson's scale, which is also commonly used.

Among the comorbid conditions, anemia should be highlighted because its incidence and prevalence increase with age<sup>23</sup> and it has a pervasive effect on cancer treatment.<sup>55</sup> Anemia is an independent risk factor for death, and chemotherapy-related toxicity<sup>56</sup>; it is the main cause of fatigue and functional dependence<sup>23</sup> and may be associated with congestive heart failure, coronary deaths, and cognitive decline.<sup>56</sup> Controversy lingers on the definition of anemia. The common definition of the World Health Organization (WHO), defines anemia as hemoglobin levels below 12 g/dL for women and 13 g/dL for men.<sup>55</sup> This definition was recently challenged by a number of studies. The Women's Health and Aging Study (WHAS) showed that hemoglobin levels lower than 13.4 g/dL were an independent risk factor for death among 1,003 home-dwelling women aged 65 and over, followed prospectively for a period of 8 years.<sup>57</sup> The same study demonstrated that the risk of functional dependence increased inversely with hemoglobin levels lower than 13 g/dL.<sup>58</sup> Other studies showed that the risk of functional dependence and mobility impairment increased inversely for levels of hemoglobin lower than 14 g/dL both in men and women.<sup>59,60</sup> Clearly, the values proposed by the WHO should be reexamined in light of these results.

More than 50% of the causes of anemia in older individuals are reversible and include iron deficiency and B<sub>12</sub> deficiency, for which prevalence increases with age.<sup>23</sup> Particular mention is deserved for anemia related to renal insufficiency

and chronic infection that can be reversed by erythropoietin.<sup>59</sup> In these conditions, one observes a form of "relative erythropoietin insufficiency" in that older individuals may be unable to produce an adequate amount of erythropoietin to reverse anemia.

## Geriatric Syndromes

These conditions are typical, if not specific, of aging and include dementia, depression, delirium, incontinence, vertigo, falls, spontaneous bone fractures, failure to thrive, and neglect and abuse. Geriatric syndromes are associated with reduced life expectancy, and may be considered a hallmark of the secondary state in the Hamerman classification (see Table 2).<sup>40</sup> To be considered as geriatric syndromes, these conditions must interfere with a person's daily life: dementia must be moderate to severe, delirium must occur as a result of medications or organic diseases that do not commonly affect the central nervous system (eg urinary or upper respiratory infections); incontinence must be complete and irreversible, falls must occur at least three times a month or the fear of falling must prevent regular activities such as walking. Depression is associated with a decreased life expectancy, even when it is subclinical,<sup>60–62</sup> that is diagnosed only by screening tests. Depression interferes with treatment compliance and may be fully reversible by medication. A simple 15-item questionnaire, the Geriatric Depression Scale 15 (GDS 15) speedily and reliably detects individuals with subclinical depression and is part of the CGA.<sup>62</sup>

## Social Resources

The home caregiver is the fulcrum of social resources. Ideally, the caregiver should be able to recognize and manage emergencies, to support the patient physically and emotionally, to mediate conflicts among family members, and to act as spokesperson of the family with the health care provider.<sup>63</sup> By assuring compliance with treatment plans and positive interactions among health care professionals, family, and patients, the caregiver is an important resource for the practitioner managing older individuals. The practitioner should then assume responsibility for the selection, training, and support of the caregiver.

In the majority of cases, the only available caregiver is an older spouse with health problems of his or her own, or a married daughter who needs to balance her care-giving duties with family and work responsibilities.

## Nutrition

The prevalence of protein/calorie malnutrition increases with age. Isolation, depression, economic restriction, and reduced appreciation

of hunger, may all contribute to insufficient food intake, while chronic diseases and inflammatory cytokines may impede the synthesis of new proteins.<sup>22</sup> The Mini Nutritional Assessment is a simple nutritional screening test of worldwide use that identifies patients who are malnourished and those at risk of becoming malnourished and allows the prevention and early reversal of malnutrition.<sup>64</sup>

### Polypharmacy

The prevalence of polypharmacy increases with age, and, among cancer patients aged 70 and older, was found to be as high as 41%.<sup>33,34</sup> Polypharmacy includes redundant prescriptions as well as the consumption of drugs with dangerous interactions; it highlights a common problem of older individuals in developed countries: the absence of a primary care provider.<sup>65</sup> According to one study, more than 50% of individuals aged 70 and older in the United States, Canada, and Israel, while attending multiple specialty clinics, lacked a primary care physician.

### Other Forms of Geriatric Assessment

While the CGA represents the standard form of geriatric assessment, it may be complemented by laboratory data and by so-called tests of physical performances.

### Laboratory Markers of Aging

The circulating levels of inflammatory markers increase with age and so does the prevalence of disability and geriatric syndromes. Not surprisingly, functional dependence and geriatric syndromes are associated with increased levels of inflammatory cytokines in the circulation.<sup>21</sup> As chronic inflammation may activate coagulation, markers of intravascular coagulation, such as D-dimer, may also have prognostic value.<sup>20,21</sup> In home-dwelling individuals aged 70 and over, Cohen and colleagues demonstrated that increased concentrations of interleukin 6 (IL-6) or D-dimer were associated each with a 50% increased risk of functional dependence and death.<sup>20</sup> When the concentration of both substances was elevated, however, the risk increased more than threefold. These encouraging results suggest that in a non-distant future, laboratory markers of aging may become available

### Tests of Physical Performance

The difficulty in performing some activities is considered a predictor of functional dependence and disability. Of particular interest, one study showed that the risk of mortality and functional dependence can be predicted by the “get up and go test.”<sup>66</sup> This consists of asking an older

individual to get up from an armchair and walk 10 feet forward and back. Inability to get up without using the chair arms, and requiring more than 10 seconds to walk the distance are both highly predictive of functional decline.

### The Geriatric Assessment in Clinical Practice

Very little doubt exists on the benefits of geriatric assessment, but practical application is not well defined, especially in a time of shrinking health care resources. Three practical questions concern the subjects, the executors, and the extent of the CGA.

Who should undergo a CGA? The National Cancer Center Network (NCCN) recommended that all patients aged 70 and over undergo some form of geriatric assessment.<sup>67</sup> The basis of this recommendation is three prospective studies demonstrating that CGA discovered a number of relevant clinical conditions that otherwise would have been missed in patients of this age group.<sup>17,33,34</sup>

Who should perform the CGA? In our opinion, the primary care physician is best positioned to perform the CGA in older patients at regular intervals, and to communicate the findings to the oncologist and other specialists. At the meantime, all specialists caring for older individuals should at least be able to interpret the CGA and, ideally, should be able to perform it when needed.

What extent of geriatric assessment should all older patients undergo? Though most of the CGA may be based on patients' self-report,<sup>34</sup> the CGA may still be time-consuming, especially for patients who are unable to fill out a questionnaire on their own. A cost-effective approach to the CGA is to screen all patients with a simple, user-friendly test and to perform an in-depth assessment only in those patients who screen positive. For this purpose, the “get-up and go” test is commonly used because of simplicity.<sup>66</sup> The test we recommend is the one proposed by the Cardiovascular Health Study (CHS) and which involves five simple parameters (Table 4). The CHS investigators followed more than 8,500 individuals aged 65 and over for more than 8 years and found that, on the basis of these parameters, they could describe three groups of patients of different life expectancy and risk of functional dependence (Figure 4).<sup>68</sup> These were “the fit,” who had no abnormalities, the “pre-frail,” who presented one or two abnormalities, and the “frail,” with three or more abnormalities. We propose that both the pre-frail and the frail undergo a more in-depth assessment. The advantage of this classification is threefold: first, it has been well validated; second, it may become the standard classification of older individuals, according to one consensus conference; and third, it is very simple to execute.

### Geriatric Assessment and Life Expectancy

Life-expectancy is crucial for determining the benefits and risks of cancer prevention and cancer treatment in older individuals. The CGA may be utilized to estimate life expectancy with the caveat that this determination is always associated with some degree of uncertainty. Walter and colleagues proposed two methods to estimate both short-term (Table 5)<sup>69</sup> and long-term life expectancy (Figure 5).<sup>70</sup> In patients who had been discharged from the hospital these investigators validated a scoring system for a number of conditions (see Table 5). The one-year mortality rate was less than 10% for scores 0 to 1 and more than 60% for scores  $\geq 6$ . The main limitation of this system is that it was developed in a Veterans Administration Hospital, and metastatic cancer probably involved lung and colorectal cancer and androgen refractory prostate cancer metastatic to the bones, all of which have a median survival longer than 1 year. If patients with breast cancer and hormone sensitive prostate cancer had been included, the score for metastatic cancer would probably have turned out much lower. Also, thanks to new forms of treatment, the median survival of even these more malignant cancers has improved: in the case of colorectal cancer, it is now close to 2 years; in the case of hormone refractory prostate cancer, it is close to 3 years. For long-term life expectancy, the authors proposed the use of life tables: they proposed dividing the life expectancy of each age cohort into quartiles and deciding (on the basis of the CGA) to which quartile each individual belonged (Figure 6). Another method utilizes a program available free online ([www.adjuvantonline.com](http://www.adjuvantonline.com)).<sup>71</sup> Originally designed to calculate the benefit of adjuvant chemotherapy for breast and colon cancer for patients of different age and comorbidity, it may be utilized to estimate individual life expectancies, based on the results of the CGA.

### Cancer Prevention in Older Individuals

As the incidence of cancer increases with age, older individuals appear more likely than the younger ones to benefit from cancer prevention, but other conditions, such as reduced life expectancy and decreased tolerance of treatment, may lessen these benefits. Given these opposite influences of age, it is legitimate to ask what is a meaningful end point for cancer prevention in the elderly. Traditionally, reduction in cancer-related mortality has been considered a proof of the effectiveness of cancer prevention. Clinical trials in older individuals should consider alternative end points, such as preservation of function and of quality of life.<sup>72</sup>

Evaluation of Frailty	
1. Weight loss. Unintentional weight loss of {140} 10 pounds on prior year, by direct measurement of weight. 2. Grip strength < 20% below standard for BMI measured with Jamar Hydraulic Dynamometer (see below). 3. Walk time below a cut-off point for sex and height (see below). 4. Exhaustion. Measured as two statements from the CES-D depression scale. 5. Physical activity, measured on the short version of the Minnesota Leisure Time activity (see below). Men, kilocalories per week < 383; women, < 270.	
Grip Strength by Body Mass Index*	
Man	
Body Mass Index	Cut-off Grip Strength (kg)
≤ 24	≤ 29
24.1–26	≤ 30
26.1–28	≤ 30
28	≤ 32
Woman	
≤ 23	≤ 17
23.1–26	≤ 17.3
26.1–29	≤ 18
> 29	≤ 21
Walk time	
Man	
Height (cm)	Cut-off Point (sec)
≤ 173	≥ 7
> 173	≥ 6
Woman	
≤ 159	≥ 7
> 159	≥ 6
Exhaustion: score 2 or 3 on two questions of the CES-D a. I felt everything I did was an effort b. I could not get going Sores: 0 = never 1 = 1–2 days a week; 2 = 3–4 days a week; 3 = most of the time	
<b>Physical Activity</b> Patients will be asked whether they engaged in any of the following activities in the past two weeks.	
<b>High-Intensity Activities</b> <ul style="list-style-type: none"> <li>• Swimming</li> <li>• Hiking</li> <li>• Anaerobics</li> <li>• Tennis</li> <li>• Jogging</li> <li>• Racquetball</li> <li>• Walked for exercise for at least 1 hour {140} 4 miles per hour</li> </ul>	
<b>Moderate or Light-Intensity Activities</b> <ul style="list-style-type: none"> <li>• Gardening</li> <li>• Mowing</li> <li>• Raking</li> <li>• Golfing</li> <li>• Bowling</li> <li>• Biking</li> <li>• Dancing</li> <li>• Calisthenics</li> <li>• Exercise Cycle</li> <li>• Walked for exercise for at least 1 hour at a strolling pace</li> </ul>	
Patients who did not engage in any of these activities over the past 2 weeks will be considered at low physical activity.	
*Derived from height and body surface	

Preventative interventions of common use include chemoprevention and early detection of cancer.

