Prefaces

By the President of the British Ornithologists' Union

In 1964 the 'New Dictionary', as it became so well known, was termed a comprehensive book of reference on birds on a world-wide basis both by its editor and creator, Sir Landsborough Thomson, and by R.E. Moreau, then President of the BOU. The present volume is no different in this respect, but it has been very widely revised, a great part of it re-written, much fresh material added, and it forms a new and important almost encyclopaedic work, written and illustrated by several hundred experts. Once again the co-operation of authors, artists and photographers has been given unstintedly, nearly all of it in an honorary capacity, and to them all the Union owes much gratitude and praise.

To the great expertise and ability of the senior editor, Dr Bruce Campbell, and to his tireless assistant Elizabeth Lack, has fallen the task of organizing and completing this ambitious work with the help of a panel of advisors, of whom Dr David Snow must be especially mentioned. They have given readily of their time, thought and knowledge for over five years and the Union is indeed grateful. Our publisher also earns generous thanks, for he has given patient and sympathetic help all through and has worked well beyond the limits to which most publishers in his position would go.

A New Dictionary of Birds was in part a tribute to the memory of Professor Alfred Newton F.R.S., whose original *A Dictionary of Birds* was the inspiration behind Sir Landsborough Thomson's project for the Union's Centenary. *A New Dictionary of Birds* has been an important source of reference for 20 years and it so remains. That it needs this new volume to update it in so comparatively short a time is a measure of the immense output of present research into a subject for which Professor Newton did so much to originate respect and esteem. The Union that he helped to found has here been provided with a worthy successor to the two previous works.

J.F. MONK

By the President of the American Ornithologists' Union

The American Ornithologists' Union congratulates the British Ornithologists' Union for the publication of this major new work in our field. The completion in 1985 of *A Dictionary of Birds* continues and extends the service to ornithology provided first in 1896 by Alfred Newton's dictionary and then in 1964 by A. Landsborough Thomson's new dictionary. Because ornithology is expanding and diversifying so fast, the importance of having an up-to-date, comprehensive reference work of its terms is even greater now than it was at the time of Thomson's work. That work was initiated to mark the Centenary of the British Ornithologists' Union. This new dictionary was being prepared at the time that the American Ornithologists' Union celebrated its own centennial in 1983.

We are particularly indebted to the editors and to all the other people involved in its production for the role the dictionary will play in fostering communication among nations. For students it will serve as an entrance to the present status of the field. For scientists it will serve as a research tool and a bridge between disciplines. We are also glad that many of our members were able to serve as contributors to such a worthy cooperative project.

FRANCES C. JAMES

Editorial Introduction

The Dictionary consists of articles on general subjects relating to birds, and on different kinds of birds mainly treated by families.

The arrangement is alphabetical with cross-references in small capitals, so the dictionary constitutes its own index. The short entries define special terms, applications of names, or are merely cross-references to the relevant major article. No attempt has been made to provide a glossary of words that can be found in an ordinary dictionary.

Language. Scientific terms formed from classical languages do not appear as entry headings unless they are in such common use as to be practically anglicized, or unless they have no satisfactory equivalents in common speech. Synonyms in modern foreign languages are also generally excluded.

The English names of birds chosen as entry headings are those in use by British ornithologists; the inclusion of dialect or archaic names is limited to those most widely occurring. North American names and others used in the English-speaking world have also been covered as far as practicable. Scientific names of groups above generic level have been used in headings; families are treated under their English names. Scientific names of genera are not used as entry headings except where they are also the English substantive names.

References. These are generally in English and mainly limited to books, monographs or important papers, which contain fuller accounts of particular subjects. Such publications will usually give references to the international literature. In a few cases we have added references which have been too recently published to be made use of in the articles concerned.

Illustrations. The photographs have been chosen to illustrate different activities of birds. We are indebted to E.J. Hosking for advising us and for his help in collecting suitable subjects from a number of leading photographers. The drawings of birds, normally one to each family, have been assembled for us by Robert Gillmor and executed by 18 artists. The diagrammatic text figures have been supplied mainly by the authors of the articles to which they refer, but a number have been redrawn by J.W.N. Turner. We are very grateful to all of them.

Collaboration. The wide subject cover has been made possible by enlisting contributions from 280 ornithological and other specialists, drawn from every continent and from 29 countries. Artists and photographers bring the total to well over 300. The articles on general subjects are mostly by authors in the UK and the USA; the articles on bird groups are by authors from throughout the world. To all of them we are most grateful.

During the long course of the preparation of the dictionary we have had the assistance of an advisory panel which has met at intervals. Its members were Sir Hugh Elliott, BOU President in January 1979 when the project was begun, S. Cramp (part-time), R. Gillmor (part-time), E.J. Hosking, Dr J.R. Krebs, Dr J.F. Monk (part-time), Dr R.J. O'Connor, P.J.S. Olney (part-time), Dr C.M. Perrins, T. Poyser and Dr D.W. Snow.

Dr D.W. Snow has made an outstanding contribution, not only as the author of 17 articles and numerous short entries, but with invaluable help and advice on the text, and later when reading the proofs.

Drs L.G. Grimes, E.K. Dunn and P.J.K. Burton advised on the revision of many articles, and I.C.J. Galbraith was a generator of several short entries.

We must also make special mention of the part played by Prof. K.H. Voous, whose classification the panel decided to adopt, (though authors have sometimes expressed their own views). Professor Voous wrote or revised all of the relevant articles, and answered many questions from us in his immaculate handwriting.

Many authors, outside the scope of their own contributions, gave us help from time to time and, outside the list of authors, we should like to record our gratitude to Dr N.P. Ashmole, Prof. P.P.G. Bateson, N.J. Ball, A. Bell, Prof. R.J. Berry, Dr L. Birch, Dr R.I. Bowman, Mrs E. Brooks, A.R.M. Campbell, R.N. Campbell, S. Cowdrey, N.C. Davidson, Prof. J. Dorst, S. Digby Firth, Dr J.A. Gibb, Dr J. Horsfall, Dr P. Hudson, Dr I. Keymer, L. Kunzemann, Dr A.J. Lack, C.M. Lack, Dr P.C. Lack, Prof. A.M. Lucas, Dr P. Marler, K.T. Marsland, H. Mayer-Gross, Dr R.V. Melville, P.J.S. Olney, J.L.F. Parslow, Dr M.G. Ridpath, Prof. R.K. Ringer, F.N. Robinson, Dr R. Schodde, Dr J. Sincock, D. Smallwood, Dr H.N. Southern, J.K. Terres, Prof. H.B. Tordoff, M.W. Tweedie, Dr M.A. Vince, P. Ward (died 1979), P. Wayre, M.G. Wilson, I. Wyllie and Dr M. Yasuda.

Dr J.F. Monk, as President of the BOU, gave us welcome support and encouragement in all stages of production, while our publishers, Trevor and Anna Poyser, have continuously helped and co-operated all through our years of work on the dictionary, and we must record our warmest gratitude and thanks to them.

Amendment. In a work of this kind, freedom from error is unobtainable, and it has obviously been impossible to include all new information accruing during the years of preparation. The Editors welcome any intimation of necessary corrections or additions.

Note on the Classification Followed

The classification followed in this work, down to familial level, is shown in the succeeding table. It deviates from the classification used in the 1964 *Dictionary*, which for the non-passerine groups was mainly that of volumes 1–7 of the *Check-list of Birds of the World* (1931–1951) by the late J.L. Peters, which itself was essentially based on the well-known Wetmore system. The families of songbirds, by 1964 not yet fully treated by Peters' successors, followed the so-called Basle sequence with 'crows last' (Mayr and Greenway 1956), as opposed to the 'crows first' sequence of Wetmore. The first paragraph of the note on classification followed in the 1964 edition closes with the words: 'It seems likely that the *Check-list*, when completed, will be widely accepted as an international standard for general purposes of ornithology'. This turns out to have been a wish rather than a reality, for suddenly the study of the interrelationships, and hence the sequence of orders and families of birds, has found itself in such a turbulent state of development that at present nobody can foresee where it will all end. This has been caused not only by a general renewal of interest but also by the development of new methods, especially biochemical, a resurgence of morphological studies, and the discovery of new fossil material, with the additional stimulus of the availability of a deductive method known as Hennigian systematics or CLADISTICS (see also CLASSIFICATION).

The use of chemical properties of egg-white proteins throughout the whole class of birds by Charles G. Sibley and collaborators, and of the other biochemical characters by other authors, has revolutionized basic and often traditional thoughts on relationships at the familial level (e.g. Sibley 1970, Sibley and Ahlquist 1972; cf. Voous 1980). The rapids turned into waterfalls after Sibley and his staff started to investigate chemical properties of the genetic material (DNA × DNA hybridization), the first results of which have recently been published and are summarized by Sibley and Ahlquist (1984). Particularly enigmatic have become the relationships of passerine groups endemic to Australia and New Zealand at the generic, familial and near-ordinal levels.

Morphological studies on the bony stapes (ear-bone) in pre-, proto- and recent Passeriformes by Alan Feduccia (1975, 1977) have upset what had been thought well established ideas on the relationships among these birds, including the distinction between non-oscine and oscine songbirds. Careful study of new fossil material has led to noteworthy progress in the understanding of the relationships of certain groups, e.g. the Gruiformes. Other notable contributions to the recognition, sequence and relationship of higher taxa have been included in the table of classification and in the specific articles.

In this situation of uncertainty and hopeful expectation it will be understood that it has not been possible to follow all of the recently proposed changes in the classification of birds. More time is needed for their evaluation, before they are accepted and incorporated into standard lists and handbooks. Here, the starting point has been K.H. Voous's *List of Recent Holarctic Bird Species* (1973, 1977), which was augmented for world-wide use for this occasion. Throughout, Morony, Bock and Farrand's *Reference List of the Birds of the World* (1975) and additions by Bock and Farrand (1980) can be recommended as a sound base for tackling any problems of taxonomy, sequence and literature reference at the specific, generic, familial and ordinal levels relating to the comparative systematics of living birds.

K.H. VOOUS

NOTE: the publication of the *Check-list of North American Birds* 1983 (6th edn) came too late for all pertinent revisions to be incorporated in the articles, but some amendments were made in proof where practicable. (Eds).

Avian Anatomical Nomenclature

The recently published *Nomina Anatomica Avium* (Baumel *et al* 1979) is an annotated, illustrated anatomical dictionary of birds. It is a codification of the names for the anatomical parts of birds which was formulated and agreed upon by some 80 eminent avian scientists from around the world. *NAA* is the first such system of anatomical names to be developed for birds, even though mammalian models have long been in existence.

Avian anatomy has suffered from a diversity of terminologies in the literature. Multiple and inappropriate names for the structures have caused confusion. *NAA* evolved during nearly a dozen years of discussion within the International Committee on Avian Anatomical Nomenclature (ICAAN). The Committee adopted the universally acceptable language of Latin, codifying prevailing usage of satisfactory names, doing away with duplicate terms and defining ambiguous ones. New names were produced where none were previously available or those in use were grossly defective.

The terminology of *NAA* has generally been followed throughout this Dictionary and ornithologists are urged to employ it in their publications. The use of official Latin anatomical terms will help to establish a standard avian terminology.

Table of Classification

	Families	*Articles*
ORDER STRUTHIONIFORMES		
Suborder Struthiones	**Struthionidae**	OSTRICH
	Aepyornithidae (extinct)	ELEPHANT-BIRD
Suborder Rheae	**Rheidae**	RHEA
Suborder Casuarii	**Dromaiidae**	EMU
	Casuariidae	CASSOWARY
Suborder Apteryges	**Dinornithidae** (extinct) (incl.. Anomalopteryginae, Dinornithinae)	MOA
	Apterygidae	KIWI
ORDER TINAMIFORMES	**Tinamidae**	TINAMOU
ORDER PROCELLARIIFORMES		PETREL
	Diomedeidae	(Albatross)
	Procellariidae	(Shearwater)
	Hydrobatidae	(Petrel)
	Pelecanoididae	(Diving Petrel)
ORDER SPHENISCIFORMES	**Spheniscidae**	PENGUIN
ORDER GAVIIFORMES	**Gaviidae**	DIVER
ORDER PODICIPEDIFORMES	**Podicipedidae**	GREBE
ORDER PELECANIFORMES		
Suborder Phaethontes	**Phaethontidae**	TROPICBIRD
Suborder Pelecani		
Superfamily Suloidea	**Sulidae**	GANNET
	Phalacrocoracidae	CORMORANT
	Anhingidae	DARTER
Superfamily Pelecanoidea	**Pelecanidae**	PELICAN
Suborder Fregatae	**Fregatidae**	FRIGATEBIRD
ORDER CICONIIFORMES		
Suborder Ardeae	**Ardeidae**	HERON; BITTERN
Suborder Scopi	**Scopidae**	HAMERKOP
Suborder Ciconiae	**Ciconiidae**	STORK
	Balaenicipitidae	SHOEBILL
	Threskiornithidae	IBIS; SPOONBILL
ORDER PHOENICOPTERIFORMES	**Phoenicopteridae**	FLAMINGO
ORDER ANSERIFORMES		
Suborder Anhimae	**Anhimidae**	SCREAMER
Suborder Anseres	**Anatidae**	DUCK

ORDER CATHARTIFORMES	**Cathartidae**	VULTURE (2)
ORDER ACCIPITRIFORMES		
Suborder Accipitres	**Accipitridae**	HAWK; VULTURE (1)
	Pandionidae	HAWK (Osprey)
Suborder Sagittarii	**Sagittariidae**	SECRETARY-BIRD
ORDER FALCONIFORMES	**Falconidae**	FALCON
ORDER GALLIFORMES		
Suborder Galli	**Megapodiidae**	MEGAPODE
	Cracidae	CURASSOW
	Phasianidae	
	Tetraoninae, Odontophorinae	GROUSE
	Phasianinae	PHEASANT
	Numidinae	GUINEAFOWL
	Meleagridinae	TURKEY
Suborder Opisthocomi	**Opisthocomidae**	HOATZIN
ORDER MESITORNITHIFORMES	**Mesitornithidae**	MESITE
ORDER GRUIFORMES		
Suborder Turnices	**Turnicidae**	BUTTONQUAIL
	Pedionomidae	PLAINS-WANDERER
Suborder Grues		
Superfamily Ralloidea	**Rallidae**	RAIL
Superfamily Gruoidea	**Aramidae**	LIMPKIN
	Psophiidae	TRUMPETER
	Gruidae	CRANE
Suborder Heliornithes	**Heliornithidae**	FINFOOT
Suborder Rhynocheti	**Rhynochetidae**	KAGU
Suborder Eurypygae	**Eurypygidae**	SUNBITTERN
Suborder Cariamae	**Cariamidae**	SERIEMA
Suborder Otides	**Otididae**	BUSTARD
ORDER CHARADRIIFORMES		
Suborder Charadrii		
Superfamily Jacanoidea	**Jacanidae**	JACANA
Superfamily Charadrioidea	**Rostratulidae**	PAINTED SNIPE
	Haematopodidae	OYSTERCATCHER
	Ibidorhynchidae	IBISBILL
	Recurvirostridae	AVOCET
	Dromadidae	CRAB-PLOVER
	Burhinidae	THICKKNEE
	Glareolidae	COURSER; PRATINCOLE
	Charadriidae	PLOVER (1)
	Scolopacidae	SANDPIPER; PHALAROPE
	Pluvianellidae	MAGELLANIC PLOVER
Superfamily Thinocoroidea	**Thinocoridae**	SEEDSNIPE
Superfamily Chionidoidea	**Chionidae**	SHEATHBILL

Suborder Lari	**Stercorariidae**	SKUA
	Laridae	GULL
	Sternidae	TERN
	Rynchopidae	SKIMMER
Suborder Alcae	**Alcidae**	AUK
ORDER PTEROCLIDIFORMES	**Pteroclididae**	SANDGROUSE
ORDER COLUMBIFORMES	**Columbidae**	PIGEON
	Raphidae (Dodo, extinct)	DODO
	Pezophapidae (Solitaire, extinct)	
ORDER PSITTACIFORMES	**Psittacidae**	PARROT
ORDER CUCULIFORMES		
Suborder Musophagae	**Musophagidae**	TURACO
Suborder Cuculi	**Cuculidae**	CUCKOO
ORDER STRIGIFORMES	**Tytonidae**	OWL
	Strigidae	
ORDER CAPRIMULGIFORMES		
Suborder Steatornithes	**Steatornithidae**	OILBIRD
Suborder Caprimulgi	**Podargidae**	FROGMOUTH
	Aegothelidae	OWLET-FROGMOUTH
	Nyctibiidae	POTOO
	Caprimulgidae	NIGHTJAR
ORDER APODIFORMES		
Suborder Apodi	**Hemiprocnidae**	SWIFT (Hemiprocnidae)
	Apodidae	SWIFT; SWIFTLET

List of Contributors

Authorship of major articles is indicated by initials at the end of each contribution. Many articles which appeared in *A New Dictionary of Birds* have been substantially revised. In such instances the initials of the original author are within brackets followed by the initials of the revising author. In the case of minor revisions, the revisor's initials are within the brackets after those of the author.

G.L.A.-W.	**George Laidley Atkinson-Willes,** Frocester, Gloucestershire, England. Organizer, National Wildfowl Counts 1950–1983. COUNT.
P.J.B.	**Philip John Bacon,** B.Sc. (Birmingham), D.Phil. (Oxford). Institute of Terrestrial Ecology, Merlewood, Cumbria, England. ROOSTING.
A.S.B.	**Anne Susan Baker,** B.Sc. (Newcastle upon Tyne). Department of Zoology, British Museum (Natural History), London, England. ECTOPARASITE (with T. Clay and A.M. Hutson).
J.C.B.	**Jon C. Barlow,** M.Sc., Ph.D. (Kansas), Curator, Department of Ornithology, Royal Ontario Museum; Professor of Zoology, University of Toronto, Canada. VIREO.
C.J.B.(1)	**Christopher John Barnard,** B.Sc. (Liverpool), D.Phil. (Oxford). Lecturer in Zoology, University of Nottingham, England. PIRACY.
J.A.G.B.	**John Anthony Godsmark Barnes,** M.A. (Oxford). President, Lancaster and District Bird-Watching Society, England. TIT.
G.A.B.	**George A. Bartholomew.** Professor of Biology, University of California, Los Angeles, USA. TORPIDITY.
L.A.B.	**Leo Adrian Batten,** B.Sc., Ph.D. (London). Ornithological Advisor, Nature Conservancy Council, Peterborough, England. CENSUS.
J.J.B.	**Julian J. Baumel,** Ph.D. (Florida). Professor of Anatomy, Creighton University, Nebraska, USA. HEART; LYMPHATIC SYSTEM; TAIL (with A.L. Thomson); VASCULAR SYSTEM.
J.H.B.	**Jan Hendrik Becking,** M.Sc., D.Phil. (Leiden). Research Institute, Ministry of Agriculture and Fisheries, Wageningen, Netherlands. BROOD-PARASITISM; EDIBLE NESTS; EGGSHELL, ULTRASTRUCTURE OF; SWIFTLET.
M.B.	**Marc Bekoff.** Professor, University of Colorado, Boulder, USA. PLAY.
C.W.B.	**Constantine W. Benson,** O.B.E., M.A. Formerly Department of Zoology, Cambridge University, England. Died 1982. ASITY; MALAGASY REGION; MESITE; CUCKOO-ROLLER; GROUND-ROLLER; VANGA.
B.C.R.B.	**Brian Colin Ricardo Bertram,** B.A., Ph.D. (Cambridge). Curator of Mammals, Zoological Society of London, Regent's Park, London, England. OSTRICH.
C.J.B.(2)	**Colin J. Bibby,** M.A., Ph.D. Senior Research Biologist, Royal Society for the Protection of Birds, Sandy, England. MEASUREMENT.
M.E.B.	**Michael Edward Birkhead,** B.Sc. (Newcastle upon Tyne), D.Phil. (Oxford). Formerly Post-Doctoral Fellow, Edward Grey Institute of Field Ornithology, University of Oxford, England. ACCENTOR.
T.R.B.	**Timothy Robert Birkhead,** B.Sc. (Newcastle upon Tyne), D.Phil. (Oxford). Lecturer in Zoology, University of Sheffield, England. AUK.
C.R.B.	**Charles Robert Blem,** B.S. (Ohio), M.S., Ph.D. (Illinois). Professor of Biology, Virginia Commonwealth University, Richmond, USA. ENERGETICS.

J.H.R.B.	**Jeffrey Hugh Richard Boswall**. Producer, Natural History Unit, BBC, Bristol, England. HUMAN IMITATION OF BIRD SOUNDS; SOUND RECORDING; TOOLS, USE OF.
W.R.P.B.	**William Richmond Postle Bourne,** M.A., M.B., B.Chir. (Cambridge). Honorary Research Fellow, Department of Zoology, University of Aberdeen, Scotland. OIL POLLUTION; PETREL.
R.K.B.	**Richard K. Brooke.** FitzPatrick Institute of African Ornithology, Cape Town, South Africa. OXPECKER (with W.R. Siegfried).
J.P.B.-L.	**John Philip Brooke-Little,** C.V.O., K.St.J., M.A. (Oxford), F.S.A. Norroy and Ulster King of Arms, College of Arms, London, England. Chairman, Heraldry Society and Harleian Society; Hon Editor-in-Chief, The Coat of Arms. HERALDIC BIRDS.
A.B.	**André Brosset,** Dr.Sc. Director of Research, CNRS, Museum National d'Histoire Naturelle, Paris, France. MAMMALS, ASSOCIATION WITH.
M.D.B.	**Murray Duncan Bruce.** Turramurra, NSW, Australia. PITTA.
D.B.	**Donald Bruning.** Dr. Curator, Department of Ornithology, New York Zoological Society, New York, USA. BUTTONQUAIL.
D.M.B.	**David Murray Bryant,** B.Sc., Ph.D. (London). Senior Lecturer, Department of Biological Science, University of Stirling, Scotland. SWALLOW.
H.B.	**Hans Bub.** Vogelwarte Helgoland, Wilhelmshaven, Germany. AVOCET; IBISBILL.
P.J.K.B.	**Philip John Kennedy Burton,** B.Sc., Ph.D. (London). Principal Scientific Officer, British Museum (Natural History), Tring, England. HOMOLOGY; LEG; MUSCULATURE; SKULL; TONGUE; WOOD-SWALLOW (with B. E. Smythies).
E.J.M.B.	**Edward John Mawby Buxton,** M.A. (Oxford). East Tytherton, Wiltshire, England. Emeritus Fellow, New College, Oxford. OYSTERCATCHER; POETRY, BIRDS IN.
W.A.C.	**William Alexander Calder III,** B.S. (Georgia), M.S. (Washington State), Ph.D. (Duke). Professor of Ecology and Evolutionary Biology, University of Arizona, USA. SIZE.
B.C.	**Bruce Campbell,** O.B.E., Ph.D. (Edinburgh). Woodstock, Oxford, England. CONGRESSES (with A.L. Thomson); OOLOGY; NEST SITES, MAN-MADE (with D. E. Glue).
R.C.(1)	**Robert Carrick,** B.Sc. (Glasgow), Ph.D. (Edinburgh). Dornoch, Scotland. Formerly Division of Wildlife Research, CSIRO, Australia. MAGPIE (2).
P.G.C.	**Peter Guernsey Caryl,** M.A., Ph.D. (Cambridge). Department of Psychology, University of Edinburgh, Scotland. AGGRESSION; AMBIVALENCE; RITUALIZATION.
R.C.(2)	**Richard Carrington.** London, England. FABULOUS BIRDS.
R.J.S.C.	**Richard J.S. Cassels,** M.A. (Cambridge). Curator, Manawatu Museum, Palmerston North, New Zealand. MOA (with P.R. Millener).
C.K.C.	**Clive Kenneth Catchpole,** B.Sc., Ph.D. (Nottingham). Lecturer in Zoology, University of London, England. VOCALIZATION.
A.S.C.	**Anthony Stephen Cheke,** M.A. (Cambridge). Oxford, England. Leader BOU Mascarene Islands Expedition, 1973–75. DODO.
C.A.J.C.	**Clifford A.J. Christie.** Banbury Bird Hospital, Middleton Cheney, Oxon., England. CARE OF SICK, INJURED AND ORPHANED BIRDS.
T.C.	**Theresa Clay,** B.Sc., D.Sc. (Edinburgh). London, England. Formerly Deputy Keeper, Department of Entomology, British Museum (Natural History). ECTOPARASITE (with A.M. Hutson and A.S. Baker).
M.H.C.	**Mary Heimerdinger Clench,** M.Sc., D.Phil. (Yale). Adjunct Curator of Birds, Florida State Museum, Gainesville, Florida, USA. PTERYLOSIS.
N.J.C.	**Nigel James Collar,** B.A. (Cambridge), Ph.D. (East Anglia). Compiler, International Committee for Bird Preservation, Cambridge, England. BUSTARD; CRANE.
N.E.C.	**Nicholas Elias Collias,** B.Sc., Ph.D. (Chicago). Professor of Zoology, University of California, Los Angeles, USA. SPARROW-WEAVER AND SCALY-WEAVER.
C.T.C	**Charles Thompson Collins,** B.A. (Amherst College), M.S. (Michigan), Ph.D. (Florida). Professor of Biology, California State University, Long Beach, USA. SWIFT.
P.J.C.(1)	**Peter John Conder,** O.B.E., Hon. M.A. (Open University). Cambridge, England. Formerly Director, Royal Society for the Protection of Birds, Sandy, Bedfordshire, England. BIRD-WATCHING.
F.C.	**Fred Cooke,** M.A., Ph.D. (Cambridge). Professor of Biology, Queen's University, Kingston, Ontario, Canada. HARDY-WEINBERG LAW; POLYMORPHISM.
C.J.F.C.	**Charles John Franklin Coombs,** M.A., M.B., B.Ch. (Cambridge). Truro, Cornwall, England. President, Cornwall Bird-Watching and Preservation Society. CROW.
J.C.(1)	**John Cooper,** B.Sc. (London). Antarctic Research Officer, Percy FitzPatrick Institute, University of Cape Town, South Africa. PENGUIN (*Spheniscus*).

H.B.C.	**Hugh Bamford Cott,** D.Sc. (Glasgow), Sc.D. (Cambridge). Beaminster, Dorset, England. Formerly Lecturer in Zoology and Strickland Curator, University of Cambridge, England. COLORATION, ADAPTIVE; PALATABILITY OF BIRDS AND EGGS.
J.C.C.	**John C. Coulson,** D.Sc. Zoology Department, University of Durham, England. RED TIDE.
J.C.(2)	**Joel Cracraft,** Dr. Department of Anatomy, University of Illinois at Chicago, USA. EARLY EVOLUTION OF BIRDS.
C.	**Earl of Cranbrook,** M.A. (Cambridge), Ph.D. (Birmingham). Great Glemham, Suffolk, England. Formerly Senior Lecturer in Zoology, University of Malaya, Kuala Lumpur, Malaysia. GUANO, CAVE.
D.W.T.C.	**David William Thomasson Crompton,** M.A., Sc.D. (Cambridge). Lecturer in Parasitology, University of Cambridge, England, and Adjunct Professor, Division of Nutritional Sciences, Cornell University, New York, USA. ALIMENTARY SYSTEM; DROPPINGS.
T.M.C.	**Timothy Michael Crowe,** B.A. (Mass/Boston), M.Sc. (Chicago), Ph.D. (Cape Town). Senior Research Officer, FitzPatrick Institute, University of Cape Town, Rondebosch, South Africa. GUINEAFOWL.
J.P.C.	**John Patrick Croxall,** B.A. (Oxford), Ph.D. (Auckland). Head, Birds and Mammals Section, British Antarctic Survey, Cambridge, England. ANTARCTIC ; PENGUIN.
P.J.C.(2)	**Peter James Curry,** B.Sc. (Wales), M.Agr.Sc. (Melbourne). Rangeland Management Branch, Department of Agriculture, South Perth, W.A., Australia. EMU.
N.B.D.	**Nicholas Barry Davies,** M.A. (Cambridge), D.Phil. (Oxford). Department of Zoology, University of Cambridge, England. FLYCATCHER (1); TERRITORY; WAGTAIL.
S.J.J.F.D.	**Stephen John James Frank Davies,** B.A., Ph.D. (Cambridge). Director, Royal Australasian Ornithologists' Union, Moonee Ponds, Victoria, Australia. BUTCHER-BIRD (2); CASSOWARY; CURRAWONG; NEST FUNCTION.
M.S.D.	**Marian Stamp Dawkins,** B.A., D.Phil. (Oxford). Fellow, Somerville College, University of Oxford, England. SEARCH IMAGE.
W.R.J.D.	**William Richard John Dean.** Associate Member, Transvaal Museum, South Africa. ORIOLE (1).
J.T.D.	**Jean Theodore Delacour,** Lic.Sci. (Lille and Paris). In charge of the Zoological Survey of French Indochina 1923–1940. Director Los Angeles County Museums 1951–1966. Clères, France. PHEASANT (with M.W. Ridley).
R.de N.	**René de Naurois,** M.C., Hon. Professor, Université Libre de Toulouse; Correspondant du Museum National d'Histoire Naturelle, Paris, France. KAGU (with J-N. Neyrolles).
P.J.D.	**Pierre J. Devillers,** Ph.D. Institut Royal des Sciences Naturelles de Belgique, Bruxelles, Belgium. GULL.
A.W.D.	**Antony William Diamond,** B.A. (Cambridge), M.Sc., Ph.D. (Aberdeen). Canadian Wildlife Service, Ottawa, Canada. AFROTROPICAL REGION; HONEYGUIDE; MOUSEBIRD.
H.J. de S.D.	**Henry John de Suffren Disney,** M.A. (Cambridge). Berowra, NSW, Australia. Formerly Curator of Birds, The Australian Museum, Sydney, Australia. RAIL-BABBLER; THICKHEAD (both with L.G. Grimes).
R.H.D.	**Richard H. Donaghey,** B.Sc. (Sydney), M.Sc. (Alberta), Ph.D. (Monash). Burnie Technical College, Tasmania, Australia. BOWERBIRD (with C.B. Frith, A. Lill).
R.J.D.	**Robert Joseph Dooling,** B.Sc. (Omaha, NE, USA), D.Phil. (St. Louis, Mo, USA). Associate Professor, Psychology Department, University of Maryland, College Park, MD, USA. HEARING AND BALANCE.
C.J.D.	**Christopher John Duncan,** B.Sc., Ph.D. (London). Professor of Zoology, University of Liverpool, England. SMELL.
H.-R.D.	**Hans-Rainer Duncker,** Dr. rer. nat. (Kiel), Dr. med. (Hamburg). Professor of Anatomy, Institute of Anatomy and Cell Biology, Justus-Liebig-University, Giessen, Germany. RESPIRATORY SYSTEM.
E.K.D.	**Euan Kennedy Dunn,** B.Sc. (Aberdeen), Ph.D. (Durham). Editor, 'Birds of the Western Palearctic'. Oxford, England. CONTROL (3); TERN.
R.F.D.	**Roger F. Durman.** Balerno, Midlothian, Scotland. OBSERVATORY, BIRD.
J.D.	**Jan Dyck,** Cand.polyt. and mag.scient. (Copenhagen). Reader, Institute of Population Biology, University of Copenhagen, Denmark. FEATHER; PLUMAGE.
C.E.	**Carl Edelstam,** Ph.D. (Stockholm). Curator of Vertebrates, Swedish Museum of Natural History, Stockholm, Sweden. MIMICRY.
E.E.	**Eugene S.B. Eisenmann.** Formerly Research Associate, American Museum of Natural History, New York, USA. Died 1982. TROGON.
H.F.I.E.	Sir **Hugh F.I. Elliott,** Bt., O.B.E., M.A. (Oxford). Oxford, England. Overseas Civil Service (Tanganyika) 1937–1961; President BOU 1975–1979. FINFOOT.
J.A.E.	**John A. Endler,** B.A. (Berkeley, California), Ph.D. (Edinburgh). Professor of Biology, University of Utah, Salt Lake City, USA. SPECIATION; SPECIES.
M.D.E.	**M. Derrick England,** O.B.E. Late of Norwich, England. Died 1980. BARBET.
J.T.E.	**Jonathan Thor Erichsen,** B.A. (Harvard), D.Phil. (Oxford). Research Assistant Professor, Department of

Neurobiology and Behavior, State University of New York, Stony Brook, New York, USA. IRIS COLORATION; VISION.

P.R.E. **Peter Richard Evans**, M.A., Ph.D. (Cambridge), D.Phil. (Oxford). Reader in Estuarine Ecology, Department of Zoology, University of Durham, England. MIGRATION; MOULT; PLOVER (1).

S.M.E. **Stewart Martin Evans**, B.Sc., Ph.D. (Bristol). Senior Lecturer, Department of Zoology, University of Newcastle upon Tyne, England. DOMINANCE (2).

J.B.F. **J. Bruce Falls**, Dr. Department of Zoology, University of Toronto, Canada. PLAYBACK.

C.J.F. **Christopher John Feare**, B.Sc., Ph.D. (Leeds). Ministry of Agriculture, Fisheries and Food, Worplesdon, Surrey, England. CRAB-PLOVER; PESTS, BIRDS AS; STARLING.

A.F. **Alan F. Feduccia**, B.Sc. (Louisiana State), M.Sc., D.Phil. (Michigan). Professor and Associate Chairman, Department of Biology, University of North Carolina, Chapel Hill, USA. FLIGHTLESSNESS; OVENBIRD (1); WOODCREEPER.

I.J.F.-L. **Ian James Ferguson-Lees**. Rode, Bath, England. Formerly Executive Editor, *British Birds*; Past President, British Trust for Ornithology. BITTERN; TREECREEPER (1).

P.N.F. **Peter Norman Ferns**, B.Sc. (Manchester), Ph.D. (Exeter). Senior Lecturer, Zoology Department, University College, Cardiff, Wales. YAWNING.

R.S.R.F. **Richard Sidney Richmond Fitter**, B.Sc. (Econ.) (London). Chairman, Fauna and Flora Preservation Society, London, England. Chairman Steering Committee, Species Survival Commission, International Union for Conservation of Nature. NATURALIZED BIRDS.

B.M.F. **Brian Michael Fitzgerald**, B.Sc. (New Zealand), M.Sc. (Canterbury), Ph.D. (Berkeley, California). Ecology Division, Department of Scientific and Industrial Research, Lower Hutt, New Zealand. WREN (3).

J.W.F. **John W. Fitzpatrick**, B.A. (Harvard), Ph.D. (Princeton). Head, Division of Birds, Field Museum of Natural History, Chicago, Illinois, USA. FLYCATCHER (2).

J.J.M.F. **James J.M. Flegg**, B.Sc. Ph.D., A.R.C.S. (Imperial College). Head of Zoology Department, East Malling Research Station, Kent, England. Formerly Director, British Trust for Ornithology. NUMBERS; ORNITHOLOGICAL SOCIETIES; ORNITHOLOGY.

C.A.F. Sir **Charles Alexander Fleming**, K.B.E., D.Sc. (New Zealand), F.R.S. Research Associate, National Museum of New Zealand, Wellington, New Zealand. THRUSH, NEW ZEALAND.

B.K.F. **Brian Keith Follett**, B.Sc., Ph.D. (Bristol), D.Sc. (Wales), F.R.S. Professor of Zoology, University of Bristol, England. ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM (with A.R. Goldsmith).

H.A.F. **Hugh A. Ford**, Ph.D. Professor of Zoology, University of New England, Armidale, N.S.W., Australia. AUSTRALASIAN REGION (with D.L. Serventy); HONEYEATER (with F. Salomonsen).

E.T.B.F. **Eric Thomas Brazil Francis**, B.Sc. (London), Ph.D. (Reading). Formerly Reader in Vertebrate Zoology, Sheffield University, England. EXCRETORY SYSTEM.

C.B.F. **Clifford Brodie Frith**. Ornithologist and photographer, Paluma via Townsville, Queensland, Australia. BIRD-OF-PARADISE; BOWERBIRD (with R.F. Donaghey, A. Lill); SILKTAIL.

H.J.F. **Harry J. Frith**, D.Sc. Agr. (Sydney). Formerly Chief, Division of Wildlife Research, CSIRO, Canberra, Australia. Died 1982. MEGAPODE; PLAINS-WANDERER.

C.H.F. **Charles Hilary Fry**, M. A. (Cambridge), Ph.D. (Ahmadu Bello). Senior Lecturer in Zoology, University of Aberdeen, Scotland. BEE-EATER; HOOPOE; KINGFISHER; ROLLER.

R.W.F. **Robert William Furness**, B. Sc., Ph. D. (Durham). Lecturer in Zoology, University of Glasgow, Scotland. SKUA.

I.C.J.G. **Ian Courtney Julian Galbraith**, M.A. (Oxford). Head of Sub-department of Ornithology, British Museum (Natural History), Tring, England. MUSEUM.

E.F.J.G. **Ernest Francis John Garcia**, B.Sc. (London), D.Phil. (Oxford). Head of Biology Department, George Abbot County Secondary School, Guildford, England. WARBLER (1).

P.J.G.(1) **Peter Jeffrey Garson**, B.Sc. (Edinburgh), D.Phil. (Oxford). Lecturer, Zoology Department, University of Newcastle upon Tyne, England. WREN (1).

A.J.G. **Anthony J. Gaston**, B.A., D.Phil. (Oxford). Canadian Wildlife Service, Ottawa, Canada. BABBLER; CO-OPERATIVE BREEDING; TIT, LONG-TAILED.

M.J.G. **Michael John Gentle**, B.Sc., Ph.D. (London). Principal Scientific Officer, Poultry Research Centre, Roslin, Midlothian, Scotland. TASTE.

F.B.G. **Francis B. Gill**, B.Sc., Ph.D. (Michigan). Curator of Ornithology, Academy of Natural Sciences, Philadelphia, Pa. USA. SUNBIRD.

D.E.G. **David Edward Glue**, B.Sc. (London). Nest Record Officer, British Trust for Ornithology, Tring, England. NEST SITES, MAN-MADE (with B. Campbell); PELLET.

A.R.G. **Arthur Richard Goldsmith**, B.Sc. (Wales), Ph.D. (Leicester). SERC Advanced Fellow, Department of Zoology, University of Bristol, England. ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM (with B.K. Follett).

D.G.	**Derek Goodwin,** Petts Wood, Kent, England. Formerly Principal Scientific Officer, British Museum (Natural History). PIGEON.
A.F.G.	**Arthur Frederic Gotch.** Late of West Wittering, Chichester, Sussex, England. Died 1983. NAMES, SCIENTIFIC.
P.R.G.	**Peter Raymond Grant,** B.A. (Cambridge), Ph.D. (British Columbia). Professor of Biological Sciences, University of Michigan, USA. DARWIN'S FINCHES.
R.E.G.	**Rhys E. Green, Dr.** Royal Society for the Protection of Birds, Sandy, England. LARK.
J.J.D.G.	**Jeremy John Denis Greenwood,** B.A. (Oxford), Ph.D. (Manchester). Lecturer in Biological Sciences, University of Dundee, Scotland. EVOLUTION; NATURAL SELECTION; SEXUAL SELECTION.
P.J.G.(2)	**Paul John Greenwood,** M.A. (Cambridge), M.Sc. (Durham), D.Phil. (Sussex). Lecturer in Zoology, Department of Adult and Continuing Education, University of Durham, England. DISPERSAL; FREQUENCY DEPENDENT SELECTION.
L.G.G.	**Llewellyn George Grimes,** B.Sc., Ph.D. (Bristol), M.Sc. (Aberdeen). Warwick, England. BULBUL (with A.I. Ivanov); HELMET-SHRIKE; HORNBILL (with A.C. Kemp); SHRIKE; WEAVER; RAIL-BABBLER; THICKHEAD (both with H.J. de S. Disney); TURACO (with D.A. Turner).
T.C.G.	**Thomas Christman Grubb, Jr.,** B.A. (Swarthmore), M.A., Ph.D. (Wisconsin). Professor, Department of Zoology , Ohio State University, Columbus, Ohio, USA. WEATHER AND BIRDS.
A.G.	**Alfredo Guillet,** Dott. (Torino). Percy FitzPatrick Institute of African Ornithology, University of Cape Town, S. Africa. SHOEBILL (with A.L. Thomson).
J.L.G.	**James L. Gulledge.** Director, Library of Natural Sounds, Cornell University, Ithaca, New York, USA. MOCKING-THRUSH.
E.G.	**Eberhard Gwinner,** Dr. rer. nat. Professor, Head of Vogelwarte für Verhaltensphysiologie, Federal Republic of Germany. RHYTHM AND TIME MEASUREMENT.
J.H.	**Jürgen Haffer,** Dr. rer. nat. (Göttingen). Petroleum Geologist, Exploration Manager, DEMINEX Egypt Branch, Cairo (Central Office: Essen, West Germany). GEOLOGICAL FACTORS.
W.G.H.	**William G. Hale,** Ph.D.. Professor of Biology, Liverpool Polytechnic, England. SANDPIPER.
J.M.H.-C.	**Joan Margaret Hall-Craggs** (née Johnston), L.R.A.M. (Perfs.). Sub-Department of Animal Behaviour, University of Cambridge, England. MUSIC, BIRDS IN (with R.E. Jellis).
T.R.H.	**Timothy Richard Halliday,** M.A., D.Phil. (Oxford). Senior Lecturer in Biology, The Open University, Milton Keynes, England. ENDANGERED BIRDS.
N.H.H.	**Nicholas H. Hammond.** Head of Publications, Royal Society for the Protection of Birds, Sandy, Bedfordshire, England. ILLUSTRATION, BIRD.
C.J.O.H.	**Colin James Oliver Harrison,** Ph.D. (Reading). Sub-Department of Ornithology, British Museum (Natural History), Tring, England. PLUMAGE, ABNORMAL.
J.G.H.	**Jeffrey Graham Harrison,** M.B., B.Chir. (Cambridge). Late of Sevenoaks, Kent, England. Died 1978. LEG; (TONGUE); WING.
P.H.T.H.	**The Venerable Peter Harold Trahair Hartley,** M.A. (Oxford), B.Sc. (London). Framlingham, Suffolk, England. FEEDING HABITS; PREDATION.
F.H.	**François Haverschmidt,** M.A. (Utrecht). Omen, Netherlands. POTOO; TRUMPETER.
K.J.H.	**Kenneth J. Hill,** D.V.Sc., M.R.C.V.S. Unilever Research, Bedford, England. EXCRETION, EXTRARENAL.
R.A.H.	**Robert Aubrey Hinde,** D.Phil. (Oxford), Sc.D. (Cambridge), F.R.S. Royal Society Research Professor and Honorary Director of the M.R.C. Unit on the Development and Integration of Behaviour, Madingley, Cambridge, England. COPULATION; COURTSHIP FEEDING; DISPLAY; NEST BUILDING; PAIR FORMATION.
G.J.M.H.	**Graham James Michael Hirons,** B.Sc. (Wales), D.Phil. (Oxford). Hartley Research Fellow, Department of Biology, University of Southampton, England. RODING.
D.G.H.	**Dominique G. Homberger,** Dr Phil. II (Zurich). Associate Professor, Department of Zoology and Physiology, Louisiana State University, Baton Rouge, Louisiana, USA. PARROT.
E.J.H.	**Eric J. Hosking,** O.B.E., F.R.P.S., F.I.I.P. London, England. PHOTOGRAPHY (with G.K. Yeates.)
D.C.H.	**David Charles Houston,** B.Sc. (Bristol), D.Phil. (Oxford). Lecturer, Department of Zoology, University of Glasgow, Scotland. VULTURE (1).
R.W.H.	**Robert William Hudson.** Research Officer, British Trust for Ornithology, Tring, England. RANGE CHANGES.
H.G.H.	**Henry George Hurrell,** M.A. (Cambridge). Late of South Brent, Devon, England. Died 1981. DIPPER.
A.M.H.	**Anthony Michael Hutson.** Formerly in Department of Entomology, British Museum (Natural History), London, England. ECTOPARASITE (with T. Clay and A.S. Baker).
K.I.	**Klaus Immelmann,** Dr. rer. nat. (Mainz). Professor of Biology, Department of Ethology, University of Bielefeld, W. Germany. BEHAVIOUR, DEVELOPMENT OF; ESTRILDID FINCH.

I.R.I. **Ian R. Inglis**, B.Sc. (London), Ph.D. (Bristol). Principal Scientific Officer, Ministry of Agriculture, Fisheries and Food, Worplesdon, Surrey, England. SCARING.

A.I.I. **Alexandr Ivanovich Ivanov**, S.D. (Leningrad). Professor. Curator of Birds, Zoological Institute, Leningrad, USSR. BULBUL (with L.G. Grimes).

J.J. **Jürgen Jacob**, Dr. rer. (Bonn). Professor (Hamburg); Director (Biochemistry Division) Institute for Environmental Carcinogens, Ahrensburg, and Zoological Institute, University of Hamburg, W. Germany. OIL GLAND.

O.J.J. **Olli Juhani Järvinen**, M.Sc., D.Phil. (Helsinki). Professor of Zoology, University of Helsinki, Finland. DISTRIBUTION, GEOGRAPHICAL.

J.R.J. **Joseph R. Jehl Jr.**, A.B. (Cornell), Ph.D. (Michigan). Assistant Director, Hubbs-Sea World Research Institute, San Diego, California, USA. MAGELLANIC PLOVER.

R.E.J. **Rosemary Elston Jellis**, M.A. (Oxford). Late Senior Producer, British Broadcasting Corporation. Died 1983. MUSIC, BIRDS IN (with J.M. Hall-Craggs).

D.A.J. **Donald A. Jenni**, B.S. (Oregon State), M.S. (Utah State), Ph.D. (Florida). Professor of Zoology, University of Montana, Missoula, USA. JACANA.

A.R.J. **Arthur Ramsden Jennings**, M.A. (Cambridge), D.V.Sc. (Liverpool), M.R.C.V.S. Connel, Argyll, Scotland. DISEASE.

P.A.J. **Paul Austin Johnsgard**, B.S. (North Dakota State), M.S. (Washington State), Ph.D. (Cornell). Foundation Professor of Life Science, University of Nebraska, Lincoln, USA. GROUSE.

E.L.J. **Eric Lionel Jones**, B.A. (Nottingham), M.A., D.Phil. (Oxford). Professor, School of Economics, La Trobe University, Victoria, Australia. UTILIZATION BY MAN.

P.J.J. **Peter J. Jones**, Ph.D. (Oxford). Department of Forestry and Natural Resources, University of Edinburgh, Scotland. CROP MILK; HEAT REGULATION; ITINERANT BREEDING; METABOLISM; NUTRITION; QUELEA CONTROL.

G.C.A.J. **George Christoffel Alexander Junge**, D.Sc. (Amsterdam). Formerly Curator of Birds, Rijksmuseum van Natuurlijke Historie, Leiden, Netherlands. Died 1962. NIGHTJAR (with J. Marshall).

J.K.(1) **Janet Kear**, B.Sc. (London), Ph.D. (Cambridge). Assistant Director, Wildfowl Trust, Martin Mere, Lancashire, England. FLAMINGO; FOOD SELECTION; ODOUR.

J.A.K. **James Allen Keast**, B.Sc., M.Sc. (Sydney), M.A., Ph.D. (Harvard). Professor of Biology, Queen's University, Kingston, Ontario, Canada. ADAPTATIONS, ENVIRONMENTAL.

A.C.K. **Alan Charles Kemp**, B.Sc., Ph.D. (Rhodes). Head, Department of Birds, Transvaal Museum, Pretoria, South Africa. HORNBILL (with L.G. Grimes); SECRETARY-BIRD.

R.K. **Robert Kennedy.** Department of Zoology, Washington State University, USA. CREEPER, PHILIPPINE (with R. Orenstein).

R.E.K. **Robert Eyres Kenward**, B.A., D.Phil. (Oxford). Institute of Terrestrial Ecology, Furzebrook, Dorset, England. FALCONRY.

A.K.K. **Angela Kay Kepler**, B.A. (Canterbury, New Zealand), M.S. (Hawaii), Ph.D. (Cornell). Kula, Hawaii, USA. TODY.

C.B.K. **Cameron Bradford Kepler**, B.A., M.A. (California), Ph.D. (Cornell). Biologist-in-charge, Maui Field Station, Patuxent Wildlife Research Center, US Fish and Wildlife Service, USA. HAWAIIAN HONEYCREEPER.

J.K.(2) **Jiro Kikkawa**, D.Sc. (Kyoto). Professor of Zoology, University of Queensland, Australia. WHITE-EYE (1).

A.G.K. **Alan Glasgow Knox**, B.Sc., Ph.D. (Aberdeen). Sub-Department of Ornithology, British Museum (Natural History), Tring, England. KERATIN.

J.R.K. **John Richard Krebs**, M.A., D.Phil. (Oxford), F.R.S. Lecturer, Edward Grey Institute of Field Ornithology, University of Oxford, England. E.P. Abraham Fellow in Zoology, Pembroke College, Oxford. BEHAVIOUR, HISTORY OF; and COUNTING; IMPRINTING; LEARNING; MIMICRY, VOCAL (with W.H. Thorpe).

J.A.K. **James A. Kushlan**, B.S., Ph.D. (Miami). Adj. Associate Professor, University of Miami, Coral Gables, Florida, USA. HERON.

L.L. **Lionel Lambourne**, B.A. (Nottingham). Assistant Keeper, Department of Paintings, Victoria and Albert Museum, London, England. ART, BIRDS IN.

J.H.L. **John Hartley Lawton**, B.Sc., Ph.D. (Durham). Reader in Biology, University of York, England. ECOLOGY.

I.L. **Ingvar Lennerstedt**, Fil.dr. (Lund, Sweden). Department of Zoology, University of Lund, Sweden. FOOT PAPILLAE AND PADS.

J.D.L. **J. David Ligon**, B.Sc. (Oklahoma), D.Phil. (Michigan). Professor, Department of Biology, University of New Mexico, Albuquerque, New Mexico, USA. WOOD HOOPOE.

A.L. **Alan Lill**, B.Sc. (Bristol), Ph.D. (Edinburgh). Senior Lecturer, Departments of Psychology and Zoology, Monash University, Australia. BOWERBIRD (with R.F. Donaghey, C.B. Frith); LYREBIRD.

H.L.	**Hans Löhrl,** Dr. phil. (München). Egenhausen, West Germany. Formerly Vogelwarte Radolfzell. NUTHATCH; WALLCREEPER.
R.L.	**Rosemary Low.** Deputy Editor, 'Cage and Aviary Birds'. New Barnet, Herts, England. AVICULTURE; CAGE BIRD.
J.C.McL.	**John Charles McLachlan,** B.Sc. (Glasgow), Ph.D. (London). Lecturer, Department of Anatomy and Experimental Pathology, University of St. Andrews, Scotland. DEVELOPMENT, EMBRYONIC.
G.L.M.	**Gordon Lindsay Maclean,** B.Sc., Ph.D. (Rhodes), D.Sc. (Natal). Professor, Department of Zoology, University of Natal, Pietermaritzburg, South Africa. COURSER; DRINKING; PRATINCOLE; SANDGROUSE; SEEDSNIPE.
R.McN.	**Raymond McNeil,** B.Sc., M.Sc., Ph.D. (Montreal). Director, Centre de recherches écologiques de Montréal, Université de Montréal, Canada. FOOTEDNESS.
P.H.M.-B.	Sir **Philip Henry Manson-Bahr,** C.M.G., D.S.O., M.D. (London). Died 1966. England. Formerly Chairman, British Ornithologists' Club, and Vice-President, British Ornithologists' Union. MECHANICAL SOUNDS.
S.M.	**Stephen Marchant,** B.A. (Cambridge). Moruya, NSW, Australia. NEST.
M.B.M.	**Miles Berkeley Markus,** B.Sc., M.Sc. (Pretoria), M.Sc., D.I.C., Ph.D. (London). Professor, Department of Zoology, University of the Witwatersrand, Johannesburg, South Africa. FEATHERS, NUMBER OF.
J.M.	**Joe T. Marshall, Jr.** Division of Birds, U.S. National Museum, Washington DC, USA. NIGHTJAR (with G.C.A. Junge).
L.D.M.	**Larry Dean Martin,** B.S., M.S. (Nebraska), Ph.D. (Kansas). Curator, Vertebrate Paleontology, Museum of Natural History, and Professor, Systematics and Ecology, University of Kansas, Lawrence, Kansas, USA. ARCHAEOPTERYX.
G.V.T.M.	**Geoffrey Vernon Townsend Matthews,** M.A., Ph.D. (London). Deputy Director, Wildfowl Trust, Slimbridge, Gloucester, England. HOMING PIGEON; NAVIGATION.
E.M.	**Ernst Mayr,** Ph.D. (Berlin). Alexander Agassiz Professor Emeritus, Museum of Comparative Zoology, Harvard University, Cambridge, Mass., USA. NEARCTIC REGION; NEOTROPICAL REGION.
C.J.M.	**Christopher John Mead,** M.I.Biol. Head of Ringing and Migration Section, British Trust for Ornithology, Tring, England. AGE; PENDULINE TIT; WING FORMULA; WING SPAN.
H.M.	**Heimo Mikkola,** Ph.D. (Kuopio). M.Sc. (Oulu), D.Phil. (Kuopio). Fisheries Specialist, Africa Development Bank, Ivory Coast, Africa. OWL.
P.R.M.	**Philip R. Millener,** B.Sc., Ph.D. (Auckland). National Museum of Natural History, Smithsonian Institution, Washington DC, USA. MOA (with R.J.S. Cassels).
C.D.T.M.	**Clive D.T. Minton,** Ph.D. IMI Australia, Melbourne, Australia. TRAPPING.
D.W.M.	**Douglas Wayne Mock,** B.S. (Cornell), M.S., Ph.D. (Minnesota). Associate Professor, Department of Zoology, University of Oklahoma, Norman, Ok, USA. COLONIALITY.
N.W.M.	**Norman Wilfred Moore,** M.A. (Cambridge), Ph.D. (Bristol). Swavesey, Cambridge, England. Formerly Chief Advisory Officer, Nature Conservancy Council. HABITAT; TOXIC CHEMICALS.
R.A.M.	**Robert Andrew Morgan,** B.Sc. (Wales). British Antarctic Survey, Madingley Road, Cambridge, England. NEST RECORDS; THICKKNEE.
D.H.M.	**Douglas Hathaway Morse,** B.S. (Bates College), M.S. (Michigan), Ph.D. (Louisiana State). Professor of Biology and Chairman, Section of Population Biology and Genetics, Brown University, Providence, Rhode Island, USA. FLOCKING.
G.M.	**Guy Mountfort,** O.B.E. Lyndhurst, Hants, England. Past President B.O.U. BILL.
J.B.N.	**Joseph Bryan Nelson,** B.Sc. (St. Andrews), D.Phil. (Oxford). Reader in Zoology, University of Aberdeen, Scotland. GANNET; GUANO.
I.N.	**Ian Newton,** B.Sc. (London), D.Phil., D.Sc. (Oxford). Institute of Terrestrial Ecology, Monks Wood, Abbots Ripton, Huntingdon, England. FALCON; FINCH; HAWK; IRRUPTIONS.
J-N.N.	**Jean-Noël Neyrolles.** Paris, France. KAGU (with R. De Naurois).
R.J.O'C.	**Raymond Joseph O'Connor,** B.Sc. (National University of Ireland), D.Phil. (Oxford). Director, British Trust for Ornithology, Tring, England. BIOSTATISTICS; EGG; GROWTH; PARENTAL CARE; and DEVELOPMENT, EMBRYONIC (Embryonic thermoregulation).
J.C.O.	**John C. Ogden.** Senior Staff Scientist, Condor Research Center, Ventura, California, USA. IBIS; SPOONBILL; STORK; VULTURE (2).
R.O.	**Ronald Isaac Orenstein,** B.Sc., M.Sc. (Toronto), Ph.D. (Michigan), LL.B. (Toronto). Canada. CREEPER, PHILIPPINE (with R. Kennedy); CREEPER, SPOTTED; ELEPHANTBIRD; EXTINCT BIRDS; SITTELLA; TREECREEPER (2) (with D.L. Serventy).
G.H.O.	**Gordon H. Orians,** B.S. (Wisconsin), Ph.D. (UC, Berkeley). Director, Institute for Environmental Studies, and Professor of Zoology, University of Washington, Seattle, Washington, USA. ORIOLE (2).

M.O. **Myrfyn Owen,** B.Sc. (Wales), Ph.D. (Leeds). Assistant Director (Research), The Wildfowl Trust, Slimbridge, Gloucestershire, England. WILDFOWL.

R.S.P. **Ralph S. Palmer,** B.A. (Maine), Ph.D. (Cornell). Research Associate, Smithsonian Institution, Washington, DC, USA. CARDINAL GROSBEAK; COLOUR STANDARDIZATION; LIMPKIN.

S.A.P. **Shane Alwyne Parker,** B.Sc. (Adelaide). Curator of Birds, South Australian Museum, Adelaide, South Australia. CHAT, AUSTRALIAN; FANTAIL; MONARCH FLYCATCHER; WARBLER, AUSTRALIAN; WREN (2).

K.C.P. **Kenneth Carroll Parkes,** B.Sc., M.Sc., Ph.D. (Cornell). Chief Curator, Life Sciences, and Curator of Birds, Carnegie Museum of Natural History, Pittsburgh, Pennsylvania, USA. WARBLER (2).

D.T.P. **David Thomas Parkin,** B.Sc. (Durham), Ph.D. (Manchester). Senior Lecturer, Department of Genetics, University of Nottingham, England. GENETICS.

C.P. **Colin Patterson,** B.Sc., Ph.D. (London). Senior Principal Scientific Officer, Department of Palaeontology, British Museum (Natural History), London, England. CLADISTICS.

R.B.P. **Robert Berkeley Payne,** B.S. (Michigan), Ph.D. (University of California, Berkeley). Museum of Zoology and Division of Biological Sciences, University of Michigan, Ann Arbor, Michigan, USA. CUCKOO; WHYDAH (1).

C.J.P. **Colin James Pennycuick,** M.A. (Oxford), Ph.D. (Cambridge). Maytag Professor of Ornithology, University of Miami, Florida, USA. FLIGHT.

C.M.P. **Christopher Miles Perrins,** B.Sc. (London), D.Phil. (Oxford). Director, Edward Grey Institute of Field Ornithology, University of Oxford, England. BREEDING SEASONS; CLUTCH-SIZE.

D.E.P. **Derek Edmund Pomeroy,** M.A. (Cambridge), Ph.D. (Adelaide). Professor of Zoology, Makerere University, Uganda. BILL ABNORMALITIES.

A.P. **Adolf Portmann,** Ph.D. (Basel), Dr. h.c. (Aix-Marseille; Freiburg i Br.). Formerly Professor, Director, Zoological Institute, University of Basel, Switzerland. HATCHING (with W.H. Stingelin).

W.F.P. **William Frank Porter,** B.A. (Northern Iowa), M.S., Ph.D. (Minnesota). Associate Professor, Department of Environmental and Forest Biology; Director, Adirondack Ecological Center, State University of New York, Syracuse, New York, USA. PARTHENOGENESIS; TURKEY.

I.P. **Ian Prestt,** M.Sc., (Liverpool), F.I. Biol. Director, Royal Society for the Protection of Birds, Sandy, Bedfordshire, England. CONSERVATION.

J.P. **Jesu Prévost,** Ph.D. Professor, Faculty of Sciences, University of Limoges, France. PENGUIN (*Aptenodytes*).

R.P.P.-J. **Robert Parton Prŷs-Jones,** B.Sc. (Nottingham), D.Phil. (Oxford). Research Officer, Percy FitzPatrick Institute of African Ornithology, University of Cape Town, Rondebosch, South Africa. BUNTING.

E.P. **Erkki Pulliainen,** Ph.D. Professor of Zoology, University of Oulu, Finland. WAXWING.

J.D.P. **John David Pye,** B.Sc. (Wales), Ph.D. (London). Professor of Zoology, School of Biological Sciences, Queen Mary College, Mile End Road, London, England. ECHOLOCATION; (MECHANICAL SOUNDS).

D.A.R. **Derek Almey Ratcliffe,** B.Sc., D.Sc. (Sheffield), Ph.D. (Wales). Chief Scientist, Nature Conservancy Council, Peterborough, England. EGGSHELL THINNING.

J.M.V.R. **Jeremy Mark Verrinder Rayner,** M.A., Ph.D. (Cambridge). Department of Zoology, University of Bristol, England. FLIGHT, SPEEDS OF.

R.E.R. **Reginald Elson Rewell,** M.D. (London), M.R.C.P. Formerly Pathologist, Zoological Society of London, England. BLOOD.

J.F.R. **John Frank Reynolds,** M.A. (Oxford). Head of Biology, Rastrick Grammar School, Yorkshire, England. BELLY-SOAKING.

A.S.R. **Andrew Stephen Richford,** B.Sc. (Edinburgh), D.Phil. (Oxford). London, England. PAINTED SNIPE.

M.R. **Mark Ridley,** M.A., D.Phil. (Oxford). New College, Oxford. ALTRUISM; E.S.S.; FACILITATION, POSTURAL; FACILITATION, SOCIAL; FITNESS; SEXUAL DIMORPHISM; SOCIOBIOLOGY.

M.W.R. The Hon. **Matthew White Ridley,** B.A., D.Phil. (Oxford). Science editor, The Economist, London, England. PHEASANT (with J.T. Delacour).

S.D.R. **S. Dillon Ripley,** K.B.E., Sc.D. Secretary, Smithsonian Institution, Washington, DC, USA. RAIL; THRUSH.

R.B.R. **Richard B. Root,** B.S. (Michigan), Ph.D. (Berkeley). Professor, Section of Ecology and Systematics, Cornell University, Ithaca, New York, USA. GNATCATCHER.

I.C.R.R. **Ian Cecil Robert Rowley,** B.Agr.Sci. (Melbourne). Senior Principal Research Scientist, CSIRO, Helena Valley, Western Australia. CHOUGH (2).

F.S. **Finn Salomonsen,** Ph.D. (Copenhagen). Formerly Keeper of Bird Department, Zoological Museum, Copenhagen, Denmark. Died 1983. FLOWERPECKER; HONEYEATER (with H.A. Ford).

L.S. **Luc Schifferli,** Lic. Zool. (Basel, Switzerland), D.Phil. (Oxford). Schweizerische Vogelwarte (Swiss Ornithological Institute), Sempach, Switzerland. GRIT.

R.P.S. **Roberto Pablo Schlatter,** Med. Vet. (U. de Chile, Santiago), Ph.D. (Johns Hopkins, USA). Professor, Institute of Zoology, Faculty of Sciences, Universidad Austral de Chile, Valdivia, Chile. PLANTCUTTER.

J.S. **J. Schwartzkopff,** Professor Dr. Ruhr-Universität Bochum, Germany. TOUCH.

D.K.S. **Dafila Kathleen Scott,** B.A. (Oxford), Ph.D. (Cambridge). Scientist at the Wildfowl Trust, Welney, Norfolk, England. RECOGNITION, INDIVIDUAL.

P.S. Sir **Peter Markham Scott,** K.B.E., D.S.C., M.A. (Cambridge). Founder and Director, Wildfowl Trust, Slimbridge, Gloucestershire, England. DECOY; DUCK; GAMEBIRDS.

D.L.S. **Dominick Louis Serventy,** B.Sc. (W. Australia), Ph.D. (Cambridge). Formerly Principal Research Officer, CSIRO Division of Wildlife Research, Nedlands, Western Australia. AUSTRALASIAN REGION (with H.A. Ford); FROGMOUTH; OWLET-FROGMOUTH; TREECREEPER (2) (with R. Orenstein).

J.T.R.S. **John Timothy Robin Sharrock,** B.Sc., Ph.D. (Southampton). Managing Editor, 'British Birds', Blunham, Bedford, England. ATLAS.

L.L.S. **Lester LeRoy Short,** B.Sc., D.Phil. (Cornell). Chairman and Curator, Ornithology Department, American Museum of Natural History, and Professor, City University of New York, USA. HYBRID; HYBRIDIZATION, ZONE OF SECONDARY; INTROGRESSION; WOODPECKER.

A.S. **Aharon Shulov,** D.Sc. Nat. (Naples). Emeritus Professor of Zoology, Hebrew University of Jerusalem, Israel. Founder and first Director of Jerusalem Biblical Zoological Garden. BIBLE, BIRDS OF THE.

C.G.S. **Charles Gald Sibley,** Ph.D. (California). William Robertson Coe Professor of Ornithology; Curator of Birds, Peabody Museum of Natural History, Yale University, New Haven, Conn. USA. DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA.

H.S. **Helmut Sick,** Ph.D. (Berlin). Academia Brasileira de Ciências, Rio de Janeiro, Brazil. CURASSOW; HOATZIN; SERIEMA; TAPACULO; TINAMOU.

W.R.S. **Walter Roy Siegfried,** B.Sc., Ph.D. (Cape Town). Director, Percy FitzPatrick Institute of African Ornithology, University of Cape Town, Rondebosch, South Africa. HAMERKOP; OXPECKER (with R.K.Brooke); SUGARBIRD.

K.E.L.S. **Kenneth Edwin Laurence Simmons,** M.Sc., Ph.D. (Bristol). Honorary Visiting Fellow, Department of Psychology, University of Leicester, England. ANTING; COMFORT BEHAVIOUR; DISTRACTION BEHAVIOUR; DUSTING; GREBE; SMOKE BATHING; SUNNING, and PARENTAL CARE (Protection of eggs).

S.S. **Sverre Sjölander,** Dr. Zoologiska Institutionen, University of Stockholm, Sweden. DIVER.

A.F.S. **Alexander Frank Skutch,** A.B., Ph.D. (Johns Hopkins University). San Isidro de El General, Costa Rica. JACAMAR; MOTMOT; PUFFBIRD; SHRIKE-VIREO; SILKY-FLYCATCHER; SUNBITTERN; TANAGER; TOUCAN.

T.S. **Tore Slagsvold,** D.Phil. Zoologisk Avdeling, University of Trondheim, Norway. NEST SITE SELECTION.

P.J.B.S. **Peter James Bramwell Slater,** B.Sc., Ph.D., D.Sc. (Edinburgh). Professor of Natural History, University of St. Andrews, Scotland. DISPLACEMENT ACTIVITY.

G.T.S. **Graeme Talbot Smith,** B.Sc., Ph.D. (ANU). Senior Research Scientist, Division of Wildlife and Rangeland Research, CSIRO, Midland, Western Australia. SCRUB-BIRD.

N.G.S. **Neal Griffith Smith,** D.Phil. (Cornell). Smithsonian Tropical Research Institute, Balboa, Panama. NESTING ASSOCIATIONS; SHARPBILL.

B.E.S. **Bertram Evelyn Smythies,** B.A. (Oxford). Merstham, Surrey, England. Formerly Forest Service in Burma and Sarawak. CUCKOO-SHRIKE; WOOD-SWALLOW (with P.J.K. Burton).

B.S. **Barbara Katherine Snow,** B.Sc. (Reading). Wingrave, Bucks, England. Formerly of Trinidad. HUMMINGBIRD.

D.W.S.(1) **David William Snow,** M.A., D.Phil., D.Sc. (Oxford). Wingrave, Bucks, England. Formerly Senior Principal Scientific Officer, British Museum (Natural History). BANANAQUIT; CHARACTER DISPLACEMENT; COEVOLUTION; CONEBILL; COTINGA; FINCH, PLUSH-CAPPED; HONEYCREEPER; HYPOCOLIUS; LEK; MANAKIN; MATING SYSTEM; OILBIRD; PEPPER-SHRIKE; POLYANDRY; POLYGYNY; SEED DISPERSAL; SWALLOW-TANAGER.

E.J.L.S. **E.J. Lawson Soulsby,** M.A. (Cambridge), Ph.D., M.R.C.V.S., D.V.S.M. (Edinburgh). Professor of Animal Pathology and Head, Department of Clinical Veterinary Medicine, University of Cambridge, England. ENDOPARASITE.