### Chemoprevention

At least three groups of substances (hormonal agents, retinoids, and the non-steroidal anti-inflammatory drug [NSAID]) have demonstrated ability to prevent cancer in randomized clinical trials.<sup>51,73–75</sup> The selective estrogen receptor modulator (SERM) tamoxifen causes a number of complications, including endometrial cancer, deep venous thrombosis, strokes, and vasomotor and genitourinary manifestations of menopause, whose incidence increases with age.<sup>73</sup> In a decision analysis, Gail and colleagues calculated that tamoxifen may be beneficial for women aged 70 if their risk of developing breast cancer over five years is as high as 7% and if they don't present other contraindications to the drug.<sup>76</sup> The 5 $\alpha$ -reductase inhibitor finasteride prevents prostate cancer, but those individuals who develop prostate cancer on treatment present a more aggressive form of disease.<sup>74</sup>

Retinoids delay occurrence of a second head and neck cancer in smokers, but their use is complicated by substantial side effects.<sup>75</sup> A number of cohort and retrospective studies have suggested that aspirin may prevent death from cancer of the large bowel,<sup>51,52</sup> while the COX-2 inhibitor celecoxib has reduced the number and the size of colonic polyps in patients with familial polyposis,<sup>50</sup> which are predisposed to colon cancer. There is no agreement on the safest and most effective agent, on the doses and duration of treatment, and on the potential therapeutic complications. While chemoprevention of cancer appears promising, it is not yet ready for clinical use.

### Screening and Early Detection

As the prevalence of common cancers increases with age, the positive predictive value of screening tests also increases.<sup>72</sup> Improved accuracy is counterbalanced by the fact that older individuals might have undergone previous cancer screening, and that previous screening examination might have eliminated most prevalent cases of cancer.

### Breast Cancer

Serial mammograms reduce by 20 to 30% the cancer-related mortality among women aged 50 to 70.<sup>77</sup> The benefits of mammography after age 70 have been suggested by three reports. A cohort, historically controlled study, the Nijmegen study, showed a reduction in cancer-related mortality up to age 75<sup>78</sup>; two retrospective studies of the Survey Epidemiology and End Results (SEER) data showed that there was a more than twofold decrement of breast cancer related mortality for women 70 to 79 who had undergone at least two

mammograms after age 70<sup>79</sup> and that the benefit was largely independent from comorbidity.<sup>80</sup> Based on these reports, it is reasonable to recommend that older women undergo some form of breast cancer screening, if their life expectancy is 5 years or longer. A number of issues still need to be addressed.

The first issue is the role of new screening techniques, such as digital mammography or breast magnetic resonance imaging (MRI), that appear more sensitive than conventional mammography. The second is the role of clinical

examination of the breast (CBE), which is cheaper and more practical than mammography. In the Canadian study, CBE was as effective as screening mammography in women aged 50 to 60,<sup>81</sup> and in the Breast Cancer Detection Demonstration Project, it was as sensitive as mammography for invasive cancer.<sup>82</sup> The third issue is whether only women at high risk of cancer should undergo serial mammograms. As the risk of breast cancer increases with the degree of bone density, Kerlikowske and colleagues calculated that 90% of early breast cancer would still be detected in

women aged 70 to 79 if only those with bone density underwent regular mammography. With this approach, both cost and inconvenience of screening would be reduced.<sup>83</sup> The cost would be reduced by half. Clearly, new studies should focus on the most cost-effective screening strategy for older women.

### Colorectal Cancer

Early detection of cancer of the large bowel reduces the cancer-related mortality for persons aged 50 to 80. Though the only screening strategy tested in randomized controlled studies involves serial examination of the stools for occult blood, a recent decision analysis suggests that the most cost-effective approach may involve full colonoscopy every 10 years.<sup>84</sup> In selected case, virtual colonoscopy may be utilized because it is less invasive.

### Prostate Cancer

With exception for individuals at high risk (African Americans and those with a family history of prostate cancer) the value of screening asymptomatic men for prostate cancer with serial prostate-specific antigen (PSA) determinations is controversial. Also controversial is the level of PSA that should be considered abnormal<sup>85</sup> and the time interval at which the test should be performed.<sup>86</sup> According to a recent study, approximately 30% of invasive prostate cancers occur in patients with PSA < 4.0 ng/mL and 15% in those with PSA levels < 2.6 ng/dL.<sup>85</sup> If screening is instituted, it should be continued up to age 75, as a recent Swedish study demonstrated that radical prostatectomy reduces the prostate cancer-related mortality up to age 75.<sup>87</sup>

### Other Cancers

No benefits of screening women over age 60 for cervical cancer have been recognized, if these women have undergone regular Papanicolaou smear (Pap smear) examinations of the cervix earlier in life.<sup>72</sup>

In recent years, there has been a lot of interest in early detection of lung cancer. This interest stems from different reasons. First, lung cancer occurs more frequently in ex-smokers, and, in these subjects, it is a more indolent disease, amenable to cure with surgery.<sup>21,22</sup> Second, a new imaging technique, helical CT, is more sensitive to small lesions than chest. The Prostate, Colon Lung and Ovary (PCLO) study examining the value of early detection of cancer in these sites may solve some of the controversial issues.

### Cancer Treatment

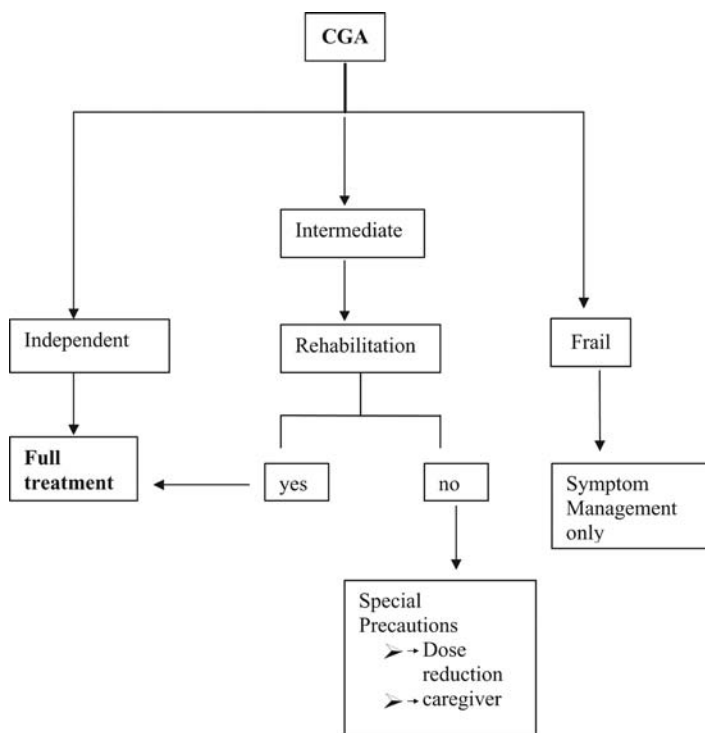

#### Surgery

According to Medicare data, age 70 and over is associated with increased incidence of surgical

**FIGURE 5** Median life expectancy for patients of different age cohort, according to the life-tables. Reproduced with permission from Walter LC, Covinsky KE.<sup>70</sup>

**FIGURE 6** Suggested approach to the treatment of older individuals with chemotherapy according to the aging state.

complications and of surgical mortality, and with more prolonged postoperative hospitalization.<sup>88</sup> The difference in outcome is mainly due to emergency surgery for obstructing cancer of the large bowel and the resulting gram-negative sepsis. With the possible exception of pneumonectomy,<sup>89</sup> elective surgery is well tolerated by independent older individuals in the absence of comorbidity. Age should never be a reason to avoid life-saving surgery. More timely and consistent screening for cancer of the large bowel may prevent most of the emergency surgery and consequent mortality.

Recent advances in anesthesia have minimized the risk of cardiovascular complications and respiratory suppression.<sup>90</sup> Thanks to the evolution of surgical techniques, surgery has become less radical and lengthy and allows the use of local anesthesia in a number of procedures, such as partial and total mastectomy, local resection of rectal tumors, and many forms of laparoscopic surgery.

### Radiation Therapy

External beam irradiation is well tolerated, even in individuals over age 80, according to a number of studies.<sup>91</sup> As the risk of mucositis increases with age, ensure adequate nutritional support for patients receiving radiation of the upper airways, the esophagus, and the pelvis. Conformational radiation therapy has greatly improved the therapeutic index of the treatment by minimizing toxicity. Another radiation technique of special interest in the elderly is brachytherapy, which has substantially reduced the duration and the toxicity of the treatment for prostate cancer and appears very promising in the postoperative management of breast cancer.

### Hormonal Therapy

The main considerations related to the use of hormonal therapy in older individuals include the following.

- The risk of deep venous thrombosis and cerebrovascular ischemia from SERMs increases with age. Age also appears to be a risk factor for endometrial cancer from tamoxifen and toremifene citrate.<sup>73</sup> It appears prudent to avoid such compounds in women at risk for the following complications: uterus present, previous venous or arterial thrombosis, or cerebrovascular disease (especially when long-term treatment is planned, as in the adjuvant or preventative setting).
- Aromatase inhibitors are now the preferred front-line hormonal treatment for metastatic breast cancer, and are preferred by many practitioners, even in the adjuvant setting. The main risk of aromatase inhibitors over the long term is osteoporosis and long bone

fractures.<sup>92</sup> It is customary to obtain a bone density measurement prior to institution of treatment and to manage with bisphosphonates women with osteoporosis or osteopenia. Though this strategy is reasonable, its effectiveness is unproven.

- Luteinizing hormone-releasing hormone (LH-RH) analogs are today the preferred form of androgen deprivation in prostate cancer. It has been a common trend during the last few years to treat patients with PSA relapse. These individuals have an expected survival in excess of 10 years and, consequently, are at risk to experience long-term complications of androgen deprivation, including osteoporosis, sarcopenia, and anemia. Intermittent androgen deprivation may minimize these complications and is compared to continuous deprivation in a randomized controlled study.<sup>93</sup> Prior to LH-RH, estrogen in low dose was the preferred form of androgen deprivation. This treatment, which prevented osteoporosis and sarcopenia, has become obsolete owing to concerns for cardiovascular and thrombotic complications. Other advantages of estrogen therapy include low cost, low incidence of hot flashes and preservation of libido.

### Cytotoxic Chemotherapy

Though the risk of chemotherapy complications increases with age, it should be emphasized that older individuals may benefit from chemotherapy to the same extent as younger individuals. Pfreundschuh and colleagues demonstrated that patients aged 60 to 75 with large cell lymphoma had better survival when they received dose-intense rather than standard treatment.<sup>94</sup> Sargent and colleagues showed that adjuvant chemotherapy for cancer of the large bowel was as effective in individuals over 70 as it was in younger ones.<sup>95</sup> Langer demonstrated similar response rate and survival for patients aged 70 and older with metastatic non-small cell lung cancer as for those younger.<sup>96</sup> Furthermore, chemotherapy may provide the best form of palliation in patients with most metastatic cancer. Proper patient selection and supportive care are the mainstay of safe and effective chemotherapy in the elderly.

Age is associated with a number of pharmacologic changes that may influence effectiveness and toxicity of chemotherapy (Table 6).<sup>97</sup>

Oral antineoplastic drugs appear very convenient for older individuals, due to dose flexibility and home administration. There is concern, however, that the bioavailability of these agents may decrease with age, especially after age 80, due to decreased absorption. Phase II studies of these agents in older individuals are desirable.

The initial dose of antineoplastic agents should be adjusted to glomerular filtration rate

Table 6 Pharmacological Changes of Age

Pharmacologic changes	Changes and Consequences	Considerations
<b>Pharmacokinetics</b>		
Absorption	Decreased for nutrient. No information on bioavailability of drugs	Support phase II trial of oral anti-neoplastic agents in individuals aged 70 and older
Distribution (Vd)	Decreased for hydrosoluble drugs, with increased risk of toxicity. Vd is determined by body composition, albumin and hemoglobin concentration	Correct anemia; when possible prevent or reverse malnutrition
Excretion	Decreased renal excretion; biliary excretion probably maintained	Adjust doses of chemotherapy to GFR in individuals over 65
Metabolism	Decreased liver metabolism due to decreased hepatocytic mass, splanchnic circulation and activity of Cy-P-450 related enzymes	No clear clinical consequences. Issue needs to be studied
<b>Pharmacodynamics</b>		
Normal Tissues	Increased risk of toxicity	No known direct prevention of overturn
<ul style="list-style-type: none"> <li>• Decreased ability of DNA repair</li> <li>• Decreased intracellular metabolism of drugs</li> </ul>		
Neoplastic tissue	Multidrug resistance	Drugs that over-turn multidrug resistance
<ul style="list-style-type: none"> <li>• Increased expression MDR1</li> <li>• Decreased cell proliferation</li> <li>• Tumor anoxia</li> <li>• Increased stromal attachment</li> </ul>		
Increased susceptibility of normal tissues	Increased risk of neutropenia and neutropenic infections, increased risk of anemia and thrombocytopenia	Prophylactic treatment with myelopoietic growth factors after chemotherapy
Hemopoietic tissue		
Mucosae	Increased risk of mucositis	Substitute IV fluorinated pyrimidines with capecitabine, when feasible Timely hospital admission and fluid resuscitation Consider AES-14 and keratinocyte growth factor
Peripheral and central nervous tissue	Increased risk of peripheral neuritis, and increased risk of chemo-brain	Avoid combination of two neurotoxic agents; avoid combination of chemotherapy and radiation to the brain
Myocardium	Increased risk of anthracycline-related cardiomyopathy	Consider use of pegylated liposomal doxorubicin "in lieu" of doxorubicin
AES-14 = ; Cy-P-450 = ; DNA = deoxyribonucleic acid; GFR = glomerular filtration rate; IV = intravenously; MDR1 = ; Vd = distribution.		

(GFR) in individuals over 65, as renal excretion declines with age. To avoid undertreatment, subsequent doses should be escalated as tolerated.<sup>67</sup>

The volume of distribution of hydrosoluble agents is determined by the body water content and by the concentration of albumin and hemoglobin in the circulation. Predictably, anemia is a risk factor for chemotherapy-induced myelotoxicity and should be reversed, when feasible.<sup>58</sup>

Myelosuppression, mucositis, peripheral neuropathy, and cardiomyopathy are the complications of chemotherapy that become more

common with age. The risk of neutropenic infections, as well as the duration and complications of hospitalization from neutropenic infections increases after age 65.<sup>98,99</sup> Myelopoietic growth factors filgrastim and PEG-filgrastim (filgrastim with polyethylene glycol [PEG] attached) are effective in older individuals and should be used prophylactically in individuals aged 65 and older with treatment regimens of moderate toxicity such as the combination of cyclophosphamide, hydroxydaunomycin (doxorubicin), Oncovin (vincristine), and prednisone (CHOP) for large cell lymphoma.<sup>100</sup> PEG-filgrastim (pegylated filgrastim) requires a single administration per

cycle of chemotherapy and has become the agent of choice. Anemia is also a common manifestation of myelosuppression. In addition to enhancing the risk of chemotherapy-related toxicity, anemia causes fatigue and functional dependence.<sup>58,100</sup> Epoetin or darbepoetin ameliorate anemia in 60 to 70% of patients.

Mucositis may lead to volume depletion from lack of fluid intake and diarrhea.<sup>97</sup> The management of mucositis may include substitution of intravenous fluorinated pyrimidines (fluorouracil and floxuridine) with oral capecitabine. Capecitabine is a prodrug activated in the neoplastic tissue that minimizes the exposure of normal tissues to the active agent. Other provisions include timely fluid resuscitation, and use of AES-14, a oral preparation of glutamine.<sup>101</sup> A recombinant keratinocyte growth factor proved effective in preventing the mucositis from high-dose chemotherapy and may be beneficial to older patients.

No antidotes to neurotoxicity are available. Precautions include avoidance of combination of neurotoxic drugs (eg, cisplatin and paclitaxel), and discontinuance of a neurotoxic drug in the presence of weakness.

Age is a risk factor for anthracycline-induced cardiomyopathy.<sup>102,103</sup> The incidence of this complication increases for total doses of doxorubicin higher than 300 mg/m<sup>2</sup>. Pegylated liposomal doxorubicin has a favorable toxicity profile with respect to doxorubicin and may be preferred in older individuals for the indications for which it was proven effective (myeloma, lymphoma, metastatic breast and ovarian cancer).<sup>104</sup> Other ways to prevent cardiomyopathy include continuous intravenous infusion of doxorubicin, which is cumbersome, and concomitant administration of dexrazoxane, which may increase the risk of myelodepression and mucositis.<sup>97</sup>

The selection of patients who can tolerate treatment is essential to safe and effective management of older individuals. On the basis of the Hamerman classification of older individuals<sup>40</sup> we recommend using the algorithm in Figure 6.

### Targeted Therapy

Targeted therapies promise to minimize the toxicity and enhance the effectiveness of treatment and, for this reason, appear almost ideal for older individuals. Limited data suggest that these agents are indeed safer. Appropriate caveats for the elderly include:

- Myelosuppression from radioisotope-tagged (tositumomab [Bexaar] and ibritumomab tiuxetan, [Zevalin]) and cytotoxic-tagged (gemtuzumab ozogamicin, Mylotarg) antibodies may increase with age. Mylotarg has also been associated with deep venous thrombosis.

- The CD-33 targeted monoclonal antibodies alemtuzumab (Campath) may cause prolonged and irreversible myelosuppression, especially if used at doses higher than recommended. Campath may also cause severe suppression of T-cell immunity and lead to infection with intracellular organisms
- Angiogenesis inhibitors (thalidomide, bevacizumab) are associated with increased risk of deep venous thrombosis in older individuals. Bevacizumab has also been associated with bleeding and hypertension.

### Supportive Care of the Older Cancer Patient

In addition to the management of treatment complications, supportive care of the older person involves management of symptoms and of conditions that may interfere with cancer treatment.

The NCCN has issued a series of guidelines to ameliorate treatment complications (Table 7). The basis of these guidelines has already been discussed.

The most common symptoms of cancer include fatigue and pain. Fatigue is common in older individuals, and may lead to prolonged functional dependence.<sup>105</sup> Management of anemia is the first step in relieving fatigue. This includes evaluation and management of the causes of anemia. Even in the absence of chronic bleeding, iron deficiency becomes more common with age, and is due at least in part to hepcidin, a

liver-synthesized protein that prevents the absorption of iron from the intestinal tract as well as from the red blood cell precursors.<sup>23</sup> Oral iron has limited activity in this situation, and parenteral iron repletion may be the treatment of choice. Vitamin B<sub>12</sub> deficiency, due to decreased digestion of food, is present in at least 5% of individuals aged 60 and older. In addition to anemia, B<sub>12</sub> deficiency may be associated with cognitive decline. Probably the most common cause of anemia in the older cancer patient is anemia of chronic disease or of chronic inflammation. This form of anemia responds well to erythropoietin. One study showed that the addition of parenteral iron enhances the response to erythropoietin.<sup>106</sup> Other causes of fatigue include increased concentration of catabolic cytokines in the circulation and sarcopenia.<sup>105</sup> When fatigue persists, despite the correction of anemia, the use of neuroanaleptic drugs or antidepressants is recommended. In addition, anecdotal reports suggest that daily exercise may prevent or limit fatigue.

Though the threshold for perception of pain increases with age, pain is a common problem in older cancer patients.<sup>107</sup> The majority of older patients, even when cognitively impaired, may report pain and its severity. In general, a vertical pain scale is preferred in older individuals owing to the possible loss of vision later. The so-called pain thermometer is probably the instrument of most common use to assess pain in the elderly. In the rare case where a patient cannot communicate, the observation of the so-called pain behavior is useful to guide pain management. Pharmacologic treatment of pain should take into account some basic principles:

- Acetaminophen is the preferred non-opioid drug, but it does not have anti-inflammatory activity and, consequently, is not very helpful with bone metastases
- The COX-2 inhibitors should be used “in lieu” of the COX-1 inhibitors in patients at high risk of bleeding (anticoagulant therapy, bleeding disorders, peptic ulcer or *Helicobacter pylori* gastritis)
- Of the COX-1 inhibitors, one should avoid indomethacin and piroxicam, due to high risk of bleeding complications
- Mild opioids (codeine, tramadol) have little place in the management of older individuals, because they need to be activated by the Cy-P450 enzymatic complex. The activity of this system declines with age and might be altered by a large number of drugs
- Age is associated with increased sensitivity to the effects of morphine and hydromorphone. These drugs are metabolized into 3- and 6-glucuronides, that are excreted from the kidneys. The 3-glucuronide is mainly responsible for the toxicity, and the 6-glucuronide for the activity, of the drugs. In older individuals, it

**Table 7 Guidelines for the Management of the Older Person with Cancer**

1. All patients aged 70 and older should undergo some form of geriatric assessment prior to institution of treatment.
  2. The dose of compounds that are excreted through the kidneys or that give origin to active and toxic metabolites excreted through the kidneys, should be adjusted to individual GFRs in persons aged 65 and older. The doses should be escalated if no toxicity is encountered.
  3. Patients aged 70 and older treated with moderately toxic chemotherapy (of dose intensity comparable to CHOP, should receive prophylactic growth factors (G-CSF or pegylated G-CSF).
  4. Hemoglobin levels should be maintained at  $\geq 12$  g/dL with epoetin.
- Patients aged 65 and older experiencing grade 3 to 4 mucositis should be admitted to the hospital and receive aggressive fluid resuscitation.

Adapted from the National Cancer Center Network  
GFR = glomerular filtration rate; CHOP = cyclophosphamide, hydroxydaunomycin (doxorubicin), Oncovin (vincristine), and prednisone; G-CSF = Granulocyte stimulating factor

is recommended that the therapy be started with short-acting agents at escalating doses and that sustained-release compounds be used only when the total dose need has been determined.