R.S. **Robert Spencer,** B.A., M.Sc. (Durham). Cockermouth, Cumbria, England. Formerly head of Ringing and Migration Section, and Director of Services, British Trust for Ornithology, Tring, England. MARKING.

D.W.S.(2) **David William Steadman,** B.Sc. (Edinboro State College), M.Sc. (Florida), D.Phil. (Arizona). Research Associate, Division of Birds, Smithsonian Institution, Washington, DC, USA. FOSSIL BIRDS.

W.H.S. **Werner Hugo Stingelin,** Ph.D. (Basel). Zoological Institute, University of Basel, Switzerland. HATCHING (with A. Portmann).

B.S. **Bernard Stonehouse,** B.Sc. (London), M.A., D.Phil. (Oxford). Scott Polar Research Institute, Cambridge, England. FRIGATEBIRD; SHEATHBILL; TROPICBIRD.

R.W.S.	**Robert W. Storer,** A.B. (Princeton), M.A., Ph.D. (California). Professor of Zoology and Curator of Birds, Museum of Zoology, University of Michigan, Ann Arbor, Michigan, USA. SWIMMING AND DIVING.
J.G.S.	**Joseph G. Strauch, Jr.** Ph.D. Adjoint Curator, University Museum (Zoology), University of Colorado, USA. SKELETON, POST-CRANIAL.
D.S.-S.	**James Denis Summers-Smith,** B.Sc. (Glasgow), Ph.D. (Reading). Guisborough, Cleveland, England. SPARROW (1).
A.L.T.	Sir **(Arthur) Landsborough Thomson,** C.B., D.Sc. (Aberdeen). President XI Orn. Int. Congr., Basel 1954. Editor, A New Dictionary of Birds, 1964. London, England. Died 1977. AVES; CONGRESSES (with B. Campbell); CROCODILE-BIRD; FAMILY; NAME, ENGLISH; NOCTURNAL HABITS; NOMENCLATURE; TAIL (with J.J. Baumel); SHOEBILL (with A. Guillet); TAMENESS; TAXONOMY; TOPOGRAPHY; YOUNG BIRD.
W.H.T.	**William Homan Thorpe,** M.A., Ph.D., Sc.D. (Cambridge), F.R.S. Emeritus Profesor of Animal Ethology, University of Cambridge, England; Past President, British Ornithologists' Union; Past President, Association for the Study of Animal Behaviour. COUNTING; IMPRINTING; LEARNING (all with J.R. Krebs); (MIMICRY, VOCAL).
N.T.	**Nikolaas Tinbergen,** Ph.D. (Leiden), M.A. (Oxford), F.R.S. Oxford, England. Formerly Professor of Experimental Zoology, University of Leiden, Netherlands; Formerly Reader in Animal Behaviour, University of Oxford, England. RECOGNITION; REDIRECTION; SIGN STIMULUS.
S.R.T.	**Susan Rhonda Tingay,** B.A. (Adelaide), Ph.D. (Western Australia). Stoneville, West Australia. MAGPIE-LARK.
L.T.	**Ludwik Tomiałojć,** B.Sc., Dr., Dr. habil. (Wrocław). Museum of Natural History, University of Wrocław, Poland. URBANIZATION.
S.G.T.	**Stephen Graham Tullett,** B.Sc., Ph.D. (Bath). Senior Scientific Officer, Department of Reproductive Physiology, Agricultural and Food Research Council's Poultry Research Centre, Roslin, Midlothian, Scotland. INCUBATION; LAYING.
D.A.T.	**Donald Arthur Turner.** East African Natural History Society, Nairobi, Kenya. TURACO (with L.G. Grimes).
G.E.S.T.	**Geoffrey Eric Slade Turner,** M.A. (Oxford). Formerly Secretary, Science Area Delegacy, University of Oxford, England. Died 1984. (FOLKLORE); (OMENS, BIRDS AS); ORNAMENTATION, BIRDS IN HUMAN.
E.K.U.	**Emil Karl Urban,** B.Sc., Ph.D. (Wisconsin), M.A. (Kansas). Professor and Chairman, Department of Biology, Augusta College, Augusta, Georgia, USA. PELICAN.
G.F.v.T.	**Gerard Frederick van Tets,** B.A., M.A., Ph.D. (British Columbia). Principal Research Scientist, CSIRO Division of Wildlife and Rangelands Research, Canberra, Australia. CORMORANT; DARTER.
H.G.V.	**Henry Gwynne Vevers,** M.B.E., M.A., D.Phil. (Oxford). Formerly Assistant Director of Science, The Zoological Society of London, England. COLOUR.
K.H.V.	**Karel Hendrik Voous,** D.Sc. (Amsterdam). Emeritus Professor of Systematic Zoology and Zoogeography, Free University, Amsterdam; Formerly Deputy Director, Zoological Museum, University of Amsterdam, Netherlands. CLASSIFICATION; ORDER; PALEARCTIC REGION.
F.V.	**François Vuilleumier,** Lic. ès sciences naturelles (Geneva), Ph.D. (Harvard). Curator, Department of Ornithology, American Museum of Natural History, New York, USA. ZOOGEOGRAPHY.
J.W.	**John Warham,** B.Sc. (Durham), Ph.D. (New Zealand). Reader, Department of Zoology, University of Canterbury, Christchurch, New Zealand. PENGUIN (*Eudyptes*).
K.E.W.	**Keith Edward Webster,** B.Sc., Ph.D., M.B., B.S. (London). Professor of Anatomy, King's College, University of London, England. NERVOUS SYSTEM.
M.W.W.	**Milton W. Weller,** A.B., M.A., D.Phil. (Missouri). Professor, Caesar Kleberg Chair in Wildlife Ecology, Texas A & M University, College Station, Texas, USA. SCREAMER.
D.R.W.	**David R. Wells,** Ph.D. (Malaya). Department of Zoology, University of Malaya, Kuala Lumpur, Malaysia. BROADBILL; FAIRY-BLUEBIRD; LEAFBIRD.
G.R.M.	**Gordon R. Williams,** B.Sc. (Sydney), M.Sc. (New Zealand), Ph.D. (Canterbury). Formerly Professor of Entomology, Lincoln College, Canterbury, New Zealand, and Director of New Zealand Wildlife Service. Died 1983. KIWI.
E.O.W.	**Edwin O'Neill Willis,** B.S. (Virginia Polytechnic Institute), M.S. (Louisiana State), Ph.D. (California). Professor Colaborador, Departamento de Zoologia, Universidade Estadual Paulista, São Paulo, Brazil. ANTBIRD.
R.F.W.	**Raffael Felix Winkler,** Dr. Phil. (Basel). Curator of Birds, Natural History Museum, Basel, Switzerland. PNEUMATIZATION OF BONE.

A

ABDOMEN: the 'belly', being the part of the body containing the excretory, reproductive, and main digestive organs (see ALIMENTARY SYSTEM; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; EXCRETORY SYSTEM); applied also to the ventral surface of the same region (see TOPOGRAPHY).

ABDUCTOR: see MUSCULATURE.

ABMIGRATION: an anomalous migratory movement of a particular type (see MIGRATION).

ABNORMALITIES: see BILL ABNORMALITIES; PLUMAGE, ABNORMAL.

ABRASION: the effect of wear on the vane of a feather, involving some reduction of the tips of the barbs or their barbules; where these tips are coloured differently from the rest of the vane, their loss may substantially change the pattern and hue of the plumage generally (see PLUMAGE).

ABUNDANCE: see NUMBERS.

ACANTHISITTIDAE: a family of PASSERIFORMES, suborder Oscines; alternative name for the Xenicidae; see WREN (3).

ACANTHIZIDAE; ACANTHIZINAE: a family and subfamily of PASSERIFORMES, suborder Oscines; WARBLER, AUSTRALIAN.

ACCENTOR: former generic name used as substantive for most species of Prunellidae (Passeriformes, suborder Oscines); in plural, general term for the family, which comprises 12 species placed in the single genus *Prunella*.

Characteristics. They are small birds (14–18 cm) with rufous or brownish-grey upperparts, streaked in most species; and with greyish underparts, usually marked in places with rufous. The general size and appearance are like those of a sparrow *Passer*, but the bill is more slender and pointed. The sexes are similar in plumage but males have longer wings and are heavier. Anatomically the Prunellidae have the fringillid character of a true crop and a muscular gizzard, adapted to a diet of seeds at some seasons. Their systematic position among the Oscines had been long debated, but recent evidence from DNA-hybridization indicates that they are closest to the ploceine weavers (see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA). (Sibley and Ahlquist 1981).

Distribution and habitat. The family is exclusively Palearctic, widely distributed from western Europe to Japan. The Alpine Accentor *P. collaris* is the most widespread species, its disjunct occurrence in high mountains having resulted in the evolution of many races; 8 subspecies are currently recognized. The Himalayan Accentor *P. himalayana* breeds as high as 5,000 m. The Robin Accentor *P. rubeculoides* is also found at high altitudes in central Asia, showing a preference for dwarf rhododendrons and other scrub, or for willows and sedges in damp meadows. The Siberian Accentor *P. montanella* breeds in the Siberian mountains and also along the lower courses of the Siberian rivers well north of the Arctic Circle. The best-known species, the Dunnock (formerly Hedge Sparrow) *P. modularis*, breeds mainly in mountains in central and eastern Europe, but is a familiar bird of gardens and cultivation, as well as woodland and scrub, in the west.

Movements. Some accentors are migratory, while others move to lower altitudes in winter. The Dunnock is sedentary in mild parts of its range, migratory in the north, and makes altitudinal movements in mountains.

Food. Accentors are unobtrusive ground feeders, often creeping about with a mouse-like action. They are mainly insectivorous in summer, and in winter subsist largely on seeds. In winter quarters some accentors regularly forage in flocks.

Behaviour. The Dunnock, the only species investigated in detail, has a complex and highly variable social organization (Birkhead 1981; Davies and Lundberg 1984, Snow and Snow 1982). Female ranges are largely exclusive. Males set up song territories in spring and compete to monopolize females. Depending on their ability to monopolize one or more females, the resulting mating systems range from polygyny (a male with two or three females) through simple pairs to polyandry (a female with two or three males) or even 'polygynandry' (several males associated with several females). The commonest mating systems are pairs and 'trios' (a female with two males). When two males share a female, one is dominant and the other subordinate. The dominant male guards the female closely, and the subordinate male may or may not succeed in mating. Only if he does, does he help in feeding the young. The likelihood that a similar social system may occur in other species is suggested by the report of two males and a female feeding the young in an Alpine Accentor nest (Dyrcz 1977).

The Dunnock's precopulatory display and method of mating are most unusual. The male pecks the female's cloaca for up 2 minutes before mating, which he does with extraordinary rapidity, jumping towards her at a slight angle and making cloacal contact for only a fraction of a second. During the precopulatory display the female's cloaca makes strong pumping movements and sometimes, at least, she ejects a small droplet of sperm. The male is very interested in the droplet, looks at it, and then immediately copulates. In view of the complex mating system, often including polyandry, this display may have evolved because it increases the male's chances of paternity (Davies 1983). From the little evidence available it seems that the Alpine Accentor's mating behaviour is similar.

Voice. The Dunnock has a complex song consisting of a succession of rapid modulated notes and trills. Males include in their songs extensive passages copied exactly from their neighbours. Females very occasionally sing. The Alpine Accentor has a longer song of similar structure and regularly sings in flight. Other calls include sharp high-pitched alarm and contact notes (Dunnock) and a rippling trill (Alpine Accentor).

Breeding. The nest, built by the female, is an open cup of plant fragments and moss, lined with hair, wool or feathers, and placed in low tree branches, shrubs, rock crevices, or on the ground. The 3–6 unmarked eggs range from blue to light bluish green. Two or three broods are normal for the Dunnock, two for the Alpine Accentor. Incubation is by the female alone in the Dunnock, but both sexes are reported to incubate in the Alpine Accentor. The incubation and fledging periods are each about 12–13 days in the Dunnock, but probably average somewhat longer in the high montane species. M.E.B.

ACCIDENTAL (SPECIES): see VAGRANT.

ACCIPITER: sometimes used in North America as a vernacular term for *Accipiter* spp., 'hawk' having there a wider connotation than in Britain (see HAWK).

ACCIPITRES: alternative ordinal or subordinal name (see ACCIPITRIFORMES).

ACCIPITRIDAE: see ACCIPITRIFORMES; HAWK.

ACCIPITRIFORMES: an order, alternatively 'Accipitres', comprising 2 suborders: Accipitres, Sagittarii; 3 families: Accipitridae (HAWK), Pandionidae (OSPREY), Sagittariidae (SECRETARY-BIRD).

The order is a cosmopolitan one and contains all birds-of-prey in the strict sense, such as hawks, kites, harriers and eagles, but not the cathartid vultures (see VULTURE (2)) and the falcons and caracaras (see FALCONIFORMES). The Old World vultures, sometimes treated as Aegypiinae, are included in the Accipitridae, whereas the Osprey *Pandion haliaetus* is given family rank Pandionidae, as in Wetmore's system.

All species are generally characterized by hooked beak and sharp curved claws, used as talons in seizing living prey. The large number of species have developed an astonishingly wide ecological radiation and an impressive variety of wing shapes and flight methods, depending on habitat and hunting techniques. The order includes the largest known fossil and Recent flying land birds, some of the former with enormous wingspan. Food ranges from small insects to relatively large terrestrial and arboreal mammals, such as small deer, sloths, and monkeys. Some have turned to feeding on carcasses of large ungulates, others to plant material including oily fruits.

ACCLIMATION: the process of adjusting to changed environmental circumstances, often with respect to temperature. Often used as a synonym of acclimatization but strictly refers to experimentally induced changes whilst the latter term is appropriate to natural change.

ACETABULUM: the hollow in the pelvic girdle, on each side, into which the head of the femur fits (see SKELETON, POST-CRANIAL).

ACQUIRED CHARACTERS: those arising during the life of the individual as the result of environmental or functional influences, as distinct from those expressing genetic constitution (see EVOLUTION; NATURAL SELECTION).

ACROMION: anterior projection of the scapula (see SKELETON, POST-CRANIAL).

ACROMYODI: see PASSERIFORMES.

ACROPODIUM: the dorsal surface of the toes.

ACROTARSAL: pertaining to the anterior surface of the tarsus.

ACUTIPLANTAR: having the hinder aspect of the tarsus coming to an angle (applied to oscine Passeriformes); opposite of LATIPLANTAR (in general, see LEG).

ADAPTATION: the production of fitness for a particular function, the term being also applied to a character (structure, behaviour, etc.) specially providing such fitness (see EVOLUTION; NATURAL SELECTION). 'Adaptive radiation' denotes divergence in the characters of related forms that enables them to exploit different kinds of opportunity. 'Convergence' denotes the adaptation of unrelated forms to similar functions, often giving rise to superficial resemblance (see CONVERGENCE). The term 'pre-adaptation' is used in cases where, coincidentally, a character existed in advance of the opportunity to which it proved particularly suited.

ADAPTATIONS, ENVIRONMENTAL: the production of fitness for particular functions.

The make-up of the bird, especially warm-bloodedness and capacity for flight, pre-adapt it for certain ways of life, ecological roles, life-zones, and habitats. Warm-bloodedness and feathery insulation permit birds to thrive at high latitudes and altitudes, fly annually to exploit habitats thousands of kilometres apart, utilize temporary habitats, as well as patchily distributed resources, and feed at different levels. Many seeming adaptations are thus really pre-adaptations.

Every aspect of the bird's life is adaptive: adaptations to the physical environment, habitat, prey and predators, and other bird species. Adaptations to the various aspects of reproduction alone are bewildering in their diversity and complexity. In this broad review it is not possible to cite the cross references involved.

Within the avian framework some of the most important adaptations to different living areas involve modification to the annual cycle: the more or less stereotyped annual sequence of breeding—moulting—outward migration—moulting—return migration—breeding. Basically the annual cycle is structured around reproduction in the spring, this usually being the time of optimum food resources. In those parts of the world with significant annual day-length changes, breeding is initiated by the changing photoperiod, a threshold being passed in the lengthening process that, via the pituitary pathway, triggers enlargement of the reproductive organs. Other phases of the annual cycle, moulting and migration, are also linked in most species to the changing photoperiod.

Each phase of the annual cycle represents a major energy drain on the bird, and may be the basis of adaptive modification. Breeding entails the setting up and defence of territory, courtship, nest-building, incubation, and the raising of the young. The moult (Payne 1972) represents the massive replacement of the body and flight feathers. Migration (Berthold 1975) may entail flights of thousands of kilometres: it is characteristically preceded by the laying down of layers of body fat (premigratory fat) to be used as fuel during the flight.

Breeding and moulting are almost invariably sequential and do not overlap. In high latitude breeding species the former commonly occupies 4–8 weeks. Erratic and unpredictable environments may necessitate modifications to the control and timing of breeding and moulting (Serventy 1971; Immelmann 1971). For example, in the interior of Australia breeding may be linked with rainfall, and only partly to the photoperiod. In such an environment, when conditions are optimal for only a brief period, there may be some overlap of breeding and moulting, and moulting may be very protracted so that it never represents a major energy-drain (Keast 1968).

Migration is, of course, very much a feature of the higher latitudes and altitudes. Whilst in most species the moult precedes migration, in a minority it is post-migratory. Presumably in such cases better resources are available in the wintering ground; or it is advantageous to leave the breeding grounds early. An alternative to the north-south (or south-north) migration of the higher latitude birds is the seasonal nomadism found in many inhabitants of warmer savanna and desert areas. Nomadism is a more random form of seasonal movement than 'true' migration and is of shorter amplitude. It brings the birds to areas where resources improve seasonally (e.g. winter rainfall areas, areas of fruiting or flowering), with the end point of the movement varying somewhat from year to year. Nomadic journeys may have a directional component (as in some African hawks and Australian interior birds) so that whether a movement be regarded as nomadic or migratory is a matter of choice. Presumably nomadic movements are usually less demanding on the bird than a 1,000 km migratory journey.

There may be one, or two, moults. Most bird species have only one, the 'complete' moult of late summer or early autumn. This post-reproductive moult entails a complete replacement of the flight, tail, and contour feathers. In a minority of species, mostly those with distinct breeding plumages, there is a prenuptial moult that is partial, involving the body feathers only. These different patterns of moulting are doubtless adaptive. Just as some races of species, but not others, are migratory so there may, or may not, be a prenuptial moult.

The component parts of the avian annual cycle are under neurendocrine control. As yet, however, despite intensive research, most of the finer control mechanisms remain unknown. The control of breeding (and of the various aspects of breeding behaviour) is well understood, but the same is not true of the moult. Whilst the thyroid is clearly linked to the moult in many species, in others this link is much less clear-cut. Little is known of the antagonistic/synergistic effects of the hormones on the pituitary, reproductive organs, and thyroid, in the control of the moulting process.

The link between hormones and migration is also inadequately understood.

Species inhabiting extreme environments often share common adaptations to those environments. Those of Arctic birds include migration, heavy body insulation, and sometimes white winter plumage. The small minority of species that over-winter in the far north commonly avoids freezing by spending the night in hollows (sometimes communally), or by burying themselves in the snow. Desert adaptations include nomadism; breeding after rain; avoiding breeding in bad years; breeding at an early age (permitting rapid population build-up); mechanisms for restricting water-loss; evaporative cooling, and modifying the effects of heat; ability to survive on a minimum of water or to drink semi-saline water; and being cryptically coloured (Serventy 1971; Immelmann 1971; Dawson 1980). Gloger's Rule (that races living in arid areas are pale-coloured) has wide application in birds, as does Bergmann's Rule (races occupying colder latitudes are larger than those inhabiting warmer areas).

At the finer level, within avifaunas and bird communities, it is now appreciated that individual species show complex ecological, behavioural, and structural adaptations for specific ways of life. These also serve to channel species within communities into different roles, thus permitting a diversity of different species to live together. There is a general link between body and bill size, and prey or food particle size (e.g. Hespenheide 1971). Migratory races of species have longer and more tapering wings than resident ones. Species living close to the ground or in thickets (e.g. quails) have rounded wings, a shape presumably linked to rapid vertical take-off. In warblers, minor differences in tarsal structure have been shown to be related to different perching habits (Leisler 1980; Osterhaus 1962). Species interactions could be a significant factor in consolidating ecological specializations.

Recent studies on migration (e.g. papers in Keast and Morton 1980) reveal not only a great diversity of adaptations associated with overwintering patterns but also a high adaptational plasticity amongst the migrants. These birds not only occupy different habitats in winter and summer but some may change their diets (e.g. from insect-eater to frugivore). Again, they are able to operate effectively in quite different bird communities in summer and winter. J.A.K.

ADAPTIVE RADIATION: denotes divergence in the characters of related forms that enables them to exploit different kinds of opportunity (see ECOLOGY).

ADDLED: term applied to egg in which the developing embryo has died, as opposed to an infertile egg in which no development has taken place.

ADDUCTOR: see MUSCULATURE.

ADENOSINE TRIPHOSPHATE (ATP): the source of energy for, *inter alia*, muscular contraction (see METABOLISM).

ADJUTANT: also 'Adjutant-bird' or 'Adjutant Stork', substantive name of species of *Leptoptilos* (see STORK).

ADRENAL GLAND: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

ADULT: theoretically, a bird that has reached its fullest development; in practice, however, a term difficult to define precisely. Size is no criterion, as a bird is virtually full-grown at a very early age (see also YOUNG BIRD). The implication is that the bird has attained, appropriately to season, definitive plumage (see PLUMAGE; MOULT); and also that it is capable of breeding (see MATURITY). For most purposes, plumage provides the only practicable criterion. Difficulties are that many species breed, some even more than once, before acquiring their best plumage; and that others do not breed in the first year of wearing it (see AGE).

ADVERTISING DISPLAY: see DISPLAY.

AEGITHALIDAE: see under PASSERIFORMES, suborder Oscines; TIT, LONG-TAILED.

AEGITHOGNATHOUS: see PALATE.

AEGOTHELIDAE: see CAPRIMULGIFORMES; OWLET-FROGMOUTH.

AEPYORNITHIDAE: see under STRUTHIONIFORMES; EARLY EVOLUTION OF BIRDS; ELEPHANT BIRD; EXTINCT BIRDS.

AERATION: see RESPIRATORY SYSTEM.

AETHINI: see AUK.

AETIOLOGY: the science of causation, especially the causes of disease (see DISEASE).

AFFERENT: carrying inwards i.e. towards the centre; applied especially to nerves, in respect of the direction in which they transmit impulses—contrasted with EFFERENT (see NERVOUS SYSTEM).

AFRICA: see AFROTROPICAL REGION (for Africa south of the Sahara); PALEARCTIC REGION (for North Africa); MALAGASY REGION (for Madagascar).

AFROTROPICAL REGION: one of the six major zoogeographical regions (see DISTRIBUTION, GEOGRAPHICAL), consisting essentially of Africa south of the Sahara but excluding Madagascar (see MALAGASY REGION) and the Comoro Islands while including the islands of Zanzibar, Pemba, Mafia and the Gulf of Guinea. Previously known as the Ethiopian Region until the former state of Abyssinia changed its name to Ethiopia and necessitated a revision of the regional name. In the north it abuts the southern border of the Palearctic Region, which runs from about 21°N in the west to $22\frac{1}{2}$°N at the Red Sea, skirting to the south of the Ahaggar and north of the Air and Ennedi massifs. The south-west corner of Arabia has sometimes been included; it contains enough Palearctic elements to exclude it from the Afrotropical Region but enough Afrotropical elements to exclude it from the Palearctic. The total area of the region is about 21 million km^2 of which about $1\frac{1}{4}$ million km^2 are south of the tropics; the southern limit is at about 35°S.

The distribution of Afrotropical birds is closely related to that of vegetation types, which in turn are influenced by climate and topography, and, within a vegetation type, to its history. A useful account of the habitats of Africa, with special reference to birds, is given in Brown *et al* (1982). The most recent authoritative study of the vegetation is incorporated in the map by White (1982), which recognizes 18 floristic divisions and about 75 vegetation types. An important feature is the extent of vegetation types that are transitional between others, or are a mosaic of different types existing side by side; together, transitions and mosaics account for about 36% of the area of the Afrotropical region. The most conspicuous avifaunal changes coincide approximately with the boundaries of major vegetational types. Bird distribution patterns analyzed by Crowe and Crowe (1982) could be divided into 31 avifaunal zones, arranged in a 3-tier hierarchy from sub-regions through provinces to districts; of these, the boundaries of the 10 provinces coincide most closely with the boundaries of phytochoria (floristic zones) in White's map. The most important distinction in the avifauna remains that between forest and non-forest species, as stressed by Moreau (1966), even though more forest species are now known to occur in other habitats as well.

The geographical pattern of vegetation types is essentially a series of latitudinal belts becoming progressively more arid and open away from the Equator. This basic pattern is complicated by topography; east of 30°E and south of about 8°S, much of the land surface is 1,000 m or more above sea level and is too cool and dry for the development of the lowland rain-forest that is found at lower altitudes. On these raised plateaus, woodland, savanna and grassland or scrub replace the forest found further west and north. About 37% of the Afrotropical Region lies at altitudes of 1,000 m or more, compared, for example, with less than 17% of the Neotropical Region; the relatively small proportion of lowland must go some considerable way towards explaining the impoverishment of the Afrotropical Region compared with other parts of the tropics.

Lowland rain forest occupies the equatorial lowlands to about 10° north and south, and east to about 28°E; it is bordered broadly by a transitional zone consisting of a mosaic of woodland, forest and grassland maintained by the burning and stock-grazing activities of man. The zone as a whole is characterized by high rainfall—150 cm a year or more—and the lack of a marked dry season; but few if any parts of the Region receive the high and dependable rainfall found in many parts of the lowland rain forests of South America or South-East Asia. There is little or no undisturbed primary rain-forest remaining in Africa, but those areas that approach this condition most nearly are dominated by tall trees with few side branches beneath the canopy at 30–50 m, festooned with epiphytes and lianes. Below these tall emergent trees are several layers of tree canopy that between them shade the ground so darkly that the vegetation there is a sparse one of scattered herbs and saplings with very few grasses. Natural breaks in the canopy, caused by falling trees, watercourses or landslips, are important because they admit the light to lower levels and so allow the growth of a dense luxuriant undergrowth. This understorey is characteristic of much African forest where man has crudely mimicked the effects of natural breaks in the canopy. Rich forest extends also along rivers, whose water allows the trees to survive far outside the climatic limits of forest set by rainfall; these 'gallery' or riverine forests are often only a few trees deep but may be important dispersal routes for forest birds.

The stratification of the forest plants into layers is often confused; the ground layer, understorey and uppermost canopy are clearly recognizable but it is often impossible to distinguish other separate strata. Characteristic birds of the ground layer and understorey are thrushes and babblers; the upper layers are far richer, abounding in cuckoos, turacos, trogons, hornbills, barbets, starlings and weavers. Flycatchers, warblers and bulbuls range widely at all levels of the forest.

Woodlands and grasslands. Beyond about 8° north and south of the Equator, the transitional mosaic of forest, woodland and grassland gives way to more uniform expanses of woodlands and wooded grasslands. The chief distinction between these and the forest habitats is that here the trees are often more widely scattered, are deciduous and have a lighter, more airy canopy, allowing enough light to reach the ground to support a luxuriant growth of perennial grasses. The term 'savanna' is often used for some of these habitats but for a variety of reasons is now to be avoided. A wide belt between about 8°–10°N and 10°–16°S is dominated by the wettest of these habitats, a closed deciduous woodland consisting chiefly of *Brachystegia* spp., *Julbernardia* spp. and, especially north of the Equator, *Isoberlinia* spp.; much of this, especially in the south, is often referred to as MIOMBO. The grassier, more open habitats are characterized by frequent dry-season fires; the trees are characteristically thick-barked and fire-resistant, the grasses grow in dense clumps with roots and stems protected deep in the soil. The characteristic birds of the grassier habitats are grass-warblers *Cisticola*, weavers (Ploceidae) and estrildid finches (Estrildidae).

Semi-arid bushlands and deserts. Drier vegetation with small scrubby trees and bushes, and scattered annual herbs and grasses, dominate three areas—a belt along the southern edge of the Sahara (the Sahel), a block in the north-east from the Gulf of Aden to northern Tanzania, and another block centred on Namibia in the south-west. Trees and shrubs are predominantly species of *Acacia* and *Commiphora*, while baobab trees *Adansonia* are conspicuous at low altitudes in the east. The vegetation is so sparse that for most of the year the appearance of the landscape is dominated by the colour of the soil. Characteristic birds are coursers, bustards and larks, but the avifauna of the trees is also quite rich and these habitats support many Eurasian migrants. The birds show a variety of adaptations to the extreme conditions, including paler plumage than relatives in moister environments, and less sedentary behaviour; some species undertake regular migrations of many hundred kilometres south from the Sahel, notably Abdim's Stork *Ciconia abdimii* and the Grasshopper Buzzard *Butastur rufipennis*. True desert is found in the Sahara, in the Chalbi Desert of northern Kenya, along the shore of the Red Sea and in the Namib Desert of the south-west.

Montane regions. Between about 1,000 m and 3,500 m, the forest on most African mountains changes continuously in its species composition and in the growth form of its trees. The sharp division between lowland and montane forest so firmly stressed by Moreau (1966) and others is less widely accepted now (Diamond and Hamilton 1980). On isolated small mountains, and those near the coast (such as the Usambaras where Moreau worked), vegetation changes occur at lower altitudes, and possibly more sharply, than in forests nearer the centre of the continent. Above the tree-line there is often a zone of heathy bushes and low trees which merges into a more open moorland community of tussock-grasses, rushes, and, on the highest mountains, giant lobelias and ragworts. The 'Afromontane' zone of White (1982) contains many endemic plants and is recognized as a distinct floristic division, occurring on the scattered mountains of the Region in an archipelago-like distribution. Many bird species are common to this zone wherever it occurs, except in Ethiopia where the montane forest avifauna is notably depauperate. Moreau (1966) interpreted the disjunct distribution of these montane species as indicating that montane forest was previously much more widespread, but present historical evidence does not support this (see below).

History. Two major historical phenomena have shaped the present Afrotropical avifauna. Widespread volcanic and tectonic activity in the Miocene period, ending about 7 million years ago, raised the eastern and southern parts of the continent a thousand metres or so and generated most of the volcanic massifs there; it also broke the previous connection between the forests of Africa and those of Asia, a connection that is reflected in the affinities of the non-passerine forest avifauna (Snow 1980). The Quaternary period, from about 2 million years ago, has shown continued volcanic activity but has also suffered dramatic climatic changes related to the ice ages at higher latitudes. The classic description of the effects of these changes on the Afrotropical avifauna by Moreau (1966 and references therein) needs to be modified in at least two chief respects. First, the assumption that the distinction between lowland and montane forest is determined by temperature did not take into account the very major influence of moisture; second, the cold periods coinciding with the glacial maxima of the ice-ages were not also wet in Africa, as Moreau supposed—the so-called 'pluvials'—but extremely arid. The combined effects of these two points lead to the conclusion, which is supported by a variety of evidence from deep-sea cores to pollen diagrams, that montane forest was not continuous over much larger areas of Africa than it is now, as Moreau supposed was necessary to explain the occurrence of similar species on widely-separated mountains, but is probably as extensive now (apart from its recent reduction by man) as at any time in the last hundred thousand years (Diamond and Hamilton 1980 and references therein). The increased aridity of glacial periods confined forests to the most climatically stable areas; these 'refuges' are identifiable now as centres of endemism and species diversity within areas of apparently homogeneous habitat. During arid periods, the Sahara desert extended as far as 500 km south of its present boundary, and the Kalahari Desert occupied most of the area now occupied by the lowland rain-forest of Zaire and reached as far east as Victoria Falls as recently as 10,000 years ago.

Characteristic forms. Endemic Afrotropical taxa are few above the generic level: they include one order, the mousebirds, and 5 families—Hamerkop, Secretary-bird, guineafowl, turacos and wood-hoopoes, as well as the Ostrich (Struthionidae) which has become endemic, as it were, only by recent extinction elsewhere. The Region is particularly rich in francolins, bustards, barbets, honeyguides, larks, grass-warblers *Cisticola*, helmet-shrikes, shrikes and estrildid finches (Ploceidae and Estrildidae). The 2 species of oxpecker (Buphaginae) are of special interest because they have evolved as symbionts of the spectacular African fauna of large herbivorous mammals. On the other hand, the Region is poor in parrots and woodpeckers, and the number of species in the Region as a whole is substantially fewer than in the Neotropical Region.

One of the most dramatic features of the Afrotropical avifauna is the enormous influx of migrants from the Palearctic region in the northern winter (Moreau 1972). About a third of all Palearctic species winter wholly or mainly in the Region, occupying every habitat except lowland rain-forest and some reaching as far south as the Cape. Several species occasionally breed in their African 'winter' quarters, and the close affinity of many species of the southern grasslands with Palearctic species suggests that other African taxa may have originated in this way (Snow 1980). AFTERFEATHER: (also called aftershaft). This is a structure resembling a feather in miniature attached to the underside of a feather at the superior umbilicus. Six types may be recognized of which the most developed is that found in Casuariiformes, where the afterfeather closely resembles the main feather, so that each feather appears double. In its simplest type the afterfeather lacks an aftershaft (hyporachis) and merely consists of a row of barbs (an aftertuft) attaching to the rim of the superior umbilicus. It is found in the New World vultures (Cathartinae). Several groups entirely lack afterfeathers, e.g. Ostrich *Struthio*, pigeons, cuckoos and swallows. Most workers assume that the function of afterfeathers is to increase the thermal insulating property of the feathers. This is supported by the facts, (1) that they nearly always have a downy structure, (2) that they are best developed on body feathers, especially down and semiplumes, but small or lacking on remiges and rectrices, and (3) that some birds, e.g. ptarmigans *Lagopus*, have larger afterfeathers in the winter than in the summer plumage. See FEATHER; FEATHERS, NUMBERS OF.

AGAMI: *Agamia agami* (see HERON).

AGE: elapsed time, since hatching, of a live bird. Analogous to age in human beings but only able to be measured accurately for birds for those individually marked as nestlings (see MARKING). In studies of populations (see ECOLOGY) the age of first breeding is particularly important: for small temperate zone passerines it is generally during the first summer but may be deferred for several years in larger species (averages ninth year for Fulmar *Fulmarus glacialis*). Even when breeding has started, age may have a significant effect on productivity as demonstrated by Coulson and White (1958) for the Kittiwake *Rissa tridactyla*. Older Kittiwakes were generally in better condition, returned to the colonies earlier in the breeding season, occupied the 'best' sites, laid larger eggs and produced bigger clutches which gave rise to more and healthier young than recent recruits to the breeding population. Such age-effects have now been demonstrated for a wide variety of birds, including small passerines, and are a very significant feature in the population ecology of many species.

The age composition of any population of birds depends on the species' mortality which is the fractional part of the population alive at the beginning of a period but dead by its end. Similarly the survival is the fractional part still alive at the end of the period, and so $S = 1 - M$ where S and M are the survival and mortality rates expressed as proportions. In many studies these figures are calculated over a year but they may also be calculated monthly or over a particular phase of the bird's life e.g. breeding season mortality. The earliest calculations of mortality were made by Lack (1943), who used reports of birds ringed so long before the analysis that no further reports could be expected; this is known as the Lack or complete data method. Later Haldane (1955) devised a maximum likelihood analysis allowing for the effects on the mortality estimate of ringed birds which were still alive: this enables the incomplete data to be included in the calculation. Both methods assume that the annual mortality rate of adult birds remains constant from year to year. Later methods, often involving detailed modelling and computer analysis, have attempted to allow both for variation in mortality rates from year to year (for instance changes related to the severity of winter weather) and for variation with the age of the bird.

Wandering Albatross *Diomedea exulans* male 30 years old. (*Photo: J.P. Croxall*).

The sample of dead birds found is much more likely to include birds dying through inexperience (e.g. dead on road, brought in by cat or stunned against a window) than those dying under more natural circumstances (e.g. egg-bound on the nest, at a secluded roost or on migration). In fact most birds die through inexperience, for they are constantly at risk from predators, disease, accident and food shortage. Newly independent fledglings are at greatest risk and mortality gradually decreases as the birds become more experienced. For many species mortality seems to be least just after the birds have bred for the first time, and is fairly constant thereafter. The two graphs (Fig. 1) show the gradual loss of individuals from a cohort of youngsters reared in the same year—one species (solid line) is long-lived with a delay of several years before breeding and the other (broken line) is a short-lived passerine breeding in its first summer. A few analyses show that particularly old birds are less likely to survive: this was first demonstrated for the Common Tern *Sterna hirundo* with increased mortality from the 19th year onwards. Where the species concerned has been studied intensively, the results of mortality analyses can be compared with known productivity and population figures. Mortality estimates computed from dead ringed birds are often high when related to such figures although survival estimates, from repeated sightings of live marked birds, are often compatible with productivity and population figures. Hence the sample of dead birds found is probably biassed towards younger rather than older individuals.

Mortality may vary between the sexes. Females are particularly at risk during the breeding season when they must produce and lay the clutch and generally undertake the major share of incubation duties. On the other hand, in some species the males have 'dangerous' displays, including conspicuous song-flights and the regular use of song-posts which may put them at risk; and territorial chases may result in their death from traffic accidents or other collisions. In species with marked sexual dimorphism, size or colour differences may also be responsible for differences in mortality.

If a steady annual adult mortality is assumed it is possible to calculate the Expectation of Further Life of an adult bird. The simplest formula is $2 - M/2M$ where M is the annual adult mortality. This gives the expected further life-span of a bird on reaching adulthood. However, for many

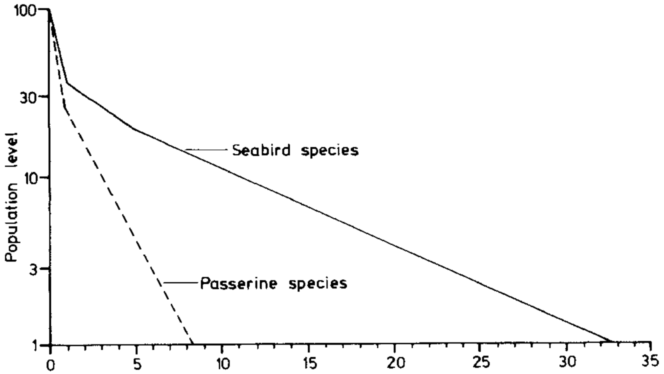

Fig. 1. The decay of two bird populations of 100 individuals at fledging. The solid line is of a seabird with 65% first year mortality, 15% *p.a.* for 4 pre-breeding years and 10% *p.a.* thereafter. On average one bird will live to 32 years of age. The broken line is for a passerine with 75% first year mortality and 35% *p.a.* thereafter: one of these would, on average, last into its ninth year. N.B. the vertical scale (population) is logarithmic.

small passerine species in the northern temperate regions, 90% or more of all eggs laid may fail to produce young that attain adulthood. Indeed, for a bird population to remain stable, each adult that breeds needs only to replace itself. Thus each adult needs, on average, only to rear two young to maturity during its life as a breeding bird—two need to be reared as each breeding attempt involves an adult of each sex. The huge changes in life expectation as mortality rates vary are evident from the following examples:

Bird	*Annual adult mortality*	*Expectation of further life of an adult*
Small passerine	70%	0.9 year
Woodpigeon *Columba palumbus*	40%	2.0 years
Swift *Apus apus*	20%	4.5 years
Yellow-eyed Penguin *Megadyptes antipodes*	10%	9.5 years
Royal Albatross *Diomedea epomophora*	3%	32.8 years

Longevity records (examples of extreme old age) provide concrete evidence of age-span but may be difficult to interpret. Species for which many recoveries have been reported are more likely to include a particularly old individual rather than those rarely marked or from parts of the world where ringing has only recently been introduced. The two tables of longevity records show the maximum recorded elapsed time between ringing and recovery of wild birds. Most have been taken from Rydzewski (1978, 1979) with additional data from British ringing files. The tables are in descending order of age and include, if available, one record (maximum three) for each main family or group. Clearly the larger birds can be expected to live longer than the smaller ones when species are compared. Lindstedt and Calder (1976) investigated the relationship between longevity records (4.08–38 years) and body mass (3.5–12,200 g) of 152 species in the wild. They obtained a good correlation between the two and showed that longevity was roughly proportional with the fifth root of body mass—$L = 17.6\,M^{0.20}$ where L is longevity in years and M body mass in kg. Thus, on average, a doubling of body mass would lead to 15% greater longevity and body mass has to increase 32-fold for a doubling in longevity (e.g. Blue Tit *Parus caeruleus* to Tawny Owl *Strix aluco*). The non-passerine list shows that waders and terns survive well despite being relatively light species. Ducks, game-birds and kingfishers mostly appear in the lower part of the table and generally lay large clutches. Among the passerines the larger temperate species head the list because very large files of recoveries are available, but it is likely that tropical passerine species will eventually be shown to be much longer lived than temperate ones (Fry 1980). Extreme longevity is symptomatic of K-SELECTION and poor longevity of R-SELECTION (see also ECOLOGY).

The records from bird collections and zoos show that captive birds live much longer than those in the wild. London Zoo in 1982 had two birds in its collections which had been resident for 50 years: a Common Caracara *Polyborus plancus* since 1932 and a Sulphur-crested Cockatoo *Cacatua galerita* since 1925. The cockatoo had been with its previous owner since about 1902 and was certainly more than 80 years old. This may be the oldest bird ever reliably recorded. Also 75% of London Zoo's Night Herons *Nycticorax nycticorax* were still alive at an age (about 8 years) when 99% of wild Grey Herons *Ardea cinerea* would have died (no data were available for Night Herons in the wild).

In normal circumstances there is no possibility of accurately measuring the age of a wild bird without marking it but instances exist of individually recognizable birds, e.g. albino waders, frequenting the same place for a decade or more. Detailed work on Bewick's Swan *Cygnus columbianus* has shown that individuals can be recognized, over periods of many years, by their bill patterns (see DUCK). One individual, Lancelot, was recorded over 19 winters. However it is often necessary to describe the age of a bird in the field or in the hand, in so far as it can be assessed. For nestlings growth is so rapid that measurements of bill, tarsus and primaries may often be used to estimate the age to within a day or so from hatching (see GROWTH) but, after fledging, a bird's age can usually be estimated only within broad limits, generally on the basis of age-specific plumages (see PLUMAGE; MOULT), from the colour and growth of the bare parts or, for young birds, from the incomplete ossification of the skull. Birds pass through a sequence of plumages and age has normally been recorded by a simple description of the bird's current plumage phase. The progression for a northern temperate passerine is as follows:

Month 6 7 8 9 10 11 12 1 2 3 4 5 6 7 8 9 10 11 12 1 2 3 4 5
Moult Major Minor Complete Minor
Juvenile *First winter* *First summer* *Adult*

First winter and first summer may be combined into *First year.*

Adult is used for the rest of the bird's life as it has reached its definitive adult plumage.

These simple descriptions of age for free-flying birds are liable to confusion, especially between different groups of workers, and are, in any case, not adequate for large non-passerine species with a long sequence of identifiable immature plumages spanning several years. Bird ringers, in the Holarctic, now use a precise code based on the calendar year:

Longevity records—Non-passerines	*years*
Oystercatcher *Haematopus ostralegus* +	36.0*
Royal Albatross *Diomedea epomophora* +	35.9
Arctic Tern *Sterna paradisaea* +	33.9*
Guillemot *Uria aalge*	32.1*
Black-headed Gull *Larus ridibundus*	32.1
Osprey *Pandion haliaetus*	31.2
Mallard *Anas platyrhynchos*	29.0*
Honey Buzzard *Pernis apivorus*	28.9*
Spoonbill *Platalea leucorodia*	28.2*
Long-eared Owl *Asio otus*	27.7*
Black-throated Diver *Gavia arctica*	27.0
White Stork *Ciconia ciconia*	26.2*
Manx Shearwater *Puffinus puffinus* +	26.0
Purple Heron *Ardea purpurea*	25.5*
Northern Fulmar *Fulmarus glacialis*	23.0
Blue-faced Booby *Sula dactylatra*	22.9*
Pink-footed Goose *Anser brachyrhynchus*	22.1
Mute Swan *Cygnus olor*	21.7
Swift *Apus apus* +	21.1*
Shag *Phalacrocorax aristotelis*	20.6*
Red-bellied Woodpecker *Melanerpes carolinus* +	20.4
Leach's Petrel *Oceanodroma leucorhoa*	19.9
Little Blue Penguin *Eudyptula minor* +	18.9*
Coot *Fulica atra*	18.3
Arctic Skua *Stercorarius parasiticus* +	18.1*
Mourning Dove *Zenaida macroura*	17.1*
Kestrel *Falco tinnunculus*	16.2*
White Pelican *Pelecanus erythrorhynchus*	16.1*
Kea *Nestor notabilis*	14.1
Little Grebe *Tachybaptus ruficollis* +	13.1
Cuckoo *Cuculus canorus*	12.9*
Kookaburra *Dacelo novaeguineae* +	12.3
Capercaillie *Tetrao urogallus*	9.3*
Quail *Coturnix coturnix*	7.6
Ruby-throated Hummingbird *Archilochus colubris* +	5.0

Ringer's age categories	*European code*	*American code*
Free flying: age unknown	2	U (Unknown)
Hatched this year	3	HY (Hatching Year)
Hatched before this year	4	AHY (After Hatching Year)
Hatched last year	5	SY (Second Year)
Hatched before last year	6	ASY (After Second Year)
Hatched the year before last	7	TY (Third Year)
Hatched earlier still	8	ATY (After Third Year)

AGGRESSION: threatening behaviour and attack. Overt aggression, in the form of pure physical assault, is usually intermingled with or overlain by a variety of postures, movements and vocalizations which serve as threat, repelling or intimidating the opponent without actual combat. A general term for this mixture of attack, threat and withdrawal is 'agonistic behaviour'. Certain behaviour must be distinguished from true aggression or the category becomes so diffuse as to be useless. For example, bird song may induce withdrawal and thus make unnecessary the physical defence of a territory, but its motivation is distinct from that of attack or threat. Raptorial killing is separated from true aggressive behaviour for similar reasons. Whilst most aggressive behaviour occurs within a species, true aggressive behaviour does occur between members of different species where these compete for resources.

Longevity records—Passerines	*years*
Blackbird *Turdus merula*	20.3
Starling *Sturnus vulgaris*	20.0
Rook *Corvus frugilegus*	19.9*
Bullfinch *Pyrrhula pyrrhula*	17.5
Swallow *Hirundo rustica*	16.0*

Treecreeper *Certhia familiaris*	6.8*
House Wren *Troglodytes aedon* +	6.2

Great Skua *Stercorarius skua* aggressive display. (*Photo: E.J. Hosking*).

In wild birds, fighting is rarely prolonged and threat is often used rather than overt fighting. This is because fighting involves costs: physical combat is exhausting, carrying a risk of injury and an increased risk of predation. Set against these costs are the benefits of gaining or owning the contested item. The theory of natural selection indicates that the level of aggression shown will depend on the balance between these benefits and the costs involved. Although it is difficult to quantify these it has, for example, been possible to measure the greater yield of flowers within the territory of sunbirds *Nectarinia reichenowi* compared with the undefended flowers outside.

Aggressive interactions may lead to the formation of a DOMINANCE hierarchy, within a group of birds, although species differ in the readiness with which this occurs. The hierarchy is best regarded as a way of reducing the detrimental effects of frequent aggressive interactions, rather than a desirable feature of social structure, but its presence may have important implications for population dynamics (see ECOLOGY). In some species, dominance rank in winter flocks is related to earlier territorial boundaries,

Pheasant *Phasianus colchicus* two males fighting. (*Photo: F. Pölking*).

an illustration of the links between aggression in different contexts.

Aggression has sometimes been regarded as an inborn drive which must be suppressed or re-channelled for successful social life. But since it enables birds to compete for food, nesting and roosting sites and mates, and spaces them out appropriately, its occurrence can be better understood in most instances in terms of the benefit it brings to the individual involved. Aggression cannot be a unitary phenomenon across such a wide range of contexts, but it appears to share causal factors in different contexts, so that its subdivision into several distinct categories is inappropriate. Outside the reproductive season, one common factor is physical proximity. Factors such as hunger, which increases fighting over food, produce this effect by bringing birds together rather than by increasing their aggressiveness. Whilst most non-reproductive fighting can thus be explained in terms of defence of the individual distance (a small defended area, centred on the bird), reproductive fighting may involve defence of a larger, fixed territory. In the Chaffinch *Fringilla coelebs*, intermediate stages between defence of the individual distance and defence of the territory can be found. The gradual modification of the defended area in this species, under the influence of androgens and experience during the spring, demonstrates close links between reproductive and winter fighting. But in the weaver bird *Quelea quelea*, the hormone which stimulates individual distance fighting (luteinizing hormone) is not the same as that which stimulates fighting over nest materials (testosterone). Thus the control of aggressive behaviour may differ in detail in different contexts, and generalizations must be made with due care. Androgens such as testosterone are important in the control of aggression in many species, and female phalaropes *Phalaropus* spp., which set up and defend the territory whilst the males incubate, have high levels of androgen. Other hormones which modify aggressive and defensive behaviour in various species are oestrogens, progesterone, prolactin and follicle stimulating hormone (FSH), but the details of such hormonal effects will probably depend on the reproductive cycle of the species concerned.

Although most aggressive behaviour can be understood in terms of benefit to the individuals involved, the effects of pain and frustration (which increase the probability of aggression) have not yet been explained in this way. Demonstrations of this effect of frustration in pigeons *Columba livia*, hens *Gallus gallus*, and Quail *Coturnix coturnix* have all involved frustration of feeding, and so it is possible that the effect could be understood in terms of the tactics of feeding in a flock. Some examples of the 're-direction of aggression', for instance where a Chaffinch which has just lost a fight attacks a feeding subordinate without provocation, may also be explicable in this way, rather than implying that aggression must be discharged once it has been aroused, as the term 're-direction' suggests. In a reproductive context, behaviour which was once described as re-directed 'aggression' (the 'swoop and soar' performance of the Black-headed Gull *Larus ridibundus*) has proved to be purely sexual in motivation, and need not be explained in terms of the re-channelling of aggressive motivation aroused by the mate.

Most aggressive behaviour is triggered by external stimuli. Despite the fact that fighting cocks will work for the opportunity to threaten a rival in the laboratory, there is little evidence that wild birds show appetitive behaviour for fighting, except as a consequence of learning. The European Robin *Erithacus rubecula*, for instance, will go specifically to places at which it has recently had fights when patrolling its territory, and may even

Snow Goose *Anser caerulescens* aggressive display. (*Photo: A.V. Krechmar*).

Galapagos Hawks *Buteo galapagoensis* fighting. (*Photo: F. Pölking*).

attack an imaginary opponent if the effect of previous experience is very intense. External stimuli from the territory, the mate and the family may all play a part in triggering aggression in different species, but stimuli from the opponent are of greatest importance. Many aspects of the form, posture and bearing of a bird determine whether it will be attacked, but some features are so important that they are termed RELEASERS, for instance the red breast of the European Robin. (Some features, such as the nape band of the Kittiwake chick *Rissa tridactyla*, have the opposite effect, inhibiting attack). Such badges on the plumage also modify the way in which birds respond to aggression by the bearer. In the Red-winged Blackbird *Agelaius phoeniceus* experimental concealment of the male's red epaulets reduced the ability of the subjects to win contests and retain their territories, since their opponents refused to submit.

Birds use a variety of postures in threat; in many species these contain intention movements of attack, and have evolved from behaviour reflecting ambivalence towards the opponent. The effect of threat postures has been analysed by noting what posture is shown in an interaction, and correlating this with the opponent's response, and also by presenting dummies mounted in a particular posture and noting the response. Threat postures may produce withdrawal without the need for physical attack. There has been dispute over whether they do this by providing information about the signaller's intention to attack (statements of intention would be open to cheating), and the processes involved in the interaction are not yet understood. Aggressive elements are also visible in the form of many courtship and parental displays in birds, but the role of aggression in courtship is not fully understood (see AMBIVALENCE).

House Martin *Delichon urbica* attacking Swallow *Hirundo rustica* when collecting nest material (mud). (*Photo: H. Schouten*).

The development of aggression has been studied in detail in only a few species, including the Junglefowl *Gallus g. spadiceus*. Its adult aggressive behaviour is only gradually built up from components which appear independently in the young bird. Although the process appears to allow opportunities for learning in the integration of these motor components, isolation during rearing disturbs not the form of the motor patterns, but rather the way in which the aggressive behaviour is used. For example, isolation-reared cocks do not switch from aggression to sexual behaviour when the hen crouches. This evidence that individuals require social experience during rearing to show normal aggressive behaviour parallels that for many higher animals, but we cannot yet explain the details of its pattern of development. AGONISTIC: term applied to behaviour relating to combat (see AGGRESSION).

AIGRETTE: see PLUME.

AILUROEDINAE: see BOWERBIRD.

AIR-PASSAGES; AIR-SACS: see RESPIRATORY SYSTEM.

AIR SPEED: see FLIGHT, SPEEDS OF.

AKALAT: substantive name used in West Africa for *Malacocincla* ('*Illadopsis*') spp. (for subfamily see BABBLER), and in East Africa for chats of the genus *Sheppardia* (for subfamily see THRUSH).

AKEPA: *Loxops coccinea* (see HAWAIIAN HONEYCREEPER).

AKIALOA: *Hemignathus obscurus*, also called 'Sicklebill' (see HAWAIIAN HONEYCREEPER).

AKIAPOLAAU: *Hemignathus wilsoni* (for family see HAWAIIAN HONEYCREEPER).

ALA MEMBRANA: the wing membrane, on the posterior margin of the forewing and manus, from which the remiges grow (see WING).

ALAR: pertaining to the wing.

ALARM: expressed, like WARNING, either visually or vocally, with the distinction that there is not necessarily a warning function, although this may be the effect on other individuals.

Great Spotted Woodpecker *Dendrocopos major* juvenile showing alarm. (*Photo: A.T. Moffett*).

ALA SPURIA: the alula or BASTARD WING (see WING).

ALAUDIDAE: a family of the PASSERIFORMES, suborder Oscines; see LARK.

ALAUWAHIO: *Loxops maculata* also called Hawaiian Creeper (for family see HAWAIIAN HONEYCREEPER).

ALBATROSS: see PETREL. See photos AGE; DISPLAY; FLIGHT.

ALBINO; ALBINISM: see PLUMAGE, ABNORMAL.

ALBUMEN: see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA; EGG.

ALCAE: see under CHARADRIIFORMES; AUK.

ALCEDINES; ALCEDINIDAE: see CORACIIFORMES; KINGFISHER.

ALCEDINOIDEA: see under CORACIIFORMES; KINGFISHER.

ALCIDAE: see under CHARADRIIFORMES; AUK.

ALETHE: generic name used as substantive common name for species of chats (see THRUSH).

ALIMENTARY SYSTEM: consists essentially of (1) the buccal apparatus (bill, mouth, tongue, salivary glands and sensory receptors), (2) the oesophagus (and crop if present), (3) stomach (proventriculus and ventriculus), (4) the small intestine (duodenum and ileum), (5) the large intestine (caeca, colon and cloaca) and (6) various glands and organs including the liver, biliary system and gall-bladder, the pancreas and the bursa of Fabricius. Most of the these components are derived from the endoderm during the development of the bird in the egg.

During the course of evolution, modern birds have acquired mechanisms for the regulation of body temperature, a high metabolic rate, powered flight and a world-wide distribution. Consequently birds feed on relatively large quantities of a great variety of substances including fish, flesh, carrion, fruit, roots, leaves, seeds, pollen, nectar and all kinds of invertebrates (see FEEDING HABITS). Their diets may change as they mature, as the seasons change or as a result of migration. Nevertheless, unless wild birds are markedly different from their domesticated relatives, we may assume that the food of any bird must supply about forty chemical compounds to provide the energy and nutrients for growth, activity, reproduction and general maintenance (see NUTRITION). The alimentary system has become adapted to obtain and process the food and extract the nutrients. Several features of the avian alimentary system are probably related to the fact that most birds are supremely modified for powered flight. For example, the relatively heavy cephalic apparatus of many mammals is not present in modern birds. Instead, trituration occurs, when necessary, in the ventriculus or gizzard, which is located deep in the body where equilibrium will not be disturbed during flight. Other features of the tract are assumed to be functional adaptations for the digestion of a particular diet (see below).

Morphology and structure. Some general information about the form of the alimentary tract is given in Figs 1 to 20. Details of the bill are given elsewhere (see BILL). The mouth accommodates the tongue, which is as varied in form as the bill (see TONGUE), and the salivary glands. The oesophagus leads out of the mouth and enters the proventriculus (Fig. 1). In some birds, a thin-walled pouch, called the crop or ingluvies (Figs 4, 6 and 8), extends from the ventral wall of the oesophagus. The oesophageal lining consists of longitudinally-folded stratified squamous epithelium which is capable of considerable distension (Fig. 5). The stomach comprises the secretory or glandular proventriculus and the muscular ventriculus or gizzard (Fig. 1). The degree of development of the secretory and muscular tissue can often be correlated with the nature of the diet (Figs 9 and 11). Much of the thickness of the proventricular wall is due to the proventricular glands consisting of secretory cells some of which produce mucus while others (oxyntico-peptic cells) secrete both hydrochloric acid and pepsinogen (pepsin precursor). The ventriculus, in birds which ingest hard or fibrous food, is generally very muscular and may contain grit or other abrasive material so that it functions not unlike a ball mill. The ventricular lumen is lined by a polysaccharide-protein substance known as koilin which protects the tissues from acidic and abrasive damage.

The pylorus connects the stomach with the small intestine which consists of the duodenum and ileum (Fig. 1). The pancreas is usually located between the descending and ascending limbs of the duodenum and its digestive secretions usually enter the small intestine at the caudal end of the ascending limb near the entry of the bile ducts. This point may be taken as the end of the duodenum and the start of the ileum. Most birds possess a gall-bladder, which is usually embedded to some extent in the right lobe of the liver. There are usually two bile ducts which carry bile either directly from the liver or in a more concentrated form from the gall-bladder into the small intestine (Fig. 2).

The length of the ileum, which is often smaller in diameter than the duodenum, appears to be related to the nature of the diet. Carnivorous birds tend to possess relatively short intestines and herbivorous birds usually have long ones. The large intestine, consisting of the paired caeca, colon and cloaca, extends from the ileo-caeco-colic junction to the vent (Fig. 1). The caeca are variable in size and shape; some birds (herons) possess one caecum and not two (Figs. 12–18) while others (kingfishers) do not seem to have any obvious caeca. The complex cloaca receives and discharges intestinal and caecal faeces and urine from the bird (Fig. 3) (see DROPPINGS). In young birds, a small diverticulum called the bursa of Fabricius extends from the mid-dorsal wall of the cloaca. The bursa has an important immunological function similar in some respects to that of the thymus.

Throughout its length, the alimentary tract is made up of concentric layers known, in the small intestine, as the mucosa, submucosa, muscularis and serosa (Fig. 19). The mucosa consists mainly of villi which are formed from a layer of epithelial cells enclosing the lamina propria (Fig. 20). The lamina contains blood vessels, connective tissue and many white corpuscles which contribute to the immune responses of the bird. Numerous white corpuscles are to be found in the caecal tissues and the caecal tonsil, which is located near the ileo-caeco-colic junction and is reminiscent of a lymph node. The surfaces of many of the epithelial cells are composed of numerous microvilli. The effect of this enormous elaboration of intestinal surface membrane, together with the increase in surface area due to the villi, is to provide a very large surface area for the absorption of nutrients from the contents of the intestinal lumen. Goblet cells, which produce mucus, are also located in the epithelium. There are usually more goblet cells in the posterior small intestine and the caeca than in the duodenum. The submucosa is similar in appearance to the lamina propria although the white corpuscles may be found in discrete colonies and more connective tissue is present in addition to nerve fibres and larger blood vessels. The muscularis consists of a relatively thick coat of circular muscle and a thinner layer of longitudinal muscle (Fig. 19). The outer serosal layer is formed from connective tissue.

The principal blood vessels of the post-pyloric part of the tract of the domestic fowl are illustrated in Fig. 1. Most blood is supplied to this part of the tract by the coeliac, anterior and posterior mesenteric arteries which originate from the dorsal aorta. The blood leaves the small intestine along the veins of the hepatic portal system which transports recently absorbed nutrients directly to the liver (see METABOLISM). The tract receives an extensive autonomic or sympathetic innervation which is partially responsible for regulation of the variable motility of the tract.

Physiology of digestion. Digestion involves the sequential mechanical and chemical breakdown of food into components which are in a suitable condition for absorption. The alimentary tract provides not only the agents for this process but also the physico-chemical conditions for their efficient action. The intestinal motility serves to move the food along the tract, to mix the food and agents of digestion for the optimum time and to present the products of digestion to the absorptive surface of the small intestine.

Abbreviations: **b.b.** brush border; **b.v.** blood vessel; **c.** caecum; **cl.** cloaca; **co.** colon; **d.** duodenum; **e.c.** epithelial cell; **g.c.** gland cell; **i.** ileum; **l.** lumen; **l.p.** lamina propria; **m.** mucosa; **sm.** submucosa; **mu.** muscularis; **p.** pancreas; **pv.** proventriculus; **s.** serosa; **u.** ureter; **v.** ventriculus.

In birds, food is moistened and swallowed quickly. The salivary glands undoubtedly produce mucus, but evidence suggests that the secretion of salivary amylase varies from species to species. The lining of the oesophagus also produces a lubricant and the food may pass straight into the proventriculus or be diverted and stored in the crop or in the extensible oesophagus. The period for which food is retained in the crop is very variable, but microbial fermentation processes may occur when it is delayed for several hours. The crop of the HOATZIN *Opisthocomus hoatzin* is muscular and is capable of squeezing the sap out of the leaves on which the bird feeds. The control of motility in the anterior part of the tract allows the direction to be reversed and regurgitation is an important process in many birds (see PARENTAL CARE; PELLET). On entering the proventriculus, the food is soon mixed with more mucus, hydrochloric acid and pepsin which begins the digestion of protein. This phase of digestion continues in the ventriculus where the muscular contractions break up the food and ensure a thorough mixing of pepsin with its substrate. The activity of pepsin depends on a low hydrogen ion concentration (*c.* < pH 3.5); the hydrogen ion concentration in the oesophagus and post-pyloric portion of the tract is usually maintained at about pH 6.5 to 7.5 which favours the activity of the other enzymes involved in digestion.

The partially digested food or chyme is forced out of the ventriculus through the pylorus into the duodenum where the main phase of chemical digestion begins. Under hormonal control, pancreatic juice and bile enter the intestinal lumen. Pancreatic juice contains a large amount of bicarbonate, which neutralizes the proventricular acid, and several enzymes including (in the domestic fowl) amylase, cholesterol esterase, esterase, lipase, phospholipase, trypsin and chymotrypsin. Bile contains the sodium salts of cholic, chenodeoxycholic and lithocholic acids. These salts are detergents which emulsify fats prior to enzymic hydrolysis by esterases, lipases and phospholipases, and also facilitate the absorption of the end products of fat digestion. Pancreatic amylase together with various disaccharidases synthesized by the mucosa hydrolyse certain carbohydrates to their constituent sugars which are then absorbed. Simultaneously, the hydrolysis of the polypeptides, which were liberated by the action of pepsin, to amino acids is completed by the trypsin, chymotrypsin and peptidases.

The chyme continues to be propelled rather more slowly along the tract and gradually indigestible materials accumulate posteriorly. Cellulose and other complex carbohydrates often form the major proportion of the contents of the large intestine together with many micro-organisms. Some of the indigestible material together with urine from the cloaca (Fig. 3) are forced by retroperistalsis into the caeca where as many as 10^{11} microbial cells per g of caecal contents may be found. The caecal bacteria of some birds, particularly galliforms, degrade plant products to volatile fatty acids which may contribute significantly to the energy budget of the bird. In other respects, the evidence for the contribution of the intestinal flora to the nutrition of the bird is equivocal; birds given an adequate diet can be reared in isolators in a germ-free state. Similarly, the functions of the caeca are not fully understood. Caecal tissue may be involved in water reabsorption, which also occurs in the colon, and in the immune responses. However, domestic birds continue to grow and develop normally in the laboratory after surgical removal of the caeca.

Certain parts of the anterior alimentary tract have acquired secondary functions during the evolution of some birds. The cells of the crop lining in both sexes of pigeons liberate a nutrititive substance which is regurgitated and fed to the squabs (see CROP MILK). The cells of the proventriculus in some species of PETREL probably produce the oily secretion which is vomited and considered to have a defensive function. Secretions from the salivary glands are used to build the nests of various species of cave swiftlet (see EDIBLE NESTS).

Generalizations about the form and function of the avian alimentary tract are difficult to make. First, the ecological relationships and diets of birds are very diverse. Secondly, most knowledge of digestive physiology in birds has been obtained from studies on the domestic fowl. Thirdly, for any given species we may expect that the amount of food and water consumed, the motility of the tract and the digestive and absorptive processes will depend on (1) the bird's age, sex and metabolic rate, (2) its nutritional, physiological and reproductive status, (3) the availability of food, (4) the physical and chemical properties of the food and (5) various environmental factors. ALLANTOIS: see DEVELOPMENT, EMBRYONIC.

ALLELE: see GENETICS.

ALLELOMIMETIC: term sometimes applied to similar behaviour on the part of two or more individuals when some element of mutual stimulation is involved.

ALLELOMORPH: sometimes abbreviated to 'allele' (see GENETICS).

ALLEN'S RULE: that among the forms of a polytypic species, extensions of the body (in birds, chiefly bill) tend to be longer in the warmer parts of the total range and shorter in the cooler parts. It is generally accepted that the adaptive basis for this rule is reduction of heat loss in cold climates (see ADAPTATIONS, ENVIRONMENTAL; ENERGETICS).

ALLOCHRONIC: existing at different levels of geological time (applied to two or more forms)—contrasted with SYNCHRONIC.

ALLOCRYPTIC: adventitious concealing coloration, as distinct from 'cryptic' coloration adapted to the purpose.

ALLOMETRY: the differential growth of one part of the body in relation to the whole or to other parts (see SIZE).

ALLOPATRIC: mutually exclusive geographically (usually applied to taxonomically related populations)—contrasted with SYMPATRIC; also used in the substantive form, ALLOPATRY. Species whose geographical ranges are closely contiguous but do not overlap are generally referred to as PARAPATRIC.

ALLOPREENING: term that has been introduced (with 'autopreening' as antonym) for preening of one bird by another bird, usually of the same species and commonly a mate—often mutual (see COMFORT BEHAVIOUR).

Allopreening of white-eyes *Zosterops*. (*N. Kikkawa*).

ALLOSEMATIC: see under SEMATIC.

ALLOSPECIES: one of the constituent species of a SUPERSPECIES.

ALLOTYPE: term sometimes applied to a paratype of the opposite sex from the holotype (see TYPE SPECIMEN).

ALPHA-CHLORALOSE: see PESTS, BIRDS AS; TOXIC CHEMICALS.

ALTERNATE PLUMAGE: in species which have two different plumages a year, the alternate plumage is usually that worn during the breeding season. The term is modern American usage, its equivalent in classical terminology is nuptial plumage (see PLUMAGE).

ALTITUDINAL DISTRIBUTION: distribution in accordance with height above sea-level in a particular area. See also MONTANE.

ALTITUDINAL MIGRATION: a local movement in which the displacement is principally a matter of altitude.

ALTRICIAL: helpless when hatched (see YOUNG BIRD).