- Oxycodone, hydrocodone, and fentanyl may be easier to handle, but in the presence of liver insufficiency, the half-life of these drugs may be increased
- Intrathecal administration of opioid is probably the safest, and should be considered in all patients with severe chronic pain and a life expectancy of three months or longer.

Any practitioner dealing with older individuals should be familiar with delirium, an alteration of mental status, whose peculiar characteristic is continuous variation in attention. Delirium may be a common manifestation of multiple causes, including new drugs, infections, electrolyte abnormalities, neoplastic involvement of the central nervous system. Less common causes of delirium include new pain, angina, or myocardial infarction. The management includes the treatment of the primary cause and the use of phenothiazines or haloperidol.

The importance of nutrition, home safety, and the caregiver have already been described in the section related to the geriatric assessment.

## Clinical Trials in the Older Patient

Individuals aged 65 and older have been underrepresented in clinical trials of cancer treatment, despite the increased incidence and prevalence of cancer with age.<sup>108,109</sup> Most of the recommendations we presented are inferred from clinical trials in younger individuals. In this section we examine age-related questions that should be addressed in clinical trials, the barrier to the enrollment of older individuals in clinical trials, and strategies to overcome these barriers.

## Age-Related Questions

These include the pharmacology of antineoplastic agents, patient selection, patient classification end points, and long-term outcome.

In view of the pharmacologic changes of aging, it appears necessary to conduct phase II trials of novel agents reserved to older individuals. The goals of these trials may include effectiveness and toxicity, as well as pharmacologic parameters, such as Area Under the Curve, half-life and disposal of the drug. These trials appear particularly necessary for oral agents because intestinal absorption declines with age. While somebody advocates phase I trials reserved to older individuals, we don't concur with this recommendation since these trials may unnecessarily delay the development of life-saving drugs due to excess of complications in older individuals. Of course, age should not be a criterion of exclusion from phase I trials.

Patient selections should be based on the nature of the trial. In trials of adjuvant treatment, only patients with a significant risk of cancer recurrence and cancer death should be enrolled in the trial. This can be estimated from individual life expectancy and the tumor stage. The Web site Adjuvant! Online <[www.adjuvantonline.com](http://www.adjuvantonline.com)> and its accompanying computer program provide a standardized means to assess this risk for cancers of the breast and of the large bowel.<sup>71</sup>

In clinical trials, patients are generally stratified according to performance status. In older individuals, performance status may not be sufficient to explain the variations in outcome.<sup>33</sup> Hopefully, a common language to classify older individuals may be adopted. The CHS classification of older individuals in fit, pre-frail, and frail appears as a reasonable complement of performance status.<sup>68</sup> At the very least, the patient's dependence in IADLs should be accounted for since this appears to be an independent predictor of chemotherapy-related toxicity.

While overall survival should still be the main end point of clinical trials with life-prolonging treatment, functional preservation and quality of life appear more important in older individuals whose life expectancy is limited.

## Barriers to Clinical Trial Enrollment

One study in patients with breast cancer and showed that women aged 65 and older were as willing as younger women to enter clinical trials, but physicians were less likely to offer the clinical trials to older women.<sup>110</sup> Hopefully, better understanding of aging will make clinicians more comfortable in offering clinical trials to older individuals. In the meantime, it is important to recognize that simply designed clinical trials with minimal diagnostic investigations may catalyze the enrollment of older patients. The Geriatric Oncology Consortium (GOC), which involves approximately 150 practices around the United States, was organized for this purpose and completed a study of 750 older individuals with solid tumors in a record time of less than two years. Hopefully, this achievement heralds the abatement of the last barriers to the participation of older individuals in clinical trials.

## Conclusions

Cancer in the older patient is becoming increasingly common. Older individuals with adequate life expectancy and treatment tolerance benefit from cancer prevention and treatment to an extent comparable with that of younger individuals.

Early detection of breast and colorectal cancer is beneficial for individuals with a life expectancy of at least five years. Ongoing studies may establish the benefits of screening

asymptomatic older persons for cancer of the lung, of the prostate, and of the ovaries.

Older individuals are more vulnerable to the complications of cancer chemotherapy, including myelosuppression, mucositis, peripheral and central neurotoxicity, and cardiotoxicity. Proper dose adjustments, prophylactic treatment of older individuals with filgrastim or PEG-filgrastim, management of anemia, and drug selection may ameliorate the risk of chemotherapy in the majority of older patients.

The primary care physician has a central role in the management of older individuals with cancer. It behooves this practitioner to estimate the patient's life expectancy and functional research, and to manage concomitant conditions that may interfere with cancer treatment, including the adequacy of social resources. The oncology specialist and the primary care physician should work together to manage incoming problems and treatment complications and should present a common front to the patients and their families.

# Integrative Medicine: Complementary and Alternative Therapies

Gary E. Deng, MD, PhD  
Barrie R. Cassileth, PhD, MS

## Definition

Many practices previously termed unorthodox or unconventional are increasingly recognized for their therapeutic value, evolving over time to become complementary and alternative medicine (CAM). That language shift was exemplified by the creation over a decade ago of the National Institutes of Health Office of Alternative Medicine, which in 1999 was renamed the “National Center for Complementary and Alternative Medicine” (NCCAM). NCCAM defines CAM as “a group of diverse medical and health care systems, practices, and products that are not presently considered to be part of conventional medicine.”

A necessary distinction between “complementary” and “alternative” therapies is required. Complementary therapies, used as adjuncts to mainstream care, are supportive measures that help control symptoms, enhance well-being, and contribute to overall patient care (Table 1).<sup>1,2</sup> Alternative therapies, conversely, are unproved or disproved, often promoted for use instead of mainstream treatment or offered as viable therapeutic options. This is especially problematic in oncology, when delayed treatment can diminish the possibility of remission and cure.<sup>3</sup> Over time, some complementary therapies are proven safe and effective. These become integrated into mainstream care, producing integrative medicine, a combination of the best of mainstream cancer care and rational, data-based, adjunctive complementary therapies.<sup>4</sup>

## Current Status

The most comprehensive and reliable findings on Americans’ use of CAM in general come from

the National Center for Health Statistics (NCHS) 2002 National Health Interview Survey (NHIS). NCHS is an agency of the Centers for Disease Control and Prevention.<sup>5</sup> Of 31,044 adults surveyed, 75% used some form of CAM. When prayer specifically for health reasons are excluded, the number was still at 50%. The survey shows most common use among women, better-educated people, those hospitalized in the previous year, and former smokers, indicating a more health conscious segment of the population. Common reasons given for use of CAM are shown in Figure 1.

By various accounts, 10% to over 60% of cancer patients have used CAM, depending primarily on the definitions applied.<sup>2,6-9</sup> The Datamonitor 2002 Survey indicated that 80% of cancer patients used an alternative or complementary modality.<sup>10</sup> There is some indication of a growth in CAM use by cancer patients in recent years.<sup>11</sup> In our clinical experience, cancer patients most commonly use CAM to help get through chemotherapy, radiation, or surgery; to confront a poor prognosis and explore all treatment options; and to prevent cancer recurrence.

In 1997, consumer expenditures related to CAM were estimated at \$36 billion to \$47 billion, including \$12 billion to \$20 billion paid out-of-pocket to CAM practitioners.<sup>8</sup> Sale of vitamins and minerals in the United States approximated \$2.1 billion in 1999, including \$6.6 billion for vitamins and \$4.2 billion for herbs.<sup>12</sup>

The advent of the Internet facilitates dissemination of information and misinformation. The keywords “alternative cancer medicine” on Google.com revealed close to 3 million results at the end of 2004 and about 28 million at the beginning of 2007. It is difficult, if not impossible, for

the public to distinguish between evidence-based information and scientific-sounding infomercials promoting services and products. (Reputable sources of information are listed in Table 2.)

Many mainstream medical professionals are reluctant to accept complementary therapies, often because supporting scientific evidence, until recently, was rarely available. That many CAM practices are based on ancient philosophical and health care paradigms also reduces their credibility, as does the language used to describe underlying theories and mechanisms that may appear strange or ridiculous to those trained in the contemporary biomedical sciences. Fortunately, recent rigorous research has produced data on the safety, efficacy, and biologic mechanisms of some complementary therapies, and presents data in scientific language.

The definition of complementary therapies is evolving. As more is learned, those shown to be safe and effective are adopted into mainstream health care. This is reflected in the establishment of integrative or complementary medicine programs in major academic medical centers, including major National Cancer Institute-designated cancer centers such as Memorial Sloan-Kettering, M. D. Anderson, Dana-Faber, and others.<sup>13</sup> Similar programs have been initiated in Canada, Australia, and Europe.

In this chapter, we introduce first the principles of Eastern medical systems, on which many current CAM therapies are based. We then introduce and review research data on complementary modalities that have been studied in cancer patients. These modalities include mind-body therapies, manual therapies and bodywork, dietary measures and supplements for cancer prevention, herbal medicine, and acupuncture. Those without a substantial body of research evidence are not discussed in detail here.

## Eastern Therapeutic Models

Complete therapeutic systems of theory and practice were developed by ancient cultures.

**Table 1** Categories and Examples of Useful Complementary Therapies

Biologically based practices	Dietary supplements (vitamins, some herbal remedies)
Mind-body practices	Meditation, guided imagery, hypnosis, relaxation techniques
Manipulative and body-based practices	Massage, reflexology
Practices from ancient medical systems	Acupuncture, Yoga

**FIGURE 1** Common reasons people use CAM. Adapted from Barnes PM et al.<sup>5</sup>

Although the beliefs on which they are based may be outmoded, some of their practices, such as herbal remedies and acupuncture, have value today. The two most prominent Eastern systems are traditional Chinese medicine (TCM) and India's ayurvedic medicine.<sup>14</sup> These paradigms embody a holistic approach to health maintenance, emphasizing interactions among internal "life forces" and harmony between individuals and their environments. These systems hold the belief that health requires a strong and balanced body and mind. If the balance is disturbed, disease occurs. Therapeutic interventions aim to restore the balance.

### Traditional Chinese Medicine

The earliest TCM text, Huang Di Nei Jing (Yellow Emperor's Canon of Internal Medicine) dates from 500 to 300 BCE. Its theory centers on the balance between Yin and Yang. Anything with cold, dark, weak, and hollow qualities are Yin; those that are hot, bright, strong, and solid are Yang. "Qi" (pronounced chee), the vital energy or life force, and "Xue," the blood, circulate around the body to regulate the balance of Yin and Yang in the major organ systems (heart, lung, spleen, liver, kidney) of the body. These organ

systems are functional entities, responsible for modern medicine's cardiovascular, respiratory, digestive, emotional and genitourinary activities, respectively.<sup>15</sup>

Traditional TCM diagnostic techniques include observation, listening, inquiry and palpation, which includes pulse taking. Findings that fit specific patterns lead to a diagnosis. TCM practitioners then prescribe herbal and/or acupuncture treatment. Herbal remedies are usually a formulation of multiple ingredients (mainly botanicals) but also, occasionally, minerals and animal products. The herbal remedies are most commonly prepared by brewing the ingredients in hot water. The ingredients are said to work in combination to achieve a synergistic effect and to balance out side effects.<sup>15</sup>

Acupuncture remains an important TCM practice. Inserting and manipulating needles at specific body points, originally to regulate the flow of Qi and restore harmony, is a viable treatment for many symptoms, and modern research shed light on its mechanisms. Many acupuncture points are rich in nerves, and contemporary investigation suggests that acupuncture may regulate nervous system activities.<sup>16,17</sup> Acupuncture is discussed in greater detail later in this chapter.

### Ayurvedic Medicine

The term "ayurveda" is a combination of Sanskrit words "ayur" (life) and "veda" (knowledge). Ayurvedic ("knowledge of life") medicine can be traced back to 1500 BCE. It was originally described in the Hindu scriptures called the Vedas and the texts known as the Samhitas. Its root is deeply embedded in Indian civilization and Hindu philosophy. Ayurveda remains intertwined with India's moral, spiritual, and cultural values to this day.<sup>18</sup>

There is much similarity between ayurveda medicine and TCM. Both view the balance of mind, body, and spirit, as well as balanced adaptation to external forces, as essential to optimal health. Three basic forces (doshas), believed to exist in all beings, include vata (motion), pitta (metabolism), and kapha (structure). "Prana" (similar to the Chinese "Qi") flows through the body and concentrates in "Chakras" (body points along the midline thought to be the focal points of interaction among the internal organs and external elements). Imbalance results in diseases.

Ayurvedic diagnostic techniques include observation, questioning the patient, and palpation, with special attention paid to pulse, tongue, eyes, and nails. Diagnoses are described as discordance of doshas in relationship to specific organ systems. Therapies are directed to balance the doshas based on the individual's body type. Main methods of treatment are cleansing and detoxifying (shodan), palliation (shaman), rejuvenation (rasayana) and spiritual healing (satvajaya).<sup>18</sup> Ayurvedic medicine has a strong mind-body component. Spiritual healing is aimed at relieving stress and negative thoughts, and achieving enlightenment. Sound therapy, imagery, exercise, and meditation are common techniques to keep consciousness in balance. Therapies used in ayurvedic medicine that have relevance to cancer care, such as yoga and meditation, are discussed in the following sections.

### Mind-Body Therapies

Current-day mind-body therapies are based on the reciprocal relationship between mind and body. Chronic stress and depression are associated with cardiovascular risk and impaired immune function.<sup>19,20</sup> Physical problems are exacerbated by social and emotional stress. Cancer is not amenable to treatment only through attention to patients' psychological needs, but relief from mood disturbance, anxiety and other mental distress greatly improves the patient's quality of life. In addition to conventional psychiatric care, several mind-body techniques are helpful.<sup>21</sup>

Mind-body modalities, including meditation, hypnosis, relaxation techniques, cognitive-behavioral therapy, biofeedback, and guided imagery have become part of mainstream care

over the years. A survey found that 19% of American adults used at least one mind-body therapy in a one-year period.<sup>22</sup> A meta-analysis of 116 studies found that mind-body therapies could reduce anxiety, depression, and mood disturbance in cancer patients, and assist their coping skills.<sup>23</sup> Mind-body techniques can also help reduce chronic low-back pain, joint pain, headache, and procedural pain.<sup>24</sup>

## Meditation

Meditation can be grouped into two categories. Concentrative mediation focuses attention on increasing mental awareness and clarity of mind. Here, attention is focused on an image, a sound, or on one's breathing. Mindfulness meditation, instead, opens attention to whatever goes through the mind and to the flow of sensations experienced from moment to moment, without attempts to discover their meaning. The emphasis on the present helps release the mind from negative past memories and from worries about the future. A common goal of many mind-body therapies is to achieve "inner peace."

Changes in brain electrical activity and immune functions have been reported in individuals who underwent a training program in mindfulness meditation. In a randomized, wait-list controlled study, significant increases in left-sided anterior activation, a pattern previously associated with positive affect, were found in the meditators. When the subjects were immunized with influenza vaccine, significant increases in specific antibody titers were observed. There was no correlation between the magnitude of increase in left-sided activation and that of the rise in antibody titer.<sup>25</sup>

In a randomized wait-list control study of 109 cancer patients, participation in a seven-week mindfulness-based stress reduction program was associated with significant improvement in mood disturbance and symptoms of stress.<sup>26</sup> A single arm study of breast and prostate cancer patients showed significant improvement in overall quality of life, stress, and sleep quality, but symptom improvement was not significantly correlated with program attendance or minutes of home practice.<sup>27</sup>

Yoga, which combines physical movement, breath control, and meditation, improved sleep quality in a trial of 39 lymphoma patients. Practicing a form of yoga that incorporates controlled breathing and visualization significantly decreased sleep disturbance when compared to wait-list controls.<sup>28</sup> Mindfulness-based stress reduction techniques must be practiced to produce beneficial effects.<sup>29</sup>

## Hypnosis

Hypnosis is an artificially induced state of consciousness in which a person is highly receptive

to suggestion. A hypnotherapist or one's own self (self-hypnosis) can induce the trancelike state (similar to deep daydreaming) by first inducing relaxation and then directing attention to specific thoughts or objects. The World Health Organization (WHO) estimates that 90% of the general population can be hypnotized, with 20 to 30% able to enter the deeper somnambulistic state. For best results, the patient and the therapist must have a good rapport with a certain level of trust; the environment must be comfortable and free from distractions; the patient must be willing to undergo the process and must desire to be hypnotized. Hypnosis was endorsed by the British Medical Society in 1955 and the American Medical Association in 1958. Research shows that hypnosis is beneficial in reducing pain, anxiety, phobias, nausea, and vomiting.

In one study, 20 excisional breast biopsy patients were randomly assigned to a hypnosis or control group (standard care). Post-surgery pain and distress were reduced in the hypnosis group.<sup>30</sup> In another study, children undergoing multiple painful procedures such as bone marrow aspiration or lumbar puncture were randomized to receive hypnosis, a package of cognitive behavioral coping skills, or no intervention. Those who received either hypnosis or cognitive behavioral therapy experienced more pain relief than control patients. The effects were similar between hypnosis and cognitive behavioral therapy. Both therapies also reduce anxiety and distress, with hypnosis showing greater effectiveness.<sup>31</sup> Hypnosis was studied in a randomized controlled trial of 60 patients undergoing elective plastic surgery. Peri- and postoperative anxiety and pain were significantly reduced in the hypnosis group when compared to the control group, who received only stress reduction training. Reduction in anxiety and pain was achieved along with significant reduction in intraoperative requirements for sedatives and analgesics.<sup>32</sup>

In a study of 67 bone marrow transplant patients, subjects were randomized to one of the four intervention groups: hypnosis training, cognitive behavioral coping skills training, therapist contact control, or usual care. Oral pain from mucositis was reduced in the hypnosis group.<sup>33</sup> A National Institutes of Health (NIH) Technology Assessment Panel found strong evidence for hypnosis in alleviating cancer-related pain.<sup>34</sup> Hypnosis effectively treats anticipatory nausea in pediatric<sup>35</sup> and adult cancer patients<sup>36</sup> and reduces postoperative nausea and vomiting.<sup>32</sup>

Selection of proper patients and the qualifications of the hypnotherapist contribute to safe hypnotherapy. The WHO cautions that hypnosis should not be performed on those with psychosis or certain personality disorders. A small percentage of patients may experience dizziness, nausea, or headache. These symptoms usually result from

patients brought out of trance by inexperienced hypnotherapists.

## Relaxation Techniques

Randomized, controlled trials demonstrate that relaxation training and guided imagery significantly ameliorate anxiety and distress. A randomized study of relaxation therapy versus alprazolam showed that both approaches significantly decreased anxiety and depression, although the effect of alprazolam was slightly quicker for anxiety and stronger for depressive symptoms.<sup>37</sup> Relaxation achieves the effect without side effects and at a lower cost. A randomized trial of 82 radiation therapy patients found significant reductions in tension, depression, anger, and fatigue for those who received relaxation training or imagery.<sup>38</sup>

A meta-analysis of 59 studies showed improved sleep induction and maintenance with psychological interventions.<sup>39</sup> Although pharmaceuticals may produce a rapid response, some studies suggest that behavioral therapies help to maintain longer-term improvement in sleep quality. The NIH consensus panel concluded that behavioral techniques, particularly relaxation and biofeedback, produce improvements in some aspects of sleep, but the magnitude of improvement in sleep onset and time may not achieve clinical significance.<sup>34</sup>

## Manual Therapies and Bodywork

The many types of bodywork have in common the manipulation or movement of parts of the body to achieve health benefits. Osteopathy and chiropractic teach complete systems of diagnosis and treatment. Massage therapy has variations, such as Swedish massage and shiatsu. Other bodywork techniques, such as the Alexander Technique and Pilates, address posture and movement, while yoga, tai chi, Reiki, and polarity therapy incorporate strong mind-body components.<sup>14</sup>

## Osteopathic and Chiropractic Manipulation

Osteopathy was developed in late 19th century by Andrew Taylor Still, a trained engineer and physician who believed that "structure governs function." Osteopathy is taught as a complete system of medical care. In the United States, training blends conventional medical, surgical, and obstetrical practices with osteopathic manipulative treatments (OMT), involving manipulation of the bones, muscles, and tendons to promote blood flow and enhance the body's healing powers. Doctors of Osteopathy (DOs) are licensed to perform surgery and prescribe medicine in the United States after completion of licensure examinations and graduate medical education.

Some DOs focus on the conventional medical approach and provide general medical care, while others focus more on manipulative treatment. In Europe, osteopaths rely more on the latter.<sup>40</sup>

Chiropractic was also originated in the late 19th century in the United States. The founder, Daniel David Palmer, believed that the proper alignment of the spinal column is essential to optimal health. Palmer believed that subluxations impede normal function of the nervous system and lead to illness, and that spinal manipulation (adjustment) was required to correct the problem. Chiropractic is widely accepted by the regulatory authority and third-party payers, if not by mainstream medicine. In 1987, the US Supreme Court upheld a lower-court finding charging the American Medical Association of antitrust violations in its attempt to eliminate the chiropractic profession. Chiropractic services are included in Medicare, in over half of health maintenance organizations, and in 75% of private health insurance plans.<sup>41,42</sup>

Although manipulative techniques in osteopathic and chiropractic care are offered to treat many medical conditions, most controlled clinical trials of these techniques were conducted in patients with lower back pain.<sup>43</sup> Systematic reviews and meta-analysis supported its benefits in acute<sup>44</sup> and chronic<sup>45</sup> back pain. A randomized controlled trial compared standard medical therapies to osteopathic manipulation in the treatment of chronic lower back pain. No statistically significant difference was found for pain and range of motion, although those receiving osteopathy required significantly less medication and used less physical therapy.<sup>46</sup> A recent systemic review of spinal manipulation concluded that there is moderate evidence of its short-term efficacy in treating acute and chronic lower back pain, but insufficient data to draw conclusions regarding its efficacy for lumbar radiculopathy.<sup>47</sup>

## Massage Therapy

Massage therapists apply pressure to muscle and connective tissue to reduce tension and pain, improve circulation, and encourage relaxation. Swedish massage, the most common type in the US, is gentle and comprises five basic strokes (stroking, kneading, friction, percussion, and vibration). The movement is rhythmic and free-flowing. The practice of massage therapy requires state certification or licensure.