ALTRUISM: in its biological usage defined as an act that has the effect of increasing the chance of survival (or more precisely, FITNESS) of another individual, but decreases the chance of survival of the altruist. Avian examples of altruism include any form of care of the young, whether the 'parent' in question is the young bird's genetic parent, a foster parent (see BROOD-PARASITISM) or some other bird (as occurs when there are helpers at the nest; see CO-OPERATIVE BREEDING). An altruistic act may be purely behavioural, such as feeding or protecting the young, or it may involve some physiological or anatomical trait. A bee's sting, for example, is an altruistic adaptation, for the bee dies after stinging, but benefits its colony.

In its everyday usage for describing human behaviour, altruism not only means that some benefit is transferred to the recipient at a cost to the altruist, but also that the altruist intended to be kind. The subjective motive of the altruist is ignored in biology, and there is no reason to suppose that an animal intends to produce a biologically altruistic effect when it does so. If a cuckoo's foster parent really knew the effects of its action, it would probably stop feeding the cuckoo.

Evolution. The existence of altruism is a paradox for the Darwinian theory of evolution, which claims that those individuals that reproduce most will come to prevail in the population. This theory predicts that altruism, in which by definition the recipient reproduces more than the altruist, should not exist. Four solutions to the paradox have been suggested, of which three are at present thought valid.

One solution is the theory of GROUP SELECTION. Although altruism is not beneficial to the individual altruist, it does benefit the group of altruists and recipients as a whole; therefore a group containing altruists would produce more offspring in all than a group that lacked altruists. So by inter-group selection, altruism could come to prevail. Group selection is thought not to have much effect in nature because, when modelled precisely, it is found to require conditions that are unlikely to exist very often, and it is very open to 'cheating'.

The three mechanisms that can account for altruism are named kin selection, reciprocal altruism and manipulation. KIN SELECTION, an idea mainly developed by W.D. Hamilton, can explain altruism between genetically related individuals. Parents are selected to feed their young because by doing so they are helping an individual that is genetically similar. Altruism between other kinds of genetic relatives can be selected for exactly the same reason. So kin selection has probably been important in the evolution of some species with helpers at the nest. In some of these it has been confirmed that the helpers are close relatives.

Reciprocal altruism can explain altruism between genetically unrelated as well as related individuals. If an individual can expect to be repaid in the future for acting altruistically now, then it would be selected to be altruistic. Reciprocal altruism will only be favoured by natural selection in species which are sufficiently intelligent to recognize particular individuals. In other species, cheaters (who receive altruism but do not repay) will not be discriminated against, and the system will break down. This theory cannot account for the initial spread of an altruistic trait, since the mechanism relies on an altruist encountering a reciprocator.

The altruism of some birds to brood parasites is presumably explained by manipulation. The parasite is in some way able to deceive, or manipulate, its foster-parent into feeding it.

Although these mechanisms by which altruism might evolve have been identified, few cases of altruism have been studied in sufficient detail for it to be known which mechanism was responsible for its evolution. M.R.

Dawkins, R. 1976. The Selfish Gene. Oxford.

ALULA: see WING.

AMADINI: see ESTRILDID FINCH.

AMAKIHI: *Loxops virens* (for family see HAWAIIAN HONEYCREEPER).

AMAZON: substantive name of Neotropical *Amazona* spp. (see PARROT).

AMBIENS: a muscle of the leg (see MUSCULATURE). The presence or absence of this has been used as a taxonomic character. Garrod (1874) even proposed to divide birds into two subclasses, Homalogonatae ('typically-kneed', i.e. ambiens present) and Anomalogonatae (ambiens absent), but his classification produced too many inconsistencies in relation to other characters and was soon abandoned. The ambiens is a reptilian feature and, broadly speaking, is present in what we regard as the more primitive groups of birds and absent from the more highly developed, including the Apodiformes and the Passeriformes. It may be noted that the ambiens is present in the Falconiformes but not in the Strigiformes; and also that differences in this respect occur within certain groups, notably the Psittacidae and the Columbidae.

AMBIVALENCE: term applied to behaviour that is the outcome of two (or more) conflicting tendencies, such as approach and avoidance, or attacking and copulating with the partner. Ambivalent motivation is present in many social interactions. For instance, among Gannets *Sula bassana*, in which the male is exceptionally aggressive towards the female even in well established pairs, the male bites the female's nape during copulation, revealing the presence of aggressive as well as sexual tendencies during this act.

During phylogeny, ambivalent behaviour has given rise to social displays used in communication. Some displays are a mosaic of elements of the conflicting tendencies. The 'upright posture' of the Herring Gull *Larus argentatus*, used in threat, includes a downward pointing bill and upward stretched neck (preparations for a pecking attack) and raised carpal joints (preparation to deliver a wing blow) combined with signs of fear, a withdrawn neck and flattened plumage. Since the posture combines elements of both tendencies, it is termed formally ambivalent. Where the elements of the conflicting tendencies are shown in rapid alternation (for instance in 'pendulum fights' of songbirds at a territorial boundary) the term successive ambivalence may be used. Where behaviour involves only the elements which are common to both conflicting tendencies, the term compromise activity is used. For example, in a conflict between flying towards and sidling towards an object, buntings (*Emberiza* spp.) show tail flicks, a component of both flying and sidling.

The motivation of an ambivalent movement may be inferred firstly by scoring the overt behaviour shown in rapid alternation with it ('time score method'). For instance, agonistic postures tend to alternate with attack and escape rather than with feeding or preening; but where displays alternate with other displays, this method is not helpful. Secondly, the context in which the behaviour is shown can be examined. If stimuli for two incompatible types of behaviour are known to be present, it is likely that the behaviour seen is ambivalent, and both 'natural experiments' and laboratory experiments can provide evidence of this sort. Thirdly, the orientation adopted during the act may also provide an indication of subtle variations in motivation. Finally, where a movement is formally ambivalent, the form itself may provide clues to its motivation, although the possibility that the movement has become divorced from its original motivation during the course of evolution must be considered. (Comparisons between species using this type of evidence provided the first indications of the importance of ambivalence in social behaviour.) Physiological work, in which areas of the brain were stimulated electrically, had been expected to provide a further line of evidence, but has proved difficult to interpret; it has not provided unequivocal support in any instance for analyses based on the behaviour alone.

The generality of the actual behavioural tendencies involved may vary considerably. Some agonistic postures depend specifically on the arousal of attack and escape tendencies, others on the arousal of the tendency to attack together with any incompatible tendency. 'Beak hiding' in the Kittiwake *Rissa tridactyla* occurs when fear interacts with any tendency towards approach or staying. In the buntings described above, the conflict was between tendencies to move towards the object in alternative ways.

The presence of ambivalence in some social interactions (for instance, during a fight) is easy to understand, but the reasons for its presence in others (such as mating) are less obvious. One possibility is that it is a consequence of the evolutionary origin of the signal postures used, which constrains future evolution much as the pentadactyl limb constrains the evolution of wings or flippers. Alternatively, it may represent a compromise between conflicting selection pressures on the individual. For example, aggressive courtship by the male dove *Streptopelia roseogrisea* (='*risoria*') delays ovulation, but may confer advantages in preventing cuckoldry. (N.T.) P.G.C.

Baerends, G.P. 1975. An evaluation of the conflict hypothesis as an explanatory principle for the evolution of displays. *In*: Baerends, G.P., Beer, C. & Manning, A. (eds.). Function and Evolution in Behaviour. Oxford.

Blurton-Jones, N.G. 1968. Observations and experiments on causation of threat displays of the Great Tit (*Parus major*). Anim. Behav. Monographs 1:75–158.

Delius, J.D. 1973. Agonistic behaviour of juvenile gulls, a neuroethological study. Anim. Behav. 21:236–246.

AMERICA: see NEARCTIC REGION; NEOTROPICAL REGION. Note that the term 'Middle America' is now much used to designate the area comprising Mexico, Central America, and Panama (the last being by political history part of South America), and sometimes including the West Indies. This usage has the consequence that 'North America' is often used in ornithological literature as excluding Mexico.

AMERICAN USAGE: as regards vernacular names, see under NAME, ENGLISH.

AMETHYST: *Philodice mitchellii* (for family see HUMMINGBIRD).

AMINO-ACIDS: see ENERGETICS.

AMNION: see DEVELOPMENT, EMBRYONIC.

AMNIOTA: term embracing reptiles, birds, and mammals.

AMNIOTIC CLOSURE: term for the protective sealing of the eyes and ears during the first few days of life in some birds, the function being analogous to that earlier performed for the embryo by the amnion (see GROWTH; YOUNG BIRD).

AMPHIRHINAL: see NARIS.

AMPULLA: term for a vesicle, among other things the dilated end of a semicircular canal in the labyrinth of the ear (see HEARING AND BALANCE).

ANABOLISM: see ENERGETICS.

ANALOGUE: a structure adaptively similar to another but of basically different nature—compare HOMOLOGUE.

ANATIDAE: see under ANSERIFORMES; DUCK. The family comprises birds variously designated as 'ducks', 'geese', and 'swans'; but the application of these primary English names cuts across the taxonomic arrangement. For all, see under DUCK.

ANATOMY: bodily structure; also the science of this. By derivation, the term relates to internal structure as revealed by dissection, as contrasted with external form (see MORPHOLOGY); but the two terms have come to be used almost synonymously. Special branches of anatomy, such as osteology, deal with particular systems of the body; 'histology' refers to the microscopic structure of the tissues; 'morbid anatomy' is diseased structure, or the branch of pathology dealing with this. The structure of birds is dealt with in this work under the names of the systems, organs, and tissues of the body, and under other special heads.

ANCONEAL: pertaining to the elbow; sometime used with reference to the whole dorsal surface of the wing.

ANGEL: see RADAR.

ANGULAR: a paired bone of the lower jaw (see SKULL).

ANHIMAE; ANHIMIDAE: see under ANSERIFORMES; SCREAMER.

ANHINGA: used (America) as vernacular name of *Anhinga anhinga* (see DARTER).

ANHINGIDAE: see under PELECANIFORMES; DARTER.

ANI: substantive name of *Crotophaga* spp. (see CUCKOO).

ANIANIAU: *Loxops parva* (see HAWAIIAN HONEYCREEPER).

ANIMAL KINGDOM: in the perspective of the Animal Kingdom as a whole, the taxonomic position of birds may be defined as: Sub-kingdom Metazoa, Phylum Chordata, Subphylum Vertebrata, Class Aves (see AVES).

Parker, T.J. & Haswell, W.A. 1962. Text-book of Zoology. Vol. 2 (7th edn, revised by Marshall, A.J.). London.

Young, J.Z. 1981 (3rd edn.). The Life of Vertebrates. Oxford.

ANISODACTYL: having three toes directed forwards and one (hallux) backwards (see LEG).

ANKLE: the intertarsal joint—sometimes popularly mistaken, in birds, for the knee (see LEG; SKELETON, POST-CRANIAL).

ANKYLOSIS: a stiffening or fixed union of a joint, a natural feature of development in some joints, but also occurring as a pathological condition of joints that are normally movable (see SKELETON, POST-CRANIAL).

ANOMALOGONATAE: see AMBIENS.

ANOMALOPTERYGIDAE: see STRUTHIONIFORMES; MOA.

ANOSMATIC: without olfactory sense (see SMELL).

ANSERANATINAE: see DUCK.

ANSERES: see below.

ANSERIFORMES: an order, alternatively 'Anseres', comprising 2 suborders: Anhimae, Anseres; 2 families: Anhimidae (SCREAMER), Anatidae (DUCK). Although these groups show affinities in their anatomy, they are very different in external appearance and mode of life. Among the most obvious characters common to both are the unspotted eggs and the nidifugous young clad in thick down. In the Anseres (in the subordinal sense) the front 3 toes are connected by a web and the small hind-toe is placed high; in the Anhimae there is only a slight web, and the hind-toe is long and on the same level as the others. In the Anseres the bill and tongue have special characteristics.

ANTAGONISTIC DISPLAY: see DISPLAY.

ANTARCTIC: usually defined as the continent of Antarctica (including the Antarctic Peninsula), its offlying islands, sea ice and surrounding ocean and islands northwards to the Antarctic Convergence, the circumpolar boundary where north-flowing Antarctic surface water sinks beneath warmer, south-flowing sub-Antarctic water.

At the water surface this shows as a zone in which temperature changes by 3°C in half a degree of latitude and whose mean position is usually constant to within 100 km, roughly following the 50°S parallel in the Atlantic and Indian Oceans but lying between 55°S and 62°S in the Pacific Ocean.

Biologically the Antarctic can be divided into several regions. The continental Antarctic region comprises the central high plateau and coastal fringe zones, the latter including Peter I Øya, Scott and Balleny Islands and the east coast of the Antarctic Peninsula south of *c*. 64°S. The maritime Antarctic region includes the west coast of the Antarctic Peninsula and its offshore islands to *c*. 70°S, Bouvetøya and the South Shetland, South Orkney and South Sandwich Islands.

The sub-Antarctic region includes South Georgia and Heard Islands, lying just south and Kerguelen and Macquarie Islands lying just north, of the Convergence. Iles Crozet and the Prince Edward Islands, although further north, are close enough to the Convergence for the sinking cold Antarctic water to upwell against them. Still further north (and not far south of the sub-tropical Convergence, the northern limit of sub-Antarctic surface water) are the temperate oceanic islands of the Tristan da Cunha group (including Gough Island) and St. Paul and Amsterdam Islands; these have much in common with the New Zealand shelf islands (e.g. Auckland, Campbell and Chatham Islands) and the Falkland Islands.

Land climate and vegetation. Of the 14.3 million km^2 surface of the Antarctic Continent most is covered with a thick sheet of glacial ice at a mean elevation of about 2,000 m with peaks rising to 5,140 m. Only about 8,000 km^2 of rock and soil are exposed, mainly on the Antarctic Peninsula and around the edge of the continent. Of this much is either too inhospitable or too far from the sea to be suitable for birds, which principally use rock ledges, rock debris, shingle beaches and fast sea ice for breeding. The continental climate is cold, dry and windy. Temperatures on the continental plateau rarely exceed $-20°C$ in summer and the world's lowest temperature record of $-89.2°C$ was made at an inland site. However, mean annual temperatures at coastal sites range from $-10°C$ to $-12°C$ (summer means $-1°C$ to $-3°C$; winter means $-16°C$ to $-17°C$). Precipitation is virtually all as snow and rarely more than 40 $cm\,yr^{-1}$ on the coast, less inland where some areas are complete deserts. Winds are strong and reach a mean velocity of 72 $km\,hr^{-1}$ on the Adélie Coast with gusts of over 240 $km\,hr^{-1}$.

In the maritime Antarctic region the climate is milder, being cold, wet and windy. Mean temperatures from December to March may be at or just above freezing, precipitation reaches 100 $cm\,yr^{-1}$ and mean wind velocity rarely exceeds 30 $km\,hr^{-1}$. In protected areas at low altitudes a modified feldmark vegetation exists, dominated by mosses and lichens, the former developing, under favourable conditions, into moss peat banks over 1 m deep. Numerous crevices and ledges are available for birds but the ground is unsuitable for burrowing although storm petrels are often abundant in scree and debris slopes. Rocky promontories and beaches provide many breeding sites, especially for penguins.

At the sub-Antarctic islands mean monthly air temperature remains above freezing for at least half the year (annual range $-2°C$ to 8°C). Precipitation is usually between 100–150 cm, mostly as rain in summer, and often as snow in winter, and cloudy, windy weather with frequent mist and low cloud is typical. The Atlantic and Indian Ocean sectors are generally colder than the Pacific at the same latitude, partly due to the eccentric position of the Antarctic Continent. At these islands moss and lichen communities are abundant on higher ground (which rises to 2,900 m at South Georgia) but at lower elevations thick vegetation and often deep, peaty soils provide shelter, nest sites and nest material for both surface and burrow-dwelling birds. The most important vegetation type is tussock grassland, usually dominated by species of *Poa*, which may form a continuous cover to 2 m high. Short grass and rush tundra meadows are frequent on flat land and carpets of large-leaved perennial herbs may occur in sheltered places. Peat bogs, usually with small lakes and ponds, are present. In contrast to more southerly areas where ice abrasion and other factors result in a biologically impoverished intertidal zone, sub-Antarctic islands have a rich intertidal fauna, and luxuriant coastal kelp beds also contribute to tideline debris.

Oceanography. One important feature is the Antarctic Convergence where Antarctic surface and sub-Antarctic intermediate water meet. Below the latter is a southward flowing layer of warm circumpolar deep water. This rises close to the surface not far from the edge of the Antarctic Continent, in the area of the Antarctic Divergence, the boundary between the east flowing currents near the continent and the west flowing currents of the main Antarctic Ocean. This divergence is a major upwelling area and the abundant nutrients brought to the surface there facilitate vast phytoplankton blooms in the austral summer. Although the waters to the south of the Antarctic Convergence are generally considerably richer than temperate waters, and coastal waters exceptionally so, there are areas of the open ocean, especially in the Pacific, that are of low productivity. The key organism nourished in the highly productive regions is krill, a collective term for crustaceans of the genus *Euphausia*, particularly *E. superba*. As the food either directly, or indirectly through many fish and squid, of most Antarctic whales, seals and birds, it is the hub of the Antarctic food web and a vital factor in sustaining the vast animal biomass of the Antarctic Ocean in summer.

Avifauna. The birds are dominated by representatives of those two most marine of all orders, the PENGUINS and PETRELS.

Within the Antarctic zone and at the islands near the Antarctic Convergence the breeding species comprise 7 penguins (Spheniscidae), 6 albatrosses (Diomedeidae), 18 petrels (Procellariidae), 3 storm-petrels (Hydrobatidae), 2 diving petrels (Pelecanoididae), 2 shags *Phalacrocorax*, 2 skuas *Stercorarius*, 2 terns *Sterna*, 1 gull *Larus* and 2 sheathbills *Chionis* plus 4 ducks *Anas* (2 at South Georgia, one each at Kerguelen and Macquarie), a pipit *Anthus antarcticus* (South Georgia only), Starling *Sturnus vulgaris* (self-introduced), Redpoll *Carduelis flammea* and an introduced rail *Gallirallus australis* at Macquarie Island (where another rail *Hypotaenidia macquariensis* and a parakeet *Cyanorhamphus novaezelandiae erythrotis* became extinct by 1894 and 1911 respectively). Farther north at the temperate sub-Antarctic islands a number of other birds occur, principally shearwaters *Puffinus*, other gadfly petrels *Pterodroma* and additional land birds, particularly at the Tristan da Cunha group and the Chatham Islands.

The most important boundaries affecting seabird distribution are the Antarctic Convergence and the northern limit of pack ice. However, as there are relatively few suitable breeding sites for seabirds in Antarctic areas, few species are confined, even in the breeding season, to only one of the resulting circumpolar zones. Thus as a breeding species only the Antarctic Petrel *Thalassoica antarctica* is restricted to the cold Antarctic sub-zone although the Adélie Penguin *Pygoscelis adeliae*, Snow Petrel *Pagodroma nivea*, and particularly the Antarctic Skua *Catharacta maccormicki* and Emperor Penguin *Aptenodytes forsteri* have by far their greatest concentrations here. Only 11 species have been recorded breeding in this zone; the 5 mentioned above, plus Chinstrap Penguin *Pygoscelis antarctica*, Southern Giant Petrel *Macronectes giganteus*, Antarctic Fulmar *Fulmarus glacialoides*, Cape Pigeon *Daption capense*, Antarctic Prion *Pachyptila desolata* and Wilson's Storm Petrel *Oceanites oceanicus*. The maritime Antarctic sub-zone (Antarctic Peninsula and adjacent islands) provides a bridge along which Antarctic and sub-Antarctic species have been able to move on a north-south axis. Chinstrap Penguin and probably Black-bellied Storm Petrel *Fregetta tropica* are at their most abundant here and at some sites 4 penguins, 5 petrels, 2 storm petrels and 2 skuas occur (together with a sheathbill, shag, gull and tern). At the sub-Antarctic islands, in addition to abundant King *Aptenodytes patagonicus*, Gentoo *Pygoscelis papua* and Crested *Eudyptes* spp. Penguins, the well vegetated areas are extensively colonized by large surface-nesting species (albatrosses and giant petrels *Macronectes* spp.) and by many species of burrowing petrels. Iles Crozet has the richest avifauna (34 breeding

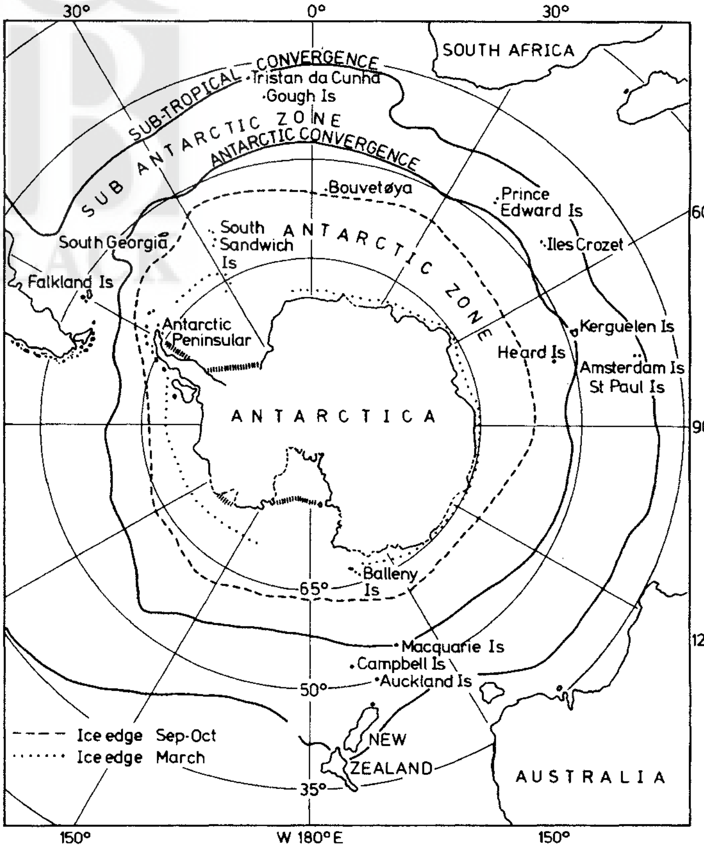

Fig. 1. The Antarctic and Sub-tropical Convergences, and apparent mean position of the ice edge in summer and winter.

species, including 16 burrowing species), followed by Kerguelen (30 species) and South Georgia and the Prince Edward Islands (26 species).

Zonal (i.e. latitude-based) speciation is much more marked than longitudinal (i.e. island-based) differentiation. Thus, except for the large and small forms of Snow Petrel, none of the species of the Antarctic zone shows regional differentiation within this zone. In the sub-Antarctic zone the only clear example is the existence of the Royal Penguin *Eudyptes chrysolophus schlegeli* at Macquarie Island and Macaroni Penguin *E.c. chrysolophus* at the other cold sub-Antarctic islands. However, part of the taxonomic complexity of the prions *Pachyptila* is due to the occurrence of morphometrically distinguishable populations at most breeding sites. In contrast there are distinct races of Rockhopper Penguin *Eudyptes chrysocome moseleyi*, Wandering Albatross *Diomedea exulans dabbenena*, Cape Pigeon *Daption capense australe*, White-chinned Petrel *Procellaria aequinoctialis conspicillata* and Black-bellied Storm Petrel *Fregetta tropica melanoleuca* at the temperate sub-Antarctic sub-zone islands and well-marked (but probably essentially clinal) disjunctions in Gentoo Penguin and Wilson's Storm Petrel farther south. There are also several examples of species which doubtless evolved in adjacent zones and which show largely non-overlapping circumpolar distributions but with varying degrees of coexistence. Thus Sooty *Phoebetria fusca* and Light-mantled Sooty *P. palpebrata* Albatrosses, Yellow-nosed *Diomedea chlororhynchos* and Grey-headed *D. chrysostoma* Albatrosses, Northern *Macronectes halli* and Southern Giant Petrels, Rockhopper and Macaroni Penguins, Thin-billed *Pachyptila belcheri* and Antarctic Prions are all respectively northerly and southerly replacement species, although the penguins and giant petrels co-exist fairly extensively at the cold sub-Antarctic islands. Antarctic and Brown *Stercorarius lonnbergi* Skuas are another 'species pair', with a zone of hybridization in the central Antarctic Peninsula and King *Phalacrocorax albiventer* and Blue-eyed *P. atriceps* Shags are basically zonal taxa which hybridize in southern South America; the status of the Kerguelen Shag *P. verrucosus* is uncertain. The New Zealand sub-Antarctic islands are an important centre of speciation for small albatrosses and crested penguins.

Breeding habitat. Most of the seabirds in the region are basically colonial, except for Light-mantled Sooty Albatross and the skuas, gull, terns and sheathbills, which defend isolated nest territories and, in the case of sheathbills and skuas, often feeding territories in penguin colonies. On the Antarctic Continent and Peninsula the smaller petrels are crevice nesters, larger ones using sheltered ledges, while the penguins often choose very exposed sites (including flat sea-ice by Emperor Penguin) as these are frequently associated with wind-assisted early break-out of pack-ice in summer, thus improving access to breeding sites. At the sub-Antarctic islands the tussock grasslands are used by nearly all species: large albatrosses, giant petrels, and Gentoo Penguins in flatter areas, smaller albatrosses usually on steep slopes and burrowing petrels underground in a wide range of conditions of slope, aspect and general topography. Storm petrels mainly nest in cliff crevices, boulder scree and moss banks and the South Georgia Diving Petrel *Pelecanoides georgicus* only in fine consolidated scree. King Penguins favour flat land usually near glacier moraines, the other penguins utilizing a wide variety of rock and boulder slopes or beaches.

General biology. The breeding biology of most Antarctic birds (see especially PENGUIN, PETREL, SHEATHBILL, SKUA) is basically very similar to that of their more temperate relatives. With the short duration of summer in high latitudes most species show high synchrony of breeding events within populations although this is least true of some inshore feeding species (e.g. Gentoo Penguin, Blue-eyed Shag, Antarctic Tern *Sterna vittata*, some storm petrels). Even so, most larger species, with correspondingly long incubation and fledging periods, commence breeding in early spring and only finish at the end of April, when food stocks are first starting to diminish. Smaller species can be more flexible in their timing and there are several cases of similar species having mutually exclusive chick-raising periods (e.g. Common *Pelecanoides urinatrix* and South Georgia *P. georgicus* Diving Petrels, Blue Petrel *Halobaena caerulea* and Fulmar Prion *Pachyptila crassirostris* as opposed to all other prions, Antarctic and Kerguelen *Sterna virgata* Terns). The fulmarine petrels (e.g. Snow, Antarctic and Cape Petrels, Antarctic Fulmar *Fulmarus glacialoides* and giant petrels) have especially short incubation and fledging periods and this may have been an important factor in determining why most members of this group and not other Procellariidae became successful colonists of the Antarctic Continent. A small number of Antarctic species consistently breed in winter. These are two burrowing petrels of more northerly sites, Great-winged Petrel *Pterodroma macroptera* and Grey Petrel *Procellaria cinerea*, which thus avoid times when their congeners are active, Wandering Albatross, with Royal Albatross *Diomedea epomophora* the only albatrosses with this strategy, and Emperor Penguin. King Penguin chicks, although remaining in the colony over winter, are only fed very occasionally and this species is essentially a summer breeder. The Emperor Penguin, however, raises its chick through the high Antarctic winter, under the most extreme conditions of any bird, and a number of ecological, physiological and behavioural adaptations combine to make this possible. Most other Antarctic seabirds show fewer special adaptations to cope with the rigorous environmental conditions of the region. Like seabirds elsewhere they have thick layers of subdermal fat and these are especially well developed in penguins, which also have a particularly dense covering of overlapping feathers and a highly developed vascular heat exchange system in the flippers and legs. Selection of nest sites that are sheltered but not prone to blockage with snow is often critical.

Climatic factors also strongly influence breeding success, either causing chick loss directly through chilling in very cold weather or indirectly by causing poor feeding conditions for adults or delaying the onset of breeding so that adults feed and chicks fledge at less favourable times. Native predators are of much less importance although locally sheathbills and skuas may be responsible for appreciable losses of eggs and small chicks. Burrowing petrels, however, have been drastically affected on many sub-Antarctic islands by introduced rats (taking eggs and chicks) and on some islands by cats (taking chicks and adults). In many areas, particularly on Macquarie Island (where erosion induced by rabbits is also a problem) and parts of Iles Crozet and Marion Island, burrowing petrels are virtually restricted to offshore predator-free islands. On South Georgia the pipit and South Georgia Pintail *Anas georgica* have been similarly affected by rats in many areas.

For many species the full rigours of the Antarctic climate are avoided by moving north in winter, whether to the pack-ice edge (Adélie Penguin, Snow and Antarctic Petrel) or, like most species, to between the Antarctic and Sub-tropical Convergences, with several species (e.g. giant petrels, Wandering Albatross, Black-browed Albatross *Diomedea melanophris*) reaching at least 35°S, particularly off coastal South America and South Africa and in the Tasman Sea. Juvenile dispersal is wide, and best documented for albatrosses and giant petrels where birds reach low latitudes in all Southern Hemisphere oceans. In many species both immatures and adults probably not infrequently encircle the globe in the zone of the West Wind Drift. A few species are transequatorial migrants: Sooty Shearwater *Puffinus griseus*, Great Shearwater *Puffinus gravis* and Mottled Petrel *Pterodroma inexpectata* all from mainly temperate sub-Antarctic sites, and Wilson's Storm Petrel and also, in the reverse direction, Arctic Tern *Sterna paradisaea* which is a widespread austral summer visitor to the Antarctic Ocean.

Population dynamics. Antarctic seabirds, like those elsewhere, are generally long-lived and delay breeding until several years old. Mean annual survival of breeding adults of Antarctic seabirds so far studied is around 90–95%, the main exceptions so far being diving petrels (70%), and most penguins (70–85%). Young birds clearly sustain high losses in the first year or so of life, but even so 45% of an age group of Wandering Albatrosses survive to 5 years of age. Mean life expectancy is correspondingly high and may reach 10–15 years for smaller petrels and 25 years for albatrosses and giant petrels. Maximum values are uncertain but there are proven field records of 16 year old Adélie Penguins, Wandering Albatrosses over 30 and Snow Petrels over 35 years of age. Most petrels commence to breed from age 4–6 but diving petrels do so from age 2 and Wilson's Storm Petrel from age 3, whereas albatrosses may commence at age 4–9, depending on species and location. Adélie and Emperor Penguins breed from age 3, King Penguins from age 4 but Royal Penguins not until 5.

One interesting feature of some Antarctic seabirds is their inability to breed in a season following that in which they raised a chick. This is not unexpected in King Penguins, Wandering and Royal Albatrosses which take nearly a year (or more) to raise a chick, but also occurs in Grey-headed (but not Black-browed), and both *Phoebetria* albatrosses. In these latter cases it is believed also to relate to the very long chick fledging period, itself probably a result of dietary restrictions.

Diet and feeding ecology. Terrestrial (and/or tideline—especially in winter) invertebrates are important to ducks, sheathbills (particularly Lesser Sheathbills *Chionis minor*), passerines (especially South Georgia Pipit), Southern Black-backed Gull *Larus dominicanus* and Kerguelen

Tern. Giant petrels, sheathbills and skuas scavenge extensively, particularly in penguin colonies; some Antarctic Skuas, however, take fish or krill at sea. The remaining species are exclusively marine and 4 main types of prey are taken; fish (especially Nototheniidae and Myctophidae), squid, krill and other, smaller crustaceans (amphipods, copepods). Fish are eaten extensively by inshore feeders like Gentoo Penguin and shags, the latter frequenting coastal kelp beds where many fish mature, but more pelagic species, like some albatrosses and Blue Petrel, also take much fish. King and Emperor Penguins, many albatrosses, *Procellaria* and *Pterodroma* petrels chiefly eat squid although some Antarctic species are considerably less nutritious than fish or krill. Krill predominates in the diet of most remaining species, especially penguins, and is also taken by many fish- and squid-eating seabirds. Small crustaceans are taken mainly by smaller seabirds e.g. diving petrels, storm petrels and particularly Antarctic Prion which (like the Broad-billed Prions *Pachyptila vittata*) has a broad, deep bill with a comb-like lamella fringing the upper mandible through which water is expelled to filter out small organisms. Apart from such specialized feeding adaptations, most Antarctic seabirds are either pursuit divers (penguins, shags and, near the surface, diving petrels) or surface feeders. This is done either by pattering along the surface like storm petrels, swooping down like gadfly petrels, plunging (chiefly terns) or, like most species, seizing prey while sitting on the surface. Most of the last type of feeding is probably done at night when krill and its associated predators reach the surface. Even for the rich and diverse seabird concentrations at sub-Antarctic islands, differences in diet, feeding technique and foraging range appear to act to reduce direct competition for food in summer, especially between related species. In winter, those that remain in high latitudes are chiefly fish and squid eaters as crustacean prey is greatly reduced in availability.

In terms of biomass and consumption penguins are the dominant Antarctic group with vast Adélie Penguin colonies around the coast of Antarctica, huge Chinstrap Penguin concentrations on the Antarctic Peninsula and adjacent islands and great numbers of crested penguins at the sub-Antarctic islands (there may be 10 million Macaroni Penguins in the South Georgia population alone). As most eat krill, it is not surprising that penguins may account for 75% of food consumed by Antarctic seabirds and in total this may approximate to krill consumption by present day Antarctic whale stocks and be not too far short of that by Antarctic seals; seabirds are thus important predators of the marine resources of Antarctic seas. ANTBIRD: substantive name, referring to the habit of following army ants, of some of the 236 species of 53 genera in the large Neotropical family Formicariidae (Passeriformes, suborder Tyranni); in the plural, general name for the family. Species of this family have radiated so as to fill many forest niches, occupied by many different families on other continents. 'Gnateaters' (9 species, 1 genus, sometimes placed in the family Conopophagidae—see GNATEATER) are rotund and short-tailed little birds that hop or cling on or near the forest floor much like small 'antpittas' (38 species, 5 genera). 'Ant-thrushes' (9 species, 2 genera) walk rail-like on or near the forest floor, pounding their lifted tails as they go. Other formicariids, from warbler-like tiny 'antwrens' and small 'antvireos' to hook-beaked large 'antshrikes,' occur from the forest floor to the canopy.

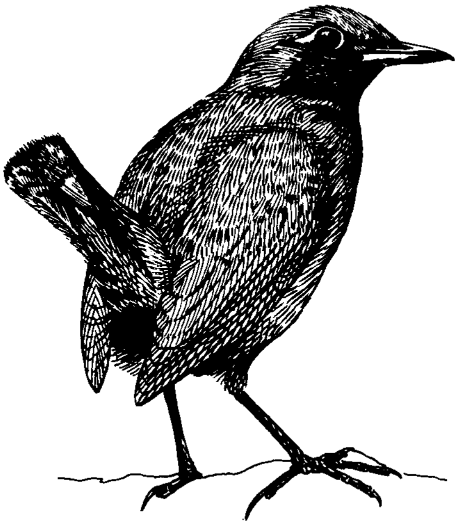
Characteristics. Antbirds vary in size from 8 to 36 cm, the longest and perhaps largest being the 154 g Giant Antshrike *Batara cinerea*. Most have dark red eyes, becoming bright vermilion in 'fire-eyes' (*Pyriglena*). A few have pale or yellow eyes. Bare green, blue or red areas (the last in *Phlegopsis*, the 'bare-eyes') sometimes surround the eye and form giant 'eye-spots', which glow like eyes of huge mammals in the forest undergrowth. One species (*Gymnocichla nudiceps*) has a bare blue crown and forehead as well as face. Colour patterns are frequently striking, being varied combinations of black, brown, rufous, white, or greenish to yellowish. Females are often duller than males, with white or brown replacing black areas; but sexes are usually alike in bare-eyes, ant-thrushes, and antpittas. Nestling fire-eye males are black, females brown; but most small young look like adult females or have a dull plumage. Some young males take on the female plumage for nearly a year.



Black-faced Ant-thrush *Formicarius analis*. (*C.E.T.K.*).

The body plumage is usually loose and sparse, becoming long and silky on the lower back and rump; the forecrown is plush and dense in fire-eyes, while several antbirds have erectile crests and one, the White-plumed Antbird *Pithys albifrons*, a white crest and beard. Many species have concealed white back or shoulder patches, exposed mainly during disputes. The wings are rounded, with 10 primaries, and functional for short flights in dense vegetation rather than for long-distance travel in the open. Tails are short to medium in length, square or rounded, with 12 feathers (8 or 10 in some species). The slender to thick dark bill is often hooked, and is swollen slightly rather than pointed. One 'bushbird' (*Clytoctantes alixi*) has a laterally flattened bill with semicircular lower mandible, used for slitting stems of banana-like plants; another (*Neoctantes niger*) has a similar bill that tears into rotten logs in swamps. Legs and feet are slender or strong, pale or dark, while claws are very sharp and curved in forms that cling crosswise on vertical saplings near the forest floor.

Habitat. Antbirds live mostly in lowland tropical forests, and 30–50 species can be found in many equatorial forests of the Amazon valley. Numbers of species decline greatly as one goes to more open tropical or subtropical environments, or into swamps or up mountains. Antpittas, however, are more diverse in the Andes than in the lowlands. Except when sunning in a ray of sunlight, antbirds almost never leave the shade even when they live in the forest canopy; at midday few will cross a wide road through the forest, and different species or subspecies occur on the opposite banks of some wide rivers in the Amazon Valley. A few (such as *Myrmochanes hemileucus*) occur primarily on species-poor islands in the middle of the Amazon and other large rivers, and fly from one island to another without staying on the nearby shores. Others live only in swampy forest or scrub of the seasonally flooded *varzeas* of the Amazon, and apparently cross rivers readily.

Distribution. Neotropical; antbirds range from north-eastern Mexico to Argentina, but are absent from Chile and from the Antilles other than Trinidad and Tobago. Only two species are restricted to Central America; other species that occur there also occur in South America.

Populations. Some antbirds, such as the Slaty Antshrike *Thamnophilus punctatus* in Panama, occupy a hectare or less per pair. Others are less common, for instance the White-plumed Antbird at 1–2 pairs per km^2 near Manaus in central Brazil. All disappear rapidly when forest or other vegetation is cut, so that certain antbirds of south-eastern Brazil (the Slender Antbird *Rhopornis ardesiaca*, for instance) are threatened with extinction. Probably many other species of antbird will disappear as forests are cut and isolated; some antbird species have already disappeared from one forest reserve, Barro Colorado Island in central Panama.

Movements. Hudson reported that the Rufous-capped Antshrike *Thamnophilus ruficapillus* leaves Argentina in winter, but most species are nonmigratory. Young birds of most species wander locally, while adult birds tend to stay on territories. Young females and females that have lost their mates sometimes wander widely. In many species that follow army ant colonies, pairs have large and overlapping home ranges; White-plumed Antbirds wander 2–3 km or more through forests at Manaus. Often the pair or individual is dominant over neighbours only in the central area of its home range, an area that corresponds to the territory in less vagile related antbirds (ones that need not follow nomadic ants so widely).

Food. Antbirds for the most part capture small insects, spiders, lizards, frogs, and similar animals. Gleaning and short-distance sallies to the lower sides of foliage are common, less often rummaging in dense dead leaves or tossing fallen leaves with swipes of the side of the bill or by picking them up with the bill. Scratching with the feet is not recorded. Giant Antshrikes have been seen attacking small birds in mist nets. Gnateaters occasionally eat small fruit, but fruit-eating is rare in the family. Ants are rarely eaten, except larvae taken when ants flee a nest at the approach of army ants; in this case the adult ants are thrown away and the larvae they carry are retained. Only a few antbirds (notably Cinereous Antshrike *Thamnomanes caesius*) are good flycatchers, but sometimes individuals capture winged ants flying from a nest. Some 28 species regularly follow army ants for prey flushed by them. Many other antbirds, as well as many species in other bird families, occasionally follow army ants. Sometimes an ant-following bird follows domestic pigs or herds of white-lipped peccaries; and one Bicoloured Antbird *Gymnopithys bicolor* came to follow the Costa Rican naturalist Alexander Skutch when he stirred the leaf litter with a stick. The two ant species followed regularly are both 'swarm raiders,' which form wide phalanxes on the forest floor or up tree trunks in lowland Neotropical forest: *Eciton burchelli* and *Labidus praedator*. Swarm raiders flush large numbers of cockroaches, spiders, and other small animals that are snapped up by waiting birds. Typically the ant-following antbirds cling crosswise on slender vertical saplings just above the ants and dart briefly to the ground for prey. Some antbirds, such as hopping Black-crowned Antpittas *Pittasoma michleri* and walking ant-thrushes *Formicarius* spp., wander on the ground on the outskirts of an advancing swarm. The Scale-backed Antbird *Hylophylax poecilinota* of equatorial South America can cling horizontally to vertical thick trunks, a type of perch usually occupied only by ant-following woodcreepers, and hence finds places over ants despite the aggression of larger antbird species.

Behaviour. Most antbirds form pairs that last for life, with rarely a divorce. White-plumed Antbird females, however, rapidly leave mates to care for single young, and find another male so as to start a new nest. Young birds occasionally stay with their parents for some months or years, although none are known to help with later nestings. Clan formation in Ocellated Antbirds *Phaenostictus mcleannani* involves the occasional association of sons and grandsons with a pair, the male offspring bringing back mates from other clans. At times the members of a clan cooperate briefly in attacking intruders from another clan. Antbirds form the centres of many of the mixed-species flocks of insectivorous birds that wander through Neotropical forests. These flocks, unlike the flocks around army ants, do not feed at concentrated food sources. Fifty species or more may be present, including 20–30 species of antbirds. Each species forages differently, some peering in dead curled-up leaves and others in green foliage. Some stay in the canopy, others in the subcanopy, midlevels, lower midlevels, lower levels, or on the ground. Others occupy only dense foliage, such as around vine tangles; and the whole flock is likely to slow down and search intensively in the dense foliage around a light gap where a forest tree has fallen. If a hawk appears, alarm calls from the most alert flycatchers warn even the species that forage inside dense foliage or in dead leaves. Certain flycatching antshrikes (*Thamnomanes* spp.), centres of Amazonian flocks, are extremely alert and noisy and hence are followed by other species, which then flush food for the antshrikes. Regular flock members often have the same territories (but defend only against their own species when meeting a neighbouring flock), roost together, and preen together. Other species join the flocks less readily or wander between one flock and another. Ground and low-level antbirds tend to ignore flocks, apparently depending on protective coloration because they forage too slowly to keep up with birds gleaning through sparser foliage high above the ground.

Antbirds usually scratch the head over the wing. Alarm behaviour often produces upward 'flicking' of the tail or downward 'pounding' of the tail, depending on the species.

Voice. Antbirds have simple songs, mostly resonant series of whistles or chattering notes. Both sexes sing; the female sometimes has a song unlike that of the male. Some, such as the Ferruginous Antbird *Myrmeciza ferruginea*, have pleasant short warbles. The strangest vocalization is that of the White-plumed Antbird, a series of several hundred buzzy *zee* notes given for up to 3 min while performing a wing-waving display. Call notes of antbird species tend to be very varied. There is often a sharp chipping note of alarm, a buzzy rattle or churr at a nuisance (like a human), and a thin whistle at distant hawks. Faint songs and chirps go to mates and young. Snarling and bugling notes, as well as songs and bill-snapping and growls, may accompany aggressive fluffing to show concealed white back, crown, or wing patches at intruders. Whimpering peeps signify subordinate status, commonly associated with hangdog fluffing or wing-quivering submissive display. Young birds peep song-like phrases and squeak when fed.

Breeding. Courtship feeding by the male often precedes copulation; mutual grooming and pair association are regular. (Aggressive displays have at times been incorrectly interpreted as courtship.) Antbird pairs work together at building simple nest cups or oven-shaped nests, the last on the ground by fire-eyes and above the ground by Brown-bellied Antwrens *Myrmotherula gutturalis*. Some nests resemble piles of debris, others are sunk in tree cavities or in the ground at the base of a tree. Ant-thrushes of the genus *Formicarius* lay white eggs deep in cavities of saplings, but most antbird eggs are speckled with brown, purple, or other colours. Blue eggs occur in some antpittas of the genus *Grallaria*, perhaps because such eggs look like the scattered foliage of the montane understorey where most live. Buff ground colour is known in some gnateaters, resembling the brown leaf litter just below their cup nests. Two eggs are the normal clutch, rarely 3; eggs are laid 2 days apart. Incubation, about 14–20 days, is by both sexes during the day and by the female at night. She fluffs out and, with her beak in her back, looks like a tuft of feathers. Eggs are covered most of the day, but White-flanked Antwrens *Myrmotherula axillaris* are off the nest 25–50% of the day despite pair cooperation. Young are brooded and fed by both parents for 9–18 days, and can hop and flutter actively on leaving the nest. Long incubation or brooding spells are the rule, as is infrequent feeding with large insects. Rufous Gnateaters *Conopophaga lineata*, however, feed small insects rapidly. Droppings are eaten or carried off by parents. Long incubation and nestling periods are found mainly in cavity-nesting species, notably the Black-faced Ant-thrush *Formicarius analis* with 20 days incubation and 18 days nestling period. Young Black-faced Ant-thrushes are covered with down at hatching, unlike the naked young of most other antbirds. Injury feigning has been recorded for some species nesting on or near the ground, and for canopy species (*Terenura spodioptila*) when young have fluttered to the ground. If 2 young survive, the male often cares for one and the female for the other. Young depend on their parents for food 1–2 months, then forage with them or wander away. Rufous Gnateater pairs leave corners of their territories for independent young, but young are driven away when they gain adult colour in Bicoloured Antbirds. Several broods may be reared in a season, and because of repeated nest destruction some pairs may nest 6 or more times per year. Breeding seasons of pairs may be short, 3–6 months, in equatorial regions as well as far from the equator; other species in the same areas nest 10 months or so per year. Some species apparently have two breeding seasons per year, while others nest all year or only during rainy seasons. (S.M.) E.O.W.

ANTCATCHER: obsolete (and misleading—see ANTBIRD) formerly applied to some medium-sized antbirds.

ANT-CHAT: substantive name of *Myrmecocichla* spp. (see THRUSH).

ANTCREEPER: substantive name of some species of Formicariidae, e.g. *Myrmoborus* spp. (see ANTBIRD).

ANTEPISEMATIC: see under EPISEMATIC.

ANTHROPOMORPHISM: denotes, in the biological context, the fallacy of describing or interpreting the actions of animals, other than Man, in terms of human actions and mental processes.

ANTIBODIES: see BLOOD; DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA.

ANTICOELOUS: see ALIMENTARY SYSTEM.

ANTICRYPTIC: see under CRYPTIC.

ANTIGEN: see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA; SEROLOGICAL CHARACTERS.

ANTING: highly specialized, stereotyped behaviour of passerine birds, whereby certain areas of plumage are treated with the defence and other body fluids of worker ants, chiefly of two non-stinging subfamilies, the Formicinae, which squirt formic acid from the tip of the gaster, and the Dolichoderinae, which exude sticky droplets of a repugnatory nature from the anal glands.

Between 200 and 250 species of passerine birds, representing some 40 families or subfamilies, have been recorded using ants, though other insects and invertebrates producing similar fluids may be used occasionally. In addition, and especially in captivity, 'anting' has been observed with a variety of substances, mainly pungent, and in the presence of smoke (see SMOKE-BATHING). True anting has been claimed for a few non-passerines, but such records remain to be substantiated; some may be due to misapprehension of other behaviour (see also COMFORT BEHAVIOUR).

Birds ant mainly in two ways: (1) directly by applying ants in the bill to the feathers ('active anting'); (2) indirectly by permitting ants to invade the plumage ('passive anting'). The direct manner, by far the commoner, is typical of babblers, starlings, tanagers, and weavers (Ploceidae). They apply ants with quivering or stroking movements, characteristically with the wing partly open and lifted out at the side and the spread tail thrust sideways. The ant fluids, often mixed with copious saliva, mainly reach the ventral tips of the primaries and to a lesser extent the head (via the wing) and the undersurface of the tail near the vent. A small minority of species, including certain crows, drongos and New World orioles, practise a more extended form of direct anting, by applying ants to other areas, sometimes with preening actions. The ants are generally used singly but, notably by many starlings and some corvids, may be collected up progressively into a wad; then eaten or discarded afterwards. Birds anting in the indirect manner are mainly larger species of thrushes and crows (Corvidae), but the tiny waxbills and allies (Estrildidae) also do so. While some crows (*Corvus* spp.) will lie spread-eagled among the ants, most indirect anters squat in a special posture with both wings thrust forward in front of the body, allowing the ants to ascend the plumage while discharging their defence fluids. The birds may stir up the insects by repositioning themselves, by shuddering their wings among the ants, e.g. the Jay *Garrulus glandarius*, or even by quivering the tail, e.g. the Red-billed Magpie *Cissa erythrorhyncha*. Many species only use one or other of the two main methods but some also apply ants directly in the bill while anting 'passively', or as in the case of the Jay, the estrildine finches and the Grey Thrush *Turdus cardis*, just go through the motions without actually picking up ants. A few, notably *Turdus* thrushes, e.g. the Blackbird *T. merula*, ant in one way or the other on different occasions. All members of the same family or subfamily may use the same method but some taxa, notably the crows, show great variation even among closely related species.

There is still controversy over the function of anting, but evidence points to it being a form of COMFORT BEHAVIOUR. It may help with feather maintenance, especially of the wings, perhaps to combat feather ectoparasites or remove stale or excess lipids (see DUSTING). Formic acid and anal fluids are insecticidal, and certain organic fluids from ants are essential oils, perhaps supplementing the bird's own preen oil. Preening often follows anting, and some birds also bathe and oil.

Most anting is reported during the period when the post-breeding and juvenile moult occurs, at least in the Northern Hemisphere, but speculation that birds ant to soothe the skin during feather replacement seems ill-founded. The correlation is more likely to be with the weather and seasonal factors that produce the maximum activity of the ants, most records being at swarms of ants, especially those related to the nuptial flights of the royal castes. Theories on the auto-erotic or self-stimulating effects of anting appear to be misguided; nor is anting a means of removing distasteful liquids from the ants before eating them.

Jay *Garrulus glandarius* in 'passive' anting position. (*Photo: Jane Burton*).

ANTIPHONAL SONG: 'duetting' (see VOCALIZATION).

ANTI-PREDATOR REACTIONS: see PARENTAL CARE.

ANTPECKER: substantive name of estrildid *Parmoptila jamesoni* (see ESTRILDID FINCH).

ANTPIPIT: substantive name of the 2 species of *Corythopis*, small and superficially pipit-like birds that forage close to the ground in the Amazonian and other forests east of the Andes in South America. They were formerly placed with the GNATEATERS in a small family, Conopophagidae, but it has recently been shown that gnateaters are specialized members of the ANTBIRD family, while the antpipits are probably aberrant members of the tyrant-flycatcher family (see FLYCATCHER (2)).

ANTPITTA: substantive names of species of *Pittasoma*, *Grallaria*, *Hylopezus*, *Myrmothera* and *Grallaricula* (see ANTBIRD).

ANTRORSE: directed forwards; applied, e.g., to rictal bristles that do not conform with the usual backward direction of plumage elements.

ANTSHRIKE: substantive name of *Taraba major*, *Thamnophilus* spp., *Sakesphorus* spp., and other large antbirds (see ANTBIRD).

ANT-TANAGER: substantive name of *Habia* spp. (see TANAGER).

ANT-THRUSH: substantive name of *Formicarius* and *Chamaeza* spp. (see ANTBIRD); and of *Neocossyphus* spp. (for subfamily see THRUSH); sometimes used also for species of Pittidae (see PITTA).

ANTVIREO: substantive name of *Dysithamnus* spp. and allies (see ANTBIRD).

ANTWREN: substantive name of *Myrmotherula* spp., *Terenura* spp., *Microrhopias quixensis*, and other small antbirds (see ANTBIRD).

ANVIL: stone or hard object used for smashing snail shells.

ANVIL-HEAD: name sometimes used for *Scopus umbretta* (see HAMERKOP).

AORTIC ARCH: see DEVELOPMENT, EMBRYONIC; VASCULAR SYSTEM.

APALIS: generic name used as substantive name of *Apalis* spp. of Africa (for subfamily see WARBLER (1)).

APAPANE: *Himatione sanguinea* (see HAWAIIAN HONEYCREEPER).

APODI; APODIDAE: see below.

APODIFORMES: an order comprising 2 suborders: Apodi, Trochili; 3 families: Hemiprocnidae (CRESTED SWIFT), Apodidae (SWIFT; SWIFTLET), Trochilidae (HUMMINGBIRD). The suborders Apodi and Trochili do not at first sight seem very similar, but in the structure of the wings and the extreme shortness of the legs they are much alike, in both the number of rectrices is 10 (not 12, as in most other birds), and they show similarities of cranial structure which are unlikely to be the result of convergence. Wing movements are very rapid in both groups. Swifts are cosmopolitan, while hummingbirds are exclusively American, with remarkable specific radiation in all altitudinal zones of northern South America.

APONEUROSIS: a flattened tendon for the insertion of a muscle (see MUSCULATURE).

APOSEMATIC: having a protective role—applied particularly to coloration. 'Proaposematic' means that the protection is in the form of a warning (e.g. of unpalatability); 'pseudaposematic' means that the warning is a bluff (protective mimicry); 'synaposematic' means that the warning signal is shared in common with other species. Compare EPISEMATIC; and, in general, see COLORATION, ADAPTIVE; MIMICRY.

APOSTLEBIRD: *Struthidea cinerea* (see under CHOUGH (2)).

APPENDICULAR SKELETON: the part of the skeleton consisting of the pectoral and pelvic girdles and the limbs; contrasted with the AXIAL SKELETON (see SKELETON, POST-CRANIAL).

APPETITIVE BEHAVIOUR: 'the variable introductory phase of an instinctive behaviour pattern or sequence' (Thorpe 1951)—compare CONSUMMATORY ACT (see BEHAVIOUR, HISTORY OF).

APPLIED ORNITHOLOGY: the application of ornithological knowledge to human activities concerned with birds (see especially AVICULTURE; CONSERVATION; DOMESTICATION; FALCONRY; GAMEBIRDS; GUANO; UTILIZATION BY MAN, with cross-references thereunder).

APTERIUM (plural APTERIA): an area of skin bare of contour feathers, lying between pterylae. Apteria may be feathered with semiplumes, down or powderdown (see PTERYLOSIS).

APTERYGES; APTERYGIDAE: see STRUTHIONIFORMES; KIWI.

AQUATIC HABIT: for adaptations to this see SWIMMING AND DIVING; SKULL; VISION.

AQUINTOCUBITALISM: or 'diastataxis' (see WING).

ARAÇARI: substantive name of *Pteroglossus* spp. (see TOUCAN).

ARAMIDAE: see under GRUIFORMES; LIMPKIN.

ARCHAEOPTERYX: *Archaeopteryx lithographica* von Meyer—the earliest known fossil bird. It is represented by five partial skeletons with feather impressions and one isolated feather:

1. Described by von Meyer in 1861, the feather is presently housed in two museums. The main specimen or slab which may include some mineralized tissues is at the Munich Museum while the counterslab is in the Museum fur Naturkunde in Berlin. According to Brodkorb (1963) this feather is the holotype for the species, but most later workers accept the London specimen as the holotype (Ostrom, 1976). The feather was found in the communal quarry at Solnhofen, Bavaria, West Germany.

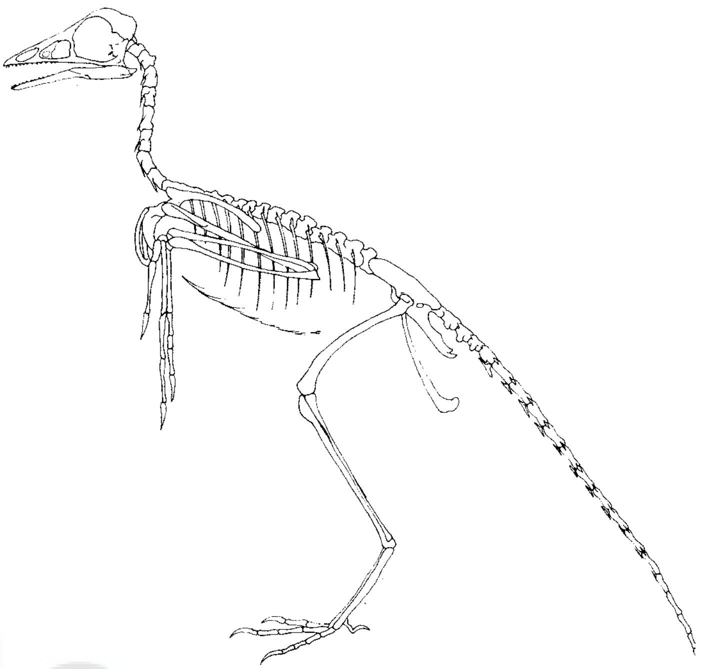

Fig. 1. Restoration of the skeleton of *Archaeopteryx* (approximately 1/3 size).

2. The London specimen was found in 1861 in the Ottmann quarry near Solnhofen. This was the first skeleton to be described in detail and its discovery lent considerable support to the then recently proposed theory of evolution. It is presently housed in the British Museum (Natural History).

3. The Berlin specimen was discovered in 1877 in the Durr quarry at Wegscheidt near Eichstatt. This is the specimen upon which Heilmann made most of his observations for his famous book on the origin of birds. It is in the Museum für Naturkunde in Berlin.

4. The Maxburg specimen was found in 1956 in the Opitsch quarry near Solnhofen. This specimen is presently in private hands although there are casts of it in the Senckenberg Museum in Frankfurt and the Solnhofen Museum in Maxburg near Solnhofen.

5. The Haarlem specimen was first recognized as an *Archaeopteryx* by Ostrom in 1970. It had been described by von Meyer in 1857 as a pterosaur, *Pterodactylus crassipes*. Ostrom (1972) proposed that *Archaeopteryx crassipes* be suppressed by the International Committee on Zoological Nomenclature. It is housed in the Tyler Museum in the Netherlands.

6. The Eichstatt specimen was found in 1951 in a small quarry near Workersaell a few miles north of Eichstatt. It was originally thought to be a small dinosaur, *Compsognathus*, but in 1973 F.X. Mayr announced that it was an *Archaeopteryx*. It was later monographed by Wellnhofer (1974) and has the distinction of being the most thoroughly described of any *Archaeopteryx* specimen.

The assignment of an isolated feather from an upper Jurassic lithographic limestone near Santa Maria de Meya, Sierra de Montsech, Lerida, Spain, to *Archaeopteryx* is extremely tentative. In reality it only demonstrates the presence in Spain of Jurassic birds, and of course the potential that a skeleton will one day be found in these same beds. The only other reasonable case that has been made for a Jurassic bird other than the German *Archaeopteryx* specimens is *Laopteryx* from the Late Jurassic Morrison Formation of the United States. Recent study of the only known specimen (a partial cranium) of *Laopteryx* demonstrates that it is a pterosaur.

Plumage. *Archaeopteryx* is the oldest and most primitive known bird, and provides us with our best evidence concerning the origin of birds and the evolution of avian structures. Perhaps the most interesting features preserved are the feather impressions. These show that *Archaeopteryx* had feathers of an essentially modern type composed of a quill supporting a system of vanes, rachi and barbs. Barbules and hamuli also seem to be present although the best evidence for the latter is the even arrangement of the barbs on the specimens. The next oldest fossil feathers were described by Schlee from Lower Cretaceous (Neocomian) amber of the Lebanon Mountains. These feathers clearly show the presence of barbules and hamuli. Taken as a whole the fossil record shows that the microstructure of the feathers was one of the earliest avian features to evolve fully. The feathers of *Archaeopteryx* are also divided into rectrices and remiges as in modern birds and the remiges have the anterior vanes narrower than the posterior vanes. This relationship is characteristic of modern flying birds where it helps to form the airfoil. Feduccia and Tordoff (1979) have argued persuasively that these asymmetrical feathers indicate that *Archaeopteryx* had some aerodynamic capabilities. The flight feathers are divided into primaries and secondaries. Coverts are also present and the whole plumage has a very modern aspect. Contour feathers are present on the legs of the Berlin specimen, but there is no evidence of horny structures or scales. This is especially surprising as well preserved metatarsal scutes have been found with at least two specimens of Mesozoic marine hesperornithiforms.

Skeleton. Our knowledge of the skull was greatly enhanced by the discovery of the Eichstatt specimen. Both it and the Berlin skull share a pointed snout with the external nares bordered primarily by the premaxillary bones. Just behind the nares is a large triangular antorbital fenestra containing a nasal septum perforated by large holes. According to Wellnhofer (1974) a separate lacrimal and prefrontal are present. The orbits are very large and contain well-developed sclerotic rings. The quadratojugal and the jugal have dorsal extensions bracing against the quadrate. The postorbital does not appear to be present. The squamosal is either very small or lost altogether. Its reduction is a derived character for *Archaeopteryx*. The skull does not seem to be mesokinetic as suggested by Bock (1964), nor was it prokinetic or rhynchokinetic. The snout was probably not covered by a horny bill, as teeth are found on the premaxillary (4 teeth), maxilla (9) and dentary (11). These counts are based on the Eichstatt skull which has the clearest preservation. The teeth have sharp-pointed, posteriorly directed, flattened crowns separated from the expanded root by a constricted neck. Similar teeth have been described from other Mesozoic toothed birds by Martin, Stewart and Whetstone (1980) who also point out that this type of tooth is found in crocodilians.

The palate is best observed in the Eichstatt specimen, but even in that specimen it is impossible to determine its detailed structure. Previous statements that it was schizognathous (neognathous) are based on the Berlin specimen and are unfounded. Although it appears to have had a very open palate with long narrow palatines like *Hesperornis*, the identity of the palatal bones must remain in doubt until a new specimen is recovered or the Eichstatt specimen is further prepared.

The London specimen preserves a relatively undistorted braincase with an endocranial cast and this, along with the shape of the braincase of the Eichstatt specimen, gives a good approximation of the shape and relative size of the lobes of the brain. The brain was small, but bird-like in its general shape and proportions.

The lower jaw is slender and has an anterior, downward bend. It does not appear to have had a mandibular fenestra and resembles *Ichthyornis* and the Hesperornithiformes in that respect. It also does not appear to have had an intramandibular joint, a feature found in *Ichthyornis* and the Hesperornithiformes.

Archaeopteryx does have a large retroarticular process which in lateral aspect resembles the type found in *Hesperonis* and crocodilians.

The Eichstatt specimen provides the clearest vertebral count and in this specimen Wellnhofer counted 9 cervical vertebrae, 14 dorsal vertebrae, 5 sacral vertebrae and 22 caudal vertebrae. The dorsal and caudal vertebrae are amphicoelous or platycoelous. The cervical vertebrae bear long cervical ribs and some of the dorsal vertebrae have slight pleurocoels. The caudal vertebrae are elongate and no pygostyle is present. Instead each caudal vertebra bears a pair of large feathers similar to the remiges on the wing. The caudal vertebrae have long pre- and post-zygapophyses and are tied together ventrally by broad intercentra. The tail itself was not flexible and tended to move as a unit.

The 7 cervical vertebrae posterior to the axis all bear cervical ribs. There are 13 thoracic ribs. They are double headed and do not attach to ossified sternal ribs nor do they bear ossified uncinate processes. According to de Beer about 12 pairs of abdominal ribs (gastralia) are present. The gastralia continue anteriorly almost to the coracoids, leaving little space for a sternum. This, coupled with the fact that no sternum is preserved in any of the specimens (radiographs recently made by Whetstone indicate that the supposed sternum of the London specimen is really some 3 vertebral centra), demonstrates that *Archaeopteryx* differs from any other known bird in lacking an ossified sternum.

The shoulder girdle of *Archaeopteryx* is also unique in having large, broad coracoids which must have almost met on the midline of the chest, forming with the huge furcula a sort of surrogate sternum. The role of the furcula in providing a site for the origin of flight muscles has been discussed by Olson and Feduccia (1979) who show that the absence of an ossified sternum does not preclude the possibility of flight for *Archaeopteryx*.

The scapulae are narrow and lie almost flat above the ribs and near the transverse processes of the vertebrae, unlike the scapulae of the coelurosaurian dinosaurs which lie more on the side of the chest. The scapulae are fused to the coracoids and tie the shoulder girdle tightly to the axial skeleton.

The furcula is relatively larger and more massive than in any other known bird. It appears to have attached to the coracoids at the site of the 'biceps tubercle.'

The humerus has a large, elongate deltoid crest and 2 distal condyles. It is slightly longer than the ulna. The ulna is slightly longer than the radius because of its low, blunt olecranon process.

The carpus shows at least 3 carpal bones. The most important of these is a large lunate carpal thought to be composed of the fused distal carpals 1 and 2. In modern birds this carpal bone forms the trochlea carpalis. The 3 metacarpal bones which form the rest of the carpometacarpus in modern birds are unfused in *Archaeopteryx*. The digits contain a full complement of unreduced phalanges. Ostrom counts the digits present as I (2 phalanges), II (3 phalanges) and III (4 phalanges). This would suggest that the digits present in modern birds are I–III (contrary to most embryological interpretations). The penultimate phalanges of the digits are elongate as they are in theropod dinosaurs. The terminal phalanges form large claws with long, sharp horny sheaths.

The pelvic girdle is best studied on the London and Berlin specimens. The ilium is fairly large and elongate anterior to the acetabulum but is short and pointed posterior to it. The ischium is recurved posteriorly and much shorter than the pubis. It curves ventrally and may have met the ischium on the other side to form an ischial symphysis similar to the long pubic symphysis. The acetabulum is partially closed and resembles *Hesperornis* and *Ichthyornis* in this respect rather than modern birds, which have the acetabulum completely open.

Although Ostrom (1976) has published a new restoration of the pelvis of *Archaeopteryx* showing the pubis directed downwards, the London and Berlin specimens leave little doubt that it was directed posteriorly as in all other known birds (opisthopubic).

The femur is relatively long and slender. It has a shallow anterior curve and resembles galliforms in this respect. It has a small lesser trochanter separated from the greater trochanter by a groove. The tibia is a long, straight bone with only a very slight cnemial crest. It is bounded laterally by a long and very slender fibula which terminates distally in an expansion flattened against the lateral border of the tibia. The fibula does not contact the tarsal joint as it does in reptiles. The distal end of the tibia bears two condyles composed, as in modern birds, of the proximal tarsal bones which fuse on to the tibia. The medial condyle and most of the intercondylar articulation is composed of the astragalus and the lateral condyle is made up of the calcaneum. There is a long triangular bone (pretibial bone) above the calcaneum which fuses with the calcaneum and the astragalus. The pretibial bone is found in all other birds but not in reptiles.

The metatarsals are fused proximally but it is difficult to determine whether the distal tarsals are fused to form a real tarsometatarsus. A short, slender metatarsal V is described for the Eichstatt specimen but it did not bear any phalanges. The trochleae are somewhat arched on the distal end and the hallux is directed posteriorly. The digits resemble those of modern birds and the claws are long, sharp, and recurved.

The invasion of the skeleton by the air sac system seems to have occurred relatively late in avian evolution. The postcranial skeletons of *Archaeopteryx*, *Hesperornis*, and *Ichthyornis* are all nonpneumatic.

Mode of life. *Archaeopteryx* was a small predator which probably caught insects and small vertebrates like lizards. Whether it was terrestrial or arboreal has recently become the subject of controversy. The presence of an opposable hallux which would enable the foot to grasp small branches and the relatively sharp claws on the hind toes suggest arboreality, while the curved femur and bipedal stance might suggest a terrestrial mode of life. The presence of a fused tarsometatarsus could be used to support either argument. The clawed digits on the wings might have been used for prey capture or they might have been used to climb trees and manipulate food. In some respects they resemble pterosaurian claws, which are generally accepted as being for climbing.