Massage therapy helps relieve symptoms commonly experienced by cancer patients. It reduces anxiety and pain<sup>48-51</sup> as well as fatigue, distress, nausea, and anxiety.<sup>48</sup> Anxiety and pain were evaluated in a crossover study of 23 inpatients with breast or lung cancer receiving reflexology (foot massage) or usual care. Patients experienced significant decreases in anxiety,

and in one of three pain measures, breast cancer patients experienced significant decreases in pain as well.<sup>49</sup> In another study, 87 hospitalized cancer patients were randomized to receive foot massage or control. Pain and anxiety scores fell with massage, with differences between groups achieving statistical and clinical significance.<sup>50</sup> The use of aromatic oil seemed to enhance the effect of massage in early studies,<sup>51,52</sup> but significant enhancement was not seen in more recent randomized controlled trials.<sup>53-55</sup> For non-cancer subacute and chronic back pain, massage therapy was found effective in a systematic review of randomized controlled trials, and preliminary data suggest it may help reduce the costs of care.<sup>56</sup>

Manual lymphatic drainage (MLD), which provides a gentle pumping action through specific hand movements, helps breast-cancer-related lymphedema. A randomized, controlled, crossover study compared the effects of MLD with those of simple lymphatic drainage (a less-robust massage regimen), in 31 women with breast-cancer-related lymphedema. MLD significantly reduced excess limb volume and dermal thickness and significantly improved quality-of-life end points.<sup>57,58</sup>

## Safety

Osteopaths and chiropractors are educated and should be well aware of contraindications for manipulation, such as acute fractures, underlying aneurysm, bone metastasis, etc. There are no data on the frequency of adverse effects from OMT, as the total number of OMT performed per year is unknown. A review of 128 articles published between 1925 and 1993 revealed 185 cases of major complications. The majority was cerebrovascular accidents (66%), the rest, disk herniations, pathologic fractures or dislocations, and an increase in pain.<sup>59</sup> There have been reports of rare, serious complications from chiropractic spinal manipulation. A Danish retrospective cohort study examined the incidence of cerebrovascular accidents after manipulation. The frequency is between 1 in every 120,000 to 900,000 cervical manipulations.<sup>60,61</sup> Complications from lumbar manipulations are rarer.<sup>42</sup> Many oncologists warn cancer patients against the use of chiropractic manipulation.

Massage therapy is safe when practiced by credentialed practitioners. Serious adverse events are rare and associated with exotic types of massage or untrained practitioners.<sup>62</sup> In work with cancer patients, the application of deep or intense pressure should be avoided, especially near lesions or anatomic distortions such as postoperative changes. Patients with bleeding tendencies should receive only gentle, light-touch massage.

## Dietary Measures and Supplements for Cancer Prevention

Epidemiologic studies show that some cancers are more or less prevalent in specific populations. This phenomenon cannot be explained entirely by genetics since, for example, Asian-American women born in the West are at greater risk for breast cancer than Asian-American women born in the East. Attempts have been made to identify “active ingredients” in diets and to see whether oral supplementation with such ingredients may reduce cancer risk.

### Diet

In general, diets high in saturated fat and caloric intake are associated with higher cancer risk. Conversely, epidemiologic as well as animal studies show that fruit and vegetable intake assists cancer prevention. Large, prospective studies are under way to determine whether dietary supplementation can reduce cancer risk. Given other health benefits, such as reduced risk of cardiovascular disease, a diet high in fruits and vegetables and low in saturated fat is advisable.

Diet plays an important role in the prevention of gastrointestinal (GI) cancers. Obesity increases the risk of esophageal and colon cancers, and high alcohol intake elevates the risk of esophageal and liver cancers. Ingestion of aflatoxin-contaminated peanuts or grains increases the risk of liver cancer. Salt-preserved foods and high salt intake are linked to stomach cancer. Dietary fiber significantly lowers the risk of colon cancer.<sup>63</sup>

Although most animal studies show that dietary fat increases the development of breast tumors, data from case-control or cohort human studies are less strong.<sup>64</sup> Type of fat is important because there is an inverse relationship between consumption of olive oil (monounsaturated fat) or fish oil (polyunsaturated fat) and breast cancer risk. Excess body weight is a significant risk factor for recurrence and for shorter survival in breast cancer patients, especially in Stage I and II patients.<sup>65</sup> Several clinical trials (the Women’s Health Initiative, the Women’s Intervention Nutrition Study, and the Women’s Healthy Eating and Lifestyle Study) are ongoing to address the relationship between dietary fat, other components of diet, and the risk of breast cancer and other diseases.

Epidemiologic studies suggest a role for low-fat diets in prostate cancer prevention. Data from case-control and prospective studies are mixed. In animal studies, low-fat diets decrease tumor growth.<sup>66</sup> Some demonstrate a direct association between increased saturated and monounsaturated fat and increased risk of prostate cancer,<sup>67,68</sup> while others find no relationship.<sup>69,70</sup> In a cohort study of more than 58,000 men,

prostate cancer risk was not associated with the intake of total fat, total saturated fatty acids, or total trans-unsaturated fatty acids, in general, although lower risk was weakly associated with increased intake of linolenic acid.<sup>71</sup>

## Dietary Supplements

Antioxidants are the best studied supplements for cancer prevention, based on their assumed protective effect against oxidative stress to the genome, proteins, and lipids. Compounds that can induce differentiation of immature cells constitute another major class of chemopreventive agents.

The largest chemoprevention study to date is the  $\alpha$ -Tocopherol,  $\beta$ -Carotene Cancer Prevention Study, a randomized controlled trial of 29,000 male smokers in Finland. Dietary supplementation with  $\alpha$ -tocopherol, a form of Vitamin E, or  $\beta$ -carotene, a precursor of Vitamin A, did not reduce the incidence of lung cancer among male smokers. On the contrary,  $\beta$ -carotene was associated with increased risk of lung cancer in current smokers and recent quitters.<sup>72</sup> Although supplementation of  $\alpha$ -tocopherol did not reduce overall incidence of lung cancer, higher serum  $\alpha$ -tocopherol status was associated with lower lung cancer risk, particularly among younger persons and those with less cumulative smoke exposure. This suggests that high levels of  $\alpha$ -tocopherol, if present during the early critical stages of tumorigenesis, may inhibit lung cancer development. Both the beneficial and the adverse effects of supplemental  $\alpha$ -tocopherol and  $\beta$ -carotene disappeared during post-intervention follow-up.<sup>73</sup>

In the  $\beta$ -Carotene and Retinol Efficacy Trial, another large chemoprevention trial of 18,000 smokers, former smokers, and workers exposed to asbestos,  $\beta$ -carotene and vitamin A supplementation again was associated with a higher risk of lung cancer.<sup>74</sup> Interestingly, sub-analyses revealed that fruit and vegetable consumption reduced lung cancer risk only in the placebo arm. The association was strongest with Rosaceae fruit or Cruciferae vegetables.<sup>75</sup> This illustrates that plant foods have a role in preventing lung cancer in high-risk populations, and that purified  $\beta$ -carotene supplements do not provide the protective effects associated with foods.

Selenium is a trace element required for the activity of the antioxidant enzyme glutathione peroxidase, which protects cell membranes from damage caused by the peroxidation of lipids.<sup>76</sup> Dietary selenium and serum selenium levels correlate inversely with the risk of several types of cancer.<sup>77</sup> Plants that grow in selenium-rich soil or animals that eat such plants are good sources of dietary selenium, and Brazil nuts are a particularly rich source of selenium.

In a multi-center, randomized, placebo-controlled study of 1,312 patients with history

of non-melanoma skin cancer (the Nutritional Prevention of Skin Cancer Trial), daily intake of 200  $\mu$ g of selenium lowered the incidence of prostate cancer by two-thirds.<sup>78</sup> The incidence of lung and colorectal cancers also was reduced. There was no significant effect on other cancers. In the Health Professionals Follow-Up Study, higher selenium levels were associated with reduced risk of advanced prostate cancer.<sup>79</sup> The association became stronger with additional controls for family history of prostate cancer, body mass index, calcium intake, lycopene, and saturated fat intake, vasectomy, and geographical region.

A randomized, placebo-controlled, double-blind, phase III prostate cancer prevention trial of 32,400 men (the Selenium and Vitamin E Cancer Prevention Trial) is under way to test the preventive efficacy of selenium and vitamin E.<sup>80,81</sup> Final results are anticipated in 2013. This study will also generate strong data regarding the safety of vitamin E; one meta-analysis of mostly cardiovascular chemopreventive trials found slightly higher mortality associated with high-dose (> 400 IU/d) vitamin E supplementation.<sup>82</sup>

Lycopene is a natural pigment found in tomato, watermelon, guava, rose hips, and pink grapefruit. It is classified as a non-provitamin A carotenoid. Epidemiologic studies suggest an inverse relationship between lycopene consumption and lung, prostate, and stomach cancers.<sup>83</sup> A prospective study of male health professionals, the Health Professionals Follow-up Study, found an association between frequent tomato or lycopene intake and reduced risk of prostate cancer. Intake of tomato sauce, in which lycopene is more bioavailable, was associated with an even greater reduction in prostate cancer risk, especially for extraprostatic cancers. The associations persisted even when fruit, vegetable, and olive oil consumption were controlled.<sup>84</sup>

Calcium may lower the risk of colorectal adenomas by suppressing cell proliferation. Increasing the daily intake of calcium via low-fat dairy food reduces the proliferative activity of colonic epithelial cells and restores markers of normal cell differentiation in patients with a history of polypectomy for colonic adenomatous polyps. Recurrence of adenoma and the average number of adenomas were both significantly reduced by calcium intake in a large placebo-controlled, double-blind trial. In another large randomized study, calcium supplementation was associated with a modest, but not significant, reduction in risk of adenoma recurrence.

Anti-inflammatory drugs such as nonsteroidals or COX-2 inhibitors also show promise in colon cancer prevention, and good evidence indicates that sulindac, aspirin, and celecoxib help prevent colonic adenomas. Unfortunately, increased risk of heart attack and stroke is found in patients taking COX-2 inhibitors.<sup>85</sup> How this

finding affects the future of this class of drugs remains to be seen.<sup>86</sup>

Soy contains isoflavones, including phytoestrogens, genistein, and daidzein. Genistein and daidzein are selective estrogen-receptor modulators (SERMs). Dietary intake of soy and high serum phytoestrogen levels are associated with lower risk of prostate cancer. In vitro studies indicate that genistein inhibits the growth of prostate cancer cells, apparently independent of genistein's estrogenic effects.<sup>87,88</sup> Prospective intervention trials have not yet been conducted to evaluate the role of soy in preventing prostate cancer. Most prospective trials included men following a diagnosis of prostate cancer.<sup>89,90</sup>

Some research suggests that soy products may decrease breast cancer risk, but the effect appears dependent on when in the woman's lifetime soy products were consumed. In animal studies, rats fed soy-enriched diets through puberty had a decreased incidence of mammary tumors later in life, but this effect was not seen when the soy-enriched diet started after puberty. Epidemiologic studies in general fail to show a protective effect for soy products, except in women who consume them during adolescence or in large amounts.<sup>91</sup> The phytoestrogen activity in soy products raises concerns about their use by breast cancer patients or survivors with estrogen-receptor-positive cancer. In theory, these products may increase the risk of breast cancer recurrence or progression. It is possible these phytoestrogens produce paradoxical effects, as both estrogenic and antiestrogenic effects are observed in vitro. The effect may depend on the concentration or other co-factors in the cells, not unlike other selective estrogen receptor modulators.

Based on existing data, the consumption of soy products in moderation is neither encouraged nor discouraged for the prevention of breast cancer. Women with estrogen-receptor-positive breast cancer should not consume large amounts of phytoestrogen-rich foods such as concentrated soy products.

## Herbal Medicine

Botanicals have been the major source of medicinal materials for millennia prior to the 20th century. Even today, a large percentage of people in developing countries rely on herbal medicines for their health care. About one-quarter of prescription drugs contain active ingredients derived from plants, including several chemotherapeutic agents (paclitaxel, docetaxel), camptothecins (irinotecan hydrochloride, topotecan hydrochloride), and vinca alkaloids (vincristine, vinorelbine tartrate).

Botanicals are a valuable source for the development of therapeutic agents, where they

are carefully studied for safety and efficacy. Sold as dietary supplements, however, they are rarely produced to the same high standards. Many therapeutic claims remain unproven, and some herbs cause significant side effects. Detrimental herb-drug interactions may occur. Finally, product inconsistency and contamination have been reported.<sup>92</sup>

### Problems and Potential of Herbal Supplements

Most claims made by producers of herbal supplements are based on historical experience, unconfirmed by clinical trials. Many herbs show direct antitumor activity from *in vitro* or animal experiments,<sup>93,94</sup> but translating preclinical to clinical use often fails because the active constituents, often unknown, are insufficiently potent or metabolized before reaching their target. The composition of herbs is complex, typically containing hundreds of constituents. Moreover, some herbal remedies function through the synergistic effects of their multiple constituents, hindering identification of active components.

Herbs and other botanical products that enhance immune function are especially popular among cancer patients and may prove useful in cancer treatment or prevention. Some show immunomodulatory effects in preclinical studies, assisting tumor rejection or resistance to pathogens.<sup>95-97</sup> However, the most popular immune-boosting herb in the United States used commonly to treat colds—Echinacea—shows disappointing results in randomized controlled trials.<sup>98-100</sup>

The popular use of herbal supplements has important public health implications (see “Herb-Drug Interactions” and “Quality Control Issues”). In order to evaluate the effectiveness and safety of herbal supplements and guide their use by the consumers, rigorous clinical trials are under way. The United States Food and Drug Administration (FDA) issued “Guidance for Industry—Botanical Drug Products” in 2004 to aid the drug development process.<sup>101</sup>

### Side Effects

Because botanicals contain biologically active constituents, they carry health risks if not used properly. The botanical kava kava, for example, proved more effective than placebo in treating anxiety, stress, and insomnia,<sup>102,103</sup> and it was considered a viable alternative to benzodiazepines because of its benefits and absence of dependency and addiction. However, later reports associate this herbal remedy with severe hepatotoxicity resulting in death.<sup>104</sup>

Red clover and black cohosh are promoted and used as “natural hormone replacement therapy” to treat postmenopausal symptoms. Red clover preparations, however, failed to

significantly reduce the numbers of hot flashes, although one preparation reduced hot flashes more rapidly than another. This may be an example of the inconsistent standardization that characterizes supplement development.<sup>105</sup> Products containing red clover should not be used by patients with estrogen-receptor-positive breast cancer as they contain phytoestrogens. Black cohosh reduced menopausal symptoms without systemic estrogenic effect in an open-label study,<sup>106</sup> but another trial of women with breast cancer showed no overall benefit.<sup>107</sup> Whether black cohosh has estrogenic activity remains under debate. Recent laboratory research showed no direct interaction of black cohosh extract with estrogen receptors.<sup>108</sup>

Herbal medicine was practiced historically by those with at least some knowledge of side effects of the herbs. Today, however, many herbal and other botanical products are readily available to US consumers under the Dietary Supplement Health and Education Act of 1994, which regulates them only as food supplements and requires no prior studies of safety and efficacy. A few herbal products have been removed from the market by the FDA due to adverse events. A recent example is agents that contain ephedrine, as its sympathomimetic activity has been associated with cardiovascular complication, including death.

### Herb-Drug Interactions

Herbs may attenuate or lessen the effect of a drug either by direct action on its target or by altering its pharmacokinetics.<sup>109,110</sup> Herbs such as feverfew, garlic, ginger, and ginkgo have anticoagulant effects and should be avoided by patients on warfarin, heparin, aspirin, and related agents. Red clover, Dong quai, and licorice, because of their phytoestrogen components, should not be used by patients on tamoxifen or aromatase inhibitors. St. John’s wort was a popular product for depression, at least equivalent in efficacy to tricyclics and selective serotonin reuptake inhibitors (SSRIs) in mild to moderate depression and with a side-effect profile superior to both.<sup>111,112</sup> It was found, however, that St. John’s wort induces cytochrome P450 CYP3A4. Reduced plasma levels of SN38, an active metabolite of irinotecan, have been reported following simultaneous use.<sup>113</sup> Such metabolic interactions preclude St. John’s wort for patients on medications metabolized by CYP3A4.<sup>114</sup>

Although not an herb, grapefruit juice was found to significantly change the plasma level of many prescription drugs. Further study found that furanocoumarin derivatives inhibit intestinal CYP3A4, which consequently increases the bioavailability of drugs that are substrate to first pass metabolism by this enzyme.<sup>115,116</sup> Interestingly, the interaction was initially discovered by

accident in an ethanol-calcium channel blocker interaction study in which grapefruit juice was used as the vehicle for the alcohol.<sup>117</sup> Details of herb-drug interaction can be found at several sources.<sup>92,118</sup>

### Quality Control Issues

The story of PC-SPES illustrates the quality control problems in herbal medicine. This 8-herb formulation was in popular use to treat prostate cancer. Although its exact mechanism of action is unclear, the constituents had been shown in preclinical studies to stimulate natural killer cells, inhibit growth of cancer cell lines, and bind to estrogen receptors where they inhibit 5 $\alpha$ -reductase. Four small clinical studies demonstrated that patients with androgen-dependent or -independent prostate cancer had lower prostate-specific antigen (PSA) levels following use of PC-SPES.<sup>119,120</sup> Patients whose disease progressed after chemotherapy or ketoconazole treatment (a difficult-to-treat population) still responded to PC-SPES.<sup>119,120</sup> Toxicities in those trials were similar to those expected from estrogen treatment, including gynecomastia (common), loss of libido, and venous thrombosis (uncommon).<sup>119,120</sup>

Unfortunately, despite promising clinical activity against prostate cancer, PC-SP was found to be contaminated with undeclared synthetic drugs, including indomethacin, warfarin, alprazolam and diethylstilbestrol (DES).<sup>121</sup> In 2002, the FDA warned consumers to stop using PC-SPES, and the manufacturer (BotanicLab, Brea, CA) recalled the product and went out of business. One report compared PC-SPES with DES head-to-head in 90 androgen-insensitive prostate cancer patients. In this prospective, multicenter, randomized phase II trial, decline of PSA, median response duration, and median time to progression were all superior in the PC-SPES group. DES was detected in several lots of PC-SPES, the amount ranging from 0.01% to 3.1% of the dose in the DES arm.<sup>122</sup> Apparently PC-SPES clinical activity is not attributable entirely to DES contamination. The studies of PC-SPES serve as a good illustration of the promise, the problems, the complexity, and the importance of rigorous scientific research of herbal products.

### Acupuncture

Acupuncture is the stimulation of certain points on the body with needles. Recent scientific research suggests that the effects of acupuncture are likely mediated by the nervous system. Release of neurotransmitters and change of brain-functional magnetic resonance imaging (MRI) signals are observed during acupuncture.<sup>16,123</sup> Traditionally, it is used for almost every ailment, but most indications are not confirmed by rigorous clinical study. However, evidence supports

the use of acupuncture in treating some common symptoms experienced by cancer patients and others.

## Pain

Pain is the most common and the best studied indication for acupuncture. Acupuncture relieves both acute (eg, postoperative dental pain) and chronic (eg, headache) pain.<sup>124,125</sup> Whether it helps musculoskeletal pain remains controversial.<sup>126,127</sup> An NIH consensus statement in 1997 supported acupuncture for adult postoperative pain, chemotherapy-related nausea and vomiting, and postoperative dental pain.<sup>124</sup> Insufficient evidence was available to support other claims of efficacy at that time, but in the ensuing years, many publications have documented the utility of acupuncture as an adjunct treatment for pain, emesis, and other symptoms.

A randomized controlled trial of 570 patients with osteoarthritis of the knee found that a 26-week course of acupuncture significantly improved pain and dysfunction when compared to sham-acupuncture control. In this study, all patients received other usual care for osteoarthritis. At week 8, improvement in function (but not in pain) was observed, indicating that long-term treatment may be required to achieve full effect.<sup>128</sup> A companion paper reported the results of a randomized controlled trial of acupuncture for chronic neck pain.

Acupuncture appears effective against cancer-related pain. A randomized placebo-controlled trial tested auricular acupuncture for patients with pain despite stable medication. A total of 90 patients were randomized to have needles placed at correct acupuncture points (treatment group), versus acupuncture or pressure at non-acupuncture points. Pain intensity decreased by 36% at 2 months from baseline in the treatment group, a statistically significant difference compared with the two control groups, for whom little pain reduction was seen.<sup>129</sup> Skin penetration per se showed no significant analgesic effect. The authors selected acupuncture points by measuring electrodermal signals. These results are especially important because most of the patients had neuropathic pain, which is often refractory to conventional treatment.

Brain imaging technology is now being used to examine the specific nervous pathways involved in acupuncture. In functional MRI studies, true acupuncture induces brain activation in the hypothalamus and nucleus accumbens, and deactivates areas of the anterior cingulate cortex, amygdala, and hippocampus. Such changes are not observed in control stimulations, which affect only sensory cortex change. Deactivation of the amygdala and hippocampus has also been observed with electroacupuncture. These data

suggest that acupuncture modulates the affective-cognitive aspect of pain perception.<sup>123</sup> Correlations between signal intensities and analgesic effects have also been reported.<sup>130</sup>

## Nausea and Vomiting

Acupuncture helps lessen chemotherapy-induced nausea and vomiting.<sup>131</sup> In one study, 104 breast cancer patients receiving highly emetic chemotherapy were randomized to receive electroacupuncture at the PC6 acupuncture point, minimal needling at non-acupuncture points, or pharmacotherapy alone. Electroacupuncture significantly reduced the number of episodes of total emesis (from a median of 15, down to 5) when compared with pharmacotherapy only. Most patients did not know the group to which they had been assigned.<sup>132</sup> The effects of acupuncture do not appear entirely due to attention, clinician-patient interaction, or placebo.

Acupressure wrist bands that render continuous stimulation of the PC6 point have also been tested for chemotherapy-related nausea and vomiting. In a randomized, controlled trial of 739 patients, nausea on the day of chemotherapy was reduced significantly in patients wearing wrist bands compared with no-band controls. No significant differences were found for delayed nausea or vomiting.<sup>133</sup> Acupuncture also suppresses nausea and vomiting caused by pregnancy,<sup>134</sup> surgery,<sup>135</sup> and motion sickness.<sup>136,137</sup>

The combination of acupuncture and serotonin receptor antagonists, the newest generation of antiemetics, showed mixed results. In a trial of patients with rheumatic disease, the combination decreased the severity of nausea and the number of vomiting episodes more than ondansetron alone in patients receiving methotrexate (an agent also used in chemotherapy).<sup>138</sup> However, a study of cancer patients receiving high-dose chemotherapy and autologous stem cell transplantation reported no significant benefit for ondansetron plus acupuncture versus ondansetron plus placebo acupuncture.<sup>139</sup>

## Other Symptoms

Acupuncture has been reported to reduce xerostomia (severe dry mouth). Radiotherapy for head and neck cancer causes acute and chronic xerostomia, which may persist despite the use of pilocarpine (Salagen) and amifostine (Ethyol). Acupuncture improved xerostomia inventory scores in 18 patients with head and neck cancer and pilocarpine-resistant xerostomia. However, a controlled trial of acupuncture versus superficial needling found increased salivary flow in patients with both conditions (68% and 50%, respectively). Although real acupuncture produced greater improvement and a longer latency phase, the difference was not significant.<sup>140</sup> Randomized

trials with proper controls and adequate power are needed before conclusions can be drawn.