Ostrom (1979) has argued that *Archaeopteryx* was a terrestrial, cursorial predator which may have had limited powers of flight, but was derived from a flightless ancestor that used its remiges as an insect net. He proposes that the forelimbs were clapped together in advance of the running bird in order to catch flying insects. This is an extension of the cursorial origin of bird flight expounded by Nopsca, and has some serious flaws. Even if one ignores the wear and tear to which such a prey capture mechanism would subject the feathers, it is difficult to see how such a predator could capture prey without creating a gust of air which would drive the prey from its grasp. It also seems unlikely that enough ground speed could be attained to provide the impetus for the early, poorly adapted, phases of powered flight.

Most workers accept some real flight capacity for *Archaeopteryx*, although all would agree that it must have been a relatively weak flyer. The small size of the brain suggests a relatively poor quality of sensory-motor coordination for flight, but probably adequate for a weak flyer traversing short distances. The brain of *Ichthyornis* is also comparatively primitive, but no one doubts that *Ichthyornis* was a good flyer. The long tail contains many free vertebrae but these are locked together so that they function as a unit. The tail itself is so designed that it must have provided some lift. In this case, the absence of a pygostyle would not preclude active, powered flight although some lack of manoeuvrability would be expected.

Origin of birds. Ostrom has argued that *Archaeopteryx* provides the best evidence concerning the origin of birds and he is correct as far as the evidence goes. However, some aspects of the anatomy of *Archaeopteryx* are not available for comparison (for instance the basicranial and otic regions of the skull) and in those areas we must rely on other Mesozoic birds or modern birds.

Archaeopteryx shows a mosaic of reptilian and avian features. Among the avian features are:

1. The presence and structure of the feathers.
2. The differentiation of the remiges into primaries and secondaries.
3. The angle between the scapula and the coracoid.
4. The fusion of the clavicles into a furcula.
5. The opisthopubic pubes.
6. The presence of a pretibial bone on the tibiotarsus.
7. The fusion of the metatarsals and probably the distal tarsals to form a tarsometatarsus.
8. The opposable hallux in the foot.

The reptilian features include:

1. Teeth on the premaxillary, maxillary and dentary. These teeth are unserrated, have a flattened triangular crown, and are separated from the expanded bony base by a distinct waist. In all of these features they resemble the teeth of crocodilians.
2. The amphicoelous or opisthocoelous articulations between the vertebral centra. All living birds have heterocoelous vertebrae at least in the anterior thoracic and cervical region.
3. The short sacral region.
4. The long tail with 20–23 free vertebrae and no pygostyle.
5. Simple unjointed ribs lacking ossified uncinate processes.
6. The presence of gastralia.
7. The absence of an ossified sternum.
8. The absence of a fused carpometacarpus.
9. The presence of clawed digits on the hand. The front foot has a lunate carpal bone and elongated penultimate digits much like the condition in theropod dinosaurs.
10. Relatively simple brain with large olfactory lobes.

Relationship of *Archaeopteryx* to modern birds. *Archaeopteryx* is maintained in a separate subclass, the Sauriurae, by Brodkorb (1963). This subclass seems to be supported by a wide variety of derived characters which include: (1) the reduction or loss of the squamosal; (2) the fusion of the proximal but not the distal ends of the metatarsals, and the fusion of the proximal metatarsals in a row rather than having the proximal end of metatarsal III posterior to the proximal ends of metatarsals II and IV, as in modern birds. These features suggest that *Archaeopteryx* was not the direct ancestor of modern birds but was on a side branch of avian evolution. There must be undiscovered birds contemporary with *Archaeopteryx* that more closely resemble modern birds, and *Archaeopteryx* cannot be utilized as the sole model for avian origins.

ARCHAEORNITHES: a subclass (see under CLASS; also ARCHAEOPTERYX; FOSSIL BIRDS).

ARCTIC: unlike the Antarctic, does not represent a separate zoogeographical area but rather the northern extremities of the Palearctic and Nearctic Regions (together Holarctic). See DISTRIBUTION, GEOGRAPHICAL; NEARCTIC REGION; OCEANIC BIRDS; PALEARCTIC REGION.

ARCTOGAEA: a grouping by T.H. Huxley (1868) of the classical zoogeographical regions that excludes only the Neotropical and Australasian Regions, which he called 'Neogaea' and 'Notogaea' respectively; Arctogaea has more recently been termed 'Megagea' (see DISTRIBUTION, GEOGRAPHICAL).

ARDEAE; ARDEIDAE: see under CICONIIFORMES. For the purposes of this work, *Cochlearius* is included in the Ardeidae, although by some regarded as constituting a separate monotypic family. There are 2 subfamilies, Ardeinae (see HERON), and Botaurinae (see BITTERN).

ARENA DISPLAY: see LEK.

ARGUS: substantive name, alternatively 'argus pheasant', of the Great Argus *Argusianus argus* and the Crested Argus *Rheinardia ocellata* (see PHEASANT).

ARRANGEMENT: in taxonomy, the process (and its result) of placing the items of a category, i.e. the taxa of next lower rank, in some sequence or pattern. In any work in which birds have to be systematically listed, there arises not only the matter of assigning them to their appropriate taxa but also the question of arranging the items within a taxon—it may be species within a genus (or subgenus, if any), or genera within a family (or subfamily or tribe), or the like. Subspecies are commonly arranged, within the species, on some geographical basis; this is reasonable, as subspecies are in fact geographical forms and by definition allopatric. At other levels there is a convention that the items are arranged in a 'natural' sequence, which is supposed to keep together those that are most closely related; and the more 'primitive' (according to belief) are placed first. The objection to this, strongly voiced by some taxonomists, is that the information necessary for confidently making such an arrangement seldom exists; and that, if it did, the facts could often not be adequately expressed in any linear sequence. On this view, the so-called 'natural' arrangement is apt to be misleading; and unless the reasons are fully stated, which often is not the case, the basis cannot be critically examined and the practice is therefore devoid of scientific value. The alternative course—frankly admitting ignorance—is to arrange the items within each taxon alphabetically; this is already followed by taxonomists dealing with certain other classes of animals and has obvious convenience for the reader where the number of items is considerable. Those who advocate this procedure suggest that it remains possible to indicate views about relationships by the use of symbols. Alphabetical arrangements have not, however, been widely used by ornithologists, who generally prefer to attempt an arrangement which reflects evolutionary relationships; but they have been used to advantage in world lists of species where quick and easy reference is the primary aim.

ARRESTED MOULT: interruption of moult within a tract of feathers, usually the primaries or other flight feathers. At the time of interruption, growing feathers continue to grow to their normal length, but the next in sequence to be moulted is (are) retained until a later date. When moult recommences, it usually does so from the first retained feathers (a phenomenon sometimes separately termed 'suspended' moult) but occasionally from the original moult focus or even from a new focus in that feather tract. Moult may be arrested to allow migration or breeding at an appropriate date.

ARROWSNAKE: see BIBLE, BIRDS OF THE.

ARTAMIDAE: a family of PASSERIFORMES, suborder Oscines; WOODSWALLOW.

ART, BIRDS IN: bird subjects that have from the very earliest times featured in man's artistic efforts. Amongst the pictures which have survived through the ages not the least interesting are those painted by the ancient Egyptians; birds were thought to be 'winged souls' and some species were assigned to particular gods, a hawk being the emblem of Horus, and Thoth (god of learning) being represented by the Sacred Ibis, to quote two examples. The discovery at Hermopolis of a great number of mummified ibises, with their likenesses painted on their wrappings, seems to denote that this species was the object of a cult. The belief that a soul should not go unattended to the next life is accountable for the interesting pictures found on the walls and sarcophagi of excavated tombs. Originally food, chattels, and slaves were buried with the deceased, but later this practice gave way to pictorial records of the dead man's life and everything connected therewith. Some fascinating examples of these early Egyptian bird paintings are to be seen in the British Museum; ducks swimming in a pond, geese feeding, and—of greater interest still—a study of fowlers surrounded by a variety of birds in flight. Birds were also popular with the artists of ancient Greece, who introduced them into their still-life paintings of fruit and flowers in much the same way as did the Dutch painters many centuries later. Examples of bird studies by Greek artists were brought to light in the excavations of Pompeii and Herculaneum.

Passing from ancient times to the Middle Ages, those who have looked closely at illuminated manuscripts will have noticed how often brilliant tiny bird forms were used in decorating the elaborate borders of psalters and breviaries. At first these were inclined to be somewhat linear and frequently fabulous representations; but in the 13th century nature came to be studied more closely, with the result that the pictures gained realism and animation. In the middle of the century the Emperor Frederick II wrote his treatise on falconry, *De Arte Venandi cum Avibus* (now in the Vatican), with very carefully executed marginal illustrations of hawking scenes and bird life. Another example of this type of illustration is in the British Museum (Add. MSS. 27695, 28 841); it consists of fragments of a Latin 'Treatise of the Vices' written by one of the Cocharelli family of Genoa towards the end of the 14th century, and the characteristics of the birds which appear in this manuscript, their postures, movements, and flight denote a remarkably keen study of avian life. Another document of great interest is the sketchbook of a 14th century monk in the Pepys Library at Magdalene College, Cambridge; this contains several pages devoted to coloured studies of birds, the majority of which are identifiable.

With the Renaissance came a break with tradition, and art ceased to be controlled by the Church. Painters expressed themselves more freely and with greater imagination, and all forms of nature received their closer attention. Giotto was one of the first to adopt naturalism in art, and at Assisi is still preserved amongst his frescoes the touching scene of a group of small birds listening attentively to St Francis preaching, whilst a late-comer flutters down to join the congregation. From the 14th century onwards, birds appeared frequently in the works of the great masters, sometimes in a symbolic role or in some mythological composition, sometimes as pets in portrait studies or as colourful details in landscapes. Since many birds appear in pictures in the National Gallery in London, it is proposed to refer to a few of these pictures with an explanation of their particular significance in each instance.

Those well acquainted with religious paintings may have noticed how often the Goldfinch is depicted. On account of its preference for thistles it was adopted by the Church to symbolize the Passion of Christ, and in the National Gallery it is several times represented. Baroccio in his 'Holy Family' (No. 29) places the bird in the hand of St John, who holds it high out of reach of an interested cat; whilst in Benozzo's altarpiece (No. 283) a Goldfinch has settled at the Madonna's feet in company with a Great Tit, the latter having no particular significance so far as is known. In Cima's 'Madonna and Child' (No. 634) a Goldfinch flutters in the hand of the Christ Child. Crivelli made two very different studies of this bird (Nos. 668, 788); in both pictures the usually gay little creature sits dejectedly on a leafless branch with its back turned on the spectator. A whole 'charm' of Goldfinches captured by the brush of Rubens is to be seen fluttering in a thicket in his famous landscape 'Chateau de Steen' (No. 66).

The Peacock graces many a Nativity and Annunciation, and in his wonderful painting of the latter scene (No. 739) Crivelli has shown to the full the grace and dignity of this bird, the symbol of Immortality owing to the legend that its flesh does not decay. Botticelli introduces it into his 'Adoration of the Magi' (No. 1033). The Peacock is perhaps best known as representing Pride and Vanity; and in classical mythology it is assigned to the goddess Juno, whom it accompanies in Rubens's 'Judgment of Paris' (No. 194) and is shown having an altercation with Paris's dog. In the same picture figures Minerva's owl, here symbolizing the wisdom of its mistress, although in the Christian Church it was sometimes adopted as a Satanic symbol due to its preference for darkness and horror of the light. As a symbol of wisdom, an owl is sometimes shown with St Jerome, as in the picture by Tura (No. 773).

That such a pleasant creature and charming songster as the Blackbird should be connected with the Prince of Darkness seems hard indeed but, in the eyes of the early Church, apparently the bird's very charms were sufficient to merit such an association. The dove, besides representing the Holy Ghost, also stood for Purity and Peace and is often shown with the Blessed Virgin, especially in scenes of the Purification, it being customary on such an occasion to make an offering of a pair of Turtle Doves in the Temple. A Turtle Dove can be seen in Crivelli's 'Annunciation' to which reference has already been made. In mythology the dove is attributed to Venus. The Partridge, chosen to signify Truth, was also curiously enough sometimes symbolic of the Devil. Two of Catena's pictures include it (Nos. 234, 694), and in Antonello's 'St Jerome' (No. 1418) a Partridge and a Peacock are in the foreground with their backs turned to each other, which possibly indicates that here they represent Truth and Vanity respectively. In Crivelli's 'Madonna and Child' (No. 724), perched high on the ornate throne is a Swallow, placed there as the symbol of the Incarnation. Scenes of the Annunciation also show this bird, which was connected too with the Resurrection owing to a belief that in winter it hibernated in the mud to emerge again at springtime to herald the reblossoming of nature.

The domestic cock, associated with St Peter, denotes watchfulness and vigilance because of its early rising. It was also the emblem of St Vitus of Bohemia, under whose patronage come actors, dancers, and those who find difficulty in rising in the morning. Another bird denoting vigilance is the Crane. According to a legend the King of the Cranes was guarded each night by sentries standing on one foot with a stone in the other. If sleep overcame them the stone was supposed to drop on the other foot and awaken them.

The Eagle symbolized the Resurrection and also became the emblem of St John the Evangelist, and thus formed an appropriate support for the base of lecterns in churches, a fine contemporary example by Elizabeth Frink being in Coventry Cathedral, England. In Mantegna's 'Agony in the Garden' (No. 1417) a Golden Eagle, which has been referred to as the 'Bird of Fate', occupies a prominent place in the picture. It is also to be seen in greater detail in the painting ascribed to Damiano Mazza (No. 32) showing the bird carrying off Ganymede to Olympus. A very much finer eagle painting is contained in the picture by Rubens of 'Prometheus

Bound'. In this, as in others where birds or other animals were concerned, Rubens collaborated with Frans Snyders. The painting is now in Philadelphia, but Snyders's remarkable sketch for it can be seen in the British Museum. The story of Jupiter's attentions to Leda, in the guise of a swan, captured the imagination of more than one painter. The National Gallery picture after Michelangelo (No. 1868) shows the most intimate phase of the liaison between the god and his mortal mistress, whilst Leonardo da Vinci in his treatment of the subject (Galleria Borghese, Rome, and other versions elsewhere) depicts the couple standing happily side by side whilst their offspring hatch out of egg-shells in the background.

So far, reference has been made to the birds which appear in the paintings of the Italian school and chiefly those of a religious nature; but mention must be made of one of the great masters of the Early Netherlandish school, Hieronymus Bosch. His painting 'The Garden of Delights' in the Prado is remarkable for the extent to which the artist relied on avian symbols to convey a sense of the paranormal. Birds abound in the painting, ranging from an evil and foreboding owl to the myriads of swallows which fly in serpentine curves through the skull-like rocks. Later Dutch artists of the 17th century treated birds in a more straightforward manner, not a few of them specializing in this branch of painting. Whilst their still-life pictures very often contained a profusion of dead game-birds of every kind, the studies of live birds are very much more interesting; there are some very fine examples in the Wallace Collection (London). One painting there, by d'Hondecoeter, shows a domestic rooster and a Peacock stepping out side by side through a farm-yard with all the dash and swagger of Regency dandies. A coloured drawing by the same artist, in the British Museum, portrays the same two species engaged in a fight, with smaller fowls fluttering round them.

The Wallace Collection also has paintings of Peacocks, and of macaws and other birds of the parrot family, by Jan Weenix, a cousin of d'Hondecoeter; and there are studies of hawks by Joannes van Noord, and of Pheasants and other game-birds by Desportes. The French painter Oudry is well represented in this collection by some very fine action pictures such as 'A Fox in a Farmyard', 'Hawk attacking Partridges', 'Hawk attacking Wild Duck', and 'Wild Duck aroused'. Another 17th century bird painter of note was Jakob Bogdany, of Hungarian origin, who was employed by William III to decorate the royal palaces. He specialized in exotic fowls, which are to be seen in the large collection of his works at Kew Palace and Hampton Court.

While John White (fl. 1577–1590), who recorded the birds of Virginia and Florida on a voyage made with Sir Walter Raleigh, can claim to be the first British bird artist, his drawings in the British Museum are not widely known. Far more famous was Francis Barlow, a native of Lincolnshire, who specialized in sporting pictures and painted birds with great spirit and accuracy. The owners of large country houses were so taken with his work that they employed him to decorate their ceilings. His pictures are mostly in private collections, but his 'Owl being Mocked by Small Birds' may be seen at Ham House (London). At the British Museum, besides a drawing of an eagle carrying off a duckling, there is a large collection of his illustrations for Aesop's Fables (published 1666), quite a number of which are bird pictures. There are also water-colours by Barlow at the Victoria and Albert Museum, and the Marquess of Bath's collection at Longleat contains striking portraits of a Cassowary and an Ostrich.

The 18th century, the age of rococo, saw the great flowering of the decorative arts in Europe, which entailed much use of avian forms. Among the first productions of the Meissen porcelain manufactury, by the great modellers Johann Gottlob Kirchner and Johann Joachim Kaendler, were the large white figures of birds—vultures, swans, cocks, peacocks and pelicans, modelled from living specimens in the private menagerie of Augustus the Strong. The Meissen example was to be followed by virtually all the later porcelain factories, and the use of George Edwards' illustrations of birds by the painters and modellers of the Chelsea porcelain factory is but one example. Another important decorative innovation in the 18th century was the importation of wallpapers from China, which featured prominently the gay plumage of peacocks, Mallards and other wildfowl. These were the first Oriental pictorial depictions of birds to arrive in Europe.

The productions of sporting painting, that peculiarly English genre of the 18th and early 19th century, have perhaps few appeals for the contemporary bird-lover, for they consist of depictions of snipe and game shooting by George Morland, Samuel Howitt and James Pollard, and cock fighting scenes by Thomas Rowlandson and George Morland. One of the finest paintings of the latter sport was executed in India by Johann Zoffany, his 'Captain Mordaunt's Cock Fight' (private collection). The great anatomist George Stubbs never completed his detailed comparative studies of 'The Tiger, the Human Female and the Common Fowl', (Worcester Public Library, Massachusetts).

Although romantic poetry is suffused with avian imagery as the appropriate symbol of freedom, romantic painting provides us with surprisingly few pictures depicting birds, with the exception of some magical evocations by J.M.W. Turner in the Tate Gallery and at Petworth House, Sussex, of ducks landing and taking flight, and a powerful painting by James Ward of 'The Ascent of the Swan' in a private collection, a beautiful drawing for which is also in the Tate. The Victorian master of animal painting, Sir Edwin Landseer, also portrayed birds extremely well, notably the 'Golden Eagle and its Nest' in the Victoria and Albert Museum, and the maternal affection of the hen for its chicks which can be seen in 'The Drover's Departure' in the same collection. The great champion of the Pre-Raphaelite School's doctrines of fidelity to nature, John Ruskin, himself produced a number of studies of birds of the utmost virtuosity, notably an exquisite Kingfisher in the Ashmolean Museum, Oxford. In more humorous vein, the Royal Academician Henry Stacy Marks specialized in anthropomorphic portrayals of birds in human situations. A fine example, of parrots in conclave like politicans, is in the Russell Cotes Art Gallery, Bournemouth, England. Both Stacy Marks and Sir John Everett Millais painted genre studies of ornithologists revelling in their collections of stuffed specimens, Millais's work 'The Ruling Passion' at Glasgow Art Gallery being particularly interesting, since it was inspired by a visit to John Gould in old age.

The arrival in the 1860s of the first Japanese prints in this country, which included bird studies by Hokusai and Hiroshige, was to have a marked influence on British art. In the aesthetic 1870s it led to a remarkable concentration on two very dissimilar birds, the sparrow and the peacock. Sir Edward Burne-Jones produced several lively studies of sparrows, in Birmingham Art Gallery, England, inspired by Hokusai's depiction of the bird in the Mangwa, and the sparrow was also widely depicted on ceramics, fans and painted furniture. The peacock, which flaunted its beauties both on Chinese decorative wallpapers and on the robes of Japanese geisha in prints, inspired both J.A.M. Whistler and Albert Moore to decorate rooms with peacock motifs, Whistler's room being preserved in the Freer Gallery in Washington. Peacock feathers indeed became the virtual banner of the aesthetic movement, finding a later echo in America in the striking posters of Will Bradley and the art nouveau glass of Louis Comfort Tiffany. But the British artist most influenced by oriental art was Joseph Crawhall, whose memorable paintings of cockerels and pheasants, rendered in a fluid watercolour technique which recalls the Zen masters, can be seen at Glasgow Art Gallery.

If the peacock, symbol of vanity and luxury, was the bird most identified with the aesthetic movement, the goose was to be especially favoured by the Barbizon School in France, and their spiritual followers in the New English Art Club. Jean François Millet was particularly fond of the theme of the goose girl, with the opportunities it afforded for conveying the simple calm of rural life, and this enthusiasm was shared by followers as diverse as Camille Pissarro, and the English artists George Clausen and Edward Stott. While the Impressionists rarely painted birds, Manet's lithographs for Edgar Allen Poe's poem 'The Raven', and Monet's swaggering 'Turkeys' in the Jeu de Paume, Paris, should be mentioned. A few hours before he shot himself, Van Gogh painted a flight of black Rooks, traditionally birds of ill omen, flying low over a corn field against a stormy sky (Van Gogh Museum, Amsterdam).

In the 20th century, when man himself took flight, the bird continued to occupy its central position as a symbol in the realm of art, not only in pictorial but, surprisingly, even more in sculptural form. The smooth contours of birds provided an ideal point of departure for the highly stylized yet naturalistic technique of the French sculptor François Pompon (1855–1933) who can claim to be the finest sculptor of avian subjects since Egyptian times. His work, which includes examples of owls, pheasants, doves, turkeys, ducks, crows, marabou storks and geese can be studied in the Muséum d'Histoire Naturelle in Paris. In contrast to Pompon's classical style, the bronzes of Rembrandt Bugatti (1885–1916) are characterized by an exuberant Romantic force. They crystalize a strikingly observed moment, as, for example, a pair of courting pelicans with outstretched wings, in freely modelled studies which were produced very quickly, after long observation, in Antwerp Zoo, where examples of his work can be seen in a collection of great artistic interest. But the most important sculptor to be inspired by birds in the present century was Brancusi, whose 'Bird in Space' (Beaubourg, Paris; Peggy Guggenheim Collection, Venice) demonstrates that the inspiration of avian flight can be transposed into a strikingly beautiful abstract form.

Picasso's eclectic genius was also to find inspiration in birds. His monumental etchings for Buffon's 'Natural History' are among the most memorable of his graphic work, while later he also produced sculptural birds and ceramic owls at Vallauris, although his most famous avian image is undoubtedly the Dove of Peace. His contemporary Georges Braque also depicted the dove and the pigeon, and during what was virtually a lifetime's obsession with this subject matter produced synthesized, highly stylized abstract shapes which always retained an implicit life force.

A notable German Expressionist who depicted birds was Emil Nolde in a powerful series of watercolours of storks and cranes painted at Berlin Zoo, which can be seen at the Nolde Foundation in Seebull. Chagall and Max Ernst, the Surrealists, produced respectively blue birds symbolic of hope, and images of avian menace of nightmarish proportions. See also ILLUSTRATION, BIRD.

ARTENKREIS: see under SUPERSPECIES; RASSENKREIS.

ARTERY: see HEART; VASCULAR SYSTEM.

ARTICULAR: when used as a noun, a paired bone of the lower jaw (see SKULL).

ARTICULATION: jointing (see SKELETON, POST-CRANIAL).

ARTIFICIAL NEST SITES: see NEST SITES, MAN-MADE.

ASCENDENT MOULT: see DESCENDENT MOULT.

ASITY: the name used for the 2 *Philepitta* species in the family Philepittidae (Passeriformes, suborder Deutero-Oscines); Sunbird-Asity is used for the 2 members of the genus *Neodrepanis*.

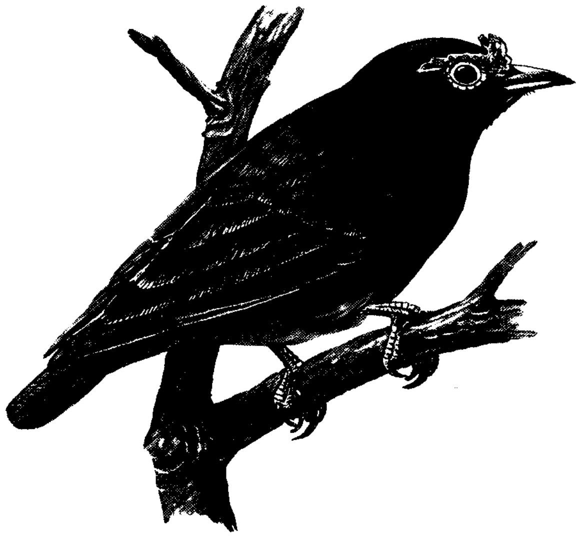
The family, confined to Madagascar, belongs to the assemblage of primitive perching birds related by the simple musculature of the syrinx, and the morphology of the bony stapes, to the tyrant-flycatcher group (Tyrannidae etc), with so many species in the New World, but represented in the Old World only by the broadbills Eurylaimidae, pittas Pittidae and New Zealand wrens Xenicidae. This relict type of distribution, and the great difference between the 2 genera, indicate that the Philepittidae are of considerable antiquity.

Characteristics. The 2 *Philepitta* spp. are *c.* 15 cm long, stoutly built, the bill not as long as the head and broad at the base, wings and feet of moderate length, tail short. The male of the Velvet Asity *P. castanea* when freshly moulted is black, most of the feathers fringed with yellow. These fringes wear off, and in the breeding season the plumage is velvety black, with a wattle of bright blue and emerald developed above the eye. The female and young male are olive above, greenish white scaled with olive below. Those of Schlegel's Asity *P. schlegeli* are very similar, but the adult male is mainly olive and yellow, with black confined to the top of the head and to the breeding wattle surrounding the eye.

The Sunbird-Asity *Neodrepanis coruscans* is *c.* 10 cm long, with a short tail and long, decurved bill. In the breeding season the male is iridescent blue above, dull yellow below, with a bright blue wattle around the eye. Unlike *Philepitta*, with apparently only one moult annually, *Neodrepanis* has two. In the off-season the male of *coruscans* is mainly olive above, and lacks the wattle. The female at all seasons is similar to the off-season male. Salomonsen's (1965) Sunbird-Asity *N. hypoxantha* differs from *coruscans* by its shorter bill, differently shaped outermost primary and much brighter yellow underparts. For many years *Neodrepanis* was associated with the sunbirds Nectariniidae, until it was shown that the throat musculature was similar to that of *Philepitta*. The external resemblance to sunbirds is due to convergence.

Habitat. All 4 species frequent dense evergreen forest, *Philepitta* for the most part the undergrowth, *Neodrepanis* probably at all levels.

Distribution. The family is confined to the forests of the humid east of Madagascar, except that *P. schlegeli* may replace *castanea* completely in the north-west.



Velvet Asity *Philepitta castanea*. (*M.W.*).

Populations. The *Philepitta* species and *Neodrepanis coruscans* are common in suitable habitat, but numbers must be continually diminishing due to replacement of forest by cultivation. Records of *N. hypoxantha* are few, but it is probably not extinct, as sometimes suggested.

Movements. All 4 species appear to be strictly sedentary.

Food. *Philepitta* is predominantly frugivorous, plucking small fruits from forest shrubs. *Neodrepanis coruscans* (and presumably *hypoxantha*) is primarily insectivorous, but also probes the corollas of certain flowers, probably for nectar.

Behaviour. *Philepitta* is sluggish and confiding, usually solitary. *Neodrepanis coruscans* is usually solitary. Despite its superficial resemblance to sunbirds, it is less active.

Voice. The male of *P. castanea* is said to have a thrust-like song, questionable in view of the primitive syrinx. A 'soft, hissing *Shee-shee* . . .' has been recorded for *N. coruscans*.

Breeding. Only the nest of *P. castanea* is known—a pear-shaped pensile structure, the top woven about the supporting branches, a projecting roof over the side entrance near the top. A clutch of 3 eggs was elongate ovate, and pure white.

ASPERGILLOSIS: see DISEASE.

ASSEMBLY, NOUN OF: a collective noun for a number of birds (or other animals) of one kind together; some of these words are of general application, while others have restricted meanings. The usual term for an assemblage of birds is 'flock'; sometimes 'flight' if they are on the wing; sometimes 'party' if the number is quite small. Other ordinary English words can of course be used for descriptive purposes in appropriate circumstances, e.g. 'assemblage', 'congregation', 'multitude', 'horde', 'host', and (on the water) 'raft'. The word 'brood' is used for the chicks or nestlings hatched from a 'clutch' or 'set' of eggs laid by one hen bird for simultaneous incubation. Birds breeding gregariously are referred to as a 'colony'. 'Pair' means a male and a female, presumably united. 'Brace' means two birds, usually dead—a measure used in counting the sportsman's 'bag'.

Then there are the special nouns of assembly which it is correct, or supposedly correct, to apply to particular kinds of birds in preference to the more general term, and only to such kinds. Some of these are genuine items from the vocabulary of medieval venery, whether now obsolete or still to some extent current (mainly among sportsmen). Others are mere inventions of later pedantry. Others again are erroneous, having found their way into the category by misconception. No attempt at an exhaustive list need be made here.

The word 'covey' is used for a family party or similarly sized flock of partridge or grouse, and is perhaps the only one of these special words that has any wide currency in English as spoken in Great Britain at the present day. There are some people, however who would always be careful to speak of a 'gaggle' or (if flying) 'skein' of geese, a 'pack' (bigger than a covey) of grouse, a 'wisp' of snipe, or a 'spring' of teal. On the other hand, one would be only half serious in speaking of a 'murder' of crows, a 'charm' of goldfinches, a 'watch' of nightingales, a 'nye' (various spellings) of pheasants, a 'clattering' of choughs, a 'covert' of coots, a 'siege' of herons or bitterns, a 'fall' of woodcock, a 'herd' of cranes, curlew, or swans, a 'trip' of dotterel, a 'bevy' of quail, a 'chattering' or 'murmuration' of starlings, or a 'dissimulation' of small birds.

There are a few specific terms for colonies, according to the kind of bird concerned. 'Rookery' and 'heronry' are of the best usage, and the former has been adopted also for penguins (Spheniscidae) by ornithologists in the Antarctic. Others are easily invented, where euphony permits, and some have wide currency—'gullery', 'ternery', 'swannery'; but 'loomery' (guillemots) is a more sophisticated usage. These inventions are not free from affectation, however, and the general term 'colony' is usually to be preferred.

Hare, C.E. 1939. The Language of Sport. London.

ASSOCIATION, INTERSPECIFIC: either between different species of birds or between birds and other than avian species—see under BROOD-PARASITISM; CROCODILE-BIRD; FEEDING HABITS; FLOCKING; HONEYGUIDE; MAMMALS, ASSOCIATION WITH; NESTING ASSOCIATION; OXPECKER; PARASITISM; TAMENESS.

ASTRAPIA: substantive name sometimes used for the BIRDS-OF-PARADISE of the genus *Astrapia*.

ASYMMETRY: a condition not usually present in any marked degree in the external characters of birds, apart from individual abnormalities. A striking exception is that of the Wrybill Plover *Anarhynchus frontalis*, in which the bill is deflected to the right (see BILL; PLOVER). Not ordinarily visible is the often great disparity between the ear openings on the two sides in owls (Strigiformes) (see HEARING AND BALANCE; OWL). As in mammals, there is some asymmetry in the internal organs; thus, only the right aortic arch develops (in mammals it is the left)—see VASCULAR SYSTEM; and only the left ovary of birds is functional as a rule (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM). See also FOOTEDNESS.

ASYNCHRONOUS HATCHING: see HATCHING.

ATAVISM: see PLUMAGE.

ATLAS (1): in ornithology, understood to mean a collection of maps showing bird distributions within a defined region. It is based on dot-distributions within a defined, regular grid, during a defined, limited time period in which fieldwork for the maps was carried out. Thus, a 'breeding bird atlas project' or a 'winter atlas scheme' would involve the gathering of information for the production of maps of the breeding or wintering distributions of birds within the defined area. Atlas projects involve every bird species present (and not just a selection of those present) in the defined area at the relevant season.

The first national breeding bird atlas project covered Britain and Ireland during 1968–1972, but others have followed in many European countries and also in various states in the USA, in parts of southern Africa, and in Australia and New Zealand. In countries where some species are breeding in all seasons, where knowledge of the avifauna is meagre or where manpower for fieldwork is in short supply, atlas projects have covered all 12 months of the year. Elsewhere, breeding or winter atlas surveys have usually been restricted to 4 or 5 months of the year (with special exceptions for species which nest earlier or later than others). Surveys usually extend over several years, to ensure complete cover and to avoid bias due to one freak year, but the time span is kept short to 'freeze' distributions, so far as possible, even for those species expanding or contracting their ranges.

Fieldwork is carried out within units of a defined grid, which may vary from 1 km × 1 km squares to much larger units, depending upon the total area of the region being surveyed and, often, on the dimensions of the most easily obtained maps. For instance, the continent-wide mapping of Europe is being carried out using the 50 km × 50 km Universal Transverse Mercator grid; mapping in Britain and Ireland uses the 10 km × 10 km squares of the National Grid; mapping in English counties often uses 2 km × 2 km squares (tetrads); mapping in France in 1970–74 used 20 km × 27 km rectangles corresponding to available maps.

Atlas surveys are often based on presence/absence, but with other information added (such as proof of breeding, see below). Some projects, however, attempt quantitative assessments within the grid units, usually based on mathematical progressions (1–10, 11–100, 101–1000, and so on).

The internationally agreed criteria for breeding evidence are as follows:

Grade A		**Present**
O	0	Species OBSERVED in breeding season.
Grade B		**Possibly breeding**
H	1	Species observed in breeding season in possible nesting HABITAT.
S	2	SINGING male(s) present (or breeding calls heard) in the breeding season.
Grade C		**Probably breeding**
P	3	PAIR observed in suitable nesting habitat in breeding season.
T	4	Permanent TERRITORY presumed through registration of territorial behaviour (song, etc.) on at least two different days a week or more apart at the same place.
D	5	DISPLAY and courtship.
N	6	Visiting probable NEST-SITE.
A	7	AGITATED behaviour, or ANXIETY calls from adults.
I	8	Brood patch on adult examined in the hand, indicating probably INCUBATING.
B	9	BUILDING nest or excavating nest-hole.
Grade D		**Confirmed breeding**
DD	10	DISTRACTION DISPLAY or injury feigning.
UN	11	USED NEST or egg shells found (occupied or laid within period of survey).
FL	12	Recently FLEDGED young (nidicolous species) or downy young (nidifugous species).
ON	13	Adults entering or leaving nest-site in circumstances indicating OCCUPIED NEST (including high nests or nest-holes, the contents of which cannot be seen) or adults seen sitting on the nest.
FY	14	Adults carrying FOOD for YOUNG or faecal sac.
NE	15	NEST containing EGGS.
NY	16	NEST with YOUNG seen or heard.

Two supranational co-ordinating bodies exist: the European Ornithological Atlas Committee (EOAC) and the North American Ornithological Atlas Committee (NAOAC). J.T.R.S.

ATLAS (2): the first vertebra, articulating with the skull (see SKELETON, POST-CRANIAL).

ATRICHORNITHIDAE: see under PASSERIFORMES, suborder Oscines; SCRUB-BIRD.

ATRIUM: a chamber, especially one or other of the anterior chambers of the heart ('atria', formerly more often called 'auricles'—see HEART).

ATTACK: see AGGRESSION.

ATTILA: generic name used as substantive name of *Attila* spp. (see FLYCATCHER (2)).

AUDITORY MEATUS: see TOPOGRAPHY.

AUGURY: see OMENS, BIRDS AS; ORNITHOMANCY.

AUK: substantive name of 3 species of Alcidae (Charadriiformes, suborder Alcae); in the plural it is the general term for the family. Auks are medium sized birds, ranging in size or weight from 14 cm and 90 g (Least Auklet *Aethia pusilla*) to 36 cm and 1,000 g (guillemots or murres *Uria* spp.): the extinct and flightless Great Auk *Alca* (*Pinguinus*) *impennis* was much larger (*c*. 5,000 g). The family is thought to have evolved from a gull-like ancestor some time during the Upper Cretaceous or Paleocene, 100–70 million years ago. Different authorities recognize between 10 and 14 living genera in 7 tribes containing 22 species. Sixteen of these are found in the Bering Sea region, 12 of which are endemic, and this is probably the auks' area of origin. Several species show geographical variation in size and colour and have been divided into subspecies (especially the Common Guillemot *Uria aalge* and Black Guillemot *Cepphus grylle*). The validity of these subspecies needs to be reassessed in the light of new material, new techniques and new ideas in avian taxonomy. The auks are unique among bird families in the diversity of developmental patterns they display. Three groups have been recognized; one (truly precocial) in which the chicks leave the nest, accompanied by their parents, 2–4 days after hatching, another (semi-precocial) in which the chicks remain at the nest-site until they have attained adult weight, and the third (intermediate) in which the chicks fledge when only part grown. Detailed studies using biochemical techniques are still needed to elucidate relationships.

Characteristics. Auks are monogamous and sexually monomorphic; males are, in general, slightly larger than females. The bill varies in form from nearly cylindrical and pointed (guillemots) to rather broad bills (auklets *Aethia* spp.) which develop during the breeding season a sublingual diverticulum (or gular pouch) which is used to transport liquid food to the nestlings. In puffins (*Fratercula* spp.) and some auklets, the bill is laterally compressed and very high in the vertical plane. Both the tail and the legs are short. The first toe is lacking or vestigial, the other three are fully webbed. The claw of the second toe in puffins is modified and used to dig out nesting burrows.

All have relatively small wings, more or less pointed, which represent a compromise between aerial and submarine flight. In the larger species (guillemots and Razorbill *Alca torda*) remiges are moulted simultaneously, so adults remain flightless for several weeks. This occurs probably because in these species wing-loading is high and, if sequential moult occurred, it would result in energetically inefficient flight. By contrast, the remiges of the smaller species (Least Auklet, Whiskered Auklet *Aethia pygmaea*) are moulted sequentially, as were those of the Great Auk.

Like many other pursuit-diving birds most auks have white ventral and dark dorsal plumage, although a few are predominantly dark (e.g. Tufted Puffin *Fratercula cirrhata*, Rhinoceros Auklet *Cerorhinca monocerata*, Black Guillemot, Pigeon Guillemot *Cepphus columba* and Spectacled Guillemot *C. carbo*). The true auks (*Uria* and *Alca* spp.) are all dark above and white below. In winter the throat is white, and black or brown in summer. A ringed or bridled mutant of the Common Guillemot occurs in the Atlantic and this has a white eye ring and auricular groove. The proportion of bridled individuals is small in southern parts of its range, and rises as high as 50% in the northern parts. Studies of hand-reared birds, of known parentage, suggest that bridling is controlled by a single gene on one of the autosomes. Its selective advantage, if any, is unknown.

In winter the Black Guillemot has varying amounts of white in the upperparts and white underparts, but apart from a white wing patch the breeding plumage is black. The winter plumage of the murrelets (*Synthliboramphus*, *Brachyramphus*) of the North Pacific is grey and white and the majority have no distinctive breeding plumage, any seasonal difference being confined to the colour of the plumage on the head. Two murrelets have very distinctive breeding dress which provides excellent camouflage for the adults while incubating. The plumage of the Marbled Murrelet *Brachyramphus marmoratus* is barred and coloured rufous and brown, and that of Kittlitz's Murrelet *B. brevirostris* is mottled blue-grey and buff.

Atlantic Puffin *Fratercula arctica*. (*B.P.*).

Bright colours, if present, are confined to bill, feet and lining of mouth. Most species of small auklets (*Aethia* spp.) and puffins develop elongated plumes on the head and brightly coloured plates on the bill just before the breeding season. In addition, the Atlantic Puffin *Fratercula arctica* and Horned Puffin *Fratercula corniculata* have these plate-like structures above and below the eye and fleshy rosettes at the gape. In the Crested Auklet *Aethia cristatella* the plates give out an odour like that of tangerine oranges.

High wing loadings result in a fast flapping flight which provides an excellent field character. Gliding over short distances may occur in very strong winds. The neck is retracted in flight and the feet may be covered by the plumage of the underparts, particularly during long flights.

On the ground the posture may be upright (true auks), duck-like (*Cepphus* spp.) or intermediate (puffins), the position and relative size of the legs differing from group to group.

Habitat, distribution and populations. Auks are predominantly pelagic, remaining at sea except during the breeding season. The family is confined mainly to the cooler parts of the Pacific and Atlantic oceans, but some inhabit fresh water in the Baltic and warm water in the Gulf of California. Eighteen species occur in the North Pacific, and 3 (Common Guillemot or Common Murre, Brünnich's Guillemot or Thick-billed Murre *Uria lomvia*, Black Guillemot or Tystie) occur in both oceans. The 2 murres are partially sympatric; the Thick-billed nests further north and the other further south reaching northern Portugal and southern California. The Black Guillemot, unlike the 2 murres, does not nest south of the Bering Strait, being replaced in the North Pacific by the closely related Pigeon Guillemot. The Atlantic Puffin of the North Atlantic is replaced by the Horned Puffin, a close relative, in the North Pacific. The 2 murrelets, Xantus' Murrelet *Synthliboramphus hypoleucus* and Craveri's Murrelet *S. craveri*, which may be conspecific, have restricted ranges off southern California and Baja California. The Great Auk occurred in the North Atlantic.

Some auks are extremely abundant and rank among the most numerous seabirds in the northern hemisphere. Puffins and guillemots are thought to number millions of pairs, as do the Little Auk or Dovekie *Alle alle*, Least Auklet, and Crested Auklet. However, auks are notoriously difficult to census, and until the 1970s few systematic attempts had been made to count them. Nevertheless, it is clear that many species have declined during the present century. Several factors are considered to be responsible: an increase in adult mortality through oiling, drowning in fishing nets, disturbance and shooting (for human consumption) at breeding colonies, changes in distribution and abundance of prey species due to changes in the marine environment or to commercial fisheries. Much of the recent research in alcid biology is a result of industry's efforts to locate oil in off-shore waters and the concomitant threat to these species.

Movements. Little detail of movements is known for most species. Guillemots are thought not to move far from their breeding grounds but ringed individuals from Britain have been located in Denmark and Norway and south to the Bay of Biscay and one (a juvenile) off Gibraltar. Some Razorbills migrate from Britain to the central Mediterranean as do some Puffins from southern populations in Britain, but those from northern populations remain in the North Sea, reaching Newfoundland. Other Puffins have turned up in the Azores. Little Auks regularly move southwards from their northern breeding grounds some reaching the Azores, and are regular winter visitors on passage in Britain.

Food. The diet of adult auks is poorly known, but most species feed on small fish or planktonic crustaceans. The diets of adult and chicks often differ, as do the diets of sympatric species. Even when the same prey are utilized, different alcid species take different size classes of prey. The prey is usually obtained by underwater pursuit, using wings for propulsion and feet for steering, but a few forms are bottom feeders. In the North Pacific there are 5 plankton feeding species (auklets) but only one (Little Auk) in the North Atlantic.

Voice. Most auks are silent at sea. Vocalizations during pair formation and social interactions at the breeding site are relatively simple, and have been described as grunts, growls and *Arrrrs* in the larger species, and as twitters, peeps and whistles in the smaller species.

Behaviour. Auks use a variety of postures and calls during pair formation and other social interactions at the breeding site. In those species with brightly coloured linings to their mouths (red or yellow) the displays often involve the simultaneous use of a body posture, open bill and vocalization. Postural displays involve components such as head turning, raised wings, and in some species a slow 'butterfly flight'. Postural displays used by auks appear to be less ritualized than they are in some other seabirds e.g. gulls Laridae and gannets Sulidae.

Breeding. Most species breed colonially near the sea, on mainland cliffs or on off-shore islands, either on ledges, vegetated seaward slopes or in boulder screes. Within colonies, some of which have as many as 8 alcid species breeding together, the spacing of breeding pairs varies between species. Coexistence is achieved through the use of different nest sites and food types. In addition, for those species which breed in the open, spacing is controlled by social behaviour, but in crevice or burrow nesting species physical features may also determine spacing. In some auks habitat selection and spacing patterns have been shown to be important in breeding success. In all species, both parents take part in incubation and in care of the young. The 4 small precocial species (Xantus' Murrelet, Craveri's Murrelet, Ancient Murrelet *Synthliboramphus antiquus* and Japanese Murrelet *S. wumizusume*) produce a clutch of 2 relatively large eggs (each weighing 22–24% of adult body weight) which give rise to well developed chicks with feet of nearly adult size. They nest in burrows or crevices from which the fledging chicks scramble down to the sea. The Ancient Murrelet is the only one of the group which has been studied in detail; it is unusual among auks in having long (72 h) incubation shifts. The young of this group are led directly to feeding areas 2–4 days after hatching. As the parents do not spend time and energy transporting food to the nest site (as in other auks), this energy saving may explain why members of this group are able to rear a brood of two.

The semi-precocial species consist of 4 groups; the puffins, *Cepphus* species, auklets and the Little Auk, and 2 species of murrelets (*Brachyramphus*). The 4 species of puffins (Atlantic, Horned, Tufted Puffin, and the misnamed Rhinoceros Auklet, which is not an auklet but a puffin) are diurnal at the breeding colonies. They breed in burrows (dug by themselves) or in rock crevices. The single immaculate or obscurely marked egg hatches after about 40 days and the chick fledges after 40–50 days at about 70–80% adult weight. Parents carry fish in the bill for feeding to the chick. The *Cepphus* species (Black Guillemot, Pigeon Guillemot and Spectacled Guillemot) are diurnal, and form loose colonies. They feed close inshore, and this minimizes travelling time and energy and allows adults normally to rear 2 chicks. Incubation shifts and intervals between chick feeds are shorter than in most other auks. Nest sites are located in rock crevices, and incubation of the 2 eggs takes about 30 days. The chicks fledge after 30–40 days at about 90% adult weight. Chicks are fed on fish and crustacea.

All the auklets, except Cassin's Auklet *Ptychoramphus aleuticus*, and the Little Auk, are diurnal and all 6 breed colonially in talus or earth burrows and lay one egg. The incubation period and nestling period of all species are in the range 30–40 days, and chicks fledge at 70–90% of adult weight. The young are fed on a plankton 'soup'. Cassin's Auklet is unique among auks and unusual among seabirds in being double brooded on the Farallon Islands, California.

The 2 members of the fourth group (Marbled Murrelet and Kittlitz's Murrelet) are unusual as they are nocturnal and breed solitarily several km inland. The Marbled Murrelet nests high up on the branches of large coniferous trees, and Kittlitz's Murrelet nests on the ground in the open above the timber line in Alaska and neighbouring islands. The breeding plumage of both species provides excellent camouflage for the adults while incubating. Each lays only a single egg, but few nests have been found, so little else is known of their breeding.

Four species (Common Guillemot, Brünnich's Guillemot, Razorbill, and extinct Great Auk) make up the intermediate group. These breed mainly in the open on cliff ledges. The eggs of *Uria* spp. are pyriform in shape which reduces their chances of rolling off the ledge. The rolling radius changes from 17 cm (fresh eggs) to 11 cm (fully incubated eggs). This is not an adaptation but rather the fortuitous outcome of a change in the eggs' centre of gravity as the embryo develops. *Uria* spp. breed in dense colonies and lay one egg (12% of adult body weight) which is rested across the tarsi when incubated. The remarkable variation in colour and pattern of the eggs enables adults to recognize their own eggs. In addition, they recognize their own chicks through their voice which is of major importance in a crowded colony. The incubation period is in the range 28–35 days and chicks fledge at 18–21 days old, are then well feathered but flightless, and they free-fall on open wings to the sea at dusk in order to avoid predators. In Brünnich's Guillemot fledging occurs synchronously in a colony and early hatched chicks are older at fledging than the later hatched chicks. Guillemot chicks are cared for by their male parent for several weeks after fledging. Males moult their primaries while they undertake a swimming migration/dispersal away from the colony with their flightless chicks. The female returns to the nest site for up to 2 weeks after the young leave and moults later. The intermediate pattern of chick development has evolved either to minimize the period of time (and hence predation) at the nest-site, or because adults are unable to provision chicks at a fast enough rate to permit them to attain near adult weight at the nest-site. Because these species nest in the open, one adult must always be present to protect and brood the chick, so reducing their feeding rate. In all other groups chicks are provisioned by both parents after about one week, once the chick is able to maintain a stable body temperature.

Studies of colour-ringed birds show that auks share the following life-history features with other seabirds; high adult survival (at least 90% per annum), deferred maturity and low reproductive output (age of first breeding is 4 or 5 years in *Alca*, *Uria* and *Fratercula*), marked nest-site tenacity and mate fidelity from year to year. See photo FLIGHT.

AUKLET: substantive name of *Aethia* spp. and *Ptychoramphus aleuticus* (see AUK).

AURICLE: in general, an ear-shaped lobe; formerly the common term (in the plural) for what are now more usually called the 'atria' of the heart (see ATRIUM; HEART).

AURICULARS: the ear coverts (see PLUMAGE; TOPOGRAPHY).

AUSTRAL: term applied in North America to a climatic life-zone, or series of zones, lying south of the 'boreal' (see BOREAL; LIFE-ZONE).

AUSTRALASIAN REGION: comprising the Australian and New Zealand Regions of some zoogeographers, but in respect of avifauna more appropriately treated as a unit with subdivisions (see DISTRIBUTION, GEOGRAPHICAL). The heart of the Australasian Region is the island continent of Australia, with an area of about 7,682,000 km^2 (including Tasmania). New Guinea (the south-eastern part of which is called Papua) covers an area of 890,000 km^2, and New Zealand and its Dependencies 271,000 km^2. The total land area of the Region, including the smaller island groups, is about 8,930,000 km^2.

Australia extends between 11° and 43° S, and nearly 40% of its total area is within the tropics. It is a land of low, subdued relief with large expanses of plain, and with a notable absence of mountains of alpine type, conditions that impart a certain uniformity of landscape and vegetation. The climate is predominantly warm and dry, the continent having an arid centre with concentric zones of more favoured country, culminating in restricted humid areas in interrupted coastal strips, particularly in the north-east, east, south-east and south-west. Both New Guinea and New Zealand, with their high mountain cordilleras and lush vegetation—the one tropical, the other temperate—present marked physiographic and vegetational contrasts to their larger neighbour.

For its area Australia has a low number of bird species; recent RAOU checklists give 734 species, of which 578 are native breeders. New Guinea has a similar number, with 910 breeding species for the two together. The list is over 300 for New Zealand but only about 45 are native land-birds (cf. 110 in the British Isles, which have a smaller area). Four of these land birds have become extinct, but several others have colonized naturally from Australia and over 30 have been introduced, chiefly from Europe.

Origin of the avifauna. Until recently it was believed that Australia had always been close to south-east Asia. Hence the most likely explanation for the origin of its avifauna was that it had developed by island-hopping from the Oriental Region (Mayr 1944). Most people now accept the theory of Continental Drift. Australia parted company with the great southern continent Gondwanaland at the beginning of the Tertiary, some 50 million years ago (Keast 1981). New Zealand probably separated somewhat earlier, as might have New Caledonia. Australia moved slowly towards south-east Asia and may not have been in a position to receive many immigrants until at most 10 million years ago. The dramatic discovery of fossil bird feathers from Lower Cretaceous deposits in Victoria showed that some birds existed in Australia early in avian evolution. Thus some birds entered Australia by the southern route, from South America, and possibly Africa, via Antarctica, which was at that time milder than it is today. The possibility of southern origins has been raised by both D.L. Serventy and Cracraft (1972). The ratites and penguins are clear candidates for a southern origin as they are now almost restricted to the Southern Hemisphere. Perhaps parrots, bronze cuckoos (*Chrysococcyx*), pigeons and caprimulgids were also ancient colonizers (Cracraft 1972, Marchant 1972). Many marine or freshwater forms could also have been present, though they could have colonized Australia later when it was isolated.

The origin of the passerines is complex. The lyrebirds *Menura* and scrub-birds *Atrichornis* appear to be related to each other and to be an ancient group. J.A. Feduccia and S.L. Olson have shown that the osteology of both is remarkably similar to that of the tapaculos (Rhinocryptidae) of South America. They raise the exciting possibility that the passerines originated in the Southern Hemisphere.

Electrophoresis of proteins and hybridization of DNA has recently indicated that most Australian passerines fall into one of a few assemblages that are not closely related to the major Asian groups. One such group includes the honeyeaters, the fairy-wrens (see WREN (2)) and the Australian warblers. Another comprises the whistlers (thickheads) Pachycephalidae, with the Australian flycatchers, wood-swallows and cuckoo-shrikes as relatives. Crows and orioles may be close to this group. When the ancestors of these groups arrived and where they came from is a matter of conjecture at this stage.

These groups include some remarkable cases of convergence in form and habit towards unrelated birds in the northern hemisphere. The *Gerygone* warblers look and behave very like Sylviid and Parulid warblers of Eurasia and America, the sittellas (*Daphoenositta*) climb trees and have dagger-shaped beaks very like nuthatches (Sittidae), and the small *Myzomela* honeyeaters closely resemble sunbirds. The evidence strongly indicates that there has been an adaptive radiation of a few early colonizers, which parallels that of the Australian marsupials.

Despite the domination of the avifauna by these few early assemblages there are several species that clearly belong to Palearctic families and which have arrived recently. There are several Sylviids (e.g. *Megalurus*, *Cincloramphus*), a few crows, thrushes (*Turdus*, *Zoothera*), silvereyes (*Zosterops*) and orioles (*Oriolus*). Australia has single species of sunbirds (*Nectarinia*), flower-peckers (*Dicaeum*) and starlings (*Aplonis*) though New Guinea has several of each of these. Among non-passerines, bee-eaters (*Merops*) and rollers (*Eurystomus*) have colonized. However, several groups have failed to colonize, including Old World vultures (Aegypiinae), sandgrouse, trogons, barbets, woodpeckers, broadbills, true finches (Fringillidae) and buntings (Emberizidae). Interestingly, flamingos are absent from the region, but were present in the Tertiary, and the Australian Banded Stilt *Cladorhynchus leucocephalus* is apparently this family's closest living relative. A few groups, e.g. the bulbuls, hornbills and shrikes, have reached the Australasian Region but not Australia itself.

New Guinea has at times been connected to Australia, most recently about 10,000 years ago. It shares many taxa with Australia, though it has many more rain-forest specialists and generally a higher proportion of birds of Asian origin. It has also acted as a source of re-invasion for Australia, notably of honeyeaters (*Meliphaga*) and fruit-doves (*Ptilinopus*).

New Zealand also probably had birds when it broke off from Gondwanaland. The extinct moas (Dinornithidae) and the kiwis (Apterygidae) are ratites. The New Zealand wrens (Acanthisittidae) are also apparently very ancient. Their closest relatives are probably the lyrebirds and scrub-birds in Australia and the primitive South American sub-oscines. The wattlebirds (Callaeidae), comprising the Saddleback *Philesturnus carunculatus*, the extinct Huia *Heteralocha acutirostris* and the Kokako *Callaeas cinerea*, are perhaps equally ancient.

Many other New Zealand birds are more obviously derived from Australian families, including the 3 honeyeaters, the warblers *Gerygone*, robins *Petroica* and fantails *Rhipidura*. This colonization is continuing, several Australian species having become established in New Zealand in the last century. In Pleistocene and early Recent times, according to Falla, a vigorous waterfowl and open-country fauna allied to Australian types flourished in New Zealand and then died out, possibly because of the onset of arid conditions. These included a swan allied to the Australian Black Swan *Cygnus atratus*, a large eagle *Harpagornis moorei*, a coot *Palaeolimnas*, a corvid, and representatives of 2 Australian monotypic ducks (*Biziura*, *Malacorhynchos*).

The other Pacific islands have received birds from Australia and the Oriental Region, with a very few from the Palearctic or the Americas. Thrushes of the genus *Turdus* reached many islands but not Australia or New Zealand. New Caledonia has the unique Kagu *Rhynochetos jubatus*, belonging to a family found nowhere else.

The Australasian Region is usually separated from the Oriental Region at Wallace's line between Bali and Lombok, though the avifaunas of the two regions have intermingled (but see DISTRIBUTION, GEOGRAPHICAL). Immigrants from the north have been discussed earlier but several groups have colonized the Oriental Region from Australia. Thickheads, monarch flycatchers and *Gerygone* occur on the Malay Peninsula, wood-swallows reached India and China. Two species of honeyeaters have also crossed Wallace's line, if *Apalopteron* on the Bonin Islands is a honeyeater.

Speciation. Most birds, and virtually all of the land-birds in the Australasian Region are endemic. Many have originated from the adaptive radiation of a few ancient groups. Some speciation has taken place on islands, especially those around New Guinea. Elsewhere there are apparent cases of double or even triple invasions (e.g. *Zosterops* on Norfolk Island). There has been some colonization of north-eastern Australia by New Guinea species, but most Australian species must have originated on that land-mass, which has few off-shore islands. Cycles of arid and mesic climates have contributed to much of this speciation. In arid times the central desert spread outwards to isolate humid refuges in the north-west, along the east coast and in the south-west. Populations in these areas would have diverged due to the different environments they offered. With the return to moister conditions these refuges expanded and were connected again (Keast 1961). In some cases the meeting populations would have diverged sufficiently to achieve reproductive isolation. There are many cases of pairs of species in south-western and south-eastern Australia (e.g. Western and Eastern Spinebill *Acanthorhynchus superciliosus* and *A. tenuirostris*) or where the south-western isolate has spread inland and eastwards (e.g. Western Whipbird *Psophodes nigrogularis*). The rosellas (*Platycercus eximius*, *P. adscitus*, *P. venustus*, *P.*

icterotis) presumably evolved in 4 separate refuges and the races of Sittella *Daphoenositta chrysoptera* in 5. In some cases refuges have been invaded twice, giving a pair of similar species (e.g. black cockatoos *Calyptorhynchus* and robins *Eopsaltria* in south-western Australia).

Migrants. With the striking exception of numerous waders (Scolopacidae, Charadriidae) which breed in the Palearctic, very few Old World migrants winter in the region. Two swifts (Apodidae) from eastern Asia are regular migrants to southern Australia as is the Oriental Cuckoo *Cuculus saturatus* to northern Australia. The eastern race of the Swallow *Hirundo rustica gutturalis* winters in New Guinea and north-western Australia, and 4 species of wagtails *Motacilla* and a reed warbler *Acrocephalus arundinaceus* occur in small numbers. The virtual absence of Palearctic migrants in Australia during the northern winter contrasts with their abundance in southern Africa and is probably a legacy of Australia's isolation from Asia in the past. Although several species move from Australia to New Guinea in the southern winter, none reaches Asia in any numbers. A wader and several seabirds migrate from New Zealand to Australia and a cuckoo from New Zealand to the Solomon Islands.

Within Australia many species show complex migratory patterns; indeed some appear nomadic in their movements.

Subregions. In Australia itself the existing fauna can be grouped into three major assemblages (Serventy and Whittell 1962): a northern tropical one (the Torresian Fauna), a south-eastern and south-western temperate one (the Bassian Fauna), and over most of the arid and semi-arid interior a widespread Eyrean Fauna. In the south-west of Australia there is an intermingling of Bassian and Eyrean elements. Kikkawa and Pearse (1969) have confirmed the validity of these divisions by numerical computer analysis, proposing an alteration of names and dividing the Torresian into two faunas by separating a western component which they term the Timorian. R. Schodde and J.H. Calaby have separated from the Torresian two faunas: the Tumbunan (montane unit) comprising the highlands of New Guinea and the sub-tropical rain-forests of eastern Australia, and the Papuasian unit in the lowlands of New Guinea and pockets of rain-forest on Cape York Peninsula.

Special characteristics. Australia and New Guinea have a whole range of ecological types as shown on other continents. But, compared with Europe and North America, temperate Australia has rather few small seed-eaters (finches are to some extent replaced by parrots) whereas nectar-feeding birds are diverse and abundant. Honeyeaters and other birds have co-evolved with the flora to become significant pollinators. Australian land-birds appear long-lived and are mostly resident, perhaps because most habitats are not strongly seasonal. Perhaps for this reason many species have complex breeding biologies. Many species breed co-operatively, sometimes as permanent groups as in babblers *Pomatostomus* and apostlebirds *Struthidea* or semicolonially as in the miners *Manorina*. The lyrebirds of Australia and the birds-of-paradise of New Guinea have spectacular displays and most are polygamous. The bowerbirds construct bowers of sticks which they decorate with colourful ornaments. Another curious breeding system is shown by the MEGAPODES, which incubate their eggs in mounds of sand or decaying vegetable matter or even volcanically heated soil.

New Zealand has a virtually flightless parrot which booms and another species which has become a meat-eater. The nocturnal kiwi has almost lost its wings and has its nostrils at the end of its beak. The extinct Huia was strikingly sexually dimorphic; the stout-beaked male broke apart dead wood while the scimitar-beaked female probed into holes.

AUSTRINGER: see FALCONRY.

AUTECOLOGY: term for the ecology of individuals—contrasted with SYNECOLOGY (see also ECOLOGY).

AUTOCHTHONOUS: applied to species, etc., meaning aboriginally INDIGENOUS.

AUTOMOLUS: generic name used as substantive name, alternatively 'foliage-gleaner', of *Automolus* spp. (see OVENBIRD (1)).

AUTOSOME: any chromosome other than a sex chromosome.

AVADAVAT: substantive name of 2 Asian *Estrilda* spp. (see ESTRILDID FINCH).

AVAILABILITY: of scientific names, see NOMENCLATURE.

AVERAGE: see BIOSTATISTICS; MEAN, ARITHMETIC.

AVES: plural of the Latin 'avis' and used as the scientific name of the Class of animals known as birds (see ANIMAL KINGDOM). The common name is, in this instance, as precise as the scientific one (see BIRD). A primary definition may indeed be taken as self-evident; the category is perfectly distinct in the mind of anyone who has grasped the elementary fact that bats are, and pterosaurs were, animals of quite different sorts. This is because birds possess obvious characteristics that distinguish them easily from all other animals. Moreover, the main characteristics are present in all birds, producing a high degree of resemblance between one kind and another.

The distinctiveness and relative uniformity in the Class are due to its high degree of specialization. This has separated birds sharply from all other kinds of animal; and it has at the same time imposed strict limits, within the Class, on the possible extent of divergence from the general type. The specialization is for flight, and it follows lines of adaptation different from those of other flying animals (see FLIGHT; WINGS, COMPARATIVE ANATOMY OF). Apart from the flightlessness of nearly all very young birds, it is true that a few species lack the power completely; but this can be regarded as a secondary loss, incurred after the main line of evolution had been determined, seeing that the associated adaptations are to a great extent retained. Thus, just as flight is the outstanding characteristic of birds in general, so the immediately obvious thing about the exceptions is that they do not fly (see EARLY EVOLUTION OF BIRDS; FLIGHTLESSNESS).

The first essential character in the specialization of birds for flight is the modification of the forelimbs as wings (see WING). That the wings are in some birds used, also or instead, as swimming organs, and in others have become rudimentary, is merely incidental. The possession of wings, except in some instances where the function has been lost, is associated with a great development of breast muscles and with a keel on the sternum for their attachment (see MUSCULATURE; SKELETON, POSTCRANIAL). It is associated also with a fused rigidity of parts of the skeleton providing a fulcrum, with remarkable lightness in weight, and with a general 'stream-lining' of the body (see PNEUMATIZATION OF BONE; RESPIRATORY SYSTEM; SIZE).

Likewise associated with flight, although also (and perhaps originally) serving other purposes, is the plumage (see FEATHER; PLUMAGE). This character is unique, as feathers are not found in any other kind of animal and are present in all birds except the very young of some forms (see YOUNG BIRD). Feathers are thus conclusively diagnostic of the Class; they are present in the earliest known fossil (see ARCHAEOPTERYX).

The modification of the forelimbs for a special purpose has the consequence that birds are necessarily bipedal in their terrestrial stance and locomotion (see LOCOMOTION, TERRESTRIAL; SIZE). It likewise throws upon the head, armed with its bill (or beak), and sometimes on an elongated as well as flexible neck, most of the 'manual' functions performed by the forelimb in many other animals (see BILL); only in relatively few birds are the hindlimbs so used to any considerable extent (see FEEDING HABITS; LEG).

Birds share with mammals alone (at least at the present day) the character of being 'warm-blooded', which together with an intense metabolism enables the possessor to lead a highly active life in a widely variable environment (see HEAT REGULATION; METABOLISM). Also correlated with the mode of life of a flying animal are the facts that a bird lays only one egg at a time, thus causing the minimum of change of weight in the gravid female (see LAYING), and that development of the young is usually very rapid, thus reducing the period of vulnerability during which the advantages of being able to fly have not yet been attained (see DEVELOPMENT, EMBRYONIC; GROWTH).

The Aves share with some other classes such characters as being chordate, vertebrate, tetrapod (four-limbed), amniote, and oviparous. In various other respects of form and function, not too greatly involved in the specialization, they show some general conformity with other vertebrate animals, although the same ends may be achieved in different ways. In complexity of structure and in development of mental functions, the Aves may be said to stand parallel, if not quite level, with the Mammalia at the highest points of evolution. For their descent see ARCHAEOPTERYX; EARLY EVOLUTION OF BIRDS; FOSSIL BIRDS.

Despite the relatively high degree of structural uniformity among birds, as contrasted with other classes, they show great ecological diversity. Birds have indeed exploited every mode of life that is open to them. They are found in every part of the world except the polar wastes (see DISTRIBUTION, GEOGRAPHICAL), and they live in extremes of climate, although sometimes only seasonally (see MIGRATION). They inhabit environments ranging from the oceanic to the montane, from open plains to tropical forest, and from deserts to habitations of mankind (see ECOLOGY). They subsist on a wide variety of vegetable and animal foods, obtained in diverse ways (see FEEDING HABITS). They breed in all sorts of situation, from burrows in the earth to the highest treetops (see NEST). They fly and run, swim and dive (see FLIGHT; LOCOMOTION, TERRESTRIAL; SWIMMING AND DIVING). They may skulk in hiding, may keep largely to the water, may run boldly in the open, or may soar conspicuously in the sky. They may be solitary or gregarious (see FLOCKING), and they may be silent or noisy, uttering harsh cries, resonant notes, or musical song (see VOCALIZATION; also MECHANICAL SOUNDS). Their behaviour has many facets, sometimes including elaborate displays (see DISPLAY). Sometimes, quite small differences in adaptation enable closely related species—or unrelated species of similar mode of life—to inhabit the same area without extreme competition.

With all these variations on the main theme, it is not surprising that categories and kinds of birds have multiplied exceedingly. Apart from birds of the past, known only from the geological record or more recently lost, there are about 8,600 species of birds living in the world today. On the classification followed in this work, these are divisible among 29 orders, comprising 181 families (see CLASSIFICATION; and Table of Classification at the beginning of this book).

AVIAN: pertaining to birds. The alternative form 'avine', although said to be classically preferable, is little used.

AVIAN POX: see DISEASE.

AVIARY: see AVICULTURE.

AVICULTURE: the keeping and breeding of non-domesticated birds in captivity. The term does not include the breeding of domesticated species such as the Budgerigar, Canary and Zebra Finch (see CAGE BIRD). It embraces a very wide range of avian families of which the most popular are parrots (Psittaciformes), especially Australian parakeets, lovebirds and the larger parrots (Amazons, cockatoos and macaws), British finches, exotic finches such as grassfinches *Poephila* from Australia, waxbills *Estrilda* from Africa and mannikins (nuns) *Lonchura* from Asia and Indonesia, exotic pheasants and waterfowl and a wide variety of species known as softbills which are omnivorous or feed mainly on fruit and insects. The latter group includes such diverse kinds as hummingbirds, sunbirds, tanagers, white-eyes *Zosterops*, barbets, toucans and turacos.