Patients with breast or prostate cancer may experience vasomotor symptoms (hot flashes) during estrogen or androgen ablation therapy. A few uncontrolled studies investigated acupuncture to treat these symptoms. Self-stimulation of implanted miniature acupuncture needles attenuated tamoxifen-related hot flashes in 8 of 12 patients with breast cancer,<sup>141</sup> and similar results were found in a case series of patients with breast<sup>142,143</sup> and prostate cancer.<sup>144</sup> Controlled trials are under way at several centers.

Fatigue following chemotherapy or irradiation, another major and common problem, has few reliable treatments in patients without a correctable cause such as anemia.<sup>145</sup> In an uncontrolled trial of fatigue after chemotherapy, acupuncture reduced fatigue 31% after 6 weeks of treatment. Among those with severe fatigue at baseline, 79% had non-severe fatigue scores at follow-up,<sup>146</sup> whereas fatigue was reduced only in 24% of patients receiving usual care in another center.<sup>147</sup>

## Adverse Effects

Acupuncture needles are regulated as a medical device in the United States. They are filiform, sterile, single-use, and very thin (28 to 40 gauge) (Figure 2). Insertion of acupuncture needles causes minimal or no pain and less tissue injury than phlebotomy or parenteral injection. Acupuncture performed by experienced, well-trained practitioners is safe. Only 6 cases of potentially serious adverse events were reported in a recent study of 97,733 patients receiving acupuncture in

FIGURE 2 Acupuncture needle.

Germany. They included exacerbation of depression, hypertensive crisis, vasovagal reaction, asthma attack, and pneumothorax. The most common minor adverse events included local bleeding and needling pain, both in fewer than .05% of patients.<sup>148</sup> It is prudent to avoid acupuncture at the site of tumor or metastasis, limbs with lymphedema, areas with considerable anatomic distortion due to surgery, and in patients with thrombocytopenia, coagulopathy or neutropenia. Cancer patients require certified practitioners who are experienced in treating patients with malignant diseases.

## Summary

The use of complementary and alternative therapies is prevalent among cancer patients and survivors. They seek these therapies because some of their health care needs are not adequately addressed by mainstream medicine. Whereas alternative therapies can be harmful to patients, complementary therapies play an important role in the overall care of cancer patients. Increased research on the safety and efficacy of complementary therapies enables evidence-based guidance for physicians and patients. Health care professionals should ask patients about their use of CAM, recognize and explore the underlying needs, discuss the pros and cons in a receptive, evidence-based manner, advise the patient after considering the balance of benefits and risks, and know where to find reliable additional information.

# Survivorship—A Reversal of Fortune

S. Jim Yeung, MD, PhD  
Carmen Escalante, MD  
Robert F. Gagel, MD

A fundamental characteristic of the human condition is the desire to survive. Parents will often sacrifice their own lives to ensure the survival of their offspring, and individuals confronted with overwhelming danger will struggle heroically. This tenacious behavior in a cancer patient, combined with the oncologic advances of the past several decades, has created a dramatic reversal of fortune for patients with cancer. For the average cancer patient, there is now a greater than 50% probability of survival; even for those with cancer who will ultimately die, survival periods have steadily lengthened in recent years.

A challenge faced by those of us who have not experienced cancer is the question of what normality is for a cancer patient who has survived a near-death experience. One answer could be that normality probably does not exist for this group. In the same way that prisoners of military conflicts, battle-hardened veterans of bloody wars, or concentration camp survivors move on with their lives, but never completely rid themselves of the terrible memories, cancer survivors move forward but are left with permanent reminders of their journey. Like the war veteran, these scars not only affect the psyche, but also other organ systems. As we cross a threshold, one where more patients survive than die, it is important to ask whether the experience during—and the unhealthful sequelae of—therapy can be improved. Although there is the sincere hope that targeted therapies currently being developed will substantially lower toxicity, a more realistic expectation is that these newer therapies will also target normal tissues where these signal transduction pathways are important.

Several trends in cancer survivorship are emerging. Perhaps the most significant is that the number of cancer survivors is growing, and they are now recognizing shared experiences with other survivors. This has led to the development of embryonic survivorship groups who are in the initial stages of organization to demand solutions to the variety of residual ailments that have resulted from their journey through cancer treatment. The initial stages had the feeling of

other nascent movements: calls for action without a clear idea of what would make things better. In recent years, this has been replaced by more clearly focused efforts that, in turn, have forced the oncology community to broaden its definition of the cancer experience to include survivorship. Not only do these survivors want to live, they not unexpectedly want to live with some semblance of the quality of life they experienced before the illness.

The major dilemma faced by this field is the difficulty of delivering a lethal blow to a cancer without causing toxicity to other organ or tissue sites. In this text, we have provided an up-to-date compilation of current knowledge and approaches, but implicit in these discussions is the recognition that we are only at the beginning of understanding mechanisms of long-term effects. Furthermore, and with good reason, there has been little effort expended to study basic mechanisms of disease in survivors beyond descriptive studies. The focus has been on creating survivorship; now that we have moved past the midpoint, it is time to reexamine priorities and include these issues as an important component of the research agenda.

In truth, the landscape is uneven. Great strides have been made in reducing death in breast cancer, Hodgkin's disease, and testicular cancer, whereas there has been little or no improvement in overall survival in lung cancer, malignant brain tumors, or pancreatic cancer. In these latter areas, the focus (by necessity) will remain on control of the malignancy.

At least two strategies can be envisioned for addressing long-term sequelae in patients with malignancies. The first is to develop therapies that are effective but less toxic. For malignancies where substantial progress has been made on improving outcomes, there are active efforts to maintain or improve efficacy while reducing long-term effects. Specific examples include the use of aromatase inhibitors in breast cancer,<sup>1</sup> the use of monoclonal antibodies for treatment of a variety of malignancies,<sup>2-4</sup> and small organic molecules that target specific molecular targets in certain cancers.<sup>5</sup>

As outcomes improve for other malignancies, it seems likely the pace of this process will increase.

A second strategy is to study the molecular mechanisms of toxicity and use this information to develop preventive therapies. This approach has proven challenging in the past because therapies effective in the treatment of cancer have a broad spectrum of activities, making it difficult to dissect the mechanisms causing a particular effect. Nonetheless there has been some success. Recognizing that anthracycline effects on cardiac muscle (free radical formation in cardiac cells)<sup>6</sup> differed from its effects in the transformed cell (inhibition of ribonucleic acid [RNA] and deoxyribonucleic acid [DNA] synthesis), investigators in this field have developed several pharmacologic agents (dexrazoxane and its analogues) that inhibit free radical formation in cardiac muscle, thereby blunting the damaging effects of anthracyclines on cardiac muscle.<sup>7</sup> Although the protection is imperfect and used predominantly in patients treated with high-dose anthracycline therapy, it highlights an example where elucidation of a difference between a mechanism of cancer therapy and organ toxicity has proven useful.

A question that will be asked is whether it makes sense, in this fast moving field of molecular targeting of cancer, to initiate studies of mechanisms of toxicity for first- and second-generation therapies with higher toxicity, those most likely to be replaced as cancer therapy moves forward. A more robust and forward-looking strategy is to focus energy on the large number of new therapeutic agents under development. This seems a more practical approach for several reasons. First, it is already clear that molecular targeting of specific biochemical pathways, singly or in combination, will be an effective therapeutic approach for treatment of cancer. As many of the same pathways have broad importance in normal tissues, it will be important to develop strategies for preventing unwanted effects in normal tissue. One example that comes immediately to mind is the effect of a broad spectrum of tyrosine kinase inhibitors that target the vascular endothelial growth factor and epidermal growth factor

receptors to cause hypertension and a broad spectrum of dermatologic disorders.<sup>8,9</sup> These findings have already spawned some research into mechanisms,<sup>10,11</sup> although there is at present no clear understanding of why inhibition of these receptor tyrosine kinases cause these effects. Although there is the temptation to treat the hypertension and dermatologic manifestations with currently available therapies as best as can be done, omitting any research into the underlying mechanisms, it is important to study the mechanisms because it is likely these agents (or others that target the same pathways) will become the mainstays of cancer therapy for the foreseeable future. Indeed, such investigation may yield insight that will not only be helpful in the treatment of these manifestations in the cancer patient, but also in the greater population, because these same signal transduction pathways are likely to be of importance in the genesis of the same medical problems during normal aging. None of this will occur quickly, but it will be important to move forward on this agenda, linked arm in arm, with the development of new treatments for cancer.

It will also be important to develop social and psychological support systems for cancer survivors. Just as survivors of war-time experiences struggle throughout their lives, cancer survivors are misunderstood by the general medical community. There is incomplete understanding outside of major cancer centers of the profound physical and psychological effects that cancer and its treatments cause. One of the areas highlighted by one Institute of Medicine report on cancer survivorship was the importance of developing a care plan for survivorship.<sup>12</sup> This report specifically suggested that patients being discharged from active cancer treatment/surveillance be provided with a “comprehensive care summary and follow-up plan that is clearly and effectively explained.” The suggested components of this care plan are shown in Table 1.

We believe that at least one additional step is needed: the development of a body of expertise to address the unique needs of cancer survivors. The

**Table 1** Components of Care Plan

Summary of Cancer Type and Treatment Specific recommendations regarding follow up Recommendations regarding specific preventive and healthy living practices Information on legal protections regarding employment and access to health insurance Information on the availability of psychosocial services in the community
---

fast pace of cancer therapy today has left the general physician woefully unprepared to participate actively in the care of the cancer survivor. New therapies sprout up on a regular basis; the only exposure the general physician has is with the one or two patients undergoing a newly developed therapy. He/she generally has no experience with anticipated long-term problems. Indeed, even the oncologic community may not understand the long-term sequelae of a treatment approved in the last year or two, an inevitable outgrowth of the fast-track approval of oncologic therapies today. Thus the growing number of these patients and the explosion of new therapeutic approaches argue persuasively for the development of a subspecialty of medicine dedicated to these issues. This issue was also highlighted in the Institute of Medicine’s report, although there was no mention in the report of the development of a group of physicians who see their role as different and separable from the role played by the oncologist. Although it is conceivable that oncologists could fulfill this need, they have been more appropriately focused on cancer treatment; and general physicians, uniquely suited for this role by their situation in the community, do not have enough exposure to a the myriad therapeutic agents used to treat cancer, nor a large enough patient population to gain this experience.

As the discipline of geriatrics was spawned by the increasing longevity of the population, so to will the growth in numbers of long-term survivors lead to development of a unique and separable subspecialty of internal medicine. There

has been a proliferation of medical and scientific groups focused on supportive care for cancer patients and internal medicine in the cancer patient that will, over time, consolidate and define this discipline of medical practice. As is the case with the geriatrician, the total number of these individuals will be small, but as they move through the medical community to educate, inform, and perform research on these topics, their presence will be noted. We anticipate that the next 50 years will be exciting years as survivorship becomes commonplace.