Since the 1960s and 1970s the emphasis has changed gradually from imported to aviary-bred birds. There are two basic reasons: worldwide legislation which has reduced and, in many cases, strictly controlled trade in fauna, which had reached unacceptably high proportions, and the satisfaction which aviculturists have discovered in breeding birds. There is a more altruistic purpose for some: to conserve declining and endangered species in captivity. Habitat destruction, especially that of rain-forests, which harbour a richer and wider range of species than other habitats, has resulted in many bird species becoming endangered. Some of these adapt well to captivity and are being bred in numbers which ensure their future survival, even if they become extinct in their natural habitat. This is especially true of many species of pheasants and some waterfowl and parrots, but species in many other groups are destined, in the future, to be saved from extinction by captive breeding.

Private aviculturists, often known as 'bird-fanciers', are playing an increasingly significant role in this work and generally have done more to establish species in captivity than have zoos. Private aviculturists have also bred multiple generations of many species which are no longer available from their country of origin because export is prohibited. For example, since Australia ceased commercial export of its fauna in 1959, almost all the Australian parakeets and grassfinches have been established in captivity and all those available are aviary-bred—not imported—birds.

Formerly aviculturists tended to keep mixed collections of a wide variety of species. Today there is more specialization, thus resulting in better breeding results. Many specialist societies have arisen; in the UK they include the Australian Finch Society, the Parrot Society and the World Pheasant Association. Specialist societies produce journals, such as the monthly magazine of the Parrot Society, which reaches breeders all over the world. The longest established society worldwide, founded in 1894, is the Avicultural Society, whose journal, the *Avicultural Magazine* (published continuously since that date), widely acclaimed as the most scientific avicultural journal, publishes detailed accounts of breeding and behavioural studies of birds in aviculture. The Avicultural Society and Parrot Society also produce annual registers of birds bred by members, valuable documents in indicating the increase in captive breedings, and the World Pheasant Association carries out regular censuses to establish the status of all species of pheasants, a number of which have larger stocks in captivity than in the wild.

Since the 1970s veterinary and technological developments have resulted in aviculture being elevated from a hobby to the status of a science. Inauguration of sexing techniques, such as surgical and faecal analysis, and the careful formulation of commercial diets, have vastly increased its efficiency. See also AGE; BEHAVIOUR, HISTORY OF; CAGE BIRD; DOMESTICATION; VOCALIZATION. R.L.

AVIFAUNA: the bird-life of an area (see under Regional articles).

AVOCET: substantive name of species in one genus of Recurvirostridae (Charadriiformes, sub-order Charadrii), used without qualification for *Recurvirostra avosetta*; in the form 'stilts and avocets', general term for the family. This almost cosmopolitan group comprises 4 avocets *Recurvirostra* spp. and 2 species in monotypic genera: the Stilt *Himantopus*

himantopus (the several races having different adjectival English names) and the Banded or Red-breasted Stilt *Cladorhynchus leucocephalus*.

Characteristics. Avocets and stilts are long-legged, long-billed wading birds ranging from 29–48 cm in length, including the bill. Avocets have strongly recurved, slender awl-like bills; stilts have slender, slightly up-tilted bills. The legs of stilts are longer in proportion to the remainder of the body than in any other birds except flamingos. In general, the feet have slight or larger webs; the hind toe is rudimentary or absent. The head is small, the neck rather long; the wings are long and pointed; the tail is short and square.

The plumage of most species shows a pattern of black and white, but some have patches of tan to chestnut on some part of the head, neck or breast. The legs of avocets are slaty, those of the stilts some tone of pink. The Stilt's bright-red iris is noticeable under good conditions. Throughout the family the sexes are either alike or little different. Immature birds tend to have some brown in the plumage. The Banded Stilt has a chest-band of bright chestnut and yellowish legs.

Habitat. Avocets and stilts frequent shallow lakes, marshes and pools. Stilts, although found at the edges of large brackish or salty lakes, appear more commonly than avocets in freshwater areas and flooded marshlands. The Banded Stilt is a bird of salt marshes. The Avocet of the Palearctic breeds in saline areas near the coast, river deltas, muddy flats and lagoons, though in parts of the Netherlands breeding area the salinity is quite low. The American *Recurvirostra americana* breeds also on the shores of marshes and lakes; the Chilean *R. andina* frequents saline lagoons in the Andes. The Red-necked Avocet *R. novaehollandiae* is found along Australian estuaries, on mudflats, fresh and brackish swamps, inland waters, claypans and saltfields.

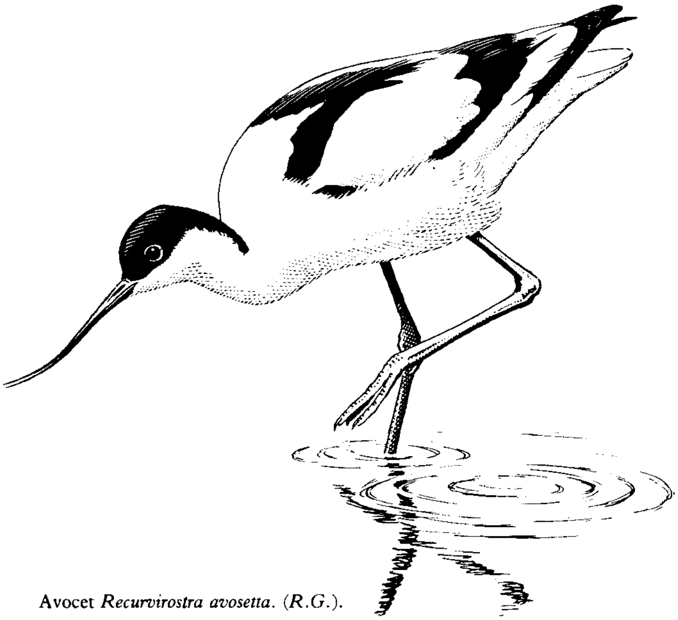
Distribution and populations. The Avocet *R. avosetta* is a Palearctic and Afrotropical species, breeding on the coasts of the North Sea and the Baltic, also around the Mediterranean and from the Caspian Sea eastwards to northern China and as far south as Iraq and Baluchistan. There is a population in south-west Africa. The Avocet ceased to nest in Britain for nearly a century after 1842; its return since the middle of the 20th century has been one of the triumphs of British wildlife conservation. Several hundred pairs now breed, out of a Baltic/North Sea population of some 10,000 pairs. The American Avocet breeds as far north as southern Canada and reaches Central America in winter; the Chilean Avocet is found from southern Peru and northern Chile to north-west Argentina. The Red-necked Avocet is patchily distributed over much of Australia and is a vagrant to New Zealand.

The Stilt is an almost cosmopolitan species with 5 recognized geographical races. The Black-winged *himantopus*, with white head and neck, breeds in the southern Palearctic from the Mediterranean east to China, also through much of southern Asia, Africa and Madagascar; it nests irregularly in central and western Europe. The Black-necked *mexicanus* breeds from southern North America to northern South America, including the West Indies and the Galapagos. The White-headed or Pied *leucocephalus* is the representative form in Australasia; melanistic birds are found in New Zealand and intermediates occur. Other races inhabit the middle latitudes of South America and Hawaii. The Banded Stilt is confined to Australia.

Movements. The winter range of the Palearctic Avocet extends from south of Brittany to Senegal and Gambia, from the Mediterranean to the Sahel south of the Sahara, in East Africa to Burundi and Tanzania, from the southern Caspian region to the Arabian peninsula. It further includes Pakistan, India and eastern China south of the Yangtze River. In mild winters many birds migrate no farther than western central Europe, e.g. in February 1975 at least 1,200 birds stayed in the Dollart (estuary of the Ems). A smaller number winter regularly in the west of England.

Food. In areas where there is little vegetation the Palearctic Avocet catches its food by a side-to-side sweep of the bill through shallow water or the surface slime exposed by the receding tide. In deeper water avocets put their heads beneath the surface and 'up-end'. In the British breeding places the main food has been found to be the larvae and imagines of Diptera (especially Chironomidae, Dolichopodidae and Ephydridae), of beetles (especially *Enochrus maritimus* and *Berosus spinosus*) and crustaceans (*Euryptemora velox*, *Mesochra lilljeborgi* and *Fabrina salina*). The other avocet species have similar feeding habits.

The Stilt also collects its food chiefly from the water surface or from floating vegetation. It consists mainly of insects and their larvae; also some freshwater molluscs and small worms and the spawn and tadpole stages of amphibia. The Banded Stilt feeds on the shrimps which multiply in the temporary sheets of water it frequents.



Avocet *Recurvirostra avosetta*. (*R.G.*).

Behaviour. Avocets when only a few hours old swim freely. Both they and stilts walk gracefully with long strides that quicken almost to a run. In water they wade to above the intertarsal joint, even belly deep in soft mud.

The sexes recognize each other by morphological and/or auditory signals, not only by individual behaviour during intraspecific contacts. The mating ceremonial begins with ritualized preening of the breast feathers, and the bill is dipped into the water. Pair formation is followed by 'false' nesting activities and grouping. The pair bond, which is particularly important to monogamous birds breeding in colonies, is strengthened by group display, which may take place either on land or in the water. It is performed by 3–12 (at first even up to 20) mainly paired birds, which endeavour to keep side by side and press close together. Occasionally copulation takes place before or after group display. Maturity is often reached at the age of 2 years, exceptionally when the bird is 1 year old. The display of the Stilt consists of dancing and jumping movements with wing-flapping and jerking of the head.

Voice. The characteristic call of the Avocet is a melodious *kluut* which gives the bird its Dutch name; repeated rapidly it becomes an alarm note. A number of others are used at the breeding colony and in display. The ordinary call of the Stilt is a rapid *kik kik kik*; that of the Banded Stilt is described as a 'wheezy puppy-like bark'.

Breeding. Avocets nest in colonies of 10–70, more rarely up to 200 or more pairs. The open nests, 2–60 m or farther apart, are made on grass, sand or mud, either bare hollows or lined with dead vegetation; in shallow water they may be built up to 25 cm. The clutch-size is usually 4, more rarely 3 or 2, exceptionally 5 eggs. Clutches of 8–12 eggs in large colonies must be due to more than one female. Laying in western Europe begins in the first third of April, but flightless young may still be seen in August. Both parents take part in incubation, which lasts 23–25 days. They also tend the young, which are able to fly in 32–42 days. There is only one brood.

The Stilt usually nests in colonies near or in shallow lagoons or on flooded areas near rivers. Some nests are substantial, built up of stalks and mud; others, in tussocks, are slight. The clutch is of 4 or 3 eggs. The relatively frequent occurrence of 5–9 eggs in one nest may be due to lack of nest-sites at some colonies. The breeding season in south-west Europe is from mid-April to June. The parents share incubation for 22–24 days and the young fledge in about 4 weeks, tended by both parents. Stilts are single-brooded. The Banded Stilt breeds in colonies, sometimes huge ones, on islands in large inland lakes. They tend to change their locations and for a long time no site was known. The clutch is of 3–4 chalky eggs.

AVOCETBILL: substantive name of the HUMMINGBIRD *Opisthoprora euryptera*, except for the AWLBILL the only member of the family with an upturned bill.

AWLBILL: substantive name of the HUMMINGBIRD *Avocettula recurvirostris*, except for the AVOCETBILL the only member of the family with an upturned bill.

AXIAL SKELETON: the part of the skeleton consisting of the skull, vertebral column, ribs, and sternum; contrasted with the APPENDICULAR SKELETON (see also SKELETON, POST-CRANIAL; SKULL).

AXILLARIES: (plural) the feathers in the axilla ('armpit')—see TOPOGRAPHY.

AXIS: the second vertebra, immediately posterior to the atlas (see SKELETON, POST-CRANIAL).

AYTHYINI: see DUCK.

AZURECROWN: substantive name of some *Amazilia* spp. (for family see HUMMINGBIRD).

B

BABAX: substantive name sometimes used for 2 species of BABBLERS of the genus *Babax*.

BABBLER: substantive name of many species of the family Timaliidae (Passeriformes, suborder Oscines); in the plural, general term for the family. (The name has also been applied to some Rhinocryptidae—see TAPACULO). The genera of Old World insectivores combined under the general name of babblers include a considerable diversity of forms which defy precise physical characterization. Although here treated as a separate family, they are often regarded as a subfamily of the Muscicapidae, together with the Old World warblers (Sylviinae), flycatchers (Muscicapinae) and thrushes (Turdinae). Unlike these, however, the babblers do not occupy any well defined group of ecological niches, and include both thrush-like and warbler-like forms, as well as genera of mixed insect- and fruit-eaters comparable to the bulbuls (Pycnonotidae). Delacour (1946, 1950) considered the Timaliidae to be closest to the Sylviidae, some genera being difficult to assign between the two. He recognized 6 tribes; the jungle babblers (Pellorneini, 5 genera), scimitar-babblers and wren-babblers (Pomatorhinini, 11 genera), tit-babblers (Timaliini, 6 genera), wren-tit and reedlings (Chamaeini, 2 genera), song-babblers (Turdoidini, 17 genera) and the rockfowl (Picathartini, 1 genus). Voous, whose treatment is followed here, raises the wren-tits and rockfowl to the status of subfamilies (Chamaeinae, Picathartinae) and adds the parrotbills (Paradoxornithinae, see PARROTBILL), including the reedlings *Panurus*, as another subfamily. The rail-babblers, often regarded as a subfamily of the Muscicapidae, are also included in the Timaliidae but are treated separately (see RAIL-BABBLER).

Characteristics. Babblers, which range in length from 10–35 cm, differ from thrushes and flycatchers in having no distinctive juvenile plumage. Juvenile birds can usually be told from adults in the hand by their softer, less pointed flight feathers, particularly the first primary, and in some species by differences in the intensity of plumage coloration. There is normally a complete post-juvenile moult commencing one or two months after fledging. In most species the sexes are alike and sexual dimorphism in body measurements is small, so that sexing of individual birds, even in the hand, may be impossible. In the few genera where the sexes are dimorphic (*Pteruthius*, *Myzornis*, *Leiothrix*, *Cutia*) the post-juvenile moult involves only the body and covert feathers and the typical rounded shape of the juvenile flight feathers is absent. The colour of the adult plumage is very variable, with some genera showing bright colours while others are uniformly dull brown. In general the brightly coloured forms are found in moist habitats, particularly evergreen rain-forest.

As a rule, babblers tend to be heavy-bodied compared with warblers or flycatchers, with stronger legs and stouter bills. The largest babblers are similar in size to small corvids and the majority of these feed on the ground, although some small forms, resembling the robins *Erithacus*, are also ground-feeding. Species which forage in the forest canopy are mainly similar to warblers in size, while those inhabiting the shrub layer or occurring in scrub range from wren-like forms to birds the size of thrushes *Turdus*. The majority, however, are sparrow-sized or smaller. The sibias, *Heterophasia* spp., which inhabit the middle storey of the forest, are at the larger end of this scale. Non-arboreal babblers are characterized by short wings and moderately long tails, both probably associated with their infrequent bouts of sustained flight.

One of the most distinctive characteristics of the babblers is their gregariousness and this may be influenced by the completely sedentary nature of most species. Migration over long distances is not found in the group, in strong contrast to the thrushes, warblers and flycatchers.

Habitat and distribution. In keeping with the range of niches occupied, babblers occur in a wide variety of terrestrial habitats, from tropical evergreen rain-forest to full desert. In the Himalayas they occupy all altitude zones up to the alpine areas above the tree-line. Arboreal species are most numerous in rain-forest, particularly in the Oriental Region (a total of 139 species occur in south-eastern Asia), while shrub- and ground-living species occupy a wider range of ecosystems. None venture into completely open habitats, the desert-living species being found in bushes along wadis or in palm groves.

The song-babblers, the largest tribe, cover the whole Old World range of the family. The jungle babblers are restricted to the Old World tropics and the tit-babblers are found in Madagascar, where they are represented by the endemic genus *Neomixis*, and in the Oriental Region. The scimitar-babblers and wren-babblers are confined to the Oriental Region, Australia and New Guinea. The rockfowl are found locally in the upper and lower Guinea forests of Africa. The wren-tit *Chamaea* is found in coastal areas of western North America, from Oregon to Baja California. Only a few species penetrate the Palearctic Region; the desert-living members of *Turdoides* are found in North Africa, Arabia and Iran and representatives of a number of otherwise Oriental genera penetrate southern and western China, *Yuhina* reaching as far north as Japan. Throughout most of the Oriental Region babblers constitute 6—15% of all passerine species in forest or scrub ecosystems. In the middle-altitude forests of the Himalayas the proportion may rise as high as 20%, but in Africa the family generally constitutes a much smaller fraction of the avifauna.

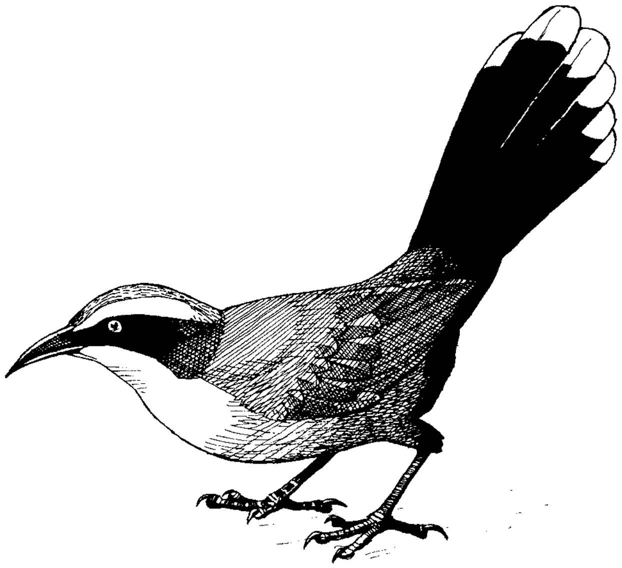
Food. Most species are insectivorous, but many augment their diet with fruit, seeds and nectar and some can be regarded as genuinely omnivorous, particularly outside the breeding season. Feeding strategies such as flycatching, hovering, or pouncing on ground-living invertebrates from a perch are rarely employed. Ground-feeding species usually rummage in leaf-litter, tossing it aside with their bills. Arboreal forms tend to feed by pedestrian searching, hopping from twig to twig, and gleaning food from the surface of leaves or bark.

Behaviour and voice. Practically all babblers occur during most of the year in small parties numbering 3–30 birds. Solitary babblers are rare, pairs are uncommon, and so are flocks of more than 30 birds of the same species. In several species which have been studied intensively, groups have been found to maintain a constant membership over weeks or months, defending a common territory against neighbouring groups. In some species of *Turdoides* only one or two pairs breed each year out of groups comprising up to 20 birds. Some non-breeders usually participate in incubation and post-juvenile group members bring food to the nestlings. Groups apparently originate through the deferred dispersal of young birds, which may remain for several years in their natal territory (Gaston 1977, 1978). Their vocalizations consist of a wide range of squawks and whistles. This pattern of behaviour and calls appears typical of all species of *Turdoides* except the Spiny Babbler *T. nipalensis*, which breeds in pairs and has a melodious, thrush-like song. It probably occurs also in many species of laughing thrushes or jay-thrushes *Garrulax*, several of which certainly defend group territories, advertising them by means of communal choruses. In the White-crested Laughing Thrush *G. leucolophus* the chorus is initiated by a single bird, others chiming in at intervals so that the noise rises to a crescendo. Similar choruses have been recorded in some species of *Turdoides* and in the Black-headed Babbler *Rhopocichla atriceps* and are delivered frequently just before groups go to roost.

Members of territorial groups usually roost in shrubs and trees but the Black-headed Babbler roosts in an old nest. Within the roost group members are in bodily contact with each other. In the Yellow-eyed Babbler *Chrysomma sinensis* roosting groups of 20–30 birds may split into several foraging parties during the day, reassembling in the evening. In the White-throated Laughing Thrush *Garrulax albogularis* the opposite occurs and large foraging groups of up to 40 birds split into sub-groups of 2–6 as they go to roost, each group occupying a different tree.

Group territorial babblers often perch in contact with one another during the day and this is frequently accompanied by ALLOPREENING. In the Jungle Babbler *Turdoides striatus* and the White-crested Laughing Thrush allopreening interactions are determined by a hierarchical structure within the group, with adults preening sub-adults more frequently than vice-versa. Groups feeding on the ground often maintain a sentinel in a nearby tree. This duty is changed at regular intervals but is assumed mainly by birds at the top of the social hierarchy, particularly the breeders. Observations of adult babblers feeding one another outside the breeding season may also relate to dominance within the group.

Although co-operative breeding is evidently widespread among babblers, the details of the social systems involved differ considerably. In the sparrow-sized Common Babbler *Turdoides caudatus* one male may breed



Grey-crowned Babbler *Pomatostomus temporalis.* (*N.W.C.*).

successively during the same season with two different females from within the same group. In the Yellow-eyed Babbler, a small species inhabiting scrub and grassland, groups fragment into pairs at the start of the breeding season, most nesting within the home range of their former group and some, but not all, having one or two non-breeding helpers. Helpers have also been recorded in the small arboreal genus *Yuhina* and the pattern seen in the Yellow-eyed Babbler may be typical of many of the smaller members of the family, although evidence is lacking for most species.

The sedentary behaviour of most babblers has undoubtedly contributed to the evolution of diverse patterns of social behaviour and to the prevalence of group territoriality and co-operative breeding. Genera such as *Turdoides* and *Garrulax* show a complexity of social relations within groups comparable with that observed in primates and other social mammals, suggesting that this behaviour has evolved over a long period. Among species which do not appear to hold group territories, the sibias form loose feeding aggregations outside the breeding season. The wren-like genera *Spelaeornis* and *Pnoepyga* occur in pairs during the breeding season and are otherwise solitary, giving regular loud vocalizations which apparently serve to advertise their presence and maintain spacing. Perhaps significantly, these genera include some of the most migratory species of babblers, breeding in the alpine zones of the Himalayas and moving down in winter to warm-temperate or subtropical altitudes. Scimitar-babblers of the genus *Pomatorhinus* are normally found in pairs which give regular antiphonal vocalizations as they move through dense undergrowth. Small parties of other babblers also keep up continuous low vocalizations while feeding, apparently to maintain contact.

Arboreal genera such as *Alcippe*, *Yuhina* and *Pteruthius*, which usually move in parties of 5–20 birds, often participate in mixed species flocks with other small insectivores such as tits *Parus* spp., warblers and flycatchers. In these associations the babbler groups sometimes appear to act as nuclei around which other species coalesce. Groups of ground-feeding *Garrulax* and *Turdoides* spp. also attract attendant birds, particularly drongos *Dicrurus* and woodpeckers in the genus *Dinopium*.

Breeding. Jungle babblers, scimitar-babblers, wren-babblers and tit-babblers normally build domed nests, either on the ground, or low down in dense vegetation. The song-babblers, on the other hand, mainly build open nests, rarely on the ground, more often in bushes or trees. The rockfowl build cups of mud on vertical or overhanging rock faces and usually nest in small loose colonies. The eggs of open-nesting song-babblers are frequently unmarked, either creamy white or blue, those of some jungle babblers and tit-babblers which build domed nests are speckled, and those of the rockfowl are heavily marked much like some corvids. The eggs of scimitar-babblers are white and those of the wren-babblers whitish with brown speckles. In the genus *Garrulax* there seems to be a relationship between egg-colour and social behaviour; species breeding in pairs usually lay speckled eggs, while those breeding in groups lay unmarked eggs.

Incubation periods, where known, are typical of insectivorous passerines, ranging from 13–16 days, and nestling periods are similar. However, the rockfowl of West Africa incubates for 24 days and young are in the nest for 26 days (Grimes and Darku 1968). Nestlings tend to leave the nest before fully capable of flight. Post-fledging dependence, by contrast, is usually prolonged, lasting for at least a month, although in group territorial species the period is hard to define because young birds remain with their natal group for at least a year and may occasionally receive food long after they have apparently achieved independence. BALEARICINAE: see CRANE.

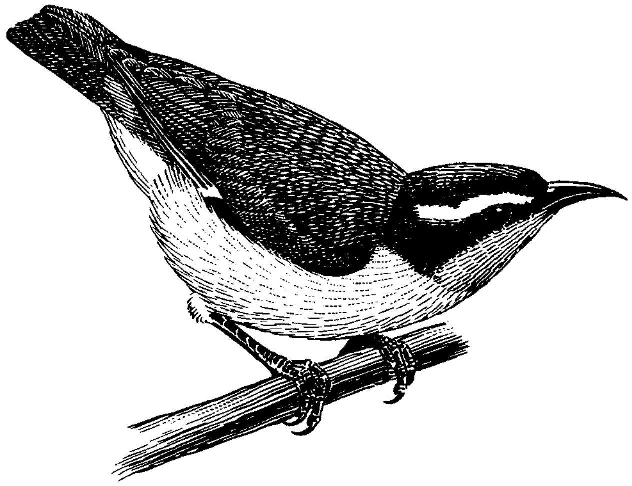
BAMBOO-WREN: substantive name of the TAPACULO *Psilorhamphus guttatus*.

BANANAQUIT: *Coereba flaveola* (Passeriformes, suborder Oscines), a widespread bird of tropical America, especially well known in the West Indies where it is the commonest bird on many islands and has acquired many local names. The Bananaquit is a small bird (about 11 cm long), mainly dark grey above and yellow below, with a white superciliary stripe (except on St Vincent and Grenada, where most individuals are blackish), and a sharply pointed decurved bill and tubular tongue adapted for sucking nectar and fruit juices. Its systematic position has been controversial. Formerly placed with the honeycreepers (see HONEYCREEPER (1)), FLOWER-PIERCERS and CONEBILLS in a family, Coerebidae, it has



Bananaquit *coereba flaveola*. (*R.G.*)

since been shown that this is almost certainly not a natural group and that the honeycreepers and flower-piercers are specialized tanagers (see TANAGER) while the Bananaquit and conebills may be closer to the American warblers (see WARBLER (2)). This is by no means certain, however, and the Bananaquit is here provisionally placed, with the conebills, in a reduced family Coerebidae. It may well be that future research will modify the present arrangement.

One of the features that distinguishes the Bananaquit from the tanagers is the form of its nest, which is roughly globular with a small doorway opening obliquely downwards. Both sexes build, constructing dormitory nests which are used only for sleeping as well as the more substantial breeding nests. Separate dormitory nests are used by the male and female of a pair. The breeding season tends to be very long, being at its height (like that of hummingbirds) when nectar-producing flowers are most abundant. The clutch consists usually of 2, less often 3, brown-spotted eggs. The incubation period is 12–13 days, and the fledging period 17–19 days, the nestlings being fed mainly by regurgitation. BANDING: see MARKING.

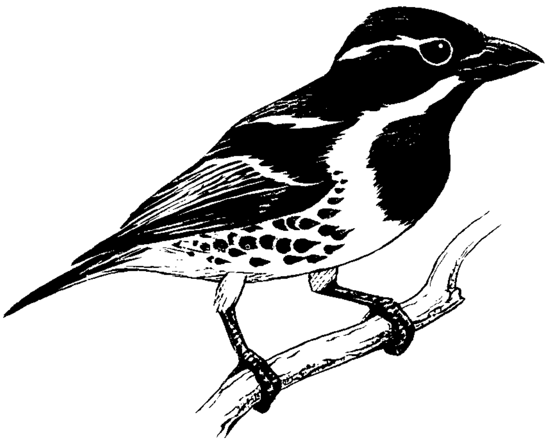
BANTAM: a miniature breed of domestic fowl.

BARB: alternatively 'ramus', a lateral branch of the rachis of a feather, i.e. a constituent unit of the vane (see FEATHER).

BARBET: substantive name of the species of Capitonidae (Piciformes, suborder Galbulae); in the plural, general term for the family, the name 'barbet' coming from the feathers and bristles around the base of the bill. Barbets are usually divided into 13 genera and 76 species and inhabit mainly the tropical forests of the Afrotropical, Oriental and Neotropical Regions. The majority (42 species in 5 genera) occur in Africa where several species have exploited much more arid habitats than those in other continents. Thus the small savanna tinker-birds (*Pogoniulus* spp.) and 3 ground nesting species (*Trachyphonus*) found in Africa do not have counterparts in Asia or tropical America. In contrast, only 12 barbets in 3 genera are found in South America. Speciation has resulted in notable instances of convergence; thus the Black-backed Barbet *Lybius minor* of central Africa is similar in several aspects to the White-mantled Barbet *Capito hypoleucus* in South America. Again each continent has produced a small-medium species with a predominantly brown plumage and each is highly social (Goodwin 1964). Although there are considerable differences in habit and external form between the small, agile and energetic members of the family, the slim longer-legged ground-nesting barbets of Africa, and the larger Asiatic forms, there seems ample justification for grouping them in one family.

Characteristics. Barbets are strongly built, thickset birds with rather large heads, ranging in size from about 9 cm in the tinker-birds of Africa to more than 33 cm in the larger members of the Asiatic genus *Megalaima*. The bill is stout, conical, and sharply tipped, proportionately longer and more formidable in some of the larger species. Several have notches in the bill to assist grip and this is well developed in the Double-toothed Barbet *Lybius bidentatus* and in the Pied or White-headed Barbet *Lybius leucocephalus*, both found in the African savanna. The legs are comparatively short and the feet are zygodactyl and well adapted for clinging woodpecker-fashion to trees; when doing this the tail is often used as a support, although the feathers are not stiffened for the purpose. The large barbets appear heavy, clumsy birds, but some of the smaller ones, such as the Red-headed Barbet *Eubucco bourcierii* of South America, are very agile. While foraging, it frequently hangs head downwards probing and boring into rotten wood. The wings are rather short and rounded, and flight, although rapid, is not usually sustained for long distances and appears weak. Progression on the ground is by rather clumsy hops.

Most of the barbets are brightly coloured, some of the Asian and South American species being the most beautifully plumaged of all birds. In these, green predominates, with red, blue and yellow markings around the head. In African barbets, black, yellow and red predominate, green is essentially absent, and there is a greater tendency towards spotting and barring than is found in species elsewhere. Although in most South American species the sexes are dimorphic and readily distinguishable in the field, this is generally not the case in Africa and Asia. Only the Red and Yellow Barbet *Trachyphonus erythrocephalus* in Africa and the Gaudy Barbet *Megalaima mystacophanes* in Asia have marked sexual dimorphism.



Spotted-flanked Barbet *Lybius lacrymosus*. (*P.J.K.B.*).

Movements. Barbets are comparatively sedentary and any movements seem to be governed by the availability of food rather than by seasonal migration.

Food. Barbets feed chiefly on fruits, berries, and buds but most species include some insects in their diet and the larger species occasionally take young birds, mice, and lizards. In many species a switch of diet, from frugivorous to insectivorous, takes place during the breeding season, and this is particularly the case in captive barbets. The African 'ground barbets' are mainly insectivorous as is the Red-headed Barbet. Some barbets work over the bark of trees like woodpeckers and bore into rotten wood in search of insects. Although most indigestible matter, such as insect wings and legs and vertebrate remains, are regurgitated as 'pellets', the skins and seeds of grapes, berries, and other fruit are passed in the faeces.

Fruit-eating barbets are very wasteful feeders, plucking and rejecting many of the berries and small fruits which they attack, while they so persistently shake their heads and wipe their bills to rid themselves of pieces of fruit which adhere to them that more seems to be cast away than is swallowed.

Behaviour. Most barbets live singly or in pairs, although some of the smaller species may, out of the breeding season, be seen in the tree-tops in parties, sometimes in the company of other birds. Little seems to be known about their territorial requirements, although many savanna species, at least, hold territories and respond vigorously to a playback of their calls. Some species of barbets when in captivity are extremely pugnacious towards conspecifics of either sex except when breeding. They usually roost in holes, often boring a special roosting hole which may be later used for breeding. In some of the smaller species a large number of birds may roost together in 'dormitories', such as woodpecker holes, that sometimes contain as many as 16 individuals. In some African barbets co-operative breeding takes place (see later).

Voice. Most barbets can hardly be described as possessing a song in the usual sense of the word, uttering instead an oft-repeated single note or a series of very monotonous notes, in many cases quite un-musical, and resembling honks, chirps or the tapping of a hammer on a hollow object. In some species the males utter a very rapid version of the *poo-poo-poo* of the Hoopoe *Upupa epops*. Duetting has been studied in several species of African barbets and reported in both Asian and American species (Payne 1971, Kunkel 1974). One of the most notable is the East African Red and Yellow Barbet. A pair of birds, usually sitting close together, will simultaneously burst into loud, cackling songs, composed of different notes and not necessarily in the same tempo but which rhythmically synchronize so well that it is difficult to tell which bird is producing which notes except by the bobbing and tail wagging display which accompanies the duet. Although usually described as a 'duet', it is sometimes a chorus of the combined efforts of a family party. In the field this duet is very similar to that of the closely related D'Arnaud's Barbet *Trachyphonus darnaudii*.

Breeding. In most cases there is little formal courtship apart from the chasing of the female by the male, although in the 'ground barbets' the male struts and postures around the female with his erectile crown feathers raised.

Barbets nest in holes, usually excavated by themselves in rotten trees, euphorbia stems, termite mounds and sand or earth banks, in which case several pairs may nest close together, forming a small colony. The nest-hole entrance of the smaller species is circular but may be quite ragged and irregular in the larger species such as the Double-toothed Barbet and *Megalaima* species. The Double-toothed Barbet often uses the same nest-hole for several consecutive seasons. D'Arnaud's Barbet bores a tunnel almost vertically downwards into level ground, swinging horizontally at the bottom to form a nest-chamber. The Pied Barbet appears to be the only species which, in the absence of suitable trees for boring, will take over deserted nests of other birds, such as swallows and martins.

No nest material is used, the 2–5 white eggs resting on the bottom of the nest-hole. Incubation (12–15 days) and rearing are shared by both parents, food being carried direct to the young in the bill except for a few of the smaller species, such as the Red-fronted Barbet *Lybius diadematus*, which regurgitate semi-digested food deep into the throats of the nestlings.

Nest sanitation varies between species and at different stages of development of the young. Faeces are sometimes swallowed whole by the parents, sometimes pounded with the wood dust at the bottom of the nest into a bolus which is carried away. This latter behaviour may account for the persistent tappings that are sometimes heard from within the nest-hole and referred to below.

The fledging period is not known with certainty for any species in the wild, but has been estimated in 2 species at more than 17 days. The young emerge well-developed and, in most cases, able to fly well, although they continue to demand food from their parents long after they appear well able to fend for themselves. Young males of the South American Red-headed Barbet emerge from the nest in almost full adult plumage with a red head.

Co-operative breeding has been proved to occur in 4 species of African barbets and suspected in others (Grimes 1976). Up to 4 adult Red and Yellow Barbets have been observed taking food to a nest-hole and ringing has shown that young of a first brood will assist in rearing a second.

Unlike, for example, the woodpeckers, there is little actual nest-chamber and not only may the adult birds incubate in what appears to be a most uncomfortable position, but the young are extremely cramped. Persistent tapping from within the hole may indicate an attempt by the growing young to enlarge the nest-chamber. This may well be one of the explanations for the extraordinary 'lesions' which occur on the heels of nestling barbets, serving as a protective grip in place of the claws which are necessarily 'folded' upwards through the cramped position. These disappear shortly after the young leave the nest. It is noteworthy that similar 'heel-pads' are present in some species of honeyguides which are parasitic on African barbets. Several instances have been recorded in captivity of the fledgling young being 'released' by the parents boring into the tree at nest-chamber level. (J.T.D.) M.D.E.

BARBICEL: a process on a barbule (radius) of a barb (ramus) of a feather; the hooked barbicels on the distal side of a barbule engage with the spoon-shaped proximal barbicels of the next barbule, thus maintaining the coherence of the vane (see FEATHER).

BARBTAIL: *Premnoplex brunnescens* (see OVEN-BIRD (1)).

BARBTHROAT: substantive name (sometimes 'hermit') of *Threnetes* spp. (for family see HUMMINGBIRD).

BARBULE: alternatively 'radius', a lateral branch of a barb (ramus) (see FEATHER).

BARE-EYE: substantive name of *Phlegopsis* spp. (see ANTBIRD).

BARE PARTS: the areas of the body surface which are not covered by feathers, namely the bill, eyes, legs and feet, together with any unfeathered skin (see INTEGUMENTARY STRUCTURES).

BARRANCOLINO: *Teledromas fuscus* (see TAPACULO).

BARWING: substantive name sometimes used for the tropical Asian BABBLERS of the genus *Actinodura*.

BASIC PLUMAGE: in species which wear the same plumage the whole year round, this is the basic plumage. If two different plumages are worn per year, the basic is usually the dull plumage worn outside the breeding season. The term is part of a modern American terminology. The equivalent of basic plumage in the classical terminology is annual or non-nuptial plumage (see PLUMAGE).

BASIOCCIPITAL: a paired bone of the SKULL.

BASIPTERYGOID: see SKULL.

BASISPHENOID: a paired bone of the SKULL.

BASSIAN: see AUSTRALASIAN REGION.

BASTARD WING or **ALULA:** also called 'ala spuria', consists of a number of small quill feathers attached to the first digit (see WING).

BATELEUR: *Terathopius ecaudatus*, an aberrant African harrier-eagle (see HAWK).

BATESIAN MIMICRY: when a relatively scarce, palatable and vulnerable species resembles an abundant, relatively unpalatable or well-protected species, and gains protection thereby. See COLORATION, ADAPTIVE; MIMICRY.

BAT-HAWK: *Machaerhamphus alcinus* (see HAWK).

BATHING: see COMFORT BEHAVIOUR and photo.

BATING: term used in FALCONRY.

BATIS: substantive name sometimes used for the puff-back flycatchers of the genus *Batis* (see FLYCATCHER (1)).

BAYA: name sometimes used alone for the Baya Weaver *Ploceus philippinus* of India and elsewhere (see WEAVER).

BAZA: substantive name of Asiatic *Aviceda* spp. (see HAWK).

BEAK: synonymous with BILL.

BEARDED TIT: *Panurus biarmicus*, for family see PARROTBILL.

BEAU GESTE HYPOTHESIS: the hypothesis, named after the novel by P.C. Wren, that territorial male songbirds may simulate the presence of many individuals by singing a repertoire of song variants. The advantage to the singer of this hypothesized deception is that potential rivals are discouraged from intruding into the singing bird's territory by the apparent high density of occupants. The deception could only work if intruders use the number of song variants heard to assess bird density in an area. The hypothesis has been criticized on a number of grounds. First, it has been said that the deception would not last long in evolutionary time, since listeners would evolve the capacity to 'correct' for large repertoires in assessing density of songsters. Second, many songbirds sit conspicuously in one position while singing many different variants, a mode of behaviour which does not seem compatible with deception.

BECARD: substantive name of the 16 species of *Pachyramphus* (with which the genus *Platypsaris* is now merged), a group of arboreal, mainly tropical, American birds formerly placed in the Cotingidae but now, on anatomical grounds, considered to be closer to the Tyrannidae (see FLYCATCHER (2)), of which, with the TITYRAS, they are currently considered to constitute a subfamily, Tityrinae.

Becards are compact, medium-sized (13–19 cm), mainly insectivorous birds, with broad, somewhat hooked bills. Most species lack bright colours, but in two, including the Rose-throated Becard *P. aglaiae*, the only species extending as far north as the southern USA, the male has a pink throat-patch. In males only, the 9th primary is highly modified, being narrow and pointed and much reduced in length. Becards build large globular and often conspicuous nests, typically high in a tree or, if lower, near the tip of an outer branch; some species habitually nest in close association with wasps' nests (see NESTING ASSOCIATION).

BECCAFICO: a familiar Italian name ('fig-eater') applied almost indiscriminately to small passerine birds frequenting gardens in autumn and often caught for the table—perhaps particularly Garden Warbler *Sylvia borin* (see WARBLER (1)).

White-throated Bee-eater *Merops albicollis*. (*N.A.*).

BEE-EATER: substantive name of all species of Meropidae (Coraciiformes, suborder Meropes); in the plural, general term for the family. A homogeneous, essentially Paleotropical family (15–38 cm in length) specializing on flying venomous Hymenoptera (ants, bees, wasps) for food. Bee-eaters forage principally by sallying, like flycatchers, and occasionally in continuous flight, like swallows, and most species take non-volant prey only exceptionally. There are 24 species, in 3 genera; *Nyctyornis* (2 species) and *Meropogon* (1 species), inhabit south-east Asian rain-forests; the species of *Merops* (including the formerly-recognized genera *Melittophagus* and *Aerops*) are mainly open-country birds of Africa and southern Asia.

Characteristics. The beak is rather long, slender, laterally compressed and decurved to a sharp point; legs are weak and the feet syndactylous. Most bee-eaters have bright, non-iridescent plumages of green, buff and chestnut, with a black line through the eye, usually a black or blue pectoral band and a contrasting yellow or red throat; but 1 species is mainly black, 2 dark blue and 2 carmine. The sexes are alike. The young hatch naked and most of them fledge in plumage like the adults'. All species nest in tunnels which they excavate in cliffs or flat sandy ground, many breeding colonially. They are sociable birds with melodious voices; several larger species are migratory and have a buoyant, wheeling flight, rather long, pointed wings and elongated central rectrices. Species weights range from 14–70 g. The largest bee-eaters are *Nyctyornis amicta* and *N. athertoni*, stout-beaked primitive birds with green plumage, loose, elongated throat feathers, rounded wings and croaking voices.

Habitat. Three species of *Merops* and the genera *Nyctyornis* and *Meropogon* inhabit the middle storeys and canopy of lowland tropical rain-forests, which is probably the ancestral habitat of the family. Other bee-eaters inhabit forest edges and secondary growth; all manner of savannas and timbered open country; marshes, grassland, farmland; and arid sub-desert steppe. They are partial to waterside situations (reed-beds, riverine woods, flooded abandoned excavations), particularly where there are also cliffs and sand-banks suitable for nesting. They perch freely on vegetation and wires, and sometimes on the ground.

Distribution. *Meropogon forsteni* is endemic to Sulawesi rain-forest and *Nyctyornis* to Oriental rain-forest from Wallace's Line to Nepal (the southern *N. amicta* just overlapping the northern *N. athertoni* in Tenasserim). *Merops viridis* and *M. leschenaulti* are Oriental and *M. orientalis* ranges from Indochina to Senegal. The *M. ornatus*/*M. philippinus*/*M. persicus* superspecies inhabits Australia, New Guinea, the Oriental Region, Madagascar and the borders of the Sahara. *M. apiaster* breeds from the Mediterranean basin at least to 50°N and 75°E, and in southern Africa. All other bee-eaters are African.

Movements. All *Merops* species except the forest forms (*M. breweri*, *M. muelleri*, *M. gularis*) and a few small nonforest forms are migratory, *M. apiaster* and the *M. philippinus* superspecies travelling thousands of km.

Food. Investigating bee-eater diets is fairly simple, and numerous studies have been made. When an insect is caught the bird generally returns to a perch to immobilize it; it is then swallowed or carried to the nest, and in either case can be identified readily. Several times a day bee-eaters regurgitate firm pellets of insect sclerites, which can easily be collected near nests and favoured perches for analysis. With few exceptions, *Merops* species prey on flying insects and 60–95% of the diet of each species are bees, wasps, hornets and related stinging insects. Honey-bees *Apis mellifera* are sought after to the extent that bee-eaters have been persecuted as pests at apiaries; a collection of pellets from any African locality nearly always contains honey-bees, which commonly form about 25% numerically (more by volume) of the entire diet and may comprise over 90% of a large sample. Only occasional drones (which are not venomous) are taken, and bee-eaters seem to distinguish the stinging workers and to select them. Venomous Hymenoptera are held at the tip of the abdomen and rubbed against the substrate until venom is discharged, when they are further beaten and then swallowed whole. The behaviour is innate but improves with practice, and the birds seem to have some immunity to venom. Carmine Bee-eaters *Merops nubicus* can evidently devenom *Apis* workers in flight, without having to return to a perch. In most bee-eaters the next largest dietary portion after Hymenoptera is beetles, then grasshoppers, bugs, flies, termites, butterflies, up to the size of cicadas *Platypleura*, dragonflies *Anax* and carpenter-bees *Xylocopa*, (each about 1 g).

The large green bee-eaters (*M. persicus*, *M. philippinus*) take Hymenoptera but specialize on Odonata (dragonflies, demoiselles) which comprise three-quarters of their diets. Carmine Bee-eaters eat many grasshoppers flushed by fire, and they sometimes use bustards, ostriches, grazing mammals, and tractors as 'animate perches'. White-throated Bee-eaters *M. albicollis*, which breed in sub-desert steppe, take some non-volant prey—insects, spiders, small lizards—from the sand, and in their forest-zone 'winter' quarters they catch in flight nutritious strips of oil-palm epicarp discarded by squirrels feeding in the crowns above them. The only other recorded vegetable matter is berries eaten during exceptionally cold weather by European Bee-eaters wintering in Zimbabwe. Rarely, some bee-eaters pluck small fish from the surface of ponds, as has recently been established by videotape analysis and pellet studies.

Behaviour. Forest bee-eaters breed solitarily, and for the rest of the year occur solitarily or in pairs, accompanied by the young for some weeks after fledging. Of the open-country bee-eaters, the smaller species in general breed solitarily then form family parties which may aggregate into small, wide-ranging flocks. But most species are gregarious the year round and breed in loose aggregations or in dense colonies of tens, hundreds, or (Rosy Bee-eaters *M. malimbicus*) tens of thousands of nests. Within their large home-ranges the more solitary species are weakly territorial when breeding; in colony-breeding species an individual distance of only a few cm is maintained and that distance around the nest burrow entrance is defended. Individuals of the more sedentary species often have favoured foraging patches which may be defended. Infringement of all of these territories is commonplace and causes vocal and postural bickering; rarely, two birds fight with interlocked beaks in the air or on the ground. *M. apiaster* and the red-throated bee-eaters *M. bullocki* and *M. bullockoides* (the only species adequately investigated) have life-long monogamy, but these and some other species have nest helpers which are the pair's progeny of a previous year and which, remaining all year with their parents, maintain a filial bond. Helpers may copulate with a parent and effectively replace it if it dies. Only a minority of pairs have one (usually) or more helpers; but *M. albicollis* probably has helpers at most nests and there may be up to 6 helpers at any one (see CO-OPERATIVE BREEDING).

Voice and display. *Merops* bee-eaters are very vocal, mostly with a variant of the pleasing liquid, monotonous *crüük*, *crüik* of *M. apiaster*. Separate functions can be ascribed to 6 common calls of *M. bullocki*, and to 5 additional copulation, food-delivery and begging calls. Vocal greeting, accompanied when intense by raised crown feathers and fanned and vibrated tail, is a daily event. Courtship displays are not elaborate and comprise an exaggerated greeting ceremony with a ritualized modification of prey-immobilizing behaviour; courtship feeding occurs. Bee-eaters roost in vegetation or, in cold weather and when breeding, in the nest; the pair, family party or even flock clusters tightly together.

Breeding. Nest holes are oval chambers at the end of a tunnel which birds dig in the soil with their beaks, kicking loosened soil out backwards. They excavate in flat ground or in a slight slope, ridge or bank. The soil may be sandy but is often hard-baked. African savanna bee-eaters breed in the rainy season, mostly in its first half, but *M. bullocki* is exceptional and breeds in the dry season. But it digs its nest burrows at the end of the previous wet season, before the soil becomes hard-baked. This species is an obligate cliff-nester; the burrow is about 6 cm diameter and 1 m long, and inclines slightly to a lip beyond which is the egg chamber. Other species have declining tunnels, 0.5–3 m long. There is no nest material, but the eggs receive some protection from an accumulating carpet of insect sclerites, from pellets. Eggs are laid and hatch after *c.* 20 days at intervals from 0.6 days (*M. pusillus*) to 1.7 days (*M. nubicus*), and clutch sizes vary from a mean of 2.9 (*M. bullocki*) to 4–9 (*M. apiaster*). Nestlings, which fledge in 20–25 days, have swollen papillae on the ankles, on which they move rapidly forwards and backwards in the nest chamber and the tunnel. Death by starvation of the younger birds in a brood is common. Accidental destruction of eggs by adults is frequent and there is some predation by reptiles; otherwise breeding success is high. BEGGING DISPLAY: see BEHAVIOUR, DEVELOPMENT OF; PARENTAL CARE.

BEHAVIOUR: the integrated pattern of movement or other overt response of an animal to internal and external stimuli. Behaviour is the product of the action of the nervous and muscular or other effector systems. See BEHAVIOUR, DEVELOPMENT OF; BEHAVIOUR, HISTORY OF.

BEHAVIOUR, DEVELOPMENT OF: the elaboration of behaviour from its first occurrence to a more perfect state. The term development in its broadest sense refers to the ontogeny of an organism from the fertilized egg cell to its death. For the study of behaviour, the most interesting part of ontogenetic development is between shortly before birth and the age at which sexual maturity is reached, because this is the period when most developmental processes and changes occur.

The study of behavioural development derives from one of the questions asked in behavioural research in general: 'How does this behaviour develop in the life of the individual?'

Research on the development of bird behaviour in particular has to cope with two features which characterize this class of vertebrates:

(a) The development of birds as compared, for example, to mammals is characterized by its remarkably high speed. Birds may reach their adult size and weight within about 1% of their total life expectancy, whereas some mammals need 30% or more, as is the case for most of the higher primates. Such speed in general development, which has been understood as an adaptation to a quick acquisition of the ideal ratio between body weight and a constant wing surface, is reflected in the evolution of some traits peculiar to the behavioural development of birds, such as the occurrence of rapid learning or the relative scarcity of play behaviour (see below).

(b) Birds lay eggs which are usually incubated by one or both parents. The embryos, like those of other egg-laying species, are much more open to various influences from the environment than are the embryos of viviparous animals, e.g. mammals. In addition, the occurrence of intensive brood care offers the opportunity for at least acoustic communication between the mother or, in some species, both parents and the developing embryo. Birds, therefore, represent ideal subjects for the study of topics such as prenatal learning or the interaction between genetic and environmental influences in general. These fields of research have received increasing attention in recent years.

Although no sharp distinction can be made in every case, two categories of behaviour which occur during ontogenetic development should be distinguished: those which are precursors of adult behaviour and, as a rule, are retained for the remainder of life, and those which have evolved in relation to the specific needs of the young bird and, as a consequence, disappear again in the course of development. (Some of the latter, however, may reappear, with different functions, in the adult, such as wing quivering in many passerine birds which is part of the begging behaviour of fledglings and part of the precopulatory behaviour of the adult female.)

Behaviour peculiar to the young bird. Special behaviour patterns of young individuals naturally show great differences between precocial and altricial species. The young of precocial species hatch with fully developed sense organs and motor skills and are able to leave the nest immediately or shortly after hatching. Altricial birds, such as parrots and passerines, hatch at a less advanced stage of development and spend a greater proportion of time in or, later, very close to the nest. They require much more intensive care by their parents in terms of food, brooding, nest sanitation and protection. Within the precocial birds, however, some variation occurs, ranging from the Anseriformes and Galliformes, the offspring of which live on yolk sacs for the first day or two and afterwards find their own food, never being fed by adults, to the gulls and auks the young of which leave their nest for short distances but return to it to be fed by their parents. The extreme situation is represented by the mound-building Indo-Australian MEGAPODES in which the hatchling lives on its own from the moment it emerges from the surface of the mound and no parental care is provided whatsoever.

(a) Hatching. The eggshell is broken by a series of blows from the bill with the egg-tooth. Blows often alternate with periods of rest, and hatching itself may take anything from a few minutes, e.g. in woodpeckers and grebes, to several days (Sooty Shearwater *Puffinus griseus*).

An exceptional way of breaking the egg-shell is found in the megapodes (Megapodiidae). In their embryos, the egg-tooth its functionless, and the eggshell is broken with the legs which in this group of gallinaceous birds are especially strongly built.

(b) Begging behaviour and adult feeding. In extremely precocial birds the change from the feeding behaviour of the young to that of the adult is gradual. In the intermediate forms, the young bird begs for its food but uses the adult movement of pecking in feeding. Thus in the Herring Gull *Larus argentatus* begging first occurs a few hours after hatching and consists of repeated pecks at the parent's bill-tip, but even at this age pecks may be directed at regurgitated food on the ground. However, in those species in which the parent puts food into the nestling's gape, as in all passerine birds, the behaviour used by the young in feeding is so different from that used by the adult that the second does not develop out of the first.

In such altricial birds, begging may be divided into three developmental stages. During the first days, the nestling gapes vertically, often with a special call in response to very varied auditory and tactile stimuli, or sometimes apparently spontaneously. Several days later, the bird begins to gape in response to visual stimuli. For about a day it may still direct the gape vertically, but gradually it begins to turn the gape towards the visual stimulus. Wing vibration and characteristic head movements (if present) appear at this stage.

During the later part of the nestling period adult feeding responses are developing quite independently. The first pecks are directed at almost any distinct object. When hungry the birds always beg; they even beg at food that has fallen to the floor, instead of pecking at it. Later the bird gets some food by pecking but begs whenever the parent appears. The parents' unwillingness to continue feeding probably helps to terminate begging. Adult feeding behaviour usually shows progressive improvements, both in its form and in the efficiency and appropriateness of food selection, and learning may well be involved. Experience seems to be of particular importance in birds which capture live prey, e.g. raptors and owls.

(c) Defaecation. Many altricial birds have a specialized method of defaecation. The nestling turns round when it has been fed, raises its cloaca and extrudes a dropping enclosed in a mucilaginous envelope, which is taken by the parent and dropped in flight some distance away from the nest. Adult defaecatory behaviour appears when the fledgling leaves the nest; at the same time the envelopes cease to be produced. Such 'nest-sanitation' does not, however, occur in all species of altricial birds: in most Estrildid finches, for example, the young defaecate within the dome-shaped nest, the interior of which is covered with faeces when the young fledge.

In addition to the behaviour patterns described so far which serve specific purposes during early developmental stages, there are other phenomena which are also restricted to or occur mainly in young birds but which may, in addition, exert an influence on adult behaviour. This is the case, for example, in play behaviour and in vocalizations called subsong.

(d) Play behaviour. One aspect of behaviour development which has recently received increased attention among mammalogists but has been rather neglected with regard to birds is play behaviour. Play is characterized by a number of criteria. It appears to be 'without purpose' since the behaviour patterns involved do not seem to fulfil the biological function for which they have been developed during their phylogenetic history; its components can be combined in various ways; and there is no mutual inhibition and no strict temporal correlation of individual behaviour patterns. Finally there seems to be no habituation since many behaviour patterns occur during play for considerable periods of time without any sign of fatigue.

For birds the occurrence of play behaviour in this sense has been recorded only rarely. This may be because in birds it seems to be more difficult to distinguish play from other activities. A more likely explanation, however, is that young birds do indeed spend less time at play than do young mammals. Such differences might be a consequence of the above-mentioned general speed of avian ontogenetic development, which leaves less time for play activities.

As in mammals, one has to distinguish between locomotory and object play. Examples of each category have been described for birds: Adélie Penguins *Pygoscelis adeliae* have been observed to ride on small ice floes on a tide run, only to come back to the starting point to repeat the process; object manipulation with dead prey, twigs, stones or feathers has been seen in many species with the object often carried into the air, dropped and then caught again. For a third category of play, frequently observed in mammals, the so-called social play, there is no sound evidence, although young birds often show some low-intensity or incomplete sequences of aggressive or sexual behaviour which have sometimes been classified as play behaviour. The most complex play known for birds is found in the corvids, mainly in the Raven *Corvus corax*, in which it probably has an important function in adapting the young to their future life in a wide variety of habitats.

(e) Subsong. In many species of birds, adult males utter a type of song which is different from territorial or courtship song and is characterized by low volume, a high degree of variability, a large number of elements and a broad frequency range. Such subsong occurs mainly in autumn as well as in early spring, before territorial song develops (see VOCALIZATION). In young birds subsong, which is often called 'recording', is particularly frequent during the late summer and autumn of the first year of life. Several authors have considered it to be a kind of play as it apparently lacks any immediate function and also shows some other remarkable similarities with the characteristics of non-vocal play (e.g. re-ordering of sequences, incomplete sequences, repetition of patterns or elaboration of new patterns).

The biological function of both play behaviour and subsong has frequently been discussed but no definite conclusions have been reached so far. It seems certain, however, that both activities provide practice for adult behaviour by enhancing muscular development and improving cognitive abilities and that, in addition, play may also provide some experience on how to adjust social relationships. (See also PLAY.)

Learning. In principle, early learning in birds does not differ from other vertebrates; and their main categories of learning have also been described for birds. One difference, however, concerns the phenomenon of IMPRINTING. It is certainly not by chance that imprinting and the occurrence of early sensitive phases for learning were not only first discovered but also are especially widespread among birds. Such a comparatively rapid and early learning process may have a selective advantage in organisms which are characterized by a speedy ontogenetic development and early dispersal of the young. They may have to acquire relevant information very early, and the long-term retention of such information may be important, not only so that it may be available when they have to look for mates and suitable habitats in adult life, but also to avoid the acquisition of 'wrong' information when they have to live in less suitable habitats or when they come into close contact with other species (e.g. in their winter quarters or during migration). Early and temporally restricted sensitivity to social and other environmental stimuli, as well as a high degree of stability in the storage of early information will, therefore, confer a definite selective advantage. Sensitive phases and stability are characteristics of imprinting processes, and this may be a reason why different kinds of imprinting, such as filial, sexual, habitat or locality imprinting, are especially widespread in birds.

Behaviour embryology. The behaviour patterns of young birds discussed so far all refer to the postnatal stage. It has long been known, however, that behaviour starts well before hatching. Although it has been suggested that embryonic activity is merely a by-product of neural maturation, some recent studies indicate that it also may have its own adaptive function. Such function may refer to the regulation of muscle and joint development, to meeting the special requirements inside the egg and also to the creation of adequate preconditions for the hatching and early post-hatching periods.

For example, embryos use behavioural activity to attain the appropriate position for breaking the eggshell. Many species of precocial birds start vocalizing days before hatching. Their vocalizations have been found to facilitate post-hatching species-recognition (see below) or to enhance the synchronization of hatching which is important for an early and synchronous departure from the nest. In the Guillemot *Uria aalge*, the young in the egg even learn to distinguish, through mutual and contingent acoustic contact, between the calls of their parents and those of other birds. This enables the offspring to react selectively to their parents immediately after they have left the egg, such an ability being an adaptation to breeding in densely packed colonies where the young come into close proximity not only to their parents but also to many other adult birds as soon as they leave the egg (see DEVELOPMENT, EMBRYONIC; GROWTH).

Development of adult behaviour. In addition to the study of behaviours which are important for the developing individual, birds have also been—perhaps again as a consequence of their high speed of ontogenetic development—favourite tools for the study of developmental processes which are important mainly for the adult organism, and which are of relevance for the understanding of regularities in behaviour development in general. During the early stages of ethology, interest concentrated on the ontogeny of what at that time was called innate or instinctive behaviour or fixed action patterns (FAPs) (see BEHAVIOUR, HISTORY OF). Later there was a shift in interest towards a more detailed analysis of the exact interplay between genetically determined predispositions and the influence of early environmental stimulation.

The reason why early studies on 'innate' behaviour have been carried out, in great detail, on birds (and fish) may be that bird behaviour, perhaps being more influenced by hereditary factors and owing to the more permanent effects of early experience (see above), seems to be less flexible than the behaviour of mammals, so that it seemed better suited for the study of relatively fixed behaviour patterns.

Some early studies have indeed shown that there are behaviour patterns which for their development do not depend on being performed. This developmental process was called maturation. The most frequently cited example was provided by Grohmann, who prevented young pigeons from using their wings whilst they were reared and found that they flew as well as controls when released. Another example of a very strong genetic component concerns the migratory behaviour of Garden Warblers *Sylvia borin*. Hand-reared individuals, held in captivity, nevertheless attempted to fly in the natural south-westerly direction and after about a month spontaneously changed the direction to south-south-east. This is in exact accordance with their free-living conspecifics which make the same course correction at exactly the same time, a correction which prevents them from flying out into the open ocean once they have arrived over southern Spain or north-western Africa. Some evidence for genetically determined behaviour, finally, comes from behaviour embryology (see above). Embryos of various species of birds start to show active movements at a time when the reflex arc between sensory organs and muscles is not yet completed. As a consequence no input from the sensory organs can yet be transferred to the muscles and the movements occurring at this time must therefore be programmed and regulated endogenously.

Such behaviours in which obviously no learning is involved are very rare, however. In the majority of cases, there is a very subtle interplay between many internal and external factors. In bird research, this has been demonstrated in three areas among others: in studies on song learning, imprinting and prenatal development.

In song development (see VOCALIZATION), three different types of constraints have been found which contribute to restrict the learning process to elements of the species-specific song. (1) In many species, some basic outline of the song as a sequence of syllables with, for example, a certain approximate duration and/or tonal quality or structure, has been found to exist independent of experience with the species' song. (2) In addition, several species, for example the Chaffinch *Fringilla coelebs* and White-crowned Sparrow *Zonotrichia leucophrys*, have a predisposition to learn species-specific song patterns in preference to those of other species. If during song learning they are exposed to different acoustic stimuli they selectively respond to those of the appropriate tonal quality, which they include in their song repertoire. (3) In other species there is a predisposition to learn the song of birds with which an 'emotional' bond of some kind exists. They may pick up preferentially song elements of a territorial neighbour, as in the Crested Lark *Galerida cristata*, or of the father, as in the Bullfinch *Pyrrhula pyrrhula*, Bengalese Finch *Lonchura striata* (domestic form) and Zebra Finch *Poephila guttata*. In these species the young male develops a copy of its father's or foster father's song even if the latter belongs to another species and/or sings an alien song, and even if 'correct' song types are heard in close proximity and perhaps more frequently than the song of the tutor. Within these constraints, however, which seem to be genetically determined, environmental factors, i.e. the particular kind of acoustic stimulation the young bird is exposed to, determine the exact type of song it will finally develop.

In imprinting, the genetical constraints are temporal. A comparison of different species reveals that the onset and duration of the sensitive phase for, for example, sexual imprinting, is different in different species and obviously adapted to the specific conditions under which the offspring grow up (e.g. duration of parental care, age at dispersal etc.). Experimental studies, however, have shown that within these temporal limits, which obviously are again genetically determined, actual imprinting can occur earlier or later during the course of the sensitive phase, according to the particular conditions, e.g. the time of exposure to the imprinting stimulus. Again, environmental factors determine the exact outcome of ontogenetic development.

The most elegant studies on the interactions between genetical and environmental factors have been done with embryos. In ducklings *Anas platyrhynchos*, for example, it has been found that birds hatched in isolation in incubators are able to respond preferentially to the maternal call of their own species as compared to the call of another species, even if they have never heard the species-specific call before. This finding suggests a strong genetical background for such selectivity. However, as the developing embryo is of course able to listen to its own vocalizations, which begin several days before hatching, some exogenous influence via feedback through the auditory system cannot be excluded. To investigate this possibility, the preferences of ducklings which had been mechanically prevented from vocalizing prior to the onset of their own vocalizations were tested. Even these ducklings showed a high degree of preference for the species-specific maternal call, thus demonstrating the high degree of innate predisposition for selective responses. The devocalized-isolated ducklings, however, presumably due to an overlap in certain acoustic features, failed in one of the discrimination tests whereas the sham-operated controls did not. Obviously, selectivity in the responses to auditory stimulation is not perfect if no auditory experience is possible at all. It can be concluded that even such strongly predetermined responses are open to some, although minor, enhancement through sensory stimulation. Such stimulation may be very brief indeed. The deficiency in discrimination ability could be avoided if the devocalization procedure was delayed so that the embryos had about 24 hours of exposure to their own vocalizations before they were muted.

In order to classify the different ways in which environmental factors influence behavioural development, a number of distinctions have been made. For example a distinction is made between environmental stimuli which have more general effects and those which have specific effects. Another distinction is between three sorts of factors: those which initiate a developmental process which without such stimulation would not have begun; those which facilitate processes that are already in operation; and those which maintain the end-products of the developmental process, the relevant parts of the behavioural repertoire.

Mechanisms. The mechanisms for the changes in behaviour occurring during ontogenetic development are difficult to assess. Some behaviour patterns may be impossible to perform at first, simply because certain sense organs and muscles are not yet functioning. Thus, a newly hatched altricial bird may be deaf and blind, with only the muscles extending the neck and legs adequately developed. In such cases, some changes in behaviour may be seen as simple consequences of sensory and motor development.

Two important mechanisms which are involved in behavioural development are changes in the central nervous system and changes in the hormone level in the blood. The former may involve the proliferation and differentiation of neurons, 'remodelling' of axons, dendrites and synapses, or changes in the biochemical synthetic pathways for neurotransmitters. One process of neurogenesis which also seems to be of importance for behavioural development, e.g. the regulation of sensitive phases, is the phenomenon of neuronal cell-death. Thousands of cells in many parts of the central nervous system undergo differentiation including axonal growth and the formation of synapses, only to be subject to complete degeneration subsequently. The function of neuronal cell-death is not yet completely understood. It seems to be a mechanism, however, which ensures the adequate innervation of post-synaptic neurons or other targets (see NERVOUS SYSTEM).

Changes in the hormone level in the blood are of particular importance with regard to sex hormones and the ontogenetic development of reproductive behaviour. For example, cockerels normally first show treading at 80 days, but testosterone injections will induce it at 15 days and crowing at 4 days. In the Herring Gull, androgen injections will produce courtship display well before the end of the first year instead of after 3 years, and in male Zebra Finches, which normally start singing at about 34–37 days of age, it has been possible to advance the onset of song to an age of only 18–19 days if testosterone is applied at day 16.

Despite the examples listed, one must mention, in conclusion, that the number of experimental studies on neural and hormonal influences on behavioural development is still rather small. Much has to be done before we come to a better understanding of the mechanisms underlying behavioural development in birds. (R.J.A.) K.I.

BEHAVIOUR, HISTORY OF: broadest definition includes all kinds of movement and responses to changes in the environment, ranging from simple reflexive movements such as breathing to complex learned skills such as playing the piano. The behaviour of birds studied by ornithologists and comparative psychologists is generally towards the more complex end of this spectrum and includes COURTSHIP, AGGRESSION, and PARENTAL CARE. This survey traces the early history of the study of behaviour leading to the emergence of ethology and comparative psychology as the two major disciplines devoted to animal behaviour, and is followed by an account of some of the major issues addressed by students of behaviour during the 20th century.

Early history: Aristotle—18th century. The earliest systematic accounts of animal behaviour are in Aristotle's *Historiai peri ta zoa*

(Enquiries about Animals). Among many aspects of bird behaviour described by Aristotle are territorial behaviour and variations in territory size from species to species, pair bonding, and the development of bird song, in which Aristotle notes that some species of birds sing abnormally when reared in the absence of their parents, a phenomenon which has been the subject of much research during the last three decades (see VOCALIZATION). Aristotle's writings remained as the definitive account until the post-renaissance, although there were some writers in the middle ages such as Frederick II of Hohenstaufen (1194–1250), author of an extensive work on bird behaviour and FALCONRY.

In the 17th and 18th centuries two major lines of development occurred in the study of behaviour. First, philosophers such as Descartes (1596–1650) and Locke (1623–1704) debated the relationship between the behaviour of animals and that of man; and second, field naturalists such as C.G. Leroy (1723–89) in France, F.A. Pernau (1660–1731) in Germany, and Gilbert White (1720–93) in England made detailed descriptions of the behaviour of animals, especially birds, in their natural environment. Leroy was the first to emphasize the value of complete catalogues of the species' repertoire of behaviour as a starting point for research (nowadays such a catalogue is referred to as an *ethogram*), while White is famous *inter alia* for his recognition that the three British *Phylloscopus* warblers, although very similar in plumage, could be readily distinguished by their songs.

The 19th and early 20th centuries. The event of overwhelming importance in the 19th century biology was the widespread acceptance of the theory of evolution, and of NATURAL SELECTION as a major force causing evolutionary change. Charles Darwin, who towered above his contemporaries as a proponent of the theory of evolution, also wrote extensively on animal behaviour. For example, he formulated the theory of SEXUAL SELECTION to account for the extremely elaborate courtship displays and flamboyant nuptial plumages of some birds, and discussed how the postures of animals may reflect their motivational state, in his book *On the expression of emotions in animals and man*.

The latter half of the 19th century also saw the beginnings of a split between laboratory-oriented students of animal behaviour and those who preferred to watch animals in the field. The former were dubbed 'comparative psychologists' by the Frenchman P. Flourens (1794–1867) and the latter were named 'ethologists' by another Frenchman, I. Geoffroy St Hilaire (1801–1865). It is worth noting parenthetically that the English philosopher John Stuart Mill used the word ethology to refer to the 'science of character formation', a definition still given in the *Concise Oxford Dictionary*, but not the one used when referring to the study of animal behaviour in the natural environment.

Particularly influential in the establishment of laboratory experiments on behaviour were D.A. Spalding's (1840–77) studies of imprinting in chicks and C. Lloyd Morgan's (1852–1936) book *An introduction to comparative psychology* (1894). In this book Lloyd Morgan enunciated his famous canon: 'In no case may we interpret an action as the outcome of the exercise of a higher psychical faculty if it can be interpreted as the outcome of one which stands lower in the psychological scale'. In other words we should not jump to conclusions such as 'magpies get together for magpie weddings' unless we can rule out all possible simpler explanations such as 'magpies get together at good feeding sites'. This variant of Occam's razor had a seminal influence on comparative psychology, especially in North America where it led indirectly to a long succession of highly controlled rigorous experimental studies of mechanisms of learning by B.F. Skinner, and many others. In much of this work it was assumed that the behaviour of animals could be reduced to simple mechanistic laws of response to reward and punishment. For zoologists most of this work appeared to focus too narrowly on a few species (mainly rats and pigeons) and it addressed questions far removed from the behaviour of animals in the wild, in which adaptation to ecological conditions and differences between species were prevailing themes.

While comparative psychologists focused their attention on behaviour produced in response to reward and punishment, zoologists were impressed with the fact that the behaviour of animals is generally organized into well-coordinated sequences leading to a particular end point. This observation was formalized in 1918 by an American, Wallace Craig (1876–1954), in his account of 'instinctive behaviour'. Craig pointed out that many behaviour sequences consist of a rather flexible, partly learned, 'appetitive' phase in which the animal appears to seek out a particular stimulus situation (e.g. a hungry lion searching for a gazelle or a territorial bird patrolling its boundaries) followed by a more rigidly pre-programmed, stereotyped 'consummatory act' which brings the sequence to an end. In the case of the lion this would be the act of prey capture; with the territorial bird it would be meeting and chasing or displaying at a rival. In other words, for Craig animals were not passive responders to events in the outside world, but were actually driven by internal motivation to search for stimuli that would trigger off a consummatory act. Similar views were propounded by the German zoologist Oscar Heinroth (1871–1945), who also suggested that consummatory acts, or FIXED ACTION PATTERNS as he called them, were species-specific traits that could be used as taxonomic criteria in the same way as morphological features.

The writings of Craig, Heinroth, and another American, C.O. Whitman, set the stage for the emergence of ethology as a major discipline in the study of behaviour. Particularly influential in this were Konrad Lorenz (b. 1903) and Niko Tinbergen (b. 1907). (It is interesting to note as an aside that in spite of its strong tradition in natural history, the stuff of ethological science, Britain lagged behind continental Europe in the establishment of ethology as an academic discipline, perhaps because natural history was viewed as being the domain of amateurs such as Eliot Howard. Julian Huxley (1887–1975), one of the few professional zoologists in Britain to take an interest in ethology early on, did not pursue it as his main line of research.)

Lorenz's theory of instinct. In addition to being trained as a medical doctor and for a short while holding a chair of philosophy at Königsberg, Lorenz made major contributions to almost every aspect of ethology. His work on the evolution of displays, on imprinting in ducks and geese, on human behaviour in relation to that of animals, are all impressive, but in some ways his major contribution was to formulate a unified theory of instinctive behaviour, building on the work of Craig and Heinroth.

According to Lorenz, each fixed action pattern in a species repertoire is innate (i.e. pre-programmed by the genes and unmodified by ontogeny) and driven from within by an 'action specific potential' or specific drive. This drive was viewed as arising from within the nervous system and it was thought to cause the animals to perform the sequence of appetitive behaviours leading to the consummatory act. The latter allowed the drive to be dissipated, so that a quiescent phase was likely to follow. Lorenz's picturesque analogy was with the flushing of water from a lavatory cistern. The 'hydraulic model', as it was called, also embodied the notion that without performance of the appropriate consummatory act, drive would 'build up' inside the animal (like the lavatory cistern filling up with water) until eventually the consummatory act could occur even in the absence of any suitable external stimulus (a so-called 'vacuum activity'). One of Lorenz's favourite examples of this was a pet Starling *Sturnus vulgaris* that hawked for non-existent flies on the ceiling as a result (Lorenz would say) of build-up of the action specific potential for hunting. The more usual discharge of a drive occurred when the animal encountered a suitable stimulus to trigger the consummatory act. Lorenz argued that for each consummatory act there existed a specific trigger stimulus (*sign stimulus*, or in a social context, *releaser*) that could 'unlock' the act. This idea was borrowed from the writings of Jacob von Uexküll. The sign stimuli were thought to be detected in the central nervous system by special inbuilt sensory mechanisms (innate releasing mechanisms or IRMs), each one specific to a particular sign stimulus.

This theory of instinct, combining as it did ideas about the ontogeny of behaviour (in the concept of innateness), perception of stimuli, and internal control of behaviour, was a masterly synthesis. It had a major influence on ethologists, as well as affecting the research of neurophysiologists, endocrinologists and even some psychiatrists, such as John Bowlby. The theory was modified and improved by a number of authors, notably Tinbergen in his hierarchical model (1951), and Lorenz himself in his most recent book on ethology (1981).

In spite of its intuitive appeal and its ability to account for many everyday 'facts' about behaviour—after all lions do set out to hunt for prey, chase and capture the victim and rest after eating—Lorenz's theory eventually fell into disfavour in the 1950s and 1960s. Part of the reason, as W.H. Thorpe pointed out, is that the theory stimulated so much new research that it rendered itself obsolete. This is, of course, to be seen as a strength and not a weakness of theory. The point can be illustrated with reference to the concept of IRMs. The early work of Tinbergen and Lorenz showed that often simple models containing only a few components of the real stimulus were sufficient to trigger a response: gull chicks would peck at a pencil as readily as at a complete model of the parent's head and stickleback males would attack any model with 'red below' even if quite unfishlike in other respects. They interpreted these results as suggesting that the perceptual pathways are equipped with special detectors tuned in to key stimulus features. In the last two decades neurophysiologists have discovered the cellular analogues of some of these IRMs in the shape of single cells receptive to particular environmental features. In the visual system of the frog, for example, there are detectors that respond only to small dark moving objects ('bug detectors') and others that respond to moving lines or edges. Thus the general concept of IRM can be replaced with a more accurate account in terms of neural processes in the visual system.

However, in other respects Lorenz's theory failed to hold up to close scrutiny. Two examples are as follows. (a) Associated with the theory was the concept of 'innate behaviour', by which Lorenz originally meant (he later altered his ground) behaviour patterns that were completely fixed by genetic instruction and therefore appeared in the adult even in the absence of any environmental input. It is now recognized that all traits, including behaviour, develop through an interaction between genetic and environmental influences, and that any dichotomy into innate and learned behaviour is therefore artificial. Rather than asking whether a behaviour is innate or learned, one should ask to what extent variation between individuals in behaviour reflects genetic or environmental variation. (b) In formulating his ideas on action specific potential, Lorenz was much influenced by the work of von Holst showing that spontaneous rhythmical activity is generated in the central nervous system of invertebrates, even in the absence of any sensory feedback whatsoever. While it is true that some motor patterns (e.g. walking in insects) can be centrally generated, this does not mean that each activity has a specific drive that builds up with time since the last performance. In fact experimental evidence shows that Lorenz's prediction does not always hold. While hunger does seem to fit (at least at a superficial level; the threshold for feeding drops with time since the last meal until, as Charlie Chaplin found, shoelaces make an acceptable substitute for spaghetti) the same is not true for other activities such as aggression. In Lorenz's controversial book *Das sogennante Böse* (1963) translated into English as *On Aggression* (1966) he argued that aggression in animals and man is motivated by a specific drive that builds up if not released. However, careful experiments with a variety of animals have shown that sometimes exactly the opposite is true; aggression builds up consequent upon performance of aggressive acts rather than declining.

Tinbergen's four questions. While Lorenz's major contribution was in the study of mechanisms and ontogeny of behaviour, Tinbergen, at least in his later years, focused on experimental studies of the survival value of behaviour. A classic example of this approach is his study showing that eggshell removal (when the parent carries the broken shell from the nest shortly after hatching) by Black-headed Gulls *Larus ridibundus* is a method of maintaining the camouflage of the nest. Other experiments of this genre include a test of the survival value of spacing-out as a defence against predators in cryptic animals, experiments on the enhancement of foraging efficiency as a result of feeding in a flock, and observations on the survival value of colonial nesting in gulls.

One of the most influential papers written by Tinbergen is his *On the aims and methods of ethology* (1963). In this paper he spelled out the distinction between four different kinds of question asked in behavioural research, and in biology in general. Tinbergen's four questions are as follows: (a) Function: 'How does this behaviour contribute to survival or reproduction of the individual?' (b) Causation: 'What are the proximate internal and external factors causing the animal to behave in a particular way at a particular time?' (c) Ontogeny: 'How does this behaviour develop in the life of the individual?' and (d) Evolution: 'What is the evolutionary history of this behaviour pattern and under which selective forces did it evolve?' Note that while this fourth question is related to the first, it addresses past history rather than the present day.

Although Tinbergen stressed the importance of distinguishing between these four questions, he also saw that research often moves from one to another. One of his favourite illustrations was that Karl von Frisch started with the functional question "Why are flowers coloured?' and this led him to demonstrate that insects have colour vision and to elucidate a great deal about the mechanisms of insect vision (a question related to causation of behaviour).

Ethology in the second half of the 20th century. It is less easy to pinpoint the current highlights of ethology than it is to trace the main points of its historical development, and what follows is necessarily no more than an illustration of the issues under investigation in recent years in the four areas specified by Tinbergen.

(a) Function. Investigations of the function or survival value of behaviour have close ties with ECOLOGY since it is the environment that ultimately generates selection pressures on behaviour, and with population GENETICS since the consequence of natural selection is a change in the frequency of genes in a population. Ecological pressures may cause closely related species to evolve differences in behaviour related to differences in habitat as well as leading to the convergent evolution of similar behavioural traits among unrelated species living in similar habitats. For example, J.H. Crook and D. Lack showed in the 1960s that, irrespective of taxonomic affiliation, birds feeding on insects or other animal food tend to be territorial while those feeding on plant material such as fruit and seeds tend to be gregarious, living in flocks and nesting in colonies. (These are, of course, statistical trends and there are many exceptions, e.g. seabirds). These results suggest that diet and habitat have an important moulding influence on social organization. Plant foods tend to occur in large patches, which facilitates gregariousness by reducing competition; living in a group may actually enhance the likelihood of finding patches of food (more pairs of eyes are better than one) and/or it may provide protection from predators (see FLOCKING, COLONIALITY). In contrast, insect food does not usually occur in great enough local abundances to be exploited by groups, so individuals or pairs defend territories to keep away competitors and secure enough for themselves. Analogous arguments have been put forward to account for correlations between diet, habitat and MATING SYSTEMS and PARENTAL CARE.

More detailed studies of the relationship between behaviour and environmental resources in individual species have borrowed the terminology of micro-economics. In this approach the costs and benefits of behaviour are measured in some suitable currency such as time or energy, and these measurements are used to account for observed variations in behaviour. For example, hummingbirds and sunbirds sometimes defend winter feeding territories but at other times they do not, and it transpires that individuals generally abandon their territories when the extra energetic gain (calories of nectar) from excluding rivals is less than the energetic cost of defence (calories spent in chasing rivals). In other words the economic defendability of the resource determines whether or not the birds are territorial (see TERRITORY; OPTIMAL FORAGING).

A third important development is the realization that many details of complex social interaction within a group can be analysed in terms of KIN SELECTION. The essential idea is that various forms of co-operation or aid-giving (see CO-OPERATIVE BREEDING, ALTRUISM) might be favoured by natural selection if the individuals involved are close relatives. For example, by helping to protect or feed its young siblings a bird may, under the appropriate ecological conditions, be able to perpetuate its own genes (some of which it shares with its siblings) as effectively as it could if it were to attempt to breed itself. The sub-discipline of SOCIOBIOLOGY is largely concerned with elucidating the ways in which altruism might be favoured by selection. Another suggested mechanism for its evolution is reciprocity: if A helps B (e.g. by sharing food) at a small cost to itself and considerable benefit to B, and B later returns the favour, both individuals have made a net gain, even though A and B are unrelated. Some evidence from primates indicates the occurrence of reciprocal altruism in Nature. A moment's thought reveals a potential difficulty for the evolution of reciprocity. If A helps B there may (to put it anthropomorphically for shorthand) be a temptation for B not to reciprocate, in which case A pays a net cost while B gains a bigger benefit than it would if it reciprocated. In general terms, the benefit to A depends on the response of B. This feature of social interaction is widespread and not just restricted to reciprocity; it has led to the extensive use of GAMES THEORY by sociobiologists as an appropriate theoretical tool for finding the 'best' STRATEGY in this kind of situation.

(b) Causation. By its nature the study of proximate causes of behaviour leads to analyses of the physiological mechanisms underlying behaviour. For example, much has been done to elucidate the hormonal control of reproductive behaviour in birds (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM). In the female Canary *Serinus canaria*, external stimuli, such as increasing daylength and male song, initiate, via control centres in the brain, development of the ovaries which produce estrogen, the hormone that stimulates nest-building. Subsequently tactile stimuli from the nest on the sensitive brood patch (itself developing under the influence of estrogen) cause a change to softer nesting materials such as feathers (the nest lining) and eventually to a decrease in nest building and

the onset of the next phase of reproduction. This small example serves to illustrate the complex way in which hormones, external stimuli, and behaviour interact in the causation of reproductive behaviour.

Some aspects of causation cannot yet be studied at the physiological level and are more fruitfully analysed in the behavioural terms. Although, for example, a great deal is known about the physiological basis of hunger, this information does not necessarily give any indication of how hunger interacts with other comparable motivational systems such as thirst or sex. Does high sexual motivation enhance or inhibit hunger? The answer to this kind of question has been primarily studied at the behavioural level, using behavioural indices, such as rate of working by pecking a key to get food, to indicate how hungry the animal is. Such studies reveal that in general motivational factors are specific in their effects (i.e. food deprivation, while increasing hunger, does not increase sexual motivation) but that there are some general aspects of motivation (e.g. a hungry animal is generally more active or 'aroused' than a satiated one).

A related question concerns the way in which behaviour is organized to cope with the problem of conflicting motivational demands. Often animals are motivated to do more than one activity at any given moment, but generally one activity suppresses all the others, so that motivational conflict is not apparent to the observer. A flock of hungry sparrows leaves the bird table and flies to a bush as soon as a cat appears (fear inhibits feeding) and to the observer arriving to see sparrows in a bush the conflict between fear and hunger may not be readily apparent.

In this example the transition from one activity to a new one was caused by an increase in the causal factors for the second activity (i.e. the appearance of the cat). This kind of transition is said to be due to motivational competition. An alternative kind of transition is one that occurs as a result of motivational disinhibition. A hungry Barbary Dove *Streptopelia risoria* provided with access to food does not simply feed until it is satiated. Instead it interrupts feeding from time to time and switches to other activities such as preening. But increasing the level of causal factors for preening (by sticking a paper clip on the bird's wing) does not alter the time of the first transition from feeding to preening. In other words the transition occurs because feeding disinhibits preening rather than because preening outcompetes feeding.

Sometimes animals show overt signs of motivational conflict, for example by rapid alternation between two activities, by INTENTION MOVEMENTS and DISPLACEMENT ACTIVITIES (see also RITUALIZATION). Displacement activities have been of particular interest to ethologists since they appear to be irrelevant to the ongoing behaviour (for example birds engaged in a fight may break off and preen or peck at the ground when fear and aggression are in conflict). It seems likely that displacement activities form a heterogeneous group in terms of their motivational mechanisms. Some can be explained as 'low priority' activities temporarily disinhibited by major ongoing activities, in much the same way as the preening response of hungry doves referred to above. The disinhibition may come about because the major activity is thwarted or because it is in motivational conflict with another activity. Other displacement activities, however, seem to be attributable to a high level of general arousal (see above) arising from motivational conflict, and they may even serve to reduce arousal although the mechanisms underlying this are not understood.

(c) Ontogeny (see also BEHAVIOUR, DEVELOPMENT OF). In the broadest sense all behaviour has its ontogenetic roots in the genes. Some behavioural differences between individuals can be ascribed to specific effects of simple genetic differences (for example the difference in mental development between normal children and those suffering from phenylketonuria (PKU) is due to a single gene difference—see GENETICS), while in other cases the link between behavioural differences and genetic differences is more tenuous and complex (e.g. differences between children in ability to play the piano). Even when the link between genes and behaviour differences is simple, the environment during development can have a dramatic modifying effect on behaviour—PKU sufferers can be behaviourally normal in spite of their genetic abnormality if reared on an appropriate diet from birth.

The proportion of variation in behaviour or any other trait that is due to genetic variation is sometimes expressed as a measure called heritability, a measure which is often abused and misunderstood. One common misconception is that a high heritability score implies that the trait is genetically fixed and resistant to environmental change. The PKU example above illustrates the fallacy of this notion: without dietary control the difference in mental ability between PKU and normal humans is largely genetic (high heritability), but the effects of the genetic difference are very much modifiable by the environment.

The student of behavioural ontogeny addresses the question of exactly how genetic and environmental factors interact in the unfolding of behaviour during development. One of the classic methods used is the isolation or Kaspar Hauser experiment in which an individual is reared in the absence of certain environmental influences to see if its behaviour still develops normally (see VOCALIZATION for such studies on bird song). These experiments have played an important role in understanding ontogeny but their results must be interpreted with caution. Sometimes, for example, the isolated animal generates its own environmental cues for development, so the isolation experiment has not isolated the animal as fully as might be thought at first. A case in point is bird song: isolated Chaffinches *Fringilla coelebs* use auditory feedback from their own vocalizations in developing their songs.

One of the important general principles to emerge from isolation experiments is that of the sensitive phase. Animals are often more sensitive to environmental effects at some ages than at others: White-crowned Sparrows *Zonotrichia leucophrys* seem to be capable of learning their song only in a short period during the first few months of life and young precocial birds are most likely to become imprinted on an object in the environment if exposed to it in the first few days after hatching (see IMPRINTING). Not all instances of LEARNING, however, are restricted to short sensitive periods and in some ways ontogeny can be said to continue until the animal dies.

(d) Evolution. There is virtually no fossil record of behaviour, the few exceptions being such things as footprints or other tracks and artifacts. Therefore inferences about behavioural evolution have to be drawn largely from comparisons of living species. Such comparisons may be used in any of three endeavours. The first is to identify homologous behavioural traits and distinguish them from analogous traits. The former are common to a taxonomic group and reflect the evolution of the group from a common ancestor; as an example, almost all passerines scratch the head by putting the foot over the wing, while non-passerines scratch from underneath the wing. Over-wing scratching probably reflects the common ancestry of passerines and is therefore homologous. In contrast, bats, cetaceans and oilbirds all use ECHO-LOCATION to find their way about, but this is not because they have all evolved from a recent common ancestor but because all three groups have independently solved the problem of orienting in the dark by evolving echo-location—the trait is analogous rather than homologous.

A second use of comparisons is to trace the probable path of evolution of a behavioural trait. For example present day shorebirds (in North America) show four kinds of mating system: (a) *Monogamy* (e.g. Western Sandpiper *Calidris mauri*); (b) *Double-clutching*, in which a female lays a first clutch of eggs which is incubated and reared by the male, while the female lays a second clutch and cares for it herself (e.g. Sanderling *Calidris alba*); (c) *Sequential polyandry* in which a female pairs with a number of males in succession, laying a clutch for each one to look after, and helps the last male herself (e.g. Spotted Sandpiper *Actitis macularia*); (d) *Simultaneous polyandry*, in which a female lays clutches for several males, leaving each of them to do the parenting (e.g. Northern Jacana *Jacana spinosa*). It is a reasonable inference from these observations that polyandry evolved from monogamy via double-clutching.

Finally, as discussed earlier, behaviour patterns can be used as an aid in taxonomy. Probably the best example of this is still Lorenz's classic work on the taxonomy of the Anatinae based on their DISPLAYS.

Conclusion. In the past many of the major advances in the study of behaviour have come from work on birds. Their conspicuousness and accessibility, together with their reliance on visual and auditory senses, their ease of maintenance in captivity and their aesthetic appeal are among the features that have led ethologists to study birds. No doubt birds will continue to occupy a central place on the ethological stage, even though the methods used to study them are rapidly changing from gumboots and binoculars to radiotelemetry, electrophoresis, and sophisticated field experiments. BELLBIRD: substantive name of *Procnias* spp. (see COTINGA); also of the Crested Bellbird *Oreoica gutturalis* (see THICKHEAD); and name of *Anthornis melanura* (see HONEYEATER).

BELL-MAGPIE: see CURRAWONG.

BELL-MINER: *Manorina melanophrys* (see HONEYEATER).

BELL-SHRIKE: sometimes used as substantive name of certain *Laniarius* spp. (see SHRIKE).

BELLY: the ABDOMEN; or the ventral surface area roughly corresponding thereto (see TOPOGRAPHY).

BELLY-SOAKING (1): specialized behaviour associated with the carrying of drinking water for the chicks by species of Pteroclididae (see SANDGROUSE).

BELLY-SOAKING (2): specialized behaviour associated with incubation by charadriiform birds, especially Charadriidae, nesting in tropical and sub-tropical environments. Belly-soaking is most frequent between about 10.00 and 13.00 h and is characteristically performed by a bird about to relieve its mate at the nest; a sitting bird does not usually leave its eggs to belly-soak unless its mate has failed to arrive for duty when called by the on-duty bird. The usual method for wetting the feathers is to walk into shallow water and repeatedly dip the underparts into the water by bending the legs. Dips may be momentary or may be prolonged into immersions. Up to 11 separate dips/immersions, sometimes interspersed with short runs during which the belly feathers are kept in the water, are used to saturate the belly feathers, the whole process taking up to a maximum of 10 min. Water may be carried up to 100 m. The African Skimmer *Rynchops flavirostris* achieves a similar end result by flying over water with dangling feet and splashing water onto its underparts.

For purely physical reasons, belly-soaking must result in evaporative cooling of both bird and eggs (which, incidentally, are often shaded rather than incubated properly); the stimulus for it is probably the combination of high ground surface temperatures (60°C on some Skimmer *Rynchops* breeding beaches) and comparatively high (30°–40°C) air temperatures just above the ground that result from intense solar radiation in calm conditions. Most published accounts of belly-soaking conclude that its primary function is to cool the eggs but the work of Howell and Bartholomew (1962) suggests that, even under conditions of intense solar radiation, the temperatures of eggs kept covered/shaded by parent birds are unlikely to reach lethal values. Since belly-soaking is a normal feature of incubatory behaviour in *Hoplopterus* spp. and *Charadrius* spp. (e.g. White-headed Plover *H. albiceps*, Yellow Wattled Lapwing *H. malabaricus*, Kittlitz's Sand Plover *C. pecuarius*, Three-banded Plover *C. tricollaris*) and is not specially associated with a return to eggs left exposed during an enforced absence, its function is probably primarily to assist heat loss from the adult rather than the eggs though the two are not mutually exclusive. Cloud and/or wind may reduce the heat load to below the threshold for releasing belly-soaking in those species in which the behaviour is, on present evidence, sporadic (Little Ringed Plover *C. dubius*, White-fronted Sand Plover *C. marginatus*, Chestnut-banded Sand Plover *C. pallidus*, Blacksmith Plover *H. armatus*, Spur-winged Plover *H. spinosus*, Black-winged Stilt *Himantopus himantopus*, Avocet *Recurvirostra avosetta*). J.F.R.

White-headed Plover *Vanellus albiceps* bringing water to its eggs. Note wing spurs and wattles. (*Photo: J.F. Reynolds*).

Namaqua Sandgrouse *Pterocles namaqua* male wetting its belly feathers. (*Photo: G.L. Maclean*).

BELT: a broad band, in some plumage patterns, across the breast or belly (see TOPOGRAPHY).

BENGALESE: see CAGE BIRD.

BENTBILL: *Oncostoma cinereigulare*, a small tyrant-flycatcher with a curiously thick, arched bill (see FLYCATCHER (2)).

BERGMANN'S RULE: that, among the forms of a polytypic species, body-size tends to be larger in cooler parts of the total range and smaller in the warmer parts (see also ALLEN'S RULE; ENERGETICS; WING).

BERRYEATER: substantive name of *Ampelion* spp. (for family see COTINGA).

BERRY-PECKER: substantive name sometimes used for the New Guinea FLOWERPECKERS of the genus *Melanocharis*.

BEWIT: term used in FALCONRY.

BIBLE, BIRDS OF THE: less than 40 species are mentioned in the Bible, out of over 400 resident in or migrating through Israel. Half of the names are included in the lists of the unclean birds mentioned in Leviticus 11 and in Deuteronomy 14; the two lists are very similar, with several variations in the order and only one name mentioned in one list and not in the other. The other names, some of which are difficult to identify, are scattered through the books and include names of birds (and other creatures) characteristic of deserts and other lonely places. Doves and young pigeons are connected with the ritual sacrifice in the Temple, and they are most frequently mentioned in the Bible. Passages striking in their beauty refer to such migrating birds as the Turtle Dove and White Stork (Song of Songs, 2, 12; Jer. 8, 7)—see also under QUAIL.

The identification of the names of birds and other animals met with difficulties as early as the time of the translation of the Bible into Greek, in the 3rd century BC. It is quite possible that in different parts of the Land of Israel different tribes, or even smaller population units, used different names for the same creatures; and when these names were included in the books of Law and the books of the Prophets they could

Table showing English names used in translating from the Hebrew as compared with the modern identifications made by Israeli zoologists.

The first column gives the names used in King James's Bible—the Authorised Version (Old Testament); where a name is widely at variance with the modern identification it is placed within quotation marks. More than one entry for the same name indicates that different Hebrew words are represented. Where the name used in the recent translation issued by the Jewish Publication Society of America is different, it follows within brackets. The second column gives selected references to the use of the name in King James's Bible; 'L' = Leviticus, chapter 11, 'D' = Deuteronomy, chapter 14.

	BIBLICAL REFERENCE	ZOOLOGICAL IDENTIFICATION
'arrowsnake' (great owl)	Isa. 34, 15	Long-eared Owl *Asio otus*
'bittern'	Isa. 14, 23; 34, 11; Zeph. 2, 14	Long-eared Owl (Aharoni) *Asio otus*
birds	Gen. 7, 14; Ps. 104, 17	general
birds, ravenous	Ezek. 39, 4	eagles *Aquila* sp.
bird, speckled (speckled bird-of-prey)	Jer. 12, 9	eagle *Aquila* sp.
'cormorant'	L; D	Fish Owl *Ketupa zeylonensis*
'cormorant' (pelican)	Isa. 34, 11; Zeph. 2, 14	pelican *Pelecanus* sp.
'crane' (swallow)	Isa. 38, 14; Jer. 8, 7	Swift *Apus apus pekinensis*
'cuckow' (sea-mew)	L	gull *Larus* sp.
'doleful creatures' (ferrets—*sic*)	Isa. 13, 21	Eagle Owl *Bubo bubo aharonii*
dove	Gen. 8, 8; Isa. 38, 14; 59, 11; 60, 8; Hos. 7, 11; 11, 11; Ps. 55, 6; Song of Songs 2, 14; 5, 2; 5, 12; 6, 9; Nah. 2, 7; Ezek, 7, 16; Jer. 48, 28	pigeon *Columba* sp.
dove, turtle	Gen. 15, 9; Lev. 1, 14; 14, 30	Turtle Dove *Streptopelia turtur*
'eagle'	Exod. 19, 4; Deut. 32, 11; Isa. 40, 31; Jer. 4, 13; Ezek. 17, 3; Ps. 103, 5; Pr. 30, 17; Lament. 4, 19	Griffon Vulture *Gyps fulvus*
'eagle' (vulture)	Hab. 1, 8; Job 39, 27	Griffon Vulture *Gyps fulvus*
'eagle' (great vulture)	D	Griffon Vulture *Gyps fulvus*
'eagle, gier' (carrion vulture)	L; D	Egyptian Vulture *Neophron percnopterus*
fowl	Gen. 7, 14	general
fowl	Ps. 8, 8	general
fowl; fowls of the mountains (birds-of-prey; ravenous birds of the mountains)	Gen. 14, 11; Isa. 18, 6	eagles *Aquila* sp.
fowl, fatted	Kings I, 4, 23	swan *Cygnus* sp.
glede	D	kite (Aharoni) *Milvus* sp. or buzzard (Margolin) *Buteo* sp.
hawk	L; D; Job 39, 26	hawk *Accipiter* sp.
'hawk, night'	L; D	falcon *Falco* sp.
heron	L; D	herons Ardeidae spp.
kite	L	Black Kite *Milvus migrans*
'kite' (falcon)	L; D	buzzard, or kite (Aharoni) *Buteo* sp. or *Milvus* sp.
'lapwing' (hoopoe)	L; D	Hoopoe *Upupa epops*
'ospray'	L; D	Black Vulture *Aegypius monachus*
ossifrage (bearded vulture)	L; D	Lämmergeier *Gypaetus barbatus*
ostrich	Lament. 4, 3	Ostrich *Struthio camelus*
'ostrich' (stork)	Job 39, 13	White Stork *Ciconia ciconia*
'owl' (ostrich)	L; Isa. 13, 21	Ostrich *Struthio camelus*
owl, great; owl	L; Isa. 34, 11	Short-eared Owl *Asio flammeus*
owl, little; owl of the desert (owl of the waste places)	L; D; Ps. 102, 6	Little Owl *Athene noctua*
owl, screech (night monster)	Isa. 34, 14	Tawny Owl *Strix aluco*
partridge	Sam. I, 26, 20; Jer. 17, 11	partridge (See-see) *Ammoperdix heyi*
'peacock'	Kings I, 10, 22	parrot Psittacidae sp.
'peacock' (ostrich)	Job 39, 13	Ostrich *Struthio camelus*
pelican	L; D; Ps. 102, 6	pelican *Pelecanus* sp.
pigeon, young	Gen. 15, 9	pigeon *Columba* sp. (juv.)
pigeon, young	Lev. 14, 30	pigeon *Columba* sp. (juv.)
quail	Exod. 16, 13; Num. 11, 31; Ps. 105, 40	Quail *Coturnix coturnix*
raven	L; Kings I, 17, 6; Song of Songs 5, 11	raven or crow *Corvus* sp.
'raven' of the valley	Pr. 30, 17	Magpie *Pica pica bactriana*
singing of birds	Song of Songs 2, 12	Nightingale *Luscinia megarhynchos*
sparrow	Ps. 102, 7	House Sparrow *Passer domesticus biblicus*
stork	L; D; Jer. 8, 7; Zach. 5, 9; Ps. 104, 17	White Stork *Ciconia ciconia*
swallow (crane)	Isa. 38, 14; Jer. 8, 7	swallow (Aharoni) or crane (Margolin) Hirundinidae sp. or Gruidae sp.
'swan' (horned owl)	L; D	Barn Owl *Tyto alba*
turtle (turtle dove)	Num. 6, 10; Song of Songs 2, 12; Jer. 8, 7	Turtle Dove *Streptopelia turtur*
'vulture' (kite)	D; Isa. 34, 15	Black Kite *Milvus migrans*
'vulture' (falcon)	Job 28, 7	buzzard *Buteo* sp.

obviously give rise to controversy. The discussion in the Talmud, centring on the difficulty of identifying birds subject to ritual prohibitions, shows that there were localities where certain birds were eaten which were considered to be unclean elsewhere (E. Billig).

The divergence in the identification of the names mentioned in the Bible grew immensely when translators and expositors came to be persons who lived outside of the Land of Israel and imagined that the animals of their own countries were identical with those mentioned in the Bible. The ever-growing number of languages into which the Bible is being translated reflects the difficulties regarding such identifications for people of countries with different flora and fauna from that of the Land of Israel. Even in revised English translations (e.g. King James's Bible) the same Hebrew names are sometimes translated in various ways, as can be seen from the appended Table; this is also true of a more recent translation such as that of the Jewish Publication Society of America. There is no unanimity even among Israeli scientists regarding the meaning of some of the Biblical names and their uses in modern Hebrew. However, the differences over the names of birds are few in comparison with those over the names of mammals.

The Table presents English translations of the names of the birds mentioned in the Hebrew Bible, along with their scientific identification as generally accepted in Israel today. The English names are those used in King James's Bible, with those in the J.P.S.A. Bible (where different) for comparison. The list of quotations is not complete, but it includes the most typical and commonly cited passages.

Two Hebrew names, *zipor* and *of*, are used for birds in general. It was admitted by some scholars, and generally accepted in Israel, that the first denominates small birds and the second the large ones. It is doubtful, however, whether such a distinction was carefully followed in the Bible. Another reservation concerns the frequent combination of two Hebrew names for Turtle Dove (*tor*) and young pigeon (*yona*—also *gozal*). There are also names which might have been used for birds but are of doubtful meaning, e.g. *sechvi* (rooster or soul), *thinshemeth* (chameleon or owl), *kipod* (owl in translation but hedgehog in colloquial Hebrew), and *atalef* (now considered to refer to a bat). The name *hogla* is commonly used now in Israel for the Stone Partridge; in the Bible it is used as a place-name (Beth Hogla).

Canon Tristram was the first man to try to base the identification of the flora and the fauna of the Bible upon their study in the Land of Israel. During several journeys, spread over some 20 years, he studied the habits of the beasts and birds as well as the local names still in use by the population. His excellent work was of value to the J.P.S.A., which undertook a new translation of the Bible on behalf of Jewish authorities in the years 1892–1915. The next step was made by Aharoni, the first zoologist to live and work permanently in Palestine. When writing a first zoological school text in Hebrew, he introduced into the everyday usage of the Hebrew-speaking school-children names which later became commonly accepted. Margolin increased the general knowledge of the flora and fauna of the Bible in Israel by teaching schoolmasters in his institution and through his books. Although Bodenheimer doubted the possibilities of exact identification of the animals of the Bible, the use of names introduced into everyday life became so widespread that now it is in practice less important whether the names used by Israelis today are or are not the same as those used by their forefathers. The living Hebrew now spoken in Israel has brought the names of birds and other animals mentioned in the Bible into common use; in this way names again attach to observable realities instead of being disputable scholastic terms.

There are few references to birds in the New Testament and they are mainly to domesticated species—hen, pigeons or doves—or to commensals such as sparrows *Passer* and the Raven *Corvus corax*, with single references to 'great eagle' and 'vulture'. This may be explained by Christ's preaching mainly to the inhabitants of villages and small towns. A.S.

BIBLIOGRAPHY: the most useful guide for the ornithologist is the section 'Aves' of the *Zoological Record*, published annually by the Zoological Society of London (see ZOOLOGICAL RECORD). Also giving short summaries as well as titles, but with a less complete coverage of ornithology, are the volumes of *Biological Abstracts* published since 1927 under the auspices of the Union of American Biological Societies. Many ornithological periodicals publish reviews, abstracts, or lists of titles of current literature. In an attempt to keep pace with the proliferation of books and papers on birds, the American Ornithologists' Union and the British Ornithologists' Union began publication in January 1983 of *Recent Literature*, a supplement to their respective journals *Auk* and *Ibis*. This gives titles and in some cases short abstracts of papers.

For lists of birds of the world see references under CLASSIFICATION. A list in French under the title *Projet de Nomenclature Française des Oiseaux du Monde* is being published by P. Devillers (1976–19—) in sections in *Le Gerfaut*, journal of L'Institut royal des Sciences naturelles de Belgique.

Several bibliographies (listed below) were published in the first part of the 20th century, but to embark on an up-to-date one would be a most formidable task.

BICEPS: see MUSCULATURE. The presence or absence of a 'biceps slip', a division of the humeral head of this flexor of the forearm, has been used as a taxonomic character.

BILL: alternatively 'beak' and technically 'rostrum', the projecting jaws of a bird, with their horny sheaths. The whole consists of the upper mandible (or maxilla) and the lower mandible: the former is based on the facial bones, especially the premaxillae, and the latter on the composite jaw-bones (see SKULL). The horny coverings of both are formed by the outer layers of the Malpighian cells of the epidermis (see SKIN). The whole horny structure is known as the rhamphotheca, the upper and lower portions being sometimes separately designated rhinotheca and gnathotheca.

Upper mandible. For descriptive purposes this may be divided into the culmen, or dorsal ridge from the tip (dertrum) of the bill to the forehead, and the upper mandibular tomia, or lateral cutting edges. In most birds the external covering is fused into a single hard sheath; in parrots, however, there is limited vertical movement on a 'hinge' between the premaxillae and the skull. In a few families, such as the albatrosses, division of the mandible into distinct horny sections is apparent. Most limicoline birds (Charadrii) have relatively soft 'leathery' coverings to their bills; in geese (*Anser* spp. etc.), while much of the sheath is soft, the tip forms a hard 'nail' well adapted to cropping vegetation. The proximal portion of the mandible may be soft and thickened, forming a sensitive cere, as in diurnal birds-of-prey, in which it is naked, and in parrots, in which it is usually feathered; or it may have a soft, swollen operculum above the nostrils, as in pigeons.

The nostrils or external nares with circular, oval, or linear openings, are usually separated by a cartilaginous or ossified medial septum, as in e.g. the owls, but in certain families such as the gulls and cranes this feature is absent (see NARIS). In the fulmars and shearwaters (Procellariidae) the nostrils are in paired tubes separated by a septum on top of the culmen, but in the storm petrels (Hydrobatidae) they are in a single tube. Darters and cormorants have only rudimentary nostrils that close after the young leave the nest; gannets, which plunge into the sea after fish from a considerable height, have no external nostrils but wide inner apertures communicating with the mouth and, like adult cormorants, they breathe through the mouth. The nostrils of most small passerine birds open into a slight superficial depression, the nasal fossa. The position of the nostrils relative to the base of the bill shows considerable differences; but only in the kiwis, nocturnal species with a highly developed olfactory system, are the nostrils located at the tip of the bill (see SMELL).

Lower mandible. The chief characters of the lower mandible are the lower mandibular tomia, or cutting edges, the mandibular ramus, extending posteriorly on either side of the jaw, and the gonys, or ventral ridge formed by the junction distally of the two halves of the jaw, as clearly seen in gulls for example. The full-length apposition of the closed mandibles is known as the commissure. The gape or rictus is the mouth

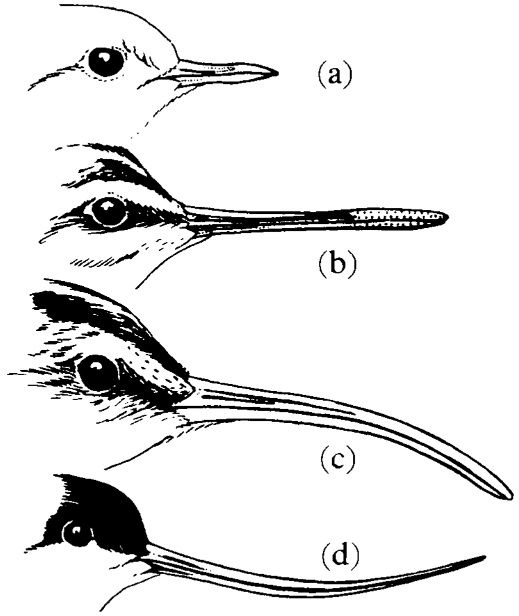

Fig. 2. (a) Golden Plover *Pluvialis apricarius*, bill of moderate length; (b) Snipe *Gallinago gallinago*, long straight bill; (c) Whimbrel *Numenius phaeopus*, long decurved bill; (d) Avocet *Recurvirostra avosetta*, long recurved bill. (*C.E.T.K.*).

opening, formed in the angle between the two mandibles when the lower jaw is dropped.

Regeneration and moult. Regeneration of the rhamphotheca of both mandibles and even of the bones of the bill damaged in combat has been recorded in storks and in the domestic fowl. As a result of damage and imperfect regeneration, or possibly genetic defect, various deformities occur. The effects of normal wear, occurring particularly at the tip of the bill in many species, are compensated by additional growth. The external surfaces of the bills of parrots and some other species are renewed by a process of irregular 'peeling'. In puffins *Fratercula* spp. the much enlarged and laterally flattened and decorated outer sheaths are shed after the breeding season, leaving smaller, unembellished bills of a different shape during winter. Laterally compressed bills occur in other genera of the Alcidae and many are brightly coloured in summer.

Appendages. Seasonal ornamentations or appendages to the bills of male birds occur in many species. Some pelicans, for example, grow several erect horny plates, which are cast after breeding; these birds also show maximum development of the membranous gular sac, which extends the whole length of the lower mandible and embraces the chin, gular region, and jugulum. In many birds, such as coots *Fulica* spp., turacos *Musophaga* spp., a megapode *Megacephalon maleo*, and scoters *Melanitta* spp., the base of the culmen and the forehead are swollen to form ornamental plates, knobs, or humps. These embellishments are seen in extreme form in the hornbills. The swellings are in most instances of light and spongy tissue, but in the Helmeted Hornbill *Rhinoplax vigil* the bones of the enlarged forehead have a dense epidermal covering with the consistency of ivory.

Sexual dimorphism. Notable dimorphism in structure is uncommon, but it is well illustrated in the bill of the Huia *Heteralocha acutirostris*, the male's being relatively short, stout, and almost straight, and the female's slender, decurved, and nearly twice as long (see WATTLEBIRD (2)). Dimorphic bills can also be seen in certain hornbills, in some of which the disparities in size and shape are considerable (e.g. the Rufous-necked Hornbill *Aceros nipalensis*). Differences between the colours of the bills of males, females, and young occur in many species; there are also seasonal changes in colour (see also SEXUAL DIMORPHISM).

Early development. The bills of embryo birds develop a calcareous, scale-like EGG-TOOTH on the tip of the upper mandible with which the eggshell is later perforated; this feature is shed within a few days of hatching. In some species, e.g. American Woodcock *Scolopax minor*, there is another egg-tooth on the lower mandible. Nestling honeyguides possess a pair of sharp mandibular and maxillary hooks which are shed about the time the eyes open; with these interlocking 'teeth'—a unique adaptation—the young parasite kills the nestlings of its host species. The linings of the mouths of altricial nestlings are usually vividly coloured, and both the plate and tongue are often embellished with coloured spots (see TONGUE). The rictal regions are first much swollen; this swelling and the soft operculum found above the nostrils of nestlings of certain species disappear as the bill hardens and assumes adult proportions. Species with highly adapted bills, such as curlews *Numenius* spp. and flamingos, have bills of generalized form in the early nestling stage.

Functions. The bill serves many of the purposes of a 'hand', the specialized forelimbs of birds being little available for these. Notably it is used in nest building, which in some instances demands a high degree of dexterity, and in preening the feathers (see COMFORT BEHAVIOUR; NEST BUILDING). It is also a weapon; and, as already noted, it may bear ornamental or other colouring, excrescences, or appendages. Above all it is used in feeding, being in effect an extension of the jaws, and it is to this function that its structure shows the greatest variety of special adaptations (see FEEDING HABITS).

Adaptation to feeding habits. The external characters of the bills of different species vary greatly in accordance with feeding behaviour. Some reveal high degrees of adaptation, in both shape and proportionate size. The following are typical examples, the characters described being not necessarily exclusive to the groups or species mentioned.

The long, dagger-shaped bills of most herons and bitterns are well adapted to seizing quick-moving prey in shallow water or among reeds. A more perfected development for grasping fish is seen in the bills of mergansers *Mergus* spp., which have saw-like tomia; the bills of toucans have similar toothed serrations for securing food. The elongated, slender bills of most wading birds of the Charadriiformes are adapted to probing in mud or sand, typical straight and pliable examples being seen in the Snipe *Gallinago gallinago* and Woodcock *Scolopax rusticola*; deeply decurved examples occur in the curlews *Numenius* spp. The avocets feed largely on the surface of shallow water and have slender, much recurved bills. In the Wrybill Plover *Anarhynchus frontalis* the whole of the distal half of the bill is curved to the right. A highly specialized mode of feeding is illustrated by the Spoonbill *Platalea leucorodia*, which has the tip of the bill flattened and enlarged in spatulate form, and in the Shoveller *Anas clypeata*, which has a wide, spoon-shaped bill. The boat-shaped bills of the Shoebill *Balaeniceps rex* and the Boatbill *Cochlearius cochlearius* are other examples. An even more extreme adaptation occurs in the skimmers, in which both the lower mandible and its supporting jaw-bones are much elongated, to serve as a projecting scoop (although laterally

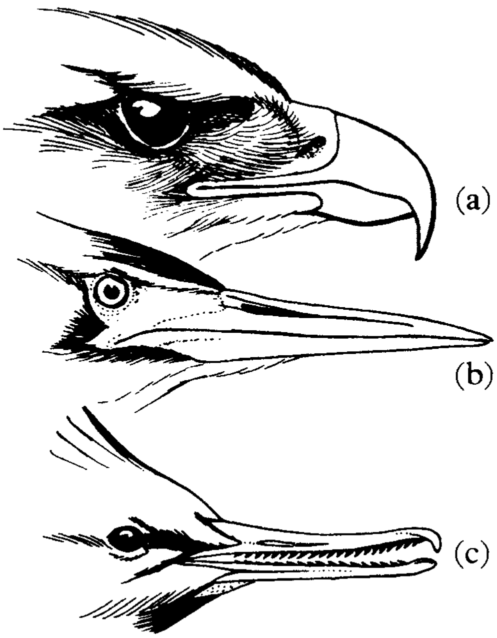

Fig. 3. (a) Golden Eagle *Aquila chrysaetos*, raptorial bill; (b) Bittern *Botaurus stellaris*, spear-like bill; (c) Red-breasted Merganser *Mergus serrator*, saw bill. (*C.E.T.K.*)

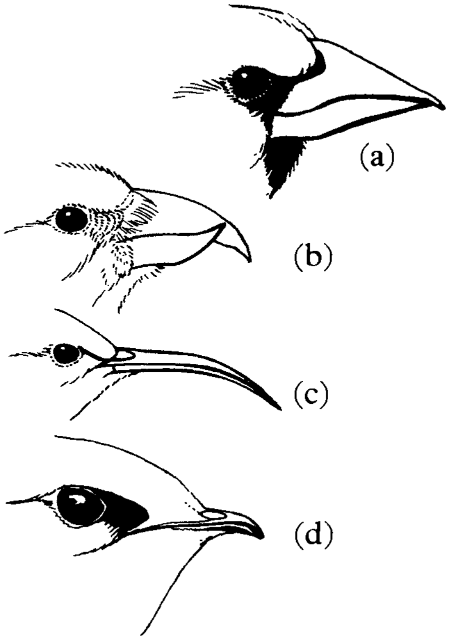

Fig. 4. (a) Hawfinch *Coccothraustes coccothraustes* strong bill; (b) Crossbill *Loxia curvirostra*, tips of mandibles crossing; (c) Scarlet-breasted Sunbird *Nectarina senegalensis*, bill adapted to nectar-feeding; (d) Alpine Swift *Apus melba*, weak bill in a bird that catches insects with open gape. (*C.E.T.K.*)

compressed) in skimming food from the surface of the water in flight. The bills of flamingos are angled downwards in the middle and equipped with a series of elaborate plates or lamellae, which sieve food from muddy water, the bill being held in an inverted position (see FLAMINGO). Lamellae are present also in the bills of swans, geese, and ducks and in prions *Pachyptila* spp. The maximum development of lamellae is seen in the brush-like mass inside the bill of the Openbill Stork *Anastomus oscitans*; this species shows a further peculiarity in that it has a gap halfway along the closed mandibles.

The finches and grosbeaks, the buntings, the weavers and sparrows, and others have stout bills, conical in section, and well adapted to cracking seeds. The commissures in this group of birds are characteristically angulated. A notably wide range of variation in the bill is found in the Reed Bunting *Emberiza schoeniclus* (see BUNTING). A species showing remarkable specialization is the Hawfinch *Coccothraustes coccothraustes*, which has a very highly developed musculature of the jaws and skull, and ridged bosses or 'anvils' on the palate and inside the lower mandible, enabling it to crack the stones of cherries and even of olives. Somewhat similar, but transverse, rasp-like ridges are found inside the bills of certain parrots; with these the hardest fruit-stones are reduced to fine particles. Another striking adaptation is illustrated by the bills of adult crossbills *Loxia* spp., the mandibles being sharply pointed and widely crossed over (to right or left in about equal numbers) to aid the rapid extraction of seeds from fir-cones.

Birds-of-prey, both diurnal and nocturnal, have powerfully hooked and sharply pointed bills, well adapted to killing and tearing up their food. The small, chiefly insectivorous members of the Falconidae have bills of delicate proportions, but in the larger eagles such as *Haliaetus* the proportions are massive. The bills of shrikes are sharply hooked at the tip and the upper mandibular tomium has a distinct 'tooth'; several 'teeth' are apparent in the upper mandibles of trogons.

Small insectivorous birds, typified by the Old World and New World warblers (see WARBLER (1) and (2)), have small and usually slender bills. Treecreepers, which seek small insects in the bark of trees, also have slender but longer and decurved bills. The long and, in some species, finely curved bills of hummingbirds are adapted to probing the corolla-tubes of flowers for nectar, as in varying degree are those of the sunbirds, the honeyeaters, the Hawaiian honeycreepers (Drepanididae), and some flowerpeckers. Some insectivorous families such as the nightjars, which are crepuscular feeders, and some birds of smaller size such as the flycatchers of the Muscicapidae and Tyrannidae, have forward-pointing rictal bristles; like the swifts and swallows, they have very broad gapes which facilitate the capture of flying insects. An adaptation to a highly specialized method of feeding is found in the Buphaginae (see OXPECKER).

Woodpeckers are equipped with sturdy chisel-tipped bills for the excavation of nest-holes in tree-trunks and for reaching wood-boring insects. G.M.

BILL ABNORMALITIES:

Types. Abnormalities are usually confined to the outer covering of the bill (the rhamphotheca, see BILL). A wide variety of abnormalities has been observed, the commonest being elongation, which is often associated with some degree of down curving. Lateral curvature, normal in the Crossbill *Loxia curvirostra*, occurs quite commonly as an abnormality in other species. Abnormalities such as these which involve distorted growth are believed to have genetic origins, although the evidence for this in wild birds is circumstantial. (In domestic fowls, there is detailed evidence for inheritance of similar deformities.)

Another common type of abnormality involves elongation of only one mandible, often accompanied by evidence that the other mandible has been broken. In some cases, at least, such birds are obliged to change their method of feeding (see below), resulting in reduced wear of the tip of the undamaged mandible. Its subsequent elongation results from normal growth. In species whose normal mandibles are unequal, such as parrots and raptors, overgrowth of the upper mandible is rare in the wild, but common in captives eating comparatively soft foods.

Frequency. Abnormalities of the bill have been reported for numerous species of many families. There is some evidence that they are more frequent in passerines than non-passerines, and there are not unexpectedly more records for species which have become commensal with man. Where large samples are available, the frequencies for individual species can be calculated: they are usually between 0.1 and 1.0%.

Behaviour and survival. In view of the close correlation between the shapes of birds' bills and their normal methods of feeding, it is remarkable that some individuals survive with bills that differ so markedly from the normal for their species. The survivors often show considerable changes in behaviour, for example turning the head on one side to feed and drink. Clearly this is difficult unless the food is on a firm surface (e.g. the ground). It may be significant that there are very few records of abnormalities in gleaners (such as warblers), despite the huge numbers handled by ringers. In such species, individuals with serious deformities would seem unlikely to survive.

Survival may be easier for commensal species that rely in part on food

Robin *Erithacus rubecula* with crossed mandibles. (*Photo: N. van Swelm*).

provided by man. Some of the grossest deformities of wild birds have occurred in Starlings *Sturnus vulgaris* and House Sparrows *Passer domesticus*. Yet a number of records concern apparently healthy wild birds of species with specialized diets which could not possibly have fed normally—for example, records exist of a Hawfinch *Coccothraustes coccothraustes*, and a Pink-footed Goose *Anser brachyrhnchus*, both lacking the distal half of the upper mandible. Their survival is evidence that feeding behaviour can show considerable improvisation. There are a few records of modification of a quite different kind; where a bird with an abnormal bill was being fed by another individual, presumably its mate.

Other effects. Whilst some birds with abnormal bills not only survive but also appear healthy, with normal weights, others fare less well. In particular, many have difficulty in preening; their plumage is in poor condition and they carry numerous ectoparasites, especially feather lice.

Pomeroy, D.E. 1962. Birds with abnormal bills. Br. Birds 55: 49–72.

BILL-CLAPPERING, -CLATTERING, -FENCING: see MECHANICAL SOUNDS.

BILLING: caressing with the bill.

BILL SOUNDS: see MECHANICAL SOUNDS.

BIMACULATION: the occurrence of two spots, e.g. in the facial plumage of certain ducks (Anatidae)—see PLUMAGE.

BIMODAL: see under BIOSTATISTICS.

BINDING-TO: term used in FALCONRY.

BINOCULAR VISION: see VISION.

BINOMINAL or **BINOMIAL SYSTEM:** see NOMENCLATURE.

BIOCENOSIS: ecological term (plural 'biocenoses') for an association of living things inhabiting a uniform division of the 'biosphere'; in other words, the ecological community found in a particular 'biotope' (see under BIOSPHERE).

BIOCHORE: see under BIOSPHERE.

BIOCYCLE: see under BIOSPHERE.

BIOLOGICAL CLOCK: see RHYTHMS AND TIME MEASUREMENT.

BIOLOGY: the science of life—the study of animate nature. The antithesis is with the physical sciences, apart from the applications of these to the study of living matter. The term 'biological' does not exclude the study of dead specimens as one of the approaches to the problems of the living organism, although sometimes loosely used as if it did.

BIOMASS: quantitative term used in ecology—the total weight of organisms per unit area of land, or the total weight of organisms of a specified kind (e.g. birds).

BIOME: term for a major biotic community, i.e. one existing in a wide area defined by certain general environmental features (and possibly including both land and fresh water)—contrast LIFE ZONE. An equivalent term in respect of animal life only is 'zoome' (and in respect of plants only, 'phytome').

BIOMETRICS: see BIOSTATISTICS.

BIONOMICS: term equivalent to ECOLOGY.

BIOSPECIES: see under SPECIES.

BIOSPHERE: ecological term for the sum total of the environments capable of supporting life, i.e. the 'habitable globe' as regards animals and plants. The biosphere is divisible into 3 'biocycles'—ocean, fresh water, and land. These in turn are divisible into 'biochores'; thus the main biochores in the terrestrial biocycle are forest, dry open land, moist open land, high montane and polar areas. Biochores are in turn made up of 'biotopes', which are particular areas substantially uniform in their environmental conditions and living inhabitants (see ECOLOGY).

BIOSTATISTICS: the application of statistical methods to the solution of biological problems. The topic is also known as *biological statistics* and sometimes as *biometry*, though this latter term is usually reserved for the study of morphological measurements of animals. Statistics have a relatively more important role in biology than in the physical sciences because of the existence of NATURAL SELECTION. Natural selection operates on the natural variation between animals: individuals with different values for the characters selected reproduce differentially into future generations. Because of this, the ability to study variation between individuals is fundamental to the study of evolutionary processes within biology, which can therefore never be exact in the sense of the physical sciences. The subject matter of biostatistics is therefore data arising from populations or groups of animals. Whilst repeated measurements on a single bird may be of interest in providing insight into a biological problem, they are of little value as conclusive evidence, even when supported by statistical treatment.

Because biostatistics has to treat of variability amongst animals, it cannot provide exact answers. There is no unique answer to questions such as 'Are male House Sparrows *Passer domesticus* heavier than female House Sparrows?' A large number of factors outside the control of the ornithologist intrude on the measurement process: factors such as season, ambient temperature, food supply, breeding physiology, and body size all influence body weight and it will therefore be in general impossible to acquire samples of individuals differing only in sex. Instead, we must work with samples of males and females and, to questions such as that posed, confine our answers to probabilistic statements as to the results of the comparison, i.e. how *likely* it is that a male sparrow will be heavier than a female, all else being equal. If the probability of a result is high enough, of course, the result can be accepted as an established fact and as a general feature of the population concerned.

Some statistical terms. Data in biostatistics are generally based on individual observations, measurements made on the smallest sampling unit. These units will often be individual birds, with each bird yielding one observation or measurement. Such individuals may be referred to as2 cases. In other studies, repeat measurements may be made on the same individual bird, so that each case yields two or more observations. For example, in avian endocrinology the same measurement may be made before and after a hormone injection: here, the case remains the individual bird but there are two observations, one 'before', the other 'after'. Similarly, in a ringing study, the two observations of the bird's location at ringing and at recovery constitute paired observations pertaining to a single case.

An observation consists of recording a character or variable for the bird. Typical examples are a measurement of wing length or body weight, noting the colour of a particular part of the plumage, or noting a food item brought to a nestling.

The term *statistical population* has a definite meaning within biostatistics and one distinct from the normal biological definition of the population as the collection of all the individuals of a given species in the specified area and time. A statistical population is the total set of observations under analysis and about which some inference is to be made; a synonym of the statistical population is the *universe*. For a very small number of species the population to be sampled may be quite definable, as for example with the population of Whooping Cranes *Grus americana* in the USA. In general, though, the biological population will be so large that the universe of possible measurements is prohibitive of analysis and a *sample* is taken from it for study. From the behaviour of this sample under statistical treatment we infer what the behaviour of the entire population is likely to be.

The term *variable* is used in biostatistics to define any characteristic in respect of which individual birds can be established to differ. The detail with which these differences can be established characterize particular classes of variables: (1) measurement variables (which may be either continuous or discrete), (2) ranked or ordinal variables and (3) nominal (or categorical) variables or *attributes*. The statistical treatment which may be afforded these different variables varies substantially between these classes.

Measurement variables are those whose values for individual birds can be ordered in a numerical fashion. *Continuous variables* are those which can, at least in theory, take an infinite number of values between any two fixed points. Thus, body weights may be measured to a precision limited only by that of the measuring instrument. For example, whilst an egg weight may be measured to only 0.1 g with a spring balance it might be measured to 0.01 g with an electrical balance or to 0.001 g with a micro-balance: the actual value is limited only by the measurement precision. Examples are weights, lengths, areas, volumes, temperatures, durations, and rates.

Discrete variables are those which can take only fixed numerical values. Thus, clutch size can take values only of 1, 2, 3, etc. eggs. It is meaningless to talk about a clutch of 2.7 eggs. In general, discrete variables are the result of counting procedures rather than of measurement procedures.

Ranked or *ordinal variables* are those which can be placed in sequence or ranking according to their value but which cannot otherwise be measured. Thus, the age of a bird increases as one goes through the sequence neonate, nestling, fledgling, juvenile, immature, and adult, so that the birds can be ranked in age according to these categories. One cannot, however, make any statement about the absolute differences in age between these categories. Thus, although one might rank the birds according to these categories as 1 = neonate, 2 = nestling, 3 = fledgling, etc., there is no implication that a bird of rank 2 is twice as old as a bird of rank 1. Furthermore, equality of differences in rank does not imply equality of differences in age.

Nominal (or *categorical*) *variables* or attributes are those which cannot be measured but which can be unequivocally described by some quality. For example, the sex of a bird is such an attribute: a bird may be characterized as a 'male' or 'female' but the sequence (male, female) is as valid as the sequence (female, male). Other examples of attribute data include species lists for a census plot (each species identity being an attribute), colour polymorphisms, behaviours. The values or names attached to these categories (whence the term 'nominal variable') are not amenable to statistical treatment such as averaging. Counts of the frequencies with which these categories occur in a sample are, however, amenable to statistical treatment.

The term *variate* is used for an individual value taken by a particular variable.

Accuracy and precision. The term *accuracy* is used to describe how close a measured value is to its true value. Any reproducible difference between the two reflects the presence of a *bias* of measurement. The term *precision* refers to the degree of similarity amongst repeated measurements of some quantity. A measurement may therefore be quite precise but inaccurate because of the presence of reproducible bias in the measuring process. The precision of an estimate can be increased by taking more readings but the accuracy of a measurement can be improved only if it is possible to assess the bias quantitatively.

In ornithology the most precise data usually arise when whole numbers are involved. Counts of clutch-size, for example, can be precise. Counts of such small numbers are also likely to be accurate. In a census of a wood the counts of Robins *Erithacus rubecula* or of Treecreepers *Certhia familiaris* may be precise but nevertheless inaccurate: not all birds may be seen in the course of searching the wood.

Measurements of continuous variables are in general approximations. The extent of this approximation is implied by the number of decimals quoted. The usual convention is that the last digit quoted represents the precision of the measurement: the statement that the weight of a Great Tit *Parus major* was 19.5 g implies that the weight is in fact somewhere between 19.45 g and 19.55 g; had it been just outside these limits we would have quoted the weight as 19.4 g or 19.6 g as appropriate. Similarly, a statement that a weight was 19.523 g implies the bird was weighed with a precision of 1 mg. This convention is frequently incorrectly ignored by ornithologists citing a spuriously large number of decimal places.

What precision of measurements should one seek? Clearly, if one weighed birds to only 1 g whilst the birds' weight ranged over only, say, 3 g, one has very little chance of detecting any seasonal or sexual differences in weight. On the other hand, measuring the weights of all birds to 1 mg is wasteful of time and effort (and the readings are probably biased in addition as a result of excretion and the like). Sokal and Rohlf (1973) suggest that the precision of measurement used should be such that the *range* (difference between the smallest and the largest measurement values) has between 30 and 300 identifiable steps. According to this, the bird with the weight range of 3 g should be measured with a precision of at least 0.1 g but not more than a precision of 0.01 g. But with a larger bird with a weight range of, say, 15 g a precision of 0.5 g would suffice.

Trailing zeros imply precision if decimal points are present. Thus, a measurement reported as 3.20 cm means the measurement is correct to within 0.1 mm. However, this convention is rarely observed in the absence of decimal points: the figure 2700 strictly means 1 more than 2699, but is widely taken as meaning an estimate determined to ±50.

Ratios. A ratio is the proportion obtained by dividing the value of one variable by the value of a second variable. Ratios are widely used in taxonomy, particularly in describing shape. The ratio obtained by dividing bill depth by bill length has been used to separate sexes amongst Herring Gulls *Larus argentatus*, for example. Although used in this form, ratios have a number of disadvantages, notably that their distributions are frequently non-normal and therefore require either transformation or the use of relatively less powerful *non-parametric statistics* in studying them. In addition, a bird with average dimensions for the two variables which enter the ratio does not have an average value for that ratio. Probably most importantly, much information is lost through the use of ratios: plots of y against x are much more informative in identifying sexual or seasonal groupings than is a simple scrutiny of the ratio of y/x.

Frequency distributions. The results of tabulating (or graphing) the counts of occurrences of the individual values of a variable against those values (Fig. 1). Where the variable concerned is categorical in type, the order of presentation of the different values is arbitrary and may be interchanged without loss of information. When the variable is ordinal, however, they are arranged in descending or ascending order. The shape of a frequency histogram of such ordinal data can be informative. Many such distributions have a bell-shaped curve, frequency falling off symmetrically on either side of some central category (Fig. 2). But distributions may be distinctly asymmetrical, the tail of the distribution being excessively extended in one direction or in the other. Such skewed distributions usually reflect either selection for or against birds with those particular values or the presence of some bias in the measurement scale. Similarly, the presence of two peaks in a bimodal distribution (Fig. 3) indicates the possible presence of discrete populations of birds.

Distributions are frequently displayed graphically (Figs 1–3) so that

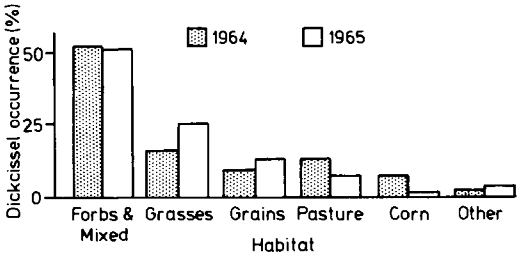

Fig. 1. Typical bar-diagram displaying qualitative data, where frequencies have been converted to percentages. Note (by comparing the results for the 2 years) that there are no constraints on the left-to-right sequencing of these categorical data. (After Wiens & Rotenberry 1981, Studies in Avian Biology).

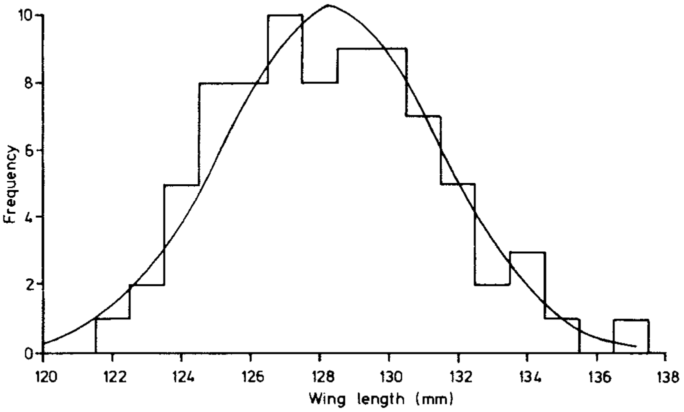

Fig. 2. Typical histogram of near-normally distributed interval data, showing the bell-shape characteristic of this distribution. The data are for wing-lengths of first-year Sanderlings *Calidris alba* trapped in autumn in Surinam (South America). (After Spaans 1980, Wader Study Group Bull.).

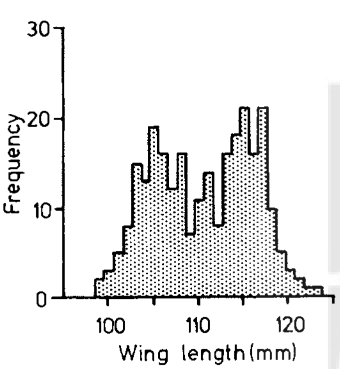

Fig. 3. A bi-modal distribution typical of a mixture of two distinct sample populations, here of male (long-winged birds) and female (short-winged birds) Skylarks *Alauda arvensis* trapped at Gibraltar Point (England) bird observatory. (After Davies 1981, Ringing & Migration).

their shape may be easily assimilated. There are two conventional ways of presenting the material. Where discrete variables are involved, so that only certain values may be found, a *bar-diagram* is used for the display (Fig. 1). Note that the bars do not touch one another, thereby indicating the non-continuity of the variable. Where the data are continuous, on the other hand, they can be presented as a *histogram* (Fig. 3), the height of each bar indicating the frequency, and the width of each bar indicating the class interval. To construct such a histogram the values of the continuous variable are tallied into specified class intervals defined by specified upper and lower limits, the upper limit of one class serving as the lower limit of the adjacent class. The class interval is usually held constant across the histogram, except perhaps at the beginning and final steps, but its width may be chosen according to convenience. Typically there are 12–20 classes displayed on a histogram.

Descriptive statistics. The first task of biostatistics is to provide some form of summary description of the data. If one measures 200 bird weights it is impracticable to describe the population by quoting the raw data: some form of summary is required. For an ordered frequency distribution two descriptive statistics are particularly important: a measure of *central tendency*, and a measure of *dispersion*. If appropriately chosen, these statistics more economically describe the data than do the histograms or bar charts previously presented.

Statistics of location or of central tendency indicate the whereabouts of the distribution as a whole (Fig. 4). The figure shows the position of three separate measures of central tendency, the mode, the median, and the mean. Which measures may best be used depend on the nature of the data (whether nominal, ordinal or continuous).

The *mode* is the most frequently represented value within the histogram or bar chart, i.e. there are more observations at that value than at any other, whether the value be discrete or that of a class interval. It is thus the highest point on a frequency distribution. The mode may be used with data of all three types, though with interval data it is of relatively little use other than as an indicator of the most commonly occurring class.

The *median* is that measure of location which splits a frequency distribution ranked by order into two equal halves. It follows that it is inapplicable to attribute data. With ordinal and continuous variables the data may be ranked by size, whereupon the median is the point at which half the observations lie below and half above. Where the number of observations is an even number, its value is conventionally computed as the mid-point of the two central members of the ranked frequency distribution. With discrete data and with interval class data several observations may fall into the central class containing the median value. In such cases it is usual to assume that the data are distributed evenly across the class and, with class interval data, to assign the median to the corresponding proportional point between the class limits. With discrete data the corresponding enumeration is performed.

The median is a particularly useful statistic wherever frequency distributions are skew: because the median depends only on the frequency representation of unusually high or unusually low values and not on the value of the variate at those observations, the position of the median is relatively insensitive to such outlying points.

The *mean* or *average* is a parametric statistic of location, computed by summing the observations made within the sample and dividing the total by the number of such observations. This summation results in extreme observations receiving considerable weight, so that the mean moves in the direction of any asymmetry in the frequency distribution.

Measures of dispersion. Frequency distributions may vary substan-

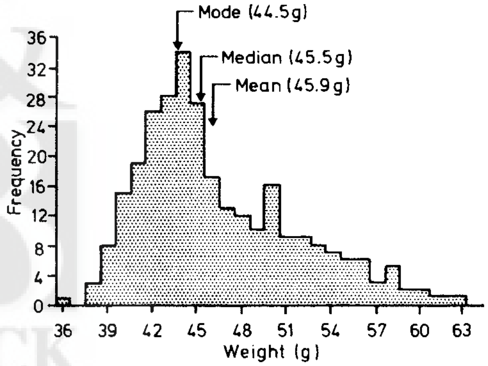

Fig. 4. An example of a skew distribution, here of weights of female Corn Buntings *Miliaria calandra*, showing the effect of the (here positive) 'tail' in moving the mean value away from the median and modal values (which are themselves separated). (Modified from Boddy & Blackburn 1978, Ringing & Migration).

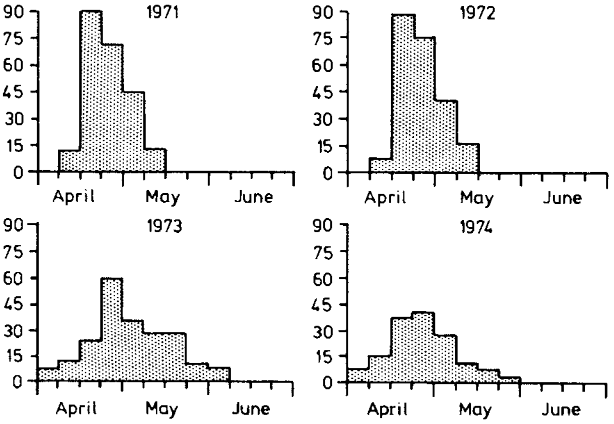

Fig. 5. Annual distributions of egg-laying dates in a New Forest (England) population of Lapwing *Vanellus vanellus* showing year-to-year variation in distribution width ('dispersion'). (After Jackson & Jackson 1975, Ringing & Migration).

tially in their apparent 'width' independent of their central location (Fig. 5). Some measure of the width of the distribution is therefore desirable.

The *range* is the simplest form of characterizing distributions and is calculated as the difference between the largest and the smallest item in the sample. This measure is obviously sensitive to outliers and is therefore only an approximate measure of the dispersion. It is worth noting in particular that as sample size increases the probability of detecting an observation with a still more extreme value increases, thereby increasing the range.

The *standard deviation* is the most widely used measure of dispersion for symmetrically distributed data. It is computed as

$$S = \sqrt{\frac{\Sigma(x - \bar{x})^2}{n - 1}}$$

or equivalently as

$$S = \sqrt{\frac{\Sigma x^2 - n\bar{x}^2}{n - 1}}$$

where x is an observed value, $\bar{x}$ is the average of all values in the sample, and n is the sample size. The former version shows that the standard deviation is a root mean square index of dispersion. That is, it is calculated by computing the deviations of each point from the mean, squaring them, weighting them for sample size and taking their square root. The squaring procedure ensures that positive and negative deviations are given equal weight and avoids the problems caused by the average deviation being zero; the squaring process has other advantages on mathematical grounds. The use of the factor $(n - 1)$ in the denominator instead of dividing by n to compute an average mean square deviation has been shown by statisticians to be necessary to obtain an unbiased estimate of the spread of the population from which the sample has been drawn.

The term *variance* is used to describe the square of the standard deviation.

The *coefficient of variation* is a statistic which expresses dispersion (in the form of standard deviation) as a percentage of the sample mean. That is,

$$CV = 100\,s/m$$

where s is standard deviation and m is sample mean.

This measure of *relative variation* allows for the fact that large animals are more likely to vary individually by any absolute amount than small animals: a Wren *Troglodytes troglodytes* will not show the same absolute variation in measurement as will an Ostrich *Struthio camelus*. The coefficient of variation provides a scale of relative variation with which meaningful comparisons between species of different size can be attempted.

Statistical significance. Because animals are inherently variable as to the characteristics ornithologists may wish to measure, statements about them are necessarily expressed (at least in principle) in probabilistic terms. That is, we are rarely in a position to assert that, say, males are larger than females; what we must say, in strict pedantry, is that males are *more likely* to be larger than females. Were there no convention amongst scientists as to how a phrase such as 'more likely' is to be interpreted there would be considerable variation in individual ornithologists' interpretations of its meaning. Conventionally, therefore, such results are assessed in terms of statistical significance, meaning the probability that a particular result would have arisen by chance were the supposed hypothesis untrue. In the example of the male-female weight difference, for example, we start with the assumption or *null hypothesis* that there is no difference between males and females. We then compute the probability that two samples drawn from this common pooled male/female population would in fact differ by the amount found in the samples actually taken. If these chances are low enough we regard the probability of the male and the female sample having been drawn from a common pool as being so low as to be unlikely and prefer the alternative hypothesis that there are in fact differences between male and female.

What is 'low enough' in this context? The conventional probability for scientific purposes is 0.05, meaning that we have five chances in a hundred of getting the two (or more) samples drawn from the common pool yielding a difference as big as that observed. Two points must be made about this limit. First, it is a purely conventional limit accepted as a working tool by scientists. Secondly, in working to this conventional value one is accepting a one in twenty chance of a sampling artefact, there really being no difference between the male and female distributions. When there is great importance attached to getting the results correct a one-in-twenty chance of error may be too high and it is possible to work to higher levels of significance, such as 0.01 or 0.001, meaning respectively a one-in-a-hundred and a one-in-one-thousand risk of falsely asserting the existence of a difference between the two samples.

This approach to testing hypotheses has a further consequence. If one conducts 100 tests of differences between males and females on the basis of a 5% significance level, as many as five of these tests are likely to yield 'significant' results by chance alone. Consequently, where repeated testing of samples is involved, it is necessary to avoid such a 'Type I' error by working to a higher level of significance than would otherwise be appropriate. On the other hand, such an approach to probability testing of hypotheses is more likely to fail to recognize real differences between male and female samples as the significance level is raised (a failure known as Type II error). That is, in protecting ourselves against the chances of falsely asserting the presence of a male/female difference, whilst the samples were in fact drawn from distributions similar for males and females, we are increasing our chances of failing to detect sex differences when male and female distributions are not identical.

Testing a significance level. How does one assess the probability of two samples drawn from a common distribution in fact differing by the amount observed in the experimental samples? One approach is to draw repeatedly from a model population with the desired characteristics, and to examine the differences between the two samples of pseudo-males and pseudo-females drawn from this population. Such a course would be extremely tedious and one normally has recourse instead to certain test statistics whose critical values are conveniently tabulated. As these test statistics have been computed only for distributions obeying certain assumptions, it is important that the data under test also obey these distributions. Thus, a test statistic calculated for a normally distributed population is inappropriate to a population whose distribution is non-normal.

To accommodate the wide variety of problems regularly encountered, statisticians have evolved a number of test statistics meeting particular problems. The rationale behind these test statistics is that they represent quantities which can be calculated for samples repeatedly taken from some underlying distribution. Corresponding to repeated sampling from the population will be a distribution of values of these test statistics, the distribution being defined either analytically or, in the case of complex population distribution, by computer simulations. It is therefore possible to examine these distributions and to establish values of the test statistic corresponding to, say, 50% of all observations lying between the chosen values, 90% of all observations lying between the specified values, 95% lying between them, etc. Of particular interest are the values corresponding to 95% of the observations defined by the critical values since this corresponds to the conventional 0.05 significance level. Were two samples drawn from a single underlying population and the corresponding test statistic computed, 95% of the drawings would yield test values within the specified critical values. Were the computed value outside these limits, one would be dealing with the rare set of 5% of the drawings from a common population. Given real samples for which such a test statistic value was calculated, one has a nineteen to one chance against the value being derived from samples belonging to the distribution concerned.

Such critical values will vary according to the size of the samples drawn. Consequently, it is possible to tabulate these values as a function of sample size. Armed with such a table, an ornithologist faced with a real sample or samples can compute the same test statistic and enquire whether the value exceeds the conventional 5% significance level.

Confidence limits. The aim in sampling is to describe the population by inferring from the observations which were taken as a sample. How good is the resulting inference? Suppose one is interested in the weights of individuals of a species just before migration. If one could weigh all individuals of the species one would know the 'true mean' (M) and the 'true variance' (σ^2) for the population. In practice one has a sample of these birds with some average weight $\bar{x}$ and sample variance S^2. One may set *confidence limits* to the estimated average $\bar{x}$ to allow statements of the form 'The probability that *limit 1* $< \bar{x} <$ *limit 2* is at least 95%' by using certain statistical methods to calculate the *lower confidence limit limit 1* and the *upper confidence limit limit 2*. Such statements claim that conventional statistical procedures have been followed and that estimates of the confidence limits would encompass the true mean in at least 95% of the experiments analysed with such procedures.

The theory behind such statements is complicated but an understanding of the methods may be obtained as follows. Suppose we took, as before, a sample of observations from the parent distribution of all observations and computed some test statistic for the sample. We could repeat this process as often as we wish, tabulating the resulting values of the test statistic for each drawing of the sample. After, say, 1,000 such samples, we would have a good idea as to the distribution of the test statistic scores and, in particular, what values of the statistic would arise in only 5% (or 1% or 0.1%, as we wish) of the samples. If we now examined a sample of real observations satisfying certain criteria (discussed below) we could likewise compute a sample test statistic. If this were so extreme as to arise in 5% or fewer of the sample drawings just discussed it would be rather improbable that these real data belonged to the parent distribution. Note that we have reached a conclusion—that the real data do not belong to the parent distribution—on the basis of comparing a computed test statistic for the sample with a critical value (for 5%, 1%, etc.) already established by simulated drawings from the parent population. These critical values depend on the size of the sample used but it is nevertheless possible to prepare tables of these critical values, both with respect to different significance levels and with respect to sample size.

If these tables had to be prepared from the results of large numbers of sample drawings as outlined above, with different procedures for each different problem, the tables would be excessively voluminous. In practice analytical expressions for the distribution of particular test statistics can be formulated and many problems can be analysed in such a way as to generate such a statistic. Examples of widely used statistics of this type include Student's t, the variance ratio F, and chi-squared (χ^2).

Parametric and non-parametric statistics. Test statistics based on analytical expressions necessarily make assumptions about the distribution of the population sampled. If these assumptions are correct, the test statistic will be correctly calculated and the conclusions valid; if incorrect, the statistic is inappropriate and the conclusions invalid. Since the population assumptions turn on values given to parameters within their algebraic expressions these methods are called *parametric*.

Many statistical techniques more recently in fashion are independent of such assumptions and are called *distribution-free* or *non-parametric* methods. These techniques are particularly valuable with ordinal and categorical data, which fail to satisfy parametric assumptions. These techniques may also prove helpful with skew or otherwise unsatisfactory distributions of continuous variables. In many instances non-parametric procedures result in an evaluation of the exact probability of getting as extreme an event as that observed. That is, this probability is directly calculated rather than inferred via a statistic subject to assumptions. This is especially valuable with very small samples, for which the validity of assumptions as to distribution is difficult to check. They are also useful in testing differences between populations known to differ in distribution. The main drawback of non-parametric methods is that they require rather larger samples than do equivalent parametric tests for which all assumptions are satisfied.

Statistical testing. Siegel (1956) summarizes the process of statistical testing into six stages: (1) state the *null hypothesis*; (2) choose an appropriate statistical test with its associated statistical model; (3) specify the target significance level and sample size; (4) find (or assume) the sampling distribution of the statistical test for the assumption that the null hypothesis is correct; (5) define *region of rejection*; and (6) compute the value of the test for the sample data and accept or reject the null hypothesis accordingly.

The *null hypothesis* is one temporarily assumed for the purposes of the statistical test. Since it is impossible to prove a negative we try to recast the problem as a positive; e.g. the surest way to prove that a colour-ringed Blackbird *Turdus merula* is not breeding in a particular forest is to show that it *is* breeding somewhere else; otherwise, however well one searched the forest one has always a residual possibility of having missed the bird. For a null hypothesis, therefore, we assume the absence of what we expect to find and seek to establish the presence of a consequential discrepancy.

The choice of statistical test depends primarily on (a) the validity of the assumptions to be made if the chosen test is to be used and (b) the type of data involved, particular tests being inapplicable to certain types of data (see above).

The *level of significance* associated with a test is necessitated by the variation inevitably associated with random sampling. Repeated sampling on the same question will give different results on different occasions, with the extent of the variation determined by measurement errors and by the natural variation of biological populations. Consequently, the results of a test are only probabilities, not determinants, and one is at risk both of falsely deciding in favour of and of falsely deciding against one's hypothesis. By convention—and one must emphasize it is convention, not an inescapable rule—we accept at maximum a one-in-twenty risk of incorrectly rejecting the null hypothesis (and thus of falsely concluding in favour of the research hypothesis under test). For some purposes we may wish to reduce this risk (a so-called 'Type I' error) to one in a hundred or even to one in a thousand. This is equivalent to demanding stronger evidence for the research hypothesis and therefore carries increasing risk of making the alternative ('Type II') error, of falsely accepting the null hypothesis and concluding one's research hypothesis is wrong. In general the chance of correctly rejecting the null hypothesis increases with sample size.

Glossary of some common statistical tests. It is not possible to describe within the scope of the present article how to conduct the various statistical tests available. For information on these readers are referred to the references below. What follows is a brief glossary of some of the commoner statistical tests, primarily to indicate their respective functions.

Analysis of variance A general class of statistical tests used for assessing the significance of differences between two or more samples. The principle used is to compare the between sample and within sample variances: if the average differences between samples are large enough relative to the variation within each sample, it is likely that biological effects are present. The implementation of this principle varies, however, according to the assumptions that one can (or must) make about relationships between the individual birds measured in each sample. For an excellent introduction see the book by Parker.

ANOVA (Anova) A synonym of analysis of variance.

Bartlett's test of homogeneity of variances A test of whether three or more samples are equally variable (see F-test for two sample case)

Binomial test A test for whether in a sample the number of birds possessing some particular attribute corresponds to the proportion expected (according to some quantitative, e.g. genetical-hypothesis) to have that attribute.

Chi-square (χ^2_{X}) A test for assessing the significance of differences in ratios between samples, e.g. do the proportions of male and female sparrows taken by Sparrowhawks and cats respectively differ? The test can accommodate more than two samples and more than two attributes, e.g. here one might also use chi-square analysis to compare Sparrowhawk, cat and small-boy-with-catapult mortality of male and female sparrows or to compare the incidence of mortality of these types in different months.

Concordance A method of testing the consistency of several sets of rank orders, e.g. in comparing the effectiveness of, say, five types of scarecrows in inhibiting crop consumption by three species of bird: is the relative effectiveness of each scarecrow the same for all three species?

Correlation A test for the presence of trend in a sample, e.g. are Blackbirds heavier in months of lower temperatures? The Pearson or product-moment correlation tests for linear trend between normally distributed variables but non-parametric correlation coefficients (Kendall's, Spearman's) are also available and can accommodate non-linear trends in which rank order and not linearity is maintained.

Covariance analysis A technique related to analysis of variance which accommodates the situation where classification of samples on some criteria has to be continuous rather than discrete (as in ANOVA).

F-test A test of whether two samples are equally variable.

g-test A test for whether a distribution is significantly skewed.

Goodness of fit test The use of chi-squared (usually) to test whether an observed frequency distribution accords with that expected on some theoretical basis.

Kendall's tau A non-parametric test of correlation (*q.v.*).

Least squares A general class of statistical computation, common to many of the tests listed here, in which the best estimate of some statistic is taken as that which minimizes the squared deviations between statistic and observations. See 'standard deviation' in the main text for a simple example.

Linear regression See *Regression.*

Mann-Whitney U-test One of the most commonly used tests of differences between the central values of two samples in which the data are not normally distributed.

Median test Performs the same function as the Mann-Whitney U-test but can be extended to comparing central values of three or more samples.

Paired sample test A term used to describe a class of test in which known relationships exist between the individuals contributing to two samples of measurements, e.g. 'before' and 'after' measurements on birds injected with hormones.

Partial correlation A method of testing the trend between two variables, say x and y, when either or both may also be correlated with some other variable z. By first correcting for the effects of z the partial correlation analysis tests whether x and y are mutually correlated in their own right rather than via common correlation with z.

Rank correlation A non-parametric test of trend, where trend is measured between the ranks of the variable concerned rather than between their absolute values. See also *Correlation.*

Regression A test for trend between two variables which assesses the rate of change of one variable (the dependent) with changes in the other (independent) variable. The technique is applicable only to normally distributed variables. Where several independent variables are present an extension—multiple regression—is available to describe the simultaneous dependences of the dependent variable on the several independent variables.

Sign-test A non-parametric test for trend measured in paired samples. If enough individuals in samples show the same trend (up or down) between two sampling occasions, probability of a real movement up or down would be high.

Signed rank-test A more powerful extension of the Sign-test which takes into account the sizes of the differences recorded of the members of a paired sample.

Spearman's correlation See *Rank correlation.*

Stepwise regression A variant of multiple regression (see regression) in which the independent variables are considered in turn for inclusion (step-up) or exclusion (step-down) from the multiple regression equation, until the equation contains only those variables that contribute significantly to the explanation of the variation in the dependent variable. It is possible for step-up regression to give a different set of independent variables from those obtained by step-down regression and these sets may, in general, differ from the set that would be obtained by an exhaustive search of all possible combinations of independent variables.

Student's t-test A test for the presence of a difference between two sample means, where the data in each sample are normally distributed and equal in variance. A special modification applies where the samples differ in variance.

Transformation The technique of applying some mathematical manipulation to data to make them conform more closely to the assumptions to be made in a particular statistical test. The statistical computations may then be validly applied to the data but the final results will require a reversal of the transformation procedure, so that, for example, symmetrical confidence intervals computed for the transformed data will yield asymmetric confidence intervals when expressed in terms of the original data. Common transformations include taking the logarithm, square root or arc-sine of the data values, the exact transformation adopted depending on the nature of the non-normality in the original data. BIOTA: term coined to comprehend both the fauna and the flora of an area (see FAUNA).

BIOTELEMETRY: see RADIO TRACKING AND BIOTELEMETRY.

BIOTIC: term applied to the organic element in the environment.

BIOTOPES: particular areas which are substantially uniform in their environmental conditions and flora and fauna.

BIOTYPE: a population of the same genotype (in the proper sense of the latter term)—see GENOTYPE.

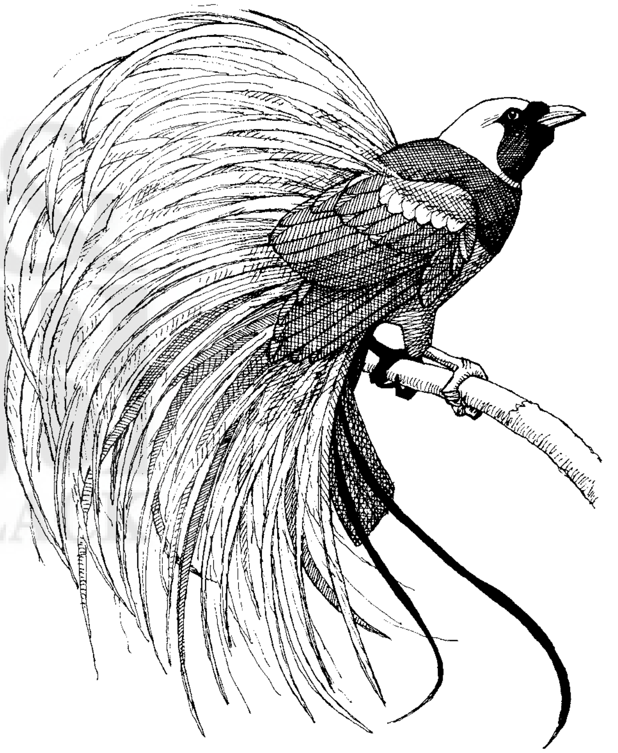
BIPEDAL: two-footed, in the sense that the forelimbs are not used for walking; but compare the special meaning of TETRAPOD, also applied to birds.

BIRD: term applied, in different contexts, either to an individual animal or to a species (or subspecific form) belonging to the class Aves; occasionally to an imaginary generalized type; also used adjectivally (e.g. bird song), or as part of the name of a species or group (e.g. tropicbird, bird-of-paradise)—see AVES.

BIRD FANCIER: see AVICULTURE.

BIRD LIME: see CONSERVATION.

BIRD OBSERVATORY: see OBSERVATORY, BIRD.



Raggiana Bird-of-paradise *Paradisaea raggiana*. (*N.W.C.*).

BIRD-OF-PARADISE: substantive name of most species of Paradisaeidae (Passeriformes, suborder Oscines) and, in the plural, general term for the family. Birds-of-paradise are most closely related to the bowerbirds (Ptilonorhynchidae). On the basis of their cranial anatomy, Bock (1963) placed the 2 groups in separate families, but Gilliard (1969) and Schodde (1976) combine them into Paradisaeidae. Bock defined 2 subfamilies, the Cnemophilinae (comprising *Loria*, *Loboparadisaea*, *Cnemophilus* and *Macgregoria*) and the Paradisaeinae containing all other genera. He concluded that birds-of-paradise and bowerbirds evolved from the primitive Cnemophilinae which are probably derived from the Sturnidae. *Macgregoria* has subsequently been transferred to the Paradisaeinae (Gilliard 1969, Diamond 1972, Schodde 1976). The Meliphagidae, Callaeidae, Cracticidae, Corvidae and the problematical *Lamprolia* of Fiji (see SILKTAIL) have also variously been considered ancestral to and/or close relatives of the birds-of-paradise.

The 43 Paradisaeidae species are usually ascribed to 20 genera. The 17 genera of Paradisaeinae contain 1–7 species while those in the Cnemophilinae are monotypic. Diamond proposed extensive alterations to this classification involving the merging of genera to reduce Cnemophilinae to 2 and Paradisaeinae to 8, but his proposals have been largely ignored in the face of a lack of information about the biology of many of the species involved.

Characteristics. Birds-of-paradise are stout-billed and strong-footed, rather starling- or crow-like in general appearance and size (lengths 12.5–100 cm including variable tail lengths) and are renowned for their spectacular plumages and courtship displays and their diverse mating systems.

Habitat. Birds-of-paradise inhabit wet forests ranging from tropical lowland to sub-alpine types.

Distribution. The family very probably originated in New Guinea, to which most species are restricted. However, the monotypic genera *Lycocorax* and *Semioptera* are confined to islands in the Moluccan Archipelago and *Ptiloris paradiseus* and *P. victoriae* to north-eastern Australia. The predominantly New Guinean ranges of *Manucodia* (*Phonygammus*) *keraudrenii* and *Ptiloris magnificus* also extend into extreme north-eastern Australia. Most mainland New Guinea species have restricted and/or patchy montane distributions and are confined to discrete altitudinal zones. Some *Manucodia*, *Paradisaea* and *Diphyllodes* species are restricted to offshore islands, although other members of these genera have extensive mainland distributions at low altitudes.

Birds-of paradise were formerly hunted intensively to provide ornate feathers for the European millinery trade. Today hunting is limited to providing material for traditional native adornment and an extensive barter trade, conducted mainly with shotguns which are rapidly replacing traditional methods and weapons, and is essentially self-regulated at unharmful levels. However the restricted ranges of several species render them vulnerable to habitat destruction accompanying agricultural expansion and modernization.

Food. The feeding ecology of most birds-of-paradise is poorly documented. A few are known to be and many others presumed to be mainly frugivorous. However, *Ptiloris* species are predominantly insectivorous, probing into and tearing apart dead wood, and bill morphology and limited feeding observations suggest that *Semioptera*, *Seleucidis*, *Drepanornis* and *Epimachus* take mainly animal food. Some *Paradisaea* species and *Cicinnurus* also take much animal food and frequently forage for insects in mixed-species flocks. Animal foods eaten by birds-of-paradise include arthropods, annelids, frogs and nestling birds; plant resources include fruits, leaves, succulent stems and nectar.

Behaviour. All *Manucodia* and *Macgregoria* species are sexually monomorphic, monogamous and both parents care for the young. *Lycocorax* and 2 *Paradigalla* species are probably monogamous too. All other species of Paradisaeinae are markedly sexually dimorphic and known or presumed to be polygamous, probably promiscuous, the female alone caring for the young. The mating systems of the 3 sexually dimorphic species of Cnemophilinae are unknown, although a brief observation of uniparental female brood-care in the Sickle-crested Bird-of-paradise *Cnemophilus macgregorii* indicated that this species may be polygamous as well.

Courtship and agonistic displays of monogamous males comprise static performances with wing and tail movements and flight chases. Cnemophiline display is undocumented, but polygamous paradisaeine males perform elaborate sequences of ritualized displays involving spectacular exhibition and manipulation of the colourful plumages. Intense sexual selection in the polygamous species has led to the evolution of diverse and highly modified species-specific male plumages. The genetic homogeneity obscured by this is reflected in the large number of inter- and intrageneric hybrids recorded from the wild in polygamous genera (Gilliard) (see HYBRID).

Males of most polygamous species display in the upper or middle vegetation layers of the forest but a few species display terrestrially. Polygamous males also exhibit arena behaviour ranging from the stripping of foliage around arboreal display perches (Frith 1981) to clearing ground courts (e.g. *Diphyllodes* and *Parotia* spp.) (see LEK). Communal lek display is typical of some or most *Semioptera*, *Astrapia* and *Paradiseaea* species, but male *Ptiloris*, *Lophorina*, *Pteridophora* and *Cicinnurus* display solitarily in trees, male *Diphyllodes* on vertical perches above a cleared ground court, and male *Parotia* on horizontal perches above a cleared ground court or actually on it (Frith and Frith 1981). Polygamous birds-of-paradise apparently show sexual bimaturism. Males typically acquire adult plumage at 4 to possibly 7 years old and females are thought to breed when much younger (Bishop and Frith 1979).

Voice and mechanical sounds. These vary from soft, often drawn-out calls to loud, explosive sounds reminiscent of gunfire. Some species exhibit limited vocal mimicry in captivity although this has not been noted in the wild. Non-vocal sounds include bill-snapping by displaying males and rustling made by modified primaries during flight and display (see MECHANICAL SOUNDS).

Breeding. Nests are typically bulky, shallow or deep cups made of leaves, ferns, twigs and vine tendrils on an external foundation of stouter sticks, but *Cnemophilus* and probably the other species of Cnemophilinae build domed nests (Gilliard). Birds-of-paradise nests are generally placed in tree forks, although *Cicinnurus* uses tree hollows.

Background colours of eggs vary from cream and grey-white to pink and reddish brown and most have contrasting, dispersed coloured markings. However, the somewhat aberrant egg of *Cnemophilus* is fine-shelled and white with a wreath of dark markings near the blunt end. Clutch size is 1–3, usually 1 or 2 eggs. Eggs range from 27.5–45.5 mm long and 21–30.6 mm wide. Recorded incubation periods for captive and wild birds range from 17–21 days and nestling periods from 17 to about 20–30 days. Fledgling Magnificent Birds-of-paradise *Diphyllodes magnificus* attain independence after about 21 days. The Trumpet Manucode *Manucodia keraudrenii* may be an occasional brood-parasite or merely breed in the nests of other species occasionally. The nests and eggs of some 12 species remain undiscovered. BIRD-OF-PREY: in the most general sense, a species that hunts and kills other animals (particularly the higher vertebrates) for food; in a more specialized sense (and regardless of habits) a member of the ACCIPITRIFORMES, CATHARTIFORMES or FALCONIFORMES; in the plural, general term for these 3 orders (see FALCON; HAWK; OSPREY; SECRETARY-BIRD; VULTURE (1); VULTURE (2)); sometimes extended to cover the Strigiformes, the qualifications 'diurnal' and 'nocturnal' then being used to distinguish the 2 groups (see OWL). The term 'raptor' is sometimes used in similar senses.

BIRD PROTECTION ACTS: see CONSERVATION.

BIRD'S NEST SOUP: see EDIBLE NESTS.

BIRD STRIKE: collision between birds and aircraft.

BIRD-WATCHING: a general term for almost all forms of admiring, observing or studying birds in the field; once chiefly confined to those who looked at birds for their own personal enjoyment. The change has come about as a result of the increased general interest in birds, stimulated by the mass of books, radio and television programmes; for instance, in Britain the membership of the Royal Society for the Protection of Birds grew from 20,000 in 1960 to 375,000 in 1984. For many people, too, the term bird-watcher is more easily understood than ornithologist, which, strictly, is confined to one who studies birds scientifically, and it has meant that many who are really amateur ornithologists now call themselves bird-watchers.

The way that people watch birds varies enormously: some are satisfied with identifying birds seen from the kitchen window; for others the ability to name birds adds enormously to the enjoyment of a country walk. Some may use special field lists to record the names of birds and even attempt to assess numbers (see CENSUS; COUNTS) that they have seen on their walks so that they may discover seasonal or local population changes on different visits to the same locality. Excellent field guides designed especially to assist in quick identification now accompany the birdwatcher virtually all over the world. For some, this type of bird-watching may be a leisurely occupation but for others it can become obsessive. Tally hunters or 'twitchers', as they have been recently called in Britain ('birders' in North America), seek to identify and list as many species as they can on each field trip, in the course of a year, and so on.

In the USA, this type of bird-watching is highly organized and the American Birding Association, founded in 1969, is the chief organization for promoting the sport and hobby of bird-listing. The magazine *Birding* has become indispensable for all serious American birders. Members list the species they have seen in various categories of time and geography. The most popular category is the life list of birds seen in North America north of Mexico, but year lists, world, provincial and state lists are amongst others published in the magazine. 'Rare bird alerts' are also highly organized. In Britain a code of conduct when observing rarities has been published by the journal *British Birds*.

Bird-listing for many is the be-all and end-all of their bird-watching. Others go on to ask questions about all aspects of bird life and try to find answers for themselves by collecting facts, testing the theories and publishing results—thus meriting the title of bird-watcher-naturalist or, more properly, ornithologist.

Early amateur bird-watchers made many interesting discoveries and by their example encouraged others. In Britain the prototype is Gilbert White (1720–1793), the curate of Selborne, who in his journal and correspondence kept a record of events in his parish, not only of his fellow countrymen but what he observed of bird and plant life. He was the first to distinguish between the Willow Warbler *Phylloscopus trochilus*, Wood Warbler *P. sibilatrix* and Chiffchaff *P. collybita*, and was one of the first to realize that Swallows *Hirundo rustica* migrated southwards rather than hibernated in the bottom of ponds. Charles Waterton (1782–1865) not only kept records of his observations in Britain but also on his travels in South America. Thought of as a somewhat eccentric landowner, he experimented with many kinds of artificial nest sites in the grounds of Walton Hall, Yorkshire, where he lived. H. Eliot Howard (1873–1940), a businessman whose bird-watching was restricted to the early morning, was the first to enunciate clearly the theory of territory.

Perhaps the best known of the early American bird-watchers were Alexander Wilson (1766–1813), often called the first modern ornithologist, and John James Audubon (1785–1851), a naturalist and painter whose work has been the inspiration of one of the world's largest conservation movements. Together they set a tradition for bird study in America. Henry D. Thoreau (1817–1862) wrote about the New England countryside and its affairs, but he was acquainted with the best American ornithologists and many of his books showed him to be a keen and accurate observer of birds. Rather like Eliot Howard, Mrs Margaret Morse Nice (1883–1974) was strictly an amateur whose 5-year study of the Song Sparrow *Zonotrichia melodia* was highly scientific and stimulated many amateurs and professionals to study the life histories of birds. But probably no one has helped more people, on both sides of the Atlantic, to an enjoyment of birds and bird-watching than Roger Tory Peterson through his field guides, paintings and writings.

Comparable in the USA to the Royal Society for the Protection of Birds is the National Audubon Society, founded in 1902 as a bird-watching organization and now with over 350,000 members. It publishes *Audubon* magazine which over the years has reflected the Society's broadened emphasis and concern for environmental matters. But of greater interest to the strict bird-watcher is the Society's *American Birds* (formerly *Audubon Field Notes*) which is published 6 times a year. The US Fish and Wildlife Service collaborates in the production of the region by region compilation of bird notes primarily from the USA and Canada. *American Birds* also reports on various nationwide surveys such as the Winter Bird Population Study, the Breeding Bird Census and the better known Christmas Bird Count which normally takes place in the second half of December each year. To make counts from various parts of America comparable, strict rules regulate the date of the count, the size of the area covered and the number of people in each group. Special reporting forms must be used and a fee is payable by all those taking part, to cover cost of analysis and publication.

'For transportation they rely mostly on their feet, but anything that will get you there is legal. And in past years they have used dog team, helicopter, canoe, airboat, hovercraft, horse and golf cart. In 1979–80 a new mode was added: the birding team at Grandfather Mountain, N. Carolina, logged a mile and a half by hang-glider' (*Audubon*, March 1980).

Whilst the Royal Society for the Protection of Birds, founded 1898, can hardly be called a bird-watching club, it does provide hides (or blinds) on some of its 80 or so reserves where its members may often see shy and rare birds at close quarters. Its colourful magazine *Birds* contains much to interest and inform bird-watchers. The RSPB also sponsors the Young Ornithologists' Club, with a membership of 80,000 young bird-watchers up to the age of 18, which publishes *Bird Life* 6 times a year.

In almost every country where there is a widespread interest, bird-watchers form clubs in towns, counties or states, which arrange regular indoor lectures and field excursions. Often the main scientific purpose of the club is the study of the birds of the club's area. The collection of records of migrants, breeding birds or unusual birds, for publication in the annual bird report for the area is by far the most common corporate manifestation of a more or less individual activity. These reports are used by historians of local avifaunas, and of the distribution of the breeding birds. In the USA there are estimated to be over 800 of such clubs whilst in Britain the figure stands at about 200.

Ad hoc groups of scientific organizations, in which the amateur bird-watching organizations have played a significant role, have often been able to collect evidence to combat threats to important avian habitats such as the impoundment of estuaries. Throughout the world there are at least 6 groups whose members concentrate their energy on counting breeding seabirds, studying seabird movements or other aspects of seabird ecology. In at least 7 countries there are Beached Bird Surveys which monitor the death-roll amongst seabirds from the effects of oil pollution, or sometimes the effects of dangerous chemicals which have been deliberately or accidentally spilled into the sea.

The speed of air travel has enabled the bird-watcher to travel the globe. The place of the former explorers, overseas civil servants and servicemen has been taken by the young bird-watchers, sometimes working for commercial firms, for example on oil rigs at sea, or reserve wardens and university students on expeditions taking advantage of the cheaper air fares to travel to distant places, partly to increase their own knowledge of birds but also to bring back descriptions of avifaunas of areas often unvisited by bird-watchers for many years. The 'special interest' tours arranged by several travel agents give for a short time their bird-watcher clients the thrill of sampling exotic avifaunas, but few such tours go far from the good class hotels and a relatively well-beaten track. BISHOP: substantive name of some *Euplectes* spp. (see WEAVER).

BITTERN: substantive name of the species of the Botaurinae, a subfamily of the Ardeidae (Ciconiiformes, suborder Ardeae); in Britain commonly used without qualification for the sole native species; in the plural, general term for the subfamily. The other subfamily is the Ardeinae, which includes the so-called 'tiger bitterns' or 'tiger herons' (see HERON). The bitterns are closely related to the herons and some authorities do not separate the 2 subfamilies.

Usually 2 genera are recognized (*Botaurus*, 4 species, and *Ixobrychus*, 8 species); recently, it has been proposed that the Zigzag Heron *Zebrilus undulatus* should be included in this subfamily (Payne and Risley 1976), but here it is retained in the Ardeinae, following Bock (1956) and others. All *Botaurus* species are allopatric and many authors treat them as one superspecies, even considering some of them conspecific; skeletal differences, however, suggest that only the Eurasian Bittern *Botaurus stellaris* and the Australian Brown Bittern *B. poiciloptilus* are close enough to be regarded as a superspecies. Three species of *Ixobrychus* (the Least Bittern *I. exilis*, the Little Bittern *I. minutus* and the Yellow or Chinese Little Bittern *I. sinensis*) also form a superspecies. The Dwarf Bittern *I. sturmii* was placed in its own genus *Ardeirallus* by Curry-Lindahl (1971), but there are no marked skeletal differences to sustain this suggestion. The

Bittern *Botaurus stellaris* regurgitating food to young. (*Photo: E.J. Hosking*).

Black or Mangrove Bittern *I. flavicollis* is polymorphic with 6 distinct plumages (black, reddish, or partly white morphs occurring in the same population) and has been generically separated in *Dupetor*, but the absence of morphological differences between it and the other smaller bitterns supports its retention in *Ixobrychus*.

Characteristics. In general, bitterns have shorter necks and legs and stouter bodies than herons. The inner toe is longer than the outer (the reverse in herons); they have 8 or, more usually, 10 tail feathers (12 in herons), and only 2 pairs of powder-down patches on the breast and rump (3 or 4 in herons including the thighs and, sometimes, the back). Their bills are strong and pointed, and the toes are long and slender with the middle toe pectinated (as in herons). In addition, the majority nest solitarily (herons are usually colonial) and they largely lack the exaggerated head, breast and scapular plumes so characteristic of the Ardeinae.

The sexes are alike in *Botaurus* (as in herons), but dimorphic in most *Ixobrychus*, the exceptions being the Dwarf Bittern and the Stripe-backed Bittern *I. involucris*.

Botaurus are large (range 60–80 cm in length) and heavy (mass not less than 370 g, with some males reaching 1,900 g). Their soft plumage is beautifully variegated with browns, buffs, blacks and yellows in a cryptic pattern of streaks and bars. The South American Pinnated Bittern *B. pinnatus* differs from the other 3 in having barring on the crown. In contrast, *Ixobrychus* are mostly much smaller (range 25–40 cm in length, apart from the Black Bittern which reaches 55–60 cm), with dove-sized bodies (mass not greater than 170 g and some as little as 45–65 g). Females are generally rather streaked above (or spotted with white in the case of Schrenk's Little Bittern *I. eurhythmus*), but 4 of the males (*exilis, minutus, sinensis, eurhythmus*) have plain backs (dark except *sinensis*) and pale wing-coverts contrasting with dark flight-feathers; 3 (*sturmii, flavicollis*, Cinnamon Bittern *I. cinnamomeus*) show uniformly coloured backs and wings; and only 1 (*involucris*) is broadly streaked on the back. The Black Bittern has the feathers of the crown and lower neck somewhat developed as plumes.

Botaurus usually walk deliberately with feet lifted and lowered slowly; they rarely perch in trees, but are able to climb reeds, if not particularly nimbly. In marked contrast, *Ixobrychus* run rapidly on the ground and readily climb in reeds, shrubs, and trees.

Distribution and habitat. The subfamily has a wide distribution: 2 species breed in Europe (*B. stellaris, I. minutus*), 2 in North America (American Bittern *Botaurus lentiginosus, I. exilis*), 3 in Africa (*B. stellaris, I. minutus, I. sturmii*), 3 in South America (*B. pinnatus, I. exilis, I. involucris*), 3 in Australia (*B. poiciloptilus, I. minutus, I. flavicollis*), and 6 in Asia (*B. stellaris, I. minutus, I. sinensis, I. eurhythmus, I. cinnamomeus, I. flavicollis*). Thus there is a fairly even scatter throughout the zoogeographical regions, but *Botaurus* are found mainly in temperate zones and both genera are largely confined between 60°N and 40°S.

Bitterns are marsh birds, feeding and breeding in wetlands with a dense cover of high sedges or long grass and scattered low shrubs. The Dwarf Bittern and the Black Bittern prefer more open situations than the often sympatric Little Bittern, and are found at the fringes of reed beds and in mangrove swamps where roots and branches of trees and bushes hang into the water.

Movements. The majority of bitterns are at least partial migrants, the northern Holarctic populations mostly moving southwards after the breeding season. Many Eurasian Bitterns winter in southern Asia, the Mediterranean basin and even Africa. Palearctic populations of the Little Bittern winter largely in Africa, apart from a few in Iraq and Iran. The American and Least Bitterns likewise move south and stragglers even turn up along the western fringes of the Old World. Within Africa, the Dwarf Bittern is markedly migratory, being present in the southern and probably the more northern parts of its range during their respective wet seasons; nearer the Equator the populations are more sedentary. A Black Bittern ringed in Malaya was recaptured 2,400 km north-west in India.

Food. Both large and small bitterns take a wide variety of prey, especially fish, amphibians, and insects, but also including crustaceans, molluscs, worms, leeches, reptiles, and even birds and small mammals. Some species or populations are almost exclusively fish-eaters, while others are largely insectivorous.

Behaviour. Bitterns are secretive and solitary (being at best only loosely colonial, and usually not at all). Although *Botaurus* may be seen flying or even feeding during the day, they are essentially crepuscular, being most active at dawn and dusk. *Ixobrychus* are also often crepuscular, but at least some species are rather more diurnal as well.

Several habits are almost or entirely peculiar to the group. Most striking is the concealment posture shared only with the tiger herons. In this the bird becomes completely rigid with the bill and neck pointed stiffly skywards and the feathers tightly compressed so that the whole body appears elongated; it keeps its underside towards the source of danger, watching with unwinking yellow eyes swivelled downwards, and revolves slowly (or whirls with great rapidity) if the observer or other threat moves around. The striped undersides (or plain dull underparts of some *Ixobrychus*) fit in remarkably with a background of dead reeds, and the bird in this posture is almost invisible. In a light breeze, at least some species will sway with the reeds. *Ixobrychus* may even let itself be picked up; W.H. Hudson described how *I. involucris* allowed him to push its head down until this touched its back and, when he removed his hand, the head and neck flew up to the original position like a steel spring. This protective posture is adopted even by downy young only a few days old.

Bitterns use their powder-down patches and pectinated middle claw to clean their plumage. Percy (1951) observed that the head is rubbed in these patches until covered with the powder, which is then allowed to soak up fish slime and oil (probably also excess preen oil) before being combed off by vigorous movements of the toothed claw.

Botaurus are highly territorial throughout the breeding season. They will even attempt to stab one another in aerial combat, and are occasionally found dying or dead from wounds. Flight activities involving 4–6 birds and lasting up to 10 min at heights up to *c.* 65 m during the middle of the breeding season may have either territorial or courtship significance. *Ixobrychus* also drive off intruders by chasing and flight-attack to the border of the territory. There is probably no real pair bond in *Botaurus*, but pairs are formed in *Ixobrychus*.

Voice. The male *Botaurus* bitterns are well known for their distinctive and far-carrying 'booming' or 'thunder-pumping' territorial calls, which may be heard both by day and by night but mostly in the evening before and during the breeding season. They usually boom from inside a reed bed, but sometimes at the edge and more rarely from a perch high in a tree. The male's oesophagus is especially modified before the breeding season so that it can be inflated and act as a resonating chamber: the bird utters a series of clicks or coughs, breathes in deeply with its head thrust forward and whole body vibrating, and then produces the deep resonant boom in a great exhalation. It is audible to the human ear at distances of 1–5 km, depending on climatic conditions; the performance is commonly repeated several times. A comparable noise is uttered by the tiger herons.

The pre-breeding calls of male *Ixobrychus* are guttural cooing and croaking sounds uttered in long sequences and are used to attract the female to the nest: apparently the only species that 'booms' is *I. flavicollis* and then only in India and Sri Lanka (Curry-Lindahl 1971).

Breeding. All bitterns nest in freshwater reed, sedge and other aquatic vegetation in marshes, lakes or the margins of large rivers. *Botaurus* build up a platform of reeds and sedges some 10–15 cm above the water level, while *Ixobrychus* make more of a nest at heights of 3–60 cm (sometimes as high as 3–6 m) above shallow water in dense vegetation or occasionally in trees. Nest building is by the female in the Eurasian and American Bitterns (*Botaurus*) but mainly by the male in the Little and Least Bitterns (*Ixobrychus*). Whether this distinction in roles applies to all species in the 2 genera is not known. Nests are solitary in *Botaurus* (except that some males are polygamous) and most *Ixobrychus*, but *I. sturmii* and *I. flavicollis* occasionally breed in small loose colonies, the latter sometimes among egrets.

The clutch size varies in those species (e.g. *I. exilis*, *I. minutus*) which have a wide latitudinal distribution, being smaller in the subtropics and tropics (2–3) than at higher latitudes (*c.* 4–7); the common range is 4–6 for the whole subfamily, but up to 10 eggs have been recorded for *Ixobrychus*. The eggs, which are smooth but with little or no gloss, vary in colour from white to bluish or greenish in *Ixobrychus* and buffish-brown to olive-brown in *Botaurus*; they generally lack markings although there may sometimes be a few fine brown speckles near the large end. The laying intervals, so far as known, are 2–3 days for the Eurasian Bittern and 1 day for the Little Bittern (sometimes 2), American Bittern and Least Bittern. Incubation generally lasts 24–26 days in *Botaurus* (females only incubating) and 17–19 days in *Ixobrychus* (both sexes incubating); it begins usually with the first egg, so hatching is asynchronous and, indeed, may be spread over as long as 12–13 days in the Eurasian Bittern. The majority of bitterns are single-brooded, but 2–3 broods have been recorded in *I. sinensis* and 2 in *I. flavicollis*.

Young bitterns are fed by regurgitation by the female in *Botaurus* and by both sexes in *Ixobrychus*. The young begin to wander from the nest at the age of 14–20 days in *Botaurus* and as early as 5–7 days in *Ixobrychus* (*minutus*, *sturmii*, *exilis*). Recorded fledging periods are in the ranges of 50–55 days (*B. stellaris*) and 25–30 days (*I. minutus*). See photo PARENTAL CARE. I.J.F.-L.

BITTERN, SUN-: see SUNBITTERN.

BLACKBIRD (1): in Britain, *Turdus merula*; also used as substantive name of some congeners elsewhere (see THRUSH). See photos COMFORT BEHAVIOUR; PARENTAL CARE; SUNNING.

BLACKBIRD (2): in North America, substantive name of certain Icteridae, especially *Agelaius* spp. (see ORIOLE (2)).

BLACKCAP: *Sylvia atricapilla* (see WARBLER (1)).

BLACK-CAPPED DONACOBIUS: *Donacobius atricapillus* (see WREN (1)).

BLACKCOCK: special name for the male of the Black Grouse *Tetrao tetrix*, the female being called 'greyhen' (see GROUSE).

BLACKEYE: substantive name of *Chlorocharis emiliae* (see WHITE-EYE).

BLACKSTART: *Cercomela melanura*, of south-western Asia and north-eastern Africa (for subfamily see THRUSH).

BLADE: see FEATHER.

BLASTODERM; BLASTODISC: see DEVELOPMENT, EMBRYONIC; EGG; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

BLEATING: see MECHANICAL SOUNDS.

BLIND: see BIRD-WATCHING.

BLOOD: the fluid that, in all vertebrates, carries oxygen from the lungs to the tissues and returns carbon dioxide (see VASCULAR SYSTEM); carries soluble products of digestion to storage or modifying organs such as the liver and to the tissues (see ALIMENTARY SYSTEM); and carries waste substances in solution to the kidneys (see EXCRETORY SYSTEM). Antibodies produced against invading organisms are distributed; so also are hormones from the endocrine glands (such as the pituitary or thyroid) to their sites of activity, which may be further endocrine glands, the specific organs to be affected, or the tissues in general (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM). Above all, blood is the vehicle by which the 'internal environment' of the tissues is kept constant.

Blood consists of two main parts, one cellular and the other fluid. The white cells or leucocytes help to combat infections, while the erythrocytes or red cells (corpuscles) have as their main function the carriage of oxygen and carbon dioxide. The erythrocytes are, of course, too small to be visible individually and so form the red coloration. The cells are suspended in the fluid element, the plasma.

Plasma. This itself consists of two parts, water and proteins (substances of very large molecules containing nitrogen). Food and waste products are dissolved in the water, while the proteins behave usually as a colloidal suspension. Antibodies are likewise proteins and in adult animals are an appreciable fraction of those in the blood. The blood proteins may be divided into classes because their molecular sizes tend to fall into definite groups, although with no absolute divisions between them. These can be separated by techniques such as electrophoresis or chromatography, in which the molecules of different sizes move at different speeds under the influence, respectively, of an electric current or of an advancing capillary front.

Erythrocytes. In all vertebrates the erythrocytes start their development as nucleated cells, but those of mammals lose their nuclei before being pushed out into the blood stream (except in conditions of disease). In birds—as also in reptiles, amphibia, and fishes—the erythrocytes retain the nuclei; they are also oval, although flattened. (In mammals the erythrocytes are round—except in the Camel, Llama, and Vicuna, where they are again oval.) In birds they are large; thus in man there are about 5 million per mm^3, but in birds about 2 million. The smaller ones are more efficient. In a remarkable series of papers in the *Proceedings of the Zoological Society of London* round about 1850, George Gulliver recorded the measurements of the red cells of many animals, including birds. He pointed out that there was a fairly consistent average for a species but wide variations between different species. However, there was no relation between these measurements and the accepted systematic classification, e.g. in the owls (Strigiformes), of which he examined several species which would still be considered as closely related. The average life of a red cell is only a few weeks, after which it is removed from the circulation by the so-called 'reticuloendothelial system' and replaced by new cells formed in the sinusoids of the bone-marrow by a process of development strictly comparable to what is found in mammals.

Haemoglobin. It is this red pigment of the cells that is fundamentally responsible for the complex series of changes by which oxygen is absorbed or liberated by the red cells as required. Chemically it is similar in all vertebrates, a protein containing iron, and recent work by the techniques mentioned above has shown in many groups of animals that is can be divided into several slightly different substances. In birds, electrophoretic methods have as yet failed to subdivide the haemoglobin in some of the birds that have been examined, e.g. some pigeons (Columbidae) and penguins (Spheniscidae). Chromatography, however, has revealed five types, some of which appear to be similar to those of man, e.g. human Haemoglobin E, which is an inherited abnormality responsible both for the rare disease called thalassaemia and for a marked degree of resistance to infestation with malaria parasites. In birds the arrangement of the five types of haemoglobin in the species examined bears some relationship to broad systematic factors. Thus, one factor found in the older groups such as Pelecaniformes, Falconiformes, or Ciconiiformes is absent in those believed to be of intermediate antiquity, such as Cuculiformes, and yet reappears in Passeriformes.

Leucocytes. As with so much detailed work on birds, most observations have been made on such domesticated species as fowls and pigeons. Their blood contains about 5000 leucocytes per mm^3, but variations have been observed with season and with laying times. In contrast to mammals, except very young ones, the blood contains a greater proportion of lymphocytes than the granulocytes which ingest invading bacteria. The granulocytes also differ in having nuclei split into many small lobes, but otherwise the cells and their mode of development differ little from those of mammals.

Blood groups. The importance of these in human blood transfusion is well known. They depend on specific antigens present in the the plasma, red cells, and other tissues, and forming several series independent of each other and controlled by a number of genes inherited according to the established laws of genetics (see GENETICS). They form, indeed, one of the best worked-out series of inherited factors, have been correlated with liability to certain diseases, and provide very important evidence with regard to the relationship between races of mankind. In domestic fowls no less than twelve distinct series have been described using saline agglutination of cells with iso-immune sera; complement fixation techniques have not proved as satisfactory. There are some cross reactions, so some antigenic material must be common to several series, but genetically they segregate independently. The 'B' system at least seems to be related to the production of antibodies to tissue grafts from other individuals, while some heterozygotes of this system appear to confer an increased survival to the lines bearing them. In the Golden Leghorn fowl an antigen for human serum has been found in the erythrocytes. The male bird may carry the double gene of his ZZ chromosome while the female can have only one on her ZW chromosome, which has analogies with some aspects of the well-known Rhesus blood group system of man, although the arrangement of the sex chromosomes as between males and females is reversed in mammals and birds. In ducks one blood group is sex-linked, a condition only recently found in one human blood group. Serological differences between species have been investigated in the genus *Streptopelia* (Columbidae); the differences between *S. 'risoria'*, *S. chinensis*, and *S. senegalensis* have been resolved serologically into a number of specific antigens, some of which are held in common between two species.

Systematic serology. Birds certainly produce antibodies to many antigens introduced from outside, e.g. bacteria and the blood of other animals; those of the former class are presumably of use to the bird as to other animals, but the latter are of course an entirely artificial phenomenon. In mammals, the specific antibodies to the blood of different species produced in one experimental animal, e.g. the Rabbit, have been shown to be related for systematically related species; but such work on birds has so far led to equivocal results. BLOOD VESSELS: see HEART; VASCULAR SYSTEM.

BLOSSOMCROWN: *Anthocephala floriceps* (for family see HUMMINGBIRD).

BLUEBILL (1): substantive name of *Spermophaga* spp. (see ESTRILDID FINCH).

BLUEBILL (2): a name in North America for the Scaup *Aythya marila*, and in Australia for the Australian Stifftail *Oxyura australis* (see DUCK).

BLUEBIRD: substantive name of *Sialia* spp., of North and Middle America (see THRUSH).

BLUEBIRD, FAIRY-: see FAIRY-BLUEBIRD; and under LEAFBIRD.

BLUE-BONNET: substantive name sometimes used for the Australian PARROT *Psephotus haematogaster*.

BLUECREST: *Orthorhyncus cristatus* (for family see HUMMINGBIRD).

BLUETAIL: *Tarsiger cyanurus*, of the eastern Palearctic (one of the bush-robins)—for subfamily see THRUSH.

BLUETHROAT: *Luscinia svecica*, of the northern Palearctic (for subfamily see THRUSH).

BOATBILL: otherwise the Boat-billed Heron *Cochlearius cochlearius*, of the Neotropical Region (see HERON).

BOATSWAIN-BIRD: see BO'SUN-BIRD.

BOBOLINK: *Dolichonyx oryzivorus*, native to North America (see ORIOLE (2)).

BOBWHITE: *Colinus virginianus*, one of the American quails (Odontophorinae)—see under PHEASANT.

BODY: see SIZE; TOPOGRAPHY; and for care of body surface see COMFORT BEHAVIOUR.

BOG-BIRD: name sometimes applied to *Balaeniceps rex* (see SHOEBILL).

BOKMAKIERIE: well-known Afrikaans name (from the duetting call) for *Telephorus zeylonus* (see SHRIKE).

BOMBYCILLIDAE: family of PASSERIFORMES, suborder Oscines, comprising subfamilies Bombycillinae (see WAXWING) and Hypocoliinae (see HYPOCOLIUS).

BONE: see PALATE; PNEUMATIZATION OF BONE; SKELETON, POST-CRANIAL; SKULL. Also, with regard to bone formation, under ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

BONXIE: alternative name for the Great Skua *Stercorarius skua* (see SKUA).

BOOBY: substantive name of certain *Sula* spp. to which 'gannet' is sometimes alternatively applied (see GANNET). See photo RITUALIZATION.

BOOM: see BITTERN.

BOOMING GROUND: special term in North America for the social display ground of the Greater Prairie Chicken *Tympanuchus cupido* (see GROUSE; LEK).

BOOTED: otherwise 'holothecal' or 'ocreate', term applied to the horny covering of the tarsus when it, or most of it, is in an undivided piece (see LEG; compare LAMINIPLANTAR; SCUTELLATE). In poultry literature 'booted' means having a feathered tarsus; in general this is not an ornithological usage, 'rough-legged' being preferred, but the adjective has that sense in the name of the Booted Eagle *Hieraaetus pennatus*.

BOREAL: term applied to a climatic zone immediately south of the Arctic; sub-divided in North America into 'Hudsonian' and 'Canadian'.

BOREAL FOREST: see TAIGA.

BO'SUNBIRD: sailors' name for *Phaethon* spp. (see TROPICBIRD). It is said to 'carry a marlin-spike in the tail'.

BOTAURINAE: see BITTERN.

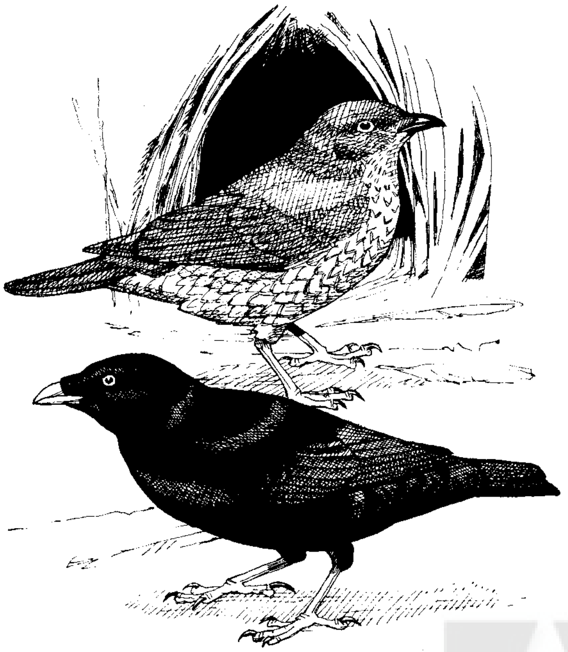
BOTULISM: see DISEASE.

BOUBOU: substantive name of some *Laniarius* spp. (see SHRIKE); to be distinguished from BRUBRU.

BOWERBIRD: name variously applied to all species of Ptilonorhynchidae (Passeriformes, suborder Oscines), or just to the polygamous species when contrasted with the monogamous ones, collectively termed catbirds (*Ailuroedus*). Bowerbirds are medium sized passerines (21–38 cm long) renowned for their arena behaviour which involves elaborate display courts and bowers made and maintained by males.

Systematics. Bock (1963) concluded from the cranial anatomy that bowerbirds and birds-of-paradise (Paradisaeidae) are closely related and descended from a common cnemophiline bird-of-paradise ancestor, but sufficiently distinct to be placed in separate families as followed here. Gilliard (1969) and Schodde (1976) combine both groups in the Paradisaeidae on zoogeographic, morphological and behavioural grounds. Other bowerbird affinities are uncertain; they have been variously allied to Sturnidae, Menuridae, Callaeidae and the 'corvine assemblage'.

Characteristics. Bowerbirds range from thrush-size almost to crow-



Satin Bowerbird *Ptilonorhynchus violaceus*, female and male (front). (*N.W.C.*).

size (*c.* 22–40 cm) and the males are usually beautiful. Most have coloured ornamental plumes of various kinds. In some almost all feathers produce brilliance by means of 'interference' effects. In others there is a brief nuchal crest, in another a ruff draping much of the back. The sexes are rarely alike. Wings and tail tend to be short, the legs short and strong; the bill is short and strong, sometimes decurved, and slightly hooked.

Distribution and habitat. Nine of the 18 species are endemic to New Guinea, 7 to Australia and 2 occur on both land masses. Distributions vary from extensive and continuous (e.g. Great Grey Bowerbird *Chlamydera nuchalis*) to very restricted (e.g. Adelbert Bowerbird *Sericulus bakeri*). Most bowerbirds inhabit wet forests, some occurring as high as 3,000–4,000 m in true cloud forest (*Amblyornis*, *Archboldia*). But *Chlamydera* species live in drier habitats such as riverine forest, open woodlands and grasslands and include the only 2 Australian species with extensive inland distributions.

Food. Bowerbirds are predominantly vegetarian and frugivorous. Present studies of 6 wet forest species in north-east New South Wales and north Queensland indicate a 9 : 1 ratio of plant to animal food in the diet. Plant foods eaten include the fruits of many tree and vine species, leaves, buds, flowers seeds and succulent stems. The serrated bill of the Tooth-billed Catbird *Scenopoeetus dentirostris* appears to be mainly an adaptation to leaf eating. Animals eaten by bowerbirds include large insects, earthworms, spiders, millipedes, frogs and small nestling birds. Bowerbirds forage at all levels in the forest vegetation from ground to canopy, but co-habiting species usually differ somewhat in their preferred feeding heights.

Mating systems. Catbirds are monogamous with biparental brood-care. Parental investment by male Green and Spotted Catbirds *Ailuroedus crassirostris* and *A. melanotis* involves defence of breeding territories, feeding the female and helping to feed young. All other bowerbirds are thought to be polygamous with brood-care provided by females. Emancipated males exhibit arena behaviour, competing to attract multiple mates by elaborate visual and vocal display at bowers or courts. Vellenga (1970) confirmed polygamy in the Satin Bowerbird *Ptilonorhynchus violaceus* and studies in north-east New South Wales show that males of this species are promiscuous (see LEK; POLYGAMY). This is likely to be true of all the polygamous species.

Most polygamous bowerbirds are sexually dimorphic in plumage (and often size), but the degree of dimorphism varies from dramatic contrast in plumage coloration in genera like *Sericulus*, *Prionodura* and *Ptilonorhynchus* to the slight differences characteristic of Archbold's Bowerbird *Archboldia papuensis* and Spotted *Chlamydera maculata* and Great Grey Bowerbirds. The monogamous catbirds and polygamous Tooth-billed Catbird, Vogelkop Gardener Bowerbird *Amblyornis inornatus*, Fawn-breasted Bowerbird *Chlamydera cerviniventris* and Lauterbach's Bowerbird *C. lauterbachi* are sexually monomorphic in plumage. In polygamous, sexually dimorphic species, males attain adult plumage later than females and are female-plumaged until mature. Thus wild male Satin Bowerbirds assume adult plumage when 7 years old (Marshall 1954) while females may breed at 2–3 years old, and male Australian Regent Bowerbirds *Sericulus chrysocephalus* acquire adult plumage at 4–6 years although females may breed when 3 years old (Disney and Lane 1971). It is not surprising that ages of 5–15 years have been recorded for *Ptilonorhynchus*.

Bowers and display. Bowers of sticks, grasses and mosses are built by polygamous males at display areas to which females are attracted to copulate. There are 4 basic bower types: court, mat, maypole and avenue. The Tooth-billed Catbird clears several square metres of forest floor and decorates this display court with fresh leaves, undersurfaces uppermost. Archbold's Bowerbird makes a simple 'mat' of mosses and dry ferns. Maypole bowers vary in complexity. The terrestrial maypole bowers of *Amblyornis* spp. range from a conical stick column surrounding a sapling emerging from a basal, saucer-shaped moss platform (*A. macgregoriae*) to elaborate roofed, stick towers based on one or more saplings (*A. subularis* and *A. inornatus*). The Golden Bowerbird *Prionodura newtoniana* builds a vast maypole bower up to 3 m high and comprising one or two stick massifs originating at arboreal sites and spreading upward and downward. The sticks are fused together with fungus. Avenue bowers comprise two vertical, parallel walls of twigs or grasses on a stick platform; Lauterbach's Bowerbird adds a short wall at each end of the avenue.

Males decorate their bowers with both natural objects such as mosses, ferns, lichens, flowers, fruits, insects, snail shells and feathers, and in the genera *Ptilonorhynchus* and *Chlamydera*, human artefacts. There are pronounced species preferences in ornament colour and Marshall (1954) suggested that these match the colours of rival, conspecific males. Avenue builders 'paint' the inside walls of their bowers with vegetable matter and saliva. The adaptive significance of this behaviour is unknown.

Gilliard (1969) showed an inverse correlation among *Amblyornis* species between the extent of male epigamic plumage coloration and bower complexity. He postulated that intense sexual selection had led to a 'transferral effect' in advanced bowerbirds in which epigamic function had been transferred from male plumage to display objects. While this is plausible, the Golden Bowerbird, in which the brilliantly coloured male builds an elaborate and huge bower, is clearly an exception.

Courtship display at the bower has been described in few species. There is a single, intriguing observation of a male *Archboldia* crawling in a fledgling-like posture over the mat bower towards a perched female. Displaying male *Amblyornis* hold objects in the bill and expose the crest where present. In *Amblyornis macgregoriae* the displaying male and visiting female maintain positions on opposite sides of the central maypole. Male Satin Bowerbirds perform strutting, bowing and wing-opening displays on the bower platform to a visiting female in the avenue. Immature males of this species display to one another and to females in rudimentary bowers as well as visiting and displaying in adult males' bowers. *Chlamydera* males execute a headturning display which exposes a pink crest on the nape in 2 species; Gilliard argued that the presence of this display in the 2 uncrested species which also build more elaborate bowers supported the 'transferral effect' hypothesis. Copulation has been observed in or near the avenue in 2 avenue builders and is probably largely restricted to the bower site in all polygamous species. Adult male bowerbirds typically build and maintain one bower per season, but *Prionodura* males 'own' more than one simultaneously. Raiding neighbours' bowers and stealing their ornaments has been noted in 3 species. Catbirds do not exhibit arena behaviour except for *A. dentirostris*.

Movements. Monogamous Green and Spotted Catbirds occupy all-purpose territories year-round. In the few polygamous species studied, females only defend the nest site and males a small area around the bower during the breeding season. The bowers of Golden, Australian Regent, Satin and Fawn-breasted Bowerbirds are evenly dispersed in suitable habitat and not clustered in dispersed leks (Gilliard). Some bowerbirds form flocks in the non-breeding season.

Voice. Bowerbirds have a wide variety of species-typical vocalizations including harsh buzzes, rattles and hisses, melodious whistles and high-pitched squeaks. Males of several polygamous species mimic cohabiting bird species and even mechanical sounds.

Breeding. The Australian species breed from September to February. Breeding seasons of New Guinea species are less well documented but probably either coincide with this timing or are at least of comparable length. Bowerbird nests are open cups built 1–30 m up in tree vegetation, except in *Prionodura* which uses crevices from 0.5 m to 15 m high. Catbird nests are bulky, those of the avenue builders shallow and frail, and the Tooth-billed Catbird constructs a tiny, cryptic cup of tendrils in a vine tangle.

Clutch size is 1–3, usually 2 eggs. The eggs of *Ailuroedus*, *Scenopoeetes*, *Amblyornis* and *Prionodura* are pale and uniform in colour but other genera have spotted and streaked eggs. Egg dimensions are 32–45 × 23–32 mm. In Green Catbirds and Satin Bowerbirds incubation takes 19–24 days and nestling development 18–21 days but there is little comparable information for other species. In north-east New South Wales Green Catbird nesting success was about 70% and Satin Bowerbird success around 20%. Females of these 2 species renest within one week of nest failure and normally rear one brood per season. The breeding biology of most other bowerbirds has been little studied.

BRACE: collective noun for two birds of the same species, irrespective of sex; mainly used in the plural (unchanged) for the enumeration of dead game (e.g. 3½ brace = 7 birds of a kind)—cf. PAIR.

BRACHYPTERACIIDAE: see CORACIIFORMES; GROUND-ROLLER.

BRACHYRAMPHINI: see AUK.

BRAILING: rendering a captive bird incapable of flight by binding the manus to the forearm so that the wing so treated cannot be unfolded (compare CLIPPING; PINIONING).

BRAIN: see NERVOUS SYSTEM.

BRAIN-FEVER BIRD: name applied to the Hawk Cuckoo *Cuculus varius* of India, both representing the sound made ('brain fever, brain fever') and suggesting the wearisome effect of its loud and constant reiteration; sometimes misapplied to other species, for the second of these reasons (see CUCKOO).

BRAMBLING: *Fringilla montifringilla*, native to the northern Palearctic (see FINCH).

BRANT: North American name for the Brent Goose *Branta bernicla* (see under DUCK).

BRASSYTAIL: *Metallura aeneocauda* (for family see HUMMINGBIRD).

BREAST: see TOPOGRAPHY.

BREAST-BAND: see TOPOGRAPHY.

BREASTBONE: see SKELETON, POST-CRANIAL.

BREATHING: see RESPIRATORY SYSTEM.

BREEDING BIOLOGY: see under specialized articles e.g. BREEDING SEASON; EGG; PARENTAL CARE.

BREEDING BIRD SURVEY: see ATLAS; CENSUS.

BREEDING CYCLE: the complete sequence of reproductive activity from initial COURTSHIP and pair formation through nesting to the final independence of the young.

BREEDING DISTRIBUTION OR RANGE: see DISTRIBUTION, GEOGRAPHICAL; RANGE CHANGES.

BREEDING SEASON: the period of the year during which, in any particular area, birds mate, build their nests, lay their eggs and raise their young; by convention, the start of the breeding season of any species in any area is normally described by taking the mean date of the first eggs of first clutches in the populations concerned. The laying dates of a large number of the world's species are still poorly known or unknown. Laying dates can, however, often be extrapolated from incubation dates, from the age of young birds or even from moulting adult birds, since many birds have a post-breeding MOULT.

Ultimate and proximate factors. Two kinds of factor govern the timing of breeding seasons (Baker 1938). A factor which results in natural selection favouring a particular time of breeding is called an ultimate factor. Birds often have their young in the nest when food is most available; in such cases food may be the ultimate factor which influences the time of breeding.

The second kind or proximate factor ties in the bird's behaviour with favourable environmental conditions. Obviously, if the ultimate factor is the availability of food for the nestlings, the parents must commence their breeding cycle much earlier than the period of peak food abundance, since there is a considerable interval between the commencement of breeding and the hatching of the young. For example, in the European Robin *Erithacus rubecula* it takes a minimum of 3 weeks from ovulation to hatching (4 days from the start of rapid follicular growth to laying, 4 days to lay 5 eggs, 13 days for incubation); even this period is an underestimate since it does not take into account the time needed for the reproductive organs to come into breeding condition, which may take 5 weeks or more (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM). While many small birds are able to produce young as quickly as the Robin, many larger ones take longer, the extreme case being probably the Wandering Albatross *Diomedea exulans*, where incubation takes 11–12 weeks. Proximate factors are discussed in more detail below.

The breeding seasons of different species. There have been a great many studies of the timing of breeding in relation to the environment; a review is given in this section (see also Lack 1954). As might be expected, the breeding season varies with the geographical location, since this may have marked effects on the local climate. Most of the more obvious variations follow the general bioclimatic laws of Hopkins (1938) whereby:

(1) spring arrives about 4–5 days later for each 1° increase in latitude;

(2) spring arrives about 4–5 days later for each 125 m increase in altitude;

(3) spring arrives later the further one moves from the sea towards the centre of a continent. This effect varies markedly in relation to local winds etc. but in the western USA spring arrives about 4 days later for each 5° eastwards.

Correlations of the timing of breeding with latitude stand out. Birds breeding at high latitudes have the shortest breeding seasons and all species are closely synchronized. Towards the Equator breeding seasons become more extended and less closely synchronized (Fig. 1). At high latitudes, the breeding cycle can be regarded as a race against the clock to get the breeding over and the chicks developed sufficiently well to migrate southwards before the onset of winter. Some birds, such as the arctic-breeding geese, arrive on the breeding grounds when the area is still snow covered and there is little or no food available. But the females are able to lay and incubate their clutches from their large body reserves and are thus able to start breeding as soon as suitable nest sites are exposed. In late springs they are delayed and may use up their body reserves to such an extent before laying that they either lay small clutches, fail to lay, or are forced to desert their eggs. The season for development of the young is very short and goslings may die if the autumn freeze-up comes before they are able to fly. As a result, geese breeding at high latitudes have very variable nesting success; in some years almost all birds fail to raise any young. Other characteristics of high latitude breeding include the tendency to have no repeat or second clutches and rapid development of young. In the waders (Charadriidae), post-breeding moult, especially of the flight feathers, may be very rapid or may be deferred until the birds have moved further south; in a few passerines the moult may be brought forward to overlap with the raising of the young.

In the tropics, especially in the least seasonal habitats such as the equatorial rain-forests, birds may be found breeding at all times of the year. Nevertheless, almost every species so far studied can be said to have a breeding season. A few species, such as the Scaly-breasted Ground Dove *Columbina passerina* in semi-arid central America and the Red-footed Booby *Sula dactylatra* in the Galapagos, show no breeding season for the population as a whole and breeding may occur at any time of year. Each bird can be said to have its own, individual reproductive cycle since it breeds for part of the year and then has a rest period during which it moults: however, these individual cycles are neither synchronized, nor necessarily annual. Within any area (outside the high latitudes) there are marked variations in the breeding seasons of the different species. In general these differences reflect the ecology of the individual species and support the hypothesis that breeding seasons of birds have evolved so that the birds have their young in the nest when food is most available. For example in central Europe the small birds of prey fit such a pattern. The Kestrel *Falco tinnunculus* breeds early so as to catch its small mammal prey before vegetation becomes too thick to find them easily; the Sparrowhawk *Accipiter nisus* breeds later, feeding its young on the fledglings of small woodland birds which have only just left the nest and are vulnerable. The Hobby *F. subbuteo*, breeding later still, feeds its young on fledgling swallows and martins (Hirundinidae) and on large insects which appear later in the season. In the Mediterranean and North Africa there are two other small birds of prey, Eleonora's Falcon *F. eleonorae* and Sooty Falcon *F. concolor*, which lay their eggs at midsummer and feed their young on the hordes of small passerines which pass southwards for the winter. There are many such general observations on the timing of breeding and the food supply; for example, most insectivores which take larvae from the leaves tend to breed earlier than those which catch flying insects: again the availability of their food is parallel with variations in breeding seasons.

Compared with the temperate regions, the pattern of breeding seasons in the tropics is less well known and more variable. Many tropical areas are as highly seasonal as temperate ones although rainfall rather than temperature is the key environmental variant. Again, however, general correlations are in accord with food being the most important ultimate factor affecting the breeding cycle; for example, insectivorous birds tend to breed early in the rains, feeding their young on the flush of insects on the new vegetation; seed-eaters, in contrast, breed a good deal later, when the grasses are well-grown and the new seeds begin to ripen.

The breeding seasons of seabirds pose special problems. In temperate and colder parts of the world, they normally accord with those of other birds; they nest in the spring and raise their young before the cold weather returns; at very high latitudes it may be critical to get the young away before the sea freezes over. In the tropical seas, the seabirds have very varied breeding seasons. In some, breeding may still be annual (though not necessarily synchronized with other seabirds in the same area), but not in others. Wideawake or Sooty Terns *Sterna fuscata* return to breed on Ascension Island in the mid Atlantic very closely synchronized, about every 9.6 months. Others have both shorter and longer cycles (Bridled Tern *Sterna anaethetus*, Seychelles, Indian Ocean, about 8 months; Audubon's Shearwater *Puffinus lherminieri*, Galapagos, 9–10 months; Brown Booby *Sula leucogaster* and the Frigatebirds *Fregata*, cycles of more than one year). In these cases, it is assumed that the interval between seasons is the minimum possible in which birds can breed, moult and return to breed again, and that the food supply does not have an annual cycle. Although such non-annual cycles are known to be widespread in seabirds, they seem very rare in land-birds even in the (relatively) season-less tropical rain-forests. Cycles of about 9 months have, however, been suggested for 2 species of forest passerines in Sarawak, the Red-winged Tree Babbler *Stachyris erythroptera* and the Little Spider Hunter *Arachnothera longirostris*.

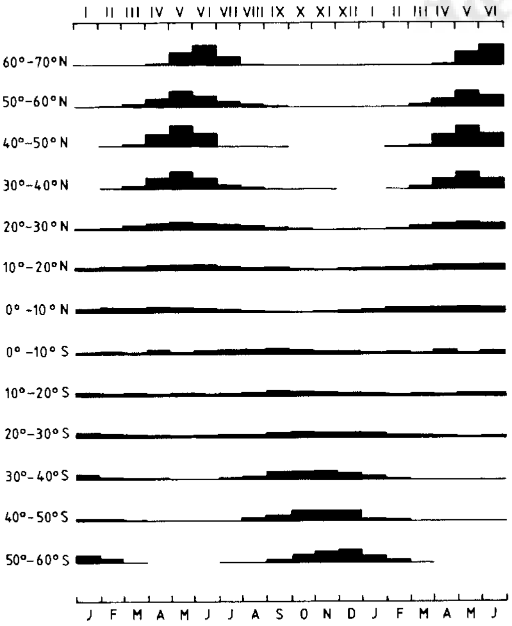

Fig. 1. Egg-laying seasons in relation to latitude (months indicated by Roman numerals and initial letters). (From Baker 1938).

A few seabirds and some large birds of prey, such as the condors and large albatrosses, take 2 years to complete a breeding cycle. In these species parental care usually takes far longer than the one year, and so the individuals breed only every other year. If, however, the birds lose their eggs or young at an early stage they will nest again the following year.

The King Penguin *Aptenodytes patagonicus* has a unique breeding cycle. In November the female lays the single egg, which becomes a large chick by the following winter. It remains dependent on its parents for food throughout the winter, but does not grow much and may even lose weight; it puts on weight and becomes independent in the following spring (December). By the time the parents have moulted, they are not ready to lay again until about January, an interval of about 14 months. The chick from this late laying is still small when winter comes and, if it survives, takes the whole of the following summer to reach independence (about March). By this time it is too late for the parents to moult and breed again before mid-winter so they do not lay until the spring (November). Hence, if successful, King Penguins raise 2 young in every 3 years. If they lose a chick they will revert to laying in November, i.e. they raise only one young every 2 years. The closely related Emperor Penguin *A. forsteri* breeds annually; the pair come on to the ice in mid-winter and the female lays the egg and leaves the male to incubate it for about 9 weeks (during which time he drops in weight from 40–20 kg). The chicks hatch at the beginning of the Antarctic spring. Although they thus have the whole of the summer period for growth, the young are not full-grown by late summer at which time they leave their parents and swim out to sea to fend for themselves and complete their growth.

Length of breeding season and number of broods. The time at which birds start breeding in each year, and the physiological and endocrinological changes involved have been the subject of much published work. Less attention, however, has been paid to the termination of breeding; in some ways it has been more difficult to study. Nevertheless in one or two species the reason for the variation in timing is fairly clear. The European Blackbird *Turdus merula* feeds its young largely on earthworms. These are easily available in midsummer if the weather has been wet and the ground is soft; Blackbirds cease breeding much earlier in a dry summer.

In many species the date at which breeding ends varies considerably between years and has a major effect on the number of broods attempted and hence the reproductive output. Many species, particularly passerines, may have a prolonged breeding season and raise several broods. The most raised in the wild seems to be about 6 consecutive broods. However, there are reports of Zebra Finches *Poephila guttata* under captive conditions raising as many as 21 consecutive broods. This species has been claimed to be an opportunistic breeder, laying in arid areas of Australia at irregular intervals after rain storms and continuing to breed until conditions deteriorate. While the laboratory breeding pattern mentioned above is consistent with such a view, more information is needed to establish this, since in at least some areas the Zebra Finch shows a more regular, seasonal pattern.

The length of the breeding season depends presumably on the relation between success of breeding and the survival of the adult birds, but this has not been studied in detail. Breeding is dangerous since it ties the parent birds to a restricted area, the nest or brood, making them more vulnerable to predation than at other times. In addition, breeding tends to defer moult and to postpone the accumulation of reserves while raising young. Hence, a further brood reduces the adults' chances of survival to the following breeding season. Whether or not they should have that brood may depend on its chances of success. In many species late broods do not produce as many surviving young as earlier ones. Natural selection has evidently favoured the tendency to have further broods up until that time at which the probable gains (in terms of surviving young) are outweighed by the reduced survival of their parents.

Although a great many passerines in the warmer parts of the world prolong their breeding season by having more than one brood, this behaviour is not common in non-passerines. One of the reasons is that non-passerines are generally larger and have a longer breeding cycle than passerines and thus less opportunity. Among the exceptions are the Barn Owl *Tyto alba* under conditions of abundant food, and some rails, notably the Moorhen *Gallinula chloropus*.

Not only do most non-passerines have only a single brood, but in some orders such as the Procellariiformes the reproductive organs start to regress soon after the egg is laid, and replacement clutches are very rare even when the egg is lost soon after laying. In the arctic geese, mentioned earlier, replacement clutches are not laid because the birds do not have the reserves nor do they have the time available to raise the young.

The breeding season, moult and migration. Although the breeding season is here considered in isolation it must be remembered that other factors, such as favourable times for MOULT and MIGRATION, may impose their own constraints on its length.

In a very few cases, the breeding seasons of individual birds may be prolonged by breeding in two different places. For example, the European Quail *Coturnix coturnix* may, on its northward migration, stop and breed in North Africa. As this area becomes more arid in late spring, the birds move on northwards and breed again in mid-Europe. Two discrete breeding areas have also been suggested for some Redpolls *Carduelis flammea*. In Africa, the Red-billed Quelea *Quelea quelea* migrates considerable distances, following the rains; it may breed in two or more different places. Other species probably have similar migration patterns, but whether they breed in more than one area is not known. Occasionally individual long distance migrants e.g. the Swallow *Hirundo rustica* have been reported breeding in their wintering range.

Ultimate factors affecting breeding seasons. Excluding the demands imposed by moult and migration (see above), the evolutionary factors which have resulted in the observed breeding seasons of birds may be divided into three. Two relate to food supply and the third to features associated with predation.

(1) Food for the chicks. It seems likely that this is an overriding factor controlling the timing of breeding in most species. Broods raised by the European Blackbird in mid-season are not only the largest, but also the young in them tend to be the heaviest; hence in this case there is good evidence that breeding may be at the best time for raising young.

It is often not known at what point in the nesting period the young need their greatest amounts of food. Indeed, in some species it may be that the fledged young are in greatest need. For example, the breeding of the East African White-backed and Rüppell's Griffon Vultures *Gyps africanus* and *G. rueppellii* may be timed so that the newly fledged young are searching for food at the time of year when the biomass of dead game is highest.

There may also be a difference between the times when food is most plentiful and the times when it is most easily caught (i.e. most available). For example, the European Kestrel and European Grey Heron *Ardea cinerea* both breed early in the year. The reason for this appears to be that their prey (small rodents and fish respectively) are easier to catch when the vegetation is not well developed. The prey species are not necessarily more common early in the season, but they are more visible and hence more easily captured.

(2) Food reserves for the laying hen. To have her young in the nest when food is most plentiful a female bird must lay her eggs very considerably before that time, when, especially in markedly seasonal areas, food may not be at all plentiful. There are a number of observations which suggest that the female may not always be able to acquire enough extra energy at this time to lay a clutch (Perrins 1970). Perhaps the most important concerns the survival of the young. In a number of species, such as the Great Tit *Parus major*, the earliest young to leave the nest may have the highest survival, all later young having progressively lower chances of survival as the season progresses (Fig. 2). By inference therefore, the later broods are not being raised at the best time of year and the breeding females would have been more successful if they had nested earlier. The male often feeds the female a considerable amount of her daily requirements at this time, again suggesting that the female needs more food than she can easily gather. Further, experiments involving the provision of extra food have resulted in the birds breeding earlier than those in adjacent areas with natural food supplies.

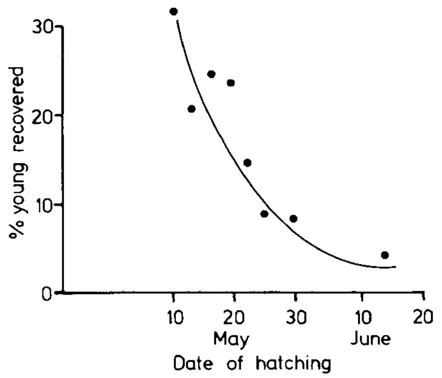

Fig. 2. Post-fledging survival of young Great Tits *Parus major* in relation to their date of hatching. Survival is measured by the percentage of the young, hatched at each point in the season, which are subsequently recaptured alive.

Many species do not seem able to build up reserves for egg-laying earlier though by no means all are likely to be prevented from breeding at the most opportune time. There are perhaps two main reasons why some birds do not lay down such reserves. Firstly the period prior to the breeding season is not a good time for finding food; secondly, in the case of small passerines laying 5 or 6 eggs or more, the amount of stored reserves would make flight difficult or impossible. The Blue Tit *Parus caeruleus*, which weighs about 10 g in winter, reaches 15 g during laying (including the weight of the enlarged reproductive organs and the egg in the oviduct) without storing food for the other eggs. It might be possible for migrants, feeding in a richer area elsewhere, to lay down reserves for breeding, but again they must lay down considerable fat for migration and the extra weight of reserves for eggs might pose a serious problem for flight.

At least two migrants are known to arrive on the breeding ground with some reserves for laying. The females of high arctic geese, e.g. the Lesser Snow Goose *Anser caerulescens caerulescens*, arrive on their nesting areas weighing about 50% more than they do at the end of incubation; this excess is sufficient to provide nutrients for egg formation and to enable the birds to survive the laying and incubation periods with little feeding. The African Red-billed Quelea also lays down reserves before laying. In their case, the clutch is small and the birds migrate only relatively short distances just before laying; even then they appear to need favourable feeding conditions at the nesting site before they start to lay.

(3) Safety from predation. There are two ways in which the timing of breeding may affect the chance of success.

(i) Safety of nest site. A number of species are reported to defer nesting until such time as the nest-site becomes safe from predation. Certain arctic species, such as the Eider *Somateria mollissima*, may defer nesting until its island sites are no longer connected to the mainland by ice. Islands, especially small ones, tend to be free of mammalian predators, so that such a delay confers obvious advantages. Similarly, the Reed Warbler *Acrocephalus scirpaceus* starts to breed only when the new reeds begin to grow up; earlier the nests would be very conspicuous and vulnerable.

(ii) Synchrony. In some species laying is closely synchronized, while in others separate pairs may not be. Close synchrony may reduce predation. For example, both early and late eggs of the Wideawake Tern suffer heavier losses than those laid in the middle of the season; then the large numbers of eggs and young 'swamp' their predators and nesting losses are relatively low. Predation may also be the underlying reason for the extremely close synchrony shown by the Quelea, which nests in colonies of enormous size and fledges its young before the predators have managed to build up locally to any great extent.

All close synchrony within colonies may not be explicable in terms of predation. Within adjacent colonies of certain seabirds, such as the Kittiwake *Rissa tridactyla*, the birds are closely synchronized but the timing of laying between such colonies may vary markedly (this phenomenon is known as the Fraser Darling effect (Darling 1952)); such intra-colony synchrony is presumably an aspect of SOCIAL FACILITATION. But the ecological reasons, if any, are far from clear, especially since the birds from the different colonies presumably mingle at sea when they are searching for food, so that supplies for different colonies are not likely to show seasonal variations to parallel the differences in laying date between the colonies. It has also been suggested that within-colony synchrony may be advantageous for food-finding since individuals can learn from one another where the best food supplies are (see FLOCKING); such information sharing could, of course, be the cause or the function of synchrony.

Proximate factors. It is of extreme importance for birds to get the timing of their breeding season right. Accordingly, there will be strong natural selection for proximate factors which give the best measure of the coming season. Since the ecology of different species varies so much, it is not surprising that different 'timing devices', often referred to as *Zeitgeber* (time-givers), are used by different species.

Birds do not slavishly follow any single proximate cue, but show considerable plasticity in the timing of breeding. Many species modify the actual time of breeding by the use of more than one cue. For example, the Great Tit may be brought into breeding condition (at least as measured by the development of gonads) by experimental increase in the daylength. Nevertheless, it does not lay at a fixed time of year; in the wild its breeding season varies by a month between years. Much of the variation can be related to spring temperatures (Marshall 1949 and see below).

The main proximate factors which have been described for birds are as follows.

(1) Exogenous factors (environmental factors).

(i) Daylength. The importance of this factor was first described by W. Rowan. The length of day varies regularly and entirely predictably throughout the world in a way that no other factor does. Given that an animal can make some measure of the daylength (see RHYTHMS AND TIME MEASUREMENT), this is an ideal marker of the seasons. This statement is less true of areas close to the Equator where changes in daylength are very small; how or whether birds breeding in such places can use daylength as a cue is a matter of dispute. But the breeding seasons of some birds are exceptionally constant, strongly suggesting that they use some such cue. For example, the mean date of laying of the Slender-billed Shearwater *Puffinus tenuirostris* in Australia varied by only a little more than a single day during a period of 7 years.

(ii) Temperature. In certain species the date of laying each spring can be closely correlated with the temperature, laying starting earlier in a warm spring than a cold one. Such a correlation has been clearly demonstrated for the Great Tit. Although, in warm springs, the individuals will need less food for body maintenance and hence have the opportunity to use more food for egg-formation earlier than in a cold spring, it seems unlikely that this is the whole reason for the correlation observed. For example, both the Pied and Collared Flycatchers *Ficedula hypoleuca* and *F. collaris* show similar correlations to that in the Great Tit between laying dates and spring temperatures, but the birds concerned are migrants and absent from the breeding grounds for most of the period concerned. Variations in temperature probably have their effect on the birds indirectly through the food supply, since insects emerge earlier in warm springs than in cold ones.

(iii) Rainfall. Birds in deserts may be stimulated to breed by heavy rain, or by the appearance of green grass. Since rainfall in deserts may not always occur at a predictable time of the year, some response directly associated with the flush of food resulting from the rainfall is of obvious advantage. Certain species come into breeding condition very quickly after it has rained. In the case of the Quelea, the sight of green grass or even the rainfall itself may stimulate nest-building. The Black-faced Wood-swallow *Artamus cinereus* of central Australia starts courtship within minutes, and copulates within 2 hours of the first rains after a prolonged drought. Local observers even claim that the birds start nest-building behaviour if a cloud crosses the sky!

(iv) Food supply. In some species food supply is likely to affect the timing of laying. However, most evidence on this point is circumstantial and few experiments have been conducted. In an experiment in which Great Tits were fed liberal supplies of food, the birds bred about a week earlier than birds in the control area; in a similar experiment with the American Red-winged Blackbird *Agelaius phoeniceus* the laying date was advanced by more than 3 weeks. Food supply in an earlier part of the year may have an important influence on the breeding season. In the Kestrel oocytes developed much faster in well-fed than poorly-fed birds, suggesting that the nutritional state of birds in spring may affect their laying dates.

(v) Presence of mate. The presence of a mate may be an essential element triggering the onset of development of the reproductive organs. For example, in the Canary *Serinus canarius* the presence of a mate in a nearby cage, or even just its song, may be sufficient to cause the female to ovulate.

(2) Intrinsic factors.

(i) Internal rhythms. In addition to being able to use external cues, birds have an internal clock which gives them a strong indication of the time at which they should undertake certain aspects of their annual cycle, such as moult, migration and breeding (see RHYTHMS AND TIME MEASUREMENT).

Birds such as Willow Warbler *Phylloscopus trochilus*, Chaffinch *Fringilla coelebs* and Short-tailed Shearwater *Puffinus tenuirostris* kept under constant conditions in the laboratory will come into breeding condition at about the correct time each year (though on average a little earlier than wild birds would normally breed). Hence each individual bird (at least in these species) has an internal clock which, in conjunction with external cues, results in the bird breeding when it does.

(ii) Age of bird. In a large number of species, birds breeding for the first time tend to lay later than older birds. In some species there is a progressive advance in laying dates with increasing age over several years. The differences are usually small though in the Song Sparrow *Zonotrichia melodia* it may be as much as 2 weeks. In the Yellow-eyed Penguin *Megadyptes antipodes* 2-year-old birds had a mean laying date of 24th September, while 3-year-olds were on average over 2 days earlier.

Evolution and inheritance. It is of such critical advantage to birds to get their timing right that it is not suprising to find that it is under tight evolutionary control. Little work has been done on this subject, but the laying date must be fairly plastic. For example, the laying dates of most North Temperate species must be very recent attributes of these birds because of the ecological changes since the last Ice Age. Most habitats were undergoing great changes during a period from about 12,000 BC to 5,000 BC and the birds moving into these habitats must have been undergoing considerable changes also.

The great selective advantage of getting the timing of breeding right may mean that change can be fast enough to observe. The laying date of the Great Tit is an inherited characteristic demonstrating that timing of laying is a character susceptible to evolutionary change (van Noordwijk *et al* 1980). In Holland there is evidence for recent changes in laying dates of a number of species. In particular, the laying date of the Black-tailed Godwit *Limosa limosa* has changed by about 2 weeks during the last 50 years, probably in response to changes in farming practice where progressively earlier hay-cutting has selected increasingly against birds which lay late in the season. BRIDLING (1): a facial plumage marking that resembles a bridle, e.g. in the Bridled Tern *Sterna anaethetus*, in a 'morph' of the Guillemot (or Murre) *Uria aalge* (see POLYMORPHISM), and in some ducks Anatidae (see PLUMAGE).

BRIDLING (2): a behaviour term applied to a form of display in the Black Noddy *Anous tenuirostris* (see TERN).

BRILLIANT: substantive name of *Heliodoxa* spp. (for family see HUMMINGBIRD).

BRISTLE: a modified feather, consisting of a shaft with usually little or no vane and resembling a stiff hair (see FEATHER; PLUMAGE).

BRISTLE-BILL: used as a substantive name of *Bleda* spp., of tropical Africa (see BULBUL).

BRISTLE-BIRD: substantive name of *Dasyornis* spp., of Australia (see WREN (2)).

BRISTLE-FRONT: substantive name of 2 species of TAPACULO of the genus *Merulaxis*.

BRISTLEHEAD, BORNEAN: *Pityriasis gymnocephala* (Passeriformes, suborder Oscines), a bird of the lowland forests of Borneo, of uncertain affinities. About 25 cm long, it is a heavily built bird with a massive hooked bill. The top and sides of the head are devoid of normal feathers, the crown being covered with short straw-coloured bristles and the auricular region with dense blackish bristles. The rest of the head and neck are red, the feathers of the lower throat with blackish bristle-like tips. The rest of the plumage is dark slate-grey, except for red thighs and, in the female only, red spots on the flanks.

The Bristlehead is insectivorous and arboreal. It is known to utter harsh notes, considered corvine by some, and a high-pitched whining note, sometimes given in chorus with others. It is highly social, and regularly joins mixed-species foraging parties; its nesting is unknown.

Its systematic position has been debated. It has been variously placed with the shrikes (Laniidae), helmet-shrikes (Prionopidae), starlings (Sturnidae), or in a family of its own, Pityriasididae (Voous). Recent evidence from DNA–DNA hybridization indicates that it is most closely related to the Australian family Cracticidae (Ahlquist *et al* 1984).

Smythies, B.E. 1981. The Birds of Borneo (3rd edn.). Kuala Lumpur.

BRISTLE-TYRANT: substantive name of a group of tyrant-flycatchers of the genus *Pogonotriccus* (see FLYCATCHER (2)).

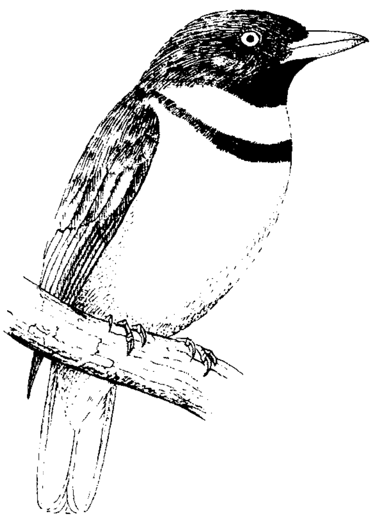
BROADBILL (1): substantive name of the species of Eurylaimidae (Passeriformes, suborder Deutero-Oscines, infraorder Eurylaimi); in the plural a term for the family.

Characteristics. Eight genera of small to medium, dumpy-shaped birds 12.7–28 cm long and in the weight range 20.5–160 g, with strong feet, rounded wings, short to graduated tail and, in most genera, a wide laterally inflated and colourful bill. Most have strikingly coloured plumage in which reds to pinks and greens and blues predominate, and black-and-light contrast-patterns are frequent. All except the monotypic *Cymbirhynchus*, *Psarisomus*, *Corydon* and *Pseudocalyptomena* are sexually dichromatic. The Philippine Broadbill *Eurylaimus steerii* has a sky-blue periocular wattle.

Electrophoretic analysis of egg-white proteins indicates a more direct relationship with cotingids and tyrannids than with pittas, from which broadbills also differ in the anatomy of the syrinx. Linked deep plantar tendons, hindering independent movement of the hallux, provide the only distinctive anatomical character not shared with some representative of these Neotropical families. Broadbill nests likewise resemble those of some cotingids.

The Sundaic green broadbills *Calyptomena* spp. have been reserved to a subfamily Calyptomeninae. A distinctive tuft of feathers covers the nostrils and in males most of the rest of the bill, which lacks lateral inflation. The gape is nevertheless relatively wider than in any eurylaimine species. Central African *Pseudocalyptomena* possesses calyptomenine colours and shape. It lacks a frontal tuft but is the only other broadbill with an uninflated bill and is probably closer to *Calyptomena* than to African eurylaimine broadbills. A gape-width/bill-length ratio places it neatly with this genus.

Distribution. Fourteen species are distributed across the humid Paleotropics from West Africa to the Philippines, 4–5 occurring together in lowland dipterocarp forest of the Sunda subregion. The family may be relict but for palaeoclimatic reasons a fossil occurrence in lower Miocene Europe is no particular evidence of later retreat before more advanced passerines. Most near competitors now are non-passerine.



Black and Yellow Broadbill *Eurylaimus ochromalus*. (*K.J.W.*).

Habitat. African *Smithornis capensis* and Asian *Cymbirhynchus* inhabit scrub and forest-edge thickets, *Cymbirhynchus* usually near water and to the landward edge of mangroves. Other broadbills are birds of the interior of inland forest, lowland or, as in *Pseudocalyptomena* and Bornean *Calyptomena whiteheadi*, exclusively montane. Several inhabit hill-slopes and *Psarisomus* retreats upward into montane moss-forest in the equatorial part of its range.

Movements. Presumed sedentary, except for *Calyptomena viridis* which wanders according to fruit supply. In Malaya it has twice been mist-netted with nocturnal migrants beyond its normal habitat and altitude range.

Food and feeding. The eurylaimine broadbills with inflated and decurved to hooked bills feed mainly on arthropods, especially large orthopterans. *Eurylaimus javanicus* is recorded taking a small lizard.

Most species forage at mid-levels of the forest profile though South-east Asian *Corydon* is strictly a canopy bird. Modes include flutter-snatching from the foliage, and searching along branches and on occasional trunks and trailing creepers (up which *Psarisomus* can climb). Many also snatch aerially for flying prey, and the 2 forest-edge species sometimes go to ground, *Cymbirhynchus* taking, besides insects, small aquatic organisms such as crabs and molluscs; even fish.

While some carnivores take occasional fruit, soft fruit and buds form most of the diet of *Calyptomena* species. *Pseudocalyptomena* also appears to eat a higher proportion of plant than animal material. Some of its behaviour has been interpreted as aerial insectivory, but *Calyptomena viridis* will also sometimes snatch flying termites. Both range widely over the forest profile.

Sluggish movements may keep broadbills from regularly joining mixed species gatherings.

Behaviour. Sundaic *Eurylaimus* species occur mainly alone or in pairs. Both members loudly advertise their position and are answered by neighbours, who remain spaced. *Cymbirhynchus*, *Smithornis* species and the calyptomenines are also usually solitary. *Calyptomena viridis* and *C. hosei* advertise their presence vocally and *viridis* pairs will repeatedly drive conspecifics off defensible fruit sources. At times they gather in small groups but, when not breeding, some other broadbills associate in considerable foraging flocks, of up to 20 in *Serilophus* and over 30 in *Psarisomus*. *Corydon*, the Dusky Broadbill, is the only species known to be permanently gregarious, in noisy groups of up to 10 individuals with a collective home range.

Voice. *Eurylaimus ochromalus* and *E. javanicus* utter an explosive, churring trill on a rising scale (preceded in *javanicus* by a sharp whistle). It is often uttered in response to thunder and neighbours invariably reply. No comparable call is recorded from the less known Philippine *E. steerii*. *Cymbirhynchus* gives a briefer but similar call, though rarely. Jerky, screaming whistles on a rising scale advertise the group position of *Corydon* and soft but carrying cooing rattles given by the green broadbills *Calyptomena viridis* and *hosei* probably also have a spacing function.

All broadbills otherwise produce whistling, popping or churring notes and a particular shrill dissyllable, possibly with short range contact function, is widely recognizable among eurylaimines: *twee-uu* in *Smithornis capensis*; *pree-u* or *wee-uk* in Sundaic *Eurylaimus* species; *wee-ark* in

Cymbirhynchus; *pee-u* in *Serilophus*; *pee-u* or *tsee-u* in *Corydon*; and *tseeay* in *Psarisomus*. *Smithornis* species also produce an apparently non-vocal throbbing croak, likened in *S. rufolateralis* to a klaxon horn, during short, circular flights on vibrating wings. In *S. capensis* it is audible at 60 m and could have territorial significance. The white back of males is exposed simultaneously. Some Asian broadbills have a whirring flight, notably *Eurylaimus steerii*, which also bill-snaps.

Breeding. All known broadbill nests are large, conspicuous pear-shaped bags with a porched entrance in the lower half, thickly built of fibre, twigs, tendrils, rootlets, leaves and grass, which hang below in a ragged beard. Several are lined internally with green leaves. They are decorated externally with cobweb, living creeper, lichen, green bryophytes or frass and slung via a long suspensor of nest-material from an inaccessible bough, liane, or the pendant tip of a bamboo or palm frond (commonly a rattan). Most are found in mid-profile positions typically over a clear space but *Calyptomena viridis*, whose nest is strapped over its support like that of a sunbird, rarely builds above 2 m from the ground. *Smithornis* species also tend to build low. *Cymbirhynchus* often uses an exposed snag isolated in water and may adopt service-wires through its habitat. All members of the *Corydon* group help to nest-build but kinship and subsequent co-operation have not been investigated (see CO-OPERATIVE BREEDING).

Broadbill eggs are white, cream or pinkish, speckled and spotted purple or reddish, sometimes sparsely, sometimes almost hiding the ground-colour. *Calyptomena* and *Smithornis* eggs are unmarked, respectively cream and white. Clutch-size varies with latitude. *Serilophus* and *Psarisomus* lay 4–5 and 4–8 eggs in the outer Himalayas, 2 and 3 in the Sunda Subregion. All Sundaic species have clutches of 2 or 3 and African *Smithornis* 1–3. *Eurylaimus ochromalus* fosters the cuckoo *Cuculus micropterus*. (C.W.M.-P.) D.R.W.

BROADBILL (2): substantive name sometimes used for some MONARCH FLYCATCHERS of the genus *Myiagra*.

BROAD-FRONT MIGRATION: see MIGRATION (under Flight performance).

BROKEN-WING TRICK: see DISTRACTION BEHAVIOUR.

BROLGA: *Grus rubicunda* the Australian CRANE.

BRONCHUS: see RESPIRATORY SYSTEM; and under SYRINX.

BRONZEWING: sometimes used alone as substantive name of various Australian 'bronzewing pigeons', in several genera (see PIGEON).

BROOD: collectively, the young hatched from a single clutch of eggs.

BROODING: sitting on the young, usually in the nest and mainly to keep them warm (although also as protection against hot sun, rain or predators) (see PARENTAL CARE); sometimes also used of sitting on eggs (see INCUBATION).

BROOD NEST: a resting place for young birds built by one or both of the parents. It may or may not be the nest in which the brood was hatched.

BROOD-PARASITISM: the exploitation by one species (the brood-parasite or nest-parasite) of the parental behaviour of another species (the host). Some bird species occasionally deposit their eggs in nests of other species, or other individuals of their own species. This quite often occurs in colonial breeders, but it is also recorded for solitary breeders with combinations such as Lapwing *Vanellus vanellus*/Ruff *Philomachus pugnax*, Kentish Plover *Charadrius alexandrinus*/Little Ringed Plover *C. dubius*, Bearded Tit *Panurus biarmicus*/Savi's Warbler *Locustella luscinioides*. In its usual sense, however, brood-parasitism refers to cases where birds lay their eggs regularly or normally in the nests of other birds, and these act as hosts by incubating the eggs and rearing the young. Brood-parasitism is not unique to birds, since parallels are found among many social insects and certain freshwater fishes. Among birds the Common Cuckoo *Cuculus canorus* and related species (see CUCKOO) are the exemplars, and insects such as bees, wasps and ants which foist their broods upon the care of others are often called cuckoo-bees, and so on.

Jay *Garrulus glandarius* female, with crest erected and abdominal feathers fluffed, about to brood her nestlings. (*Photo: P.O. Swanberg*).

Incidence of brood-parasitism. Brood-parasitism is relatively rare among birds, occurring in only about 1% of all bird species. The habit is developed to various degrees in unrelated groups. In the Anatidae, the Black-headed Duck *Heteronetta atricapilla* of South America lays in the nests of other ducks such as the Rosy-billed Pochard *Netta peposaca*, and also in the nests of coots and rails, ibises, herons, and even in the nest of a carrion-eating hawk (*Polyborus* sp., Falconidae). It may be a recent and almost accidental change of habits. This form of brood-parasitism involves no special adaptation to the host, since the parasitic duck eggs receive only protection and warmth from the host and the ducklings leave the nest and feed and care for themselves shortly after hatching. In this respect, it has a negligible effect on the breeding success of the host. Interspecific brood-parasitism also occurs in other ducks. For instance, Redheads *Aythya americana* lay eggs in the nests of other duck species, in particular of Canvasbacks *A. valisineria*. Similarly, Ruddy Ducks *Oxyura jamaicensis* parasitize nests of the Cinnamon Teal *Anas cyanoptera*, and the Palearctic Shelduck *Tadorna tadorna* regularly parasitizes the nests of Red-breasted Mergansers *Mergus serrator*. This kind of parasitism influences the breeding success of the host, because for both Canvasback and Cinnamon Teal the number of eggs found in parasitized nests is inversely related to the number of parasite's eggs. In the Shelduck the parasitic habit may be a very recent acquisition, since it is often deleterious to the parasite's ducklings. Merganser adults usually take their offspring to deeper water soon after hatching, where the Shelduck ducklings perish as they are not adapted to deep diving for food.

In the weavers (Ploceidae) and allies (Viduine finches, Estrildidae) several species, all African, are brood-parasites. The Parasitic Weaver or Cuckoo Finch *Anomalospiza imberbis* mainly parasitizes small warblers of the genera *Prinia* and *Cisticola* (see WEAVER). Often two parasite chicks are found in the same nest and the young of the host usually disappear. The whydahs and indigo-birds (*Vidua* spp., of uncertain systematic position but certainly related to the Ploceidae—see WHYDAH (1)), of which there are some 14 species, parasitize estrildid finches. This parasitism is host-specific; the young mimic their hosts in their begging calls and mouth colour and markings, and the adult parasites show song mimicry. The young parasites and hosts are usually reared together with little effect on the breeding success of the hosts.

In the Icteridae, a small group of species—the cowbirds (*Molothrus*, *Tangavius*, *Scaphidura*)—are brood-parasitic. *Molothrus* shows an interesting gradation in the elaboration of parasitic habits as one species is non-parasitic, the Bay-winged Cowbird *M. badius* of South America,

Crowned Willow Warbler *Phylloscopus coronatus* feeding young Oriental Cuckoo *Cuculus saturatus*. (*Photo: A. Knystautas, Y. Shibnev*).

which either appropriates occupied or abandoned nests of other species or, occasionally, builds a nest of its own (see ORIOLE (2)). The parasitic cowbirds are the most important brood-parasites of the New World; the Common Cowbird *M. ater* is extremely successful, parasitizing a wide range of passerines (more than 100 species). Cowbirds usually have little impact on the breeding success of the host species as parasite and host young are reared together. In the Giant Cowbird *Scaphidura oryzivora* a beneficial effect has been claimed, because the parasite young may reduce the mortality of the host young by removing botfly larvae from them (Smith 1980). The beneficial effect applies only to nests which are not placed near wasp or bee colonies. Botflies are deterred by the presence of wasps and bees; nests thus protected may suffer from parasitism by the Giant Cowbird, whose young outcompete the host young. Apparently as a consequence, hosts nesting near wasp or bee colonies reject cowbird eggs, whereas those nesting away from wasps and bees accept them (see NESTING ASSOCIATIONS).

Among the cuckoos (Cuculidae) the whole of one subfamily (Cuculinae) and some species in a second subfamily (Neomorphinae) are brood-parasitic. Altogether nearly half of the 130 species in the family are brood-parasites (see CUCKOO). Specializations connected with parasitism have reached a high level among cuckoos, and the habit is probably a very old one. Parasitic cuckoos reduce the breeding success of the host as usually only the young cuckoo survives. Nestlings of the genera *Cuculus*, *Cacomantis* and *Chrysococcyx* evict the host's eggs and young from the nest at a very early stage. They are structurally adapted to doing so, having a hollow back. In the Koel *Eudynamys scolopaceus* (and probably also *Scythops* spp.), which mainly parasitizes crows, the chicks do not show this morphological feature and they do not evict nest-mates. The parasite or parasites (since very often more than one egg is deposited in the same nest—up to 13 are recorded in one nest) are reared together with the host young. The chicks of *Clamator* spp. also do not have a hollow back and do not evict nest-mates, and often more than one egg is found in a host nest. As regards the Pied Crested Cuckoo *Clamator jacobinus*, in Africa 22% of parasitized nests of the bulbul *Pycnonotus capensis* contained more than one cuckoo egg, and for the same species in India, 39% of the nests of the babbler *Turdoides striatus* were parasitized. Often only the cuckoo nestling survives by monopolizing the food, but in some cases, especially when the cuckoo's egg is laid in a nest containing incubated eggs, thus giving the host nestlings a start, both the young cuckoo and some foster nestlings are successfully raised. In *C. jacobinus* (in India) and *C. levaillantii* (in Africa), which parasitize mainly babblers of the *Turdoides* group, the young of both host and parasite have the advantage of being fed by a group of adults, which reduces the chance of being under-nourished.

Lastly, there are the honeyguides (Indicatoridae), of which all whose breeding is known are brood-parasitic (see HONEYGUIDE). Further research will probably reveal that the remainder (including the Asian species) are brood-parasitic also, so that this may be the only bird family totally dedicated to the habit.

Restrictions on brood-parasitism. Various behavioural and structural adaptations have been evolved for the furtherance of brood-parasitism, but certain general conditions restrict the spread of the habit. It is not worthwhile to parasitize scarce species, or those whose nests are hard to find or enter. A parasite obviously cannot use host species which feed on entirely different food or are unable to bring enough to the nest. In some cases food dissimilarity is not detrimental, e.g. in the Black-headed Duck, because the duckling feeds itself; but most parasitic bird species are altricial. Most finches feed seeds to their young, therefore in such cases a young cuckoo fails to survive. Hence seed-eating cardueline finches are rarely parasitized, whereas emberizine finches, which feed insects to their young, are often parasitized. In the New World few carduelines are parasitized by cowbirds, although more than 100 species of fosterers are known and apparently some seed-eaters can rear a cowbird to fledging. Fruit-eaters among the passerines are generally avoided by cuckoos, except for some tropical and subtropical *Pycnonotus* species that feed insects to their young.

Territorial behaviour and mating system. A population of Common Cuckoos parasitizing Reed Warblers *Acrocephalus scirpaceus* in an area of about 150 ha in England was studied by Wyllie (1981). There were 6 female Cuckoos (as judged from egg-type) and at least 2 males. One female laid in almost identical sites and with the same hosts as a year previously. One female was apparently dominant and prevented the others so far as possible from laying in suitable nests in her territory. By the end of the season this dominant female had laid a minimum of 12 eggs, another female 6, a third 4, and three others 1 or 2 eggs each. There were 54 pairs of Reed Warblers and 136 of their nests were located, of which 25 (18%) were parasitized. The known outcome of 95 unparasitized nests revealed that 25 (26%) were deserted, 60 (63%) were robbed, and only 10 (11%) produced fledged young. Egg-stealing seems to be a common habit of cuckoos and apparently restricted to females, as shown by Löhrl (1979) in aviary experiments. He observed that one female swallowed 65 eggs in one breeding season. The eggs are swallowed whole and must be a substantial protein, lipid and calcium source in the diet of the female.

In the Amur region (USSR) it has been observed that at the height of the breeding season females of *Cuculus micropterus* are often accompanied by 1 or 2, sometimes 3, males, but only one male is believed to mate with the female. Similar behaviour has been observed in the sedentary race in Java, *C. micropterus concretus*. For a large number of cuckoos, especially in the tropics, nothing is known about the mating system; but at least in *Cuculus* and *Clamator* it seems that there must be a temporary pair-bond, as there is some co-operative strategy in egg-laying (see below).

In the honeyguide *Indicator xanthonotus* the males are polygynous. One marked male was observed to mate with 18 different marked females. Male Indigobirds *Vidua chalybeata* are also polygynous, sometimes mating with 3 or 4 females in a day. In both of these groups, the mating system resembles that of birds such as grouse or manakins in which males occupy fixed sites (LEKS) and display to females, which visit these places to mate. Also in cowbirds males may mate with one or more females.

In his pioneer work on Common Cuckoos parasitizing Meadow Pipits *Anthus pratensis*, Chance (1940) found no evidence of co-operation between male and female in egg-laying, but Wyllie (1981), studying cuckoos parasitizing Reed Warblers, observed that the male sometimes accompanies the female when egg-laying. This behaviour probably serves to lure the fosterer away from the nest. For the African Cuckoo *Cuculus gularis*, it was observed that the male (perhaps because of his hawk-like appearance) attracted the attention of drongos *Dicrurus adsimilis* and lured them away from the nest (drongos are particularly aggressive birds), while the female approached the nest silently and inconspicuously. Pairs of *Clamator jacobinus* in southern Africa work in close co-ordination when an egg is to be laid and the male, by provocative behaviour, deliberately draws the attention of the hosts to himself. Similar behaviour can be inferred from observations of *Clamator jacobinus* in India parasitizing nests of the babbler *Turdoides striatus*. A pair of Great Spotted Cuckoos *C. glandarius* were kept in an aviary together with a pair of Rollers *Coracias garrulus*; the male cuckoo normally showed no special interest in the rollers but, as soon as the female was ready to lay, he diverted the rollers' attention by persistently chasing them round the cage and so making it possible for the female to slip into the rollers' nest-hole. Similarly for some honeyguide species, there may be a struggle lasting a day or more before the male can lure the hosts away so that the female can get into the nest-hole.

Host selection. Other things being equal, it should be easier for a brood-parasite to exploit related species, because their incubation and fledging periods, the food requirements of the young etc., should be similar. This is the case for the viduine finches, which parasitize species of Estrildidae. Their hosts feed their young almost exclusively on grass seeds, and this is apparently a suitable diet for young viduines as they have been reared successfully in captivity on a seed diet. Exploitation of closely related species is not, however, the rule for other nest-parasites. Cowbirds may parasitize the non-parasitic cowbird *Molothrus badius*, but more regularly parasitize other passerines. The honeyguides predominantly parasitize woodpeckers, barbets and bee-eaters. This is of particular significance, because all of these, and honeyguides, have much longer fledging periods than most birds of their size.

The cuckoos, which parasitize passerines, are taxonomically the most remote from their hosts. In this group, which has a wide size range, the size of the parasite's egg is adapted to that of the host. For example the Common Cuckoo and Himalayan Cuckoo *Cuculus saturatus*, which parasitize relatively small passerines, lay relatively small eggs (2.8–3.2% of body weight), whereas in the Little Cuckoo *C. poliocephalus*, the Drongo-cuckoo *Surniculus lugubris*, and the Fan-tailed Cuckoo *Cacomantis variolosus*, which have relatively large host species, the relative egg weight is rather high (7.0–7.3%) (Becking 1975).

Host-nest selection is made solely by the female cuckoo, usually by watching from a vantage point or by intensive searching for nests in the process of construction or before the host eggs are laid. Observation of the host's nest-building activities probably controls the time of ovulation of the cuckoo egg. The egg may be retained in the oviduct for a day, so that when laid it is one day ahead in development compared with a fresh host egg. In some cuckoo species (e.g. *C. canorus*) birds of open woodland are parasitized more often than birds of dense forest or birds in treeless grasslands, perhaps because the female cuckoo can find nests more easily when perched on an observation point in the open. But some other species, such as *Cuculus saturatus*, *C. fugax* and *C. sparverioides*, are primary forest birds cuckolding forest species.

Sympatric cuckoo species usually parasitize different fosterers, but there are exceptions. In India some hosts are shared by 2 or more cuckoos, and 6 cuckoo species parasitize one Australian host. A honeyguide and a cuckoo parasitize *Spreo bicolor* in South Africa. Some cuckoos have a rather broad host range, e.g. the Common Cuckoo and Fan-tailed Cuckoo, whereas others have a very narrow host range and even species-specific host relations; for instance the Himalayan Cuckoo parasitizes small *Phylloscopus* and *Seicercus* warblers (but recently with another egg colour also found with *Cettia* (Higuchi and Sato 1984)) and the Little Cuckoo selects mainly *Cettia* warblers, and *Chrysococcyx malayanus* only the gnateater *Gerygone sulphurea*. Relationships may vary locally; for instance the sedentary race of *Cuculus micropterus* in Java parasitizes drongos and the same host is reported for India, but it parasitizes mainly shrikes in the Amur region of the USSR and Azure-winged Magpies *Cyanopica cyana* in northern China.

Egg-laying. The egg must be laid quickly to avoid unduly disturbing the host. From Chance's observations on Cuckoos parasitizing Meadow Pipits it was evident that individual females laid at two-day intervals, usually in the afternoon. When visiting a nest to lay, the females spent not more than a minute in its immediate vicinity and on average only about 9 seconds depositing the egg. All eggs were laid directly in the nest. At a Reed Warbler's nest Wyllie (1981) saw a female Cuckoo scramble through the reeds, remove the Reed Warbler's single egg and lay her own directly in the host's nest, the whole operation taking only 11 seconds. With regard to the Pied Crested Cuckoo parasitizing the Jungle Babbler, Gaston (1976) observed that a female cuckoo perched about 5 seconds *c.* 15 cm above the babbler's nest and this was sufficient for her to drop an egg into the nest. On examination it was found that one babbler egg had a circular depression on the upper side, probably caused by the impact of the cuckoo egg falling on it. In babblers' nests containing cuckoo eggs, damaged or 'slightly dented' babbler eggs were often found.

Cuckoo eggs are laid on alternate days, and each egg is probably held for a day in the oviduct, so that the embryo develops for a day before the egg is laid. This was originally observed in the Jacobin (or Pied Crested) Cuckoo (R. Liversidge), but holds also for the Common Cuckoo in Europe, as Cuckoo eggs 1–2 days incubated have been found in host nests containing incomplete clutches which have not been incubated (C.M. Perrins). Some other cuckoo species lay at intervals of 2 or 3 days, and it is not known whether their eggs are likewise developed at laying time.

The number of eggs laid in a season in a particular area by one female Cuckoo was determined by differences in colour pattern and size and estimated to be at least 12 (Wyllie); others have reported smaller numbers. In field experiments in which the host nests were collected as soon as the Cuckoo egg was laid, causing the host to nest again and to be parasitized repeatedly, individual Cuckoos laid 18–25 eggs in one season. Examination of the ovaries of several species of African cuckoos has shown that these lay *c.* 16–25 eggs in a season. The cuckoos ovulate on alternate days, and 3–6 eggs make up a series or 'clutch'.

The number of eggs laid in a season by cowbirds *Molothrus ater*, estimated by searching for parasitized nests, ranges from 7–25. Captive cowbirds lay more eggs in a series than is known for cuckoos; H. Friedmann reported a female laying 13 eggs in 14 days in nests with candy eggs. However, ovary histories of wild females show that they normally lay in series of 2–5 eggs.

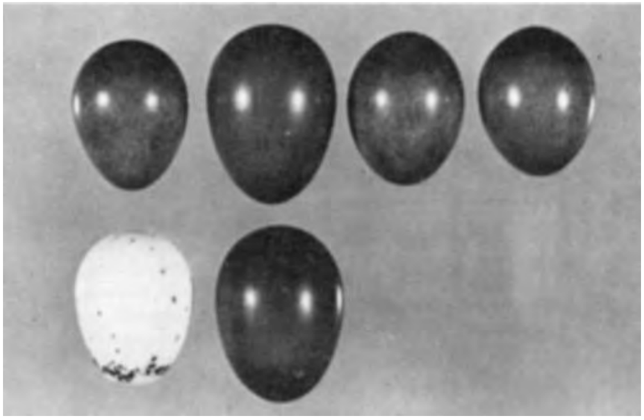
If the parasites do not find enough fosterers in a certain area, they may dump their eggs in old and deserted nests. This has been regularly observed in the Common Cuckoo, also for *Cacomantis* species (*C. variolosus* and *C. merulinus*), *Clamator jacobinus*, and even for the parasitic duck *Heteronetta atricapilla*.

Multiple laying, i.e. 2 or more parasite eggs in the same nest, has been recorded occasionally for *Cuculus*, *Cacomantis* and *Chrysococcyx* species. It is, however, far more common in *Clamator* and *Eudynamis*. In the Koel 3 eggs in the same nest are regular, 7–9 have sometimes been found, and once 13.

Egg mimicry. One of the most striking adaptations for brood-parasitism, found only in the cuckoos, is the matching of egg colour and pattern to the eggs of the host. Close matching increases the likelihood of the alien egg being accepted by the host. Classic (Leverkühn 1891) and more recent work on the introduction of alien eggs into the nests of passerines showed frequent rejection of the alien egg or desertion of the nest. Some hosts are rather discriminating, others not so. Among the most undiscriminating are some South African bulbuls (*Pycnonotus* spp.) which appear never to reject either natural or experimental parasitism by the Pied Crested Cuckoo, whose large plain white eggs are very unlike the red, heavily spotted bulbul eggs. At the other extreme the Common Iora *Aegithina tiphia* often deserts its nest if parasitized by the Banded Bay Cuckoo *Cacomantis sonneratii*. Here the egg shows such a high degree of adaptation that it can be distinguished only by microscopical examination of the eggshell surface (see EGGSHELL, ULTRASTRUCTURE OF). Cuckoo eggs are adapted to certain hosts and, among European passerines, rejection of Cuckoo eggs seems to be most pronounced among species that are only infrequently parasitized.

Some cuckoos show mimetic egg polymorphism, with egg-races or 'gentes' adapted to particular hosts. The best example is the Eurasian Common Cuckoo, which produces two main types of eggs, one spotted and the other immaculate, plain blue. The plain blue egg-type is rather common in northern and central Europe and is adapted to the Redstart *Phoenicurus phoenicurus*, chats *Saxicola* spp., and the Dunnock *Prunella modularis* (in Britain, however, this egg-type is unknown although Dunnocks are frequently parasitized, usually successfully). The spotted egg-type is variable, with different varieties adapted to pipits *Anthus* spp., wagtails *Motacilla* spp., shrikes *Lanius* spp., and Robins *Erithacus rubecula*. Another example is the South-east Asian Plaintive Cuckoo *Cacomantis merulinus*, which has a white, red-spotted egg-type matching the eggs of tailorbirds *Orthotomus* spp. and a uniform brick-red or chestnut egg-type matching the eggs of the Ashy Wren-warbler *Prinia socialis* in India or the Yellow-bellied Wren-warbler *P. flaviventris* in Java. Only very rarely are these egg-types found in a nest of the wrong host. Similarly the Koel lays a green egg-type mimicking the eggs of crows, the main fosterers in the western part of its range, and a red egg-type associated with magpie-larks, honeyeaters and orioles in Australia. Sometimes there is some ecological separation between birds laying eggs of different types. For instances, in Hyderabad City in India the Plaintive Cuckoo habitually parasitizes the locally abundant Ashy Wren-warbler (brick-red egg-type), but in the surrounding country its principal host is the Indian Tailorbird *Orthotomus sutorius* (white, brown-spotted egg-type). In Java the situation is reversed: in open scrub country it parasitizes *Prinia flaviventris*, and in villages *Orthotomus* spp.

A main problem is to explain why the egg mimicry and polymorphism do not break down in areas where more than one kind of egg-type occurs. Cuckoos laying different egg-types show no difference in voice or behaviour and live in mixed populations. It has been suggested that egg mimicry is maintained by a sex-linked gene complex on the W chromosome in the heterogametic female sex. A female would thus transmit to all her daughters the same gene complex determining egg colour that she herself has. The daughters, as a result of IMPRINTING on the foster-parent



Red egg-morph of Plaintive Cuckoo *Cacomantis merulinus*; *Above*: with eggs of Yellow-bellied Wren Warbler *Prinia flaviventris*, showing egg mimicry; *Below*: with egg of Ashy Tailorbird *Orthotomus ruficeps* (actual size). (*Photo: J.H. Becking*).

species in whose nests they hatch, would then continue to lay host-matching eggs in nests of the same species. Occasional deviations from this pattern could be explained by (1) chromosomal crossing-over (or translocation) between Z and W (see GENETICS for terminology of avian sex chromosomes); (2) breakdown of imprinting; or (3) lack of proper host nests, and other accidental situations.

Structural egg adaptations. Cuckoo eggs also show structural specializations. They tend to have thicker calcified shells than passerine eggs. For instance, *Cuculus canorus* has an eggshell thickness of 85–90 μm compared to its fosterers' 50–54 μm. This is also evident from the so-called Rey's index (egg length × width in mm, divided by eggshell weight in mg), which is 1.5–1.6 for cuckoo eggs and 2.0–2.5 for fosterers' eggs. Eggshell thickness reaches an extreme in the eggs of *Clamator* species, which are dropped from some distance into the open cup-shaped nests of the host. In *C. coromandus* the calcified shell measures 200–204 μm and in *C. jacobinus* 140–160 μm, whereas their fosterers, *Garrulax* and *Turdoides* spp., have eggshells with a thickness of 103 and 101 μm, respectively. Moreover, cuckoo eggs gain extra strength from their shape. The eggs of *Clamator* species are nearly spherical, as is evident from their shape index (egg length : maximal width) of 1.17–1.28. The eggs of other cuckoos, e.g. *Cuculus* and *Cacomantis* spp., are characterised by very rounded ends, much rounder than those of their hosts. Finally, cuckoo eggs are adapted to adverse circumstances by their rather special pore structure, showing pores with plugs of organic matter (see EGGSHELL, ULTRASTRUCTURE OF). This is presumably an adaptation against water loss, as the eggs are liable to lie for some time unattended in host nests.

Adaptations of young. Brood-parasites usually develop faster than their hosts, and early hatching gives them a head start on the host young in the nest. Incubation periods of parasitic cuckoos are usually 11–14 days, often 2–4 days shorter than their hosts. The honeyguide *Indicator minor* has an incubation period of 12 days, which is short compared to its barbet hosts. The cowbird *Molothrus ater* hatches in 11–13 days, often a day or two before its hosts. The finch *Vidua chalybeata* hatches in 10–11 days, usually 1–3 days before its host.

Nestling periods of cuckoos which evict nest-mates are relatively long, for instance 20–21 days in *Cuculus* and *Chrysococcyx*. Cuckoos which are reared with nest-mates have growth rates and nestling periods like those of their hosts, e.g. 11–15 days in *Clamator jacobinus*. Nestling periods of non-parasitic cuckoos range from 15–20 days for large terrestrial species (*Geococcyx* and *Centropus*) to 6–10 days for smaller arboreal or terrestrial ones (*Coccyzus* and *Crotophaga*). Both parasitic and non-parasitic cuckoos fledge upon reaching 50–60% of adult body weight.

Young cuckoos of the genera *Cuculus*, *Cacomantis* and *Chrysococcyx* kill their nest-mates. Upon hatching they manoeuvre an egg or nestling onto their concave back, then rear back to the rim of the nest until the egg or young bird drops over the edge. In Australia the Koel, parasitizing Magpie Larks *Grallina cyanoleuca*, is reported to evict the host nestlings, but this behaviour has never been observed in other populations of the Koel or in *Clamator* species. Young honeyguides (*Indicator* spp.) have sharp hooked bills at hatching, and kill their nest-mates by biting and stabbing.

Parasitic cuckoos which evict nest-mates are born naked and usually differ form their nest-mates by a darker slate-black skin (mainly dull brown in the host young) and a huge mouth with an orange-red palate and gape. The mouth of the young cuckoo and its persistent screaming, begging calls probably function as a 'feeding releaser' eliciting prolonged feeding by the foster parents. When handled, young cuckoos often produce a hissing sound and, with their gaping response and jerking movements, have a snake-like appearance which may deter potential predators. Some (e.g. *Clamator levaillantii*) evacuate a vile-smelling brown fluid from the cloaca as a defence mechanism.

In nest-parasites which are reared together with their nest-mates there is a tendency to mimic the host's young, both in appearance and in their calls. Morphological differences between nestling cuckoos of the genera *Clamator* and *Eudynamis* and their hosts' young are slight. Viduine young differ only slightly from their estrildid hosts, and in particular their mouth colour and markings closely match those of their nest-mates. Nestling cowbirds resemble the young of some of the species in whose nests they are raised. Vocal mimicry has been reported in nestlings of the Great Spotted Cuckoo parasitizing the Pied Crow *Corvus albus*, and the nestling Striped Cuckoo mimics the call of the chicks of its principal fosterer, the Arrow-marked Babbler *Turdoides jardineii*. Vocal mimicry has also been reported in the young of one parasitic species which kills its nest-mates, the Greater Honeyguide parasitizing the Red-throated Bee-eater *Merops bulocki*. BROOD-PATCH: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; INCUBATION.

BROOD REDUCTION: a process of selective feeding of the largest members of a brood when food is short, so that only a few large but relatively well-nourished young fledge. Were food to be shared evenly amongst the brood none would be adequately fed and all might die. When food is plentiful, however, the full brood can be fed and reared successfully, so the parents are then more productive than they would have been starting with a smaller clutch. The phenomenon is most frequent amongst (both aerial and marine) plankton-feeders and amongst birds of prey. In the latter group fighting between siblings (so-called 'CAIN AND ABEL strife') is frequently observed. An initial size gradient within the brood is usually brought about by differences in egg size and by starting incubation before laying is complete.

BROWNBUL: used as a substantive name for some African species of Pycnonotidae (see BULBUL).

BRUBRU: *Nilaus afer* (see SHRIKE)—to be distinguished from BOUBOU.

BRUSH-BIRD: earlier substantive name of *Atrichornis* spp. (see SCRUB-BIRD).

BRUSH-FINCH: substantive name of *Atlapetes* spp., of the Neotropical Region (see BUNTING).

BRUSH-RUNNER: substantive name of the South American furnariid *Coryphistera alaudina* (see OVENBIRD (1)).

BRUSH-TURKEY: name used in Australia for *Alectura lathami*; in the plural, serves as a general term for this and allied genera (see MEGAPODE).

BUBALORNITHINAE: see WEAVER.

BUCCAL: pertaining to the mouth (buccal cavity)—see TONGUE.

BUCCONIDAE: see under PICIFORMES; PUFFBIRD.

BUCEROTES; BUCEROTIDAE: see CORACIIFORMES; HORNBILL.

BUCORACINAE: see HORNBILL.

BUDGERIGAR: *Melopsittacus undulatus*; also 'betcheryygah' and other transliterations of the aboriginal name (see AVICULTURE; PARROT).

BUFFALO-WEAVER: see WEAVER.

BUFFLEHEAD: *Bucephala albeola* (see DUCK).

BULBUL: substantive name of most species of Pycnonotidae (Passeriformes, suborder Oscines), in the plural general term for the family. Other substantive names used are greenbul (several genera), brownbul, leaflove and bristlebill. The bulbuls are an Old World and largely tropical group of birds of moderate size varying in length from 13–23 cm.

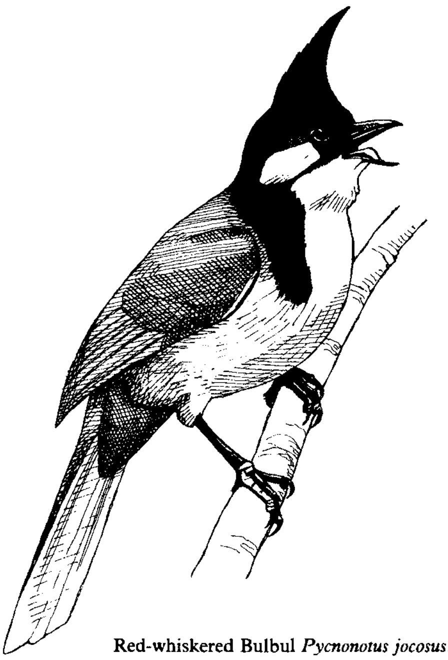
Virtually all authors have stated or implied a relationship between bulbuls and cuckoo-shrikes Campephagidae but the egg-white protein evidence does not support this. Rather the evidence suggests a relationship to the Dicruridae and possibly with the Sturnidae and Oriolidae. Over 120 species in 15 genera have been recognized. Of these, 10 genera (about 50 species) are confined to Africa and Madagascar (or to one or other), 2 (*Spizixos*, *Setornis*) are confined to southern Asia, 2 (*Pycnonotus*, *Criniger*) are found in both Africa and Asia, and *Hypsipetes* extends from Madagascar and the Mascarene Islands to eastern Asia. Hall and Moreau (1970) placed 8 species of *Pycnonotus* (some from Africa and Asia) into a superspecies and some Asian species in *Criniger* have been considered to be conspecific with certain African species.

Characteristics. Bulbuls have rather short concave wings and comparatively long tails (12 feathers) that are graduated in some species (e.g. in *Thescelocichla*), but more often either square (e.g. in *Baeopogon*) or rounded. Their bills are never large, but slender (except those in the genus *Spizixos*), notched, and usually have well developed, stiff rictal bristles near the gape. The nostrils are long or oval, more or less operculated. The tarsi and toes are always rather weak, usually small and often very short. In *Bleda* the middle and outer toe are fused to the first joint. The body feathers are long, soft and fluffy, particularly on the lower back. On the nape of some species (e.g. in *Criniger*) are long hair-like feathers which fall on to the mantle. Some bulbuls are noted for their well developed crests.

Bulbuls are not brightly coloured. Some have yellow underparts but the majority have dull colours such as olive green, brown and grey. The upperparts are usually uniform in colour, but in several species the tail is coloured rust-red or reddish brown in marked contrast to the rest of the upper parts. Any bright colours (crimson, yellow, rufous) are confined either to the throat, undertail coverts or to streaks on the head or ear coverts. The sexes are alike in colour and size and the immatures are very similar to adults and unspotted.

Field characteristics, habitat and distribution. The majority of bulbuls are found in forests of one type or other which offer a diversity of habitat allowing wide sympatry. No less than 35 of the 50 or so African species occur either in the lowland forest block of Zaire or in the montane forests of eastern Zaire. In the lowland forests of north-east Gabon 22 species occur (Brosset 1971). Other bulbuls inhabit sparsely wooded areas and quite a number, particularly in *Pycnonotus*, are found in cultivations and gardens in towns and villages.

The most widely distributed and common species in Africa is the African Bulbul *Pycnonotus barbatus*. It has numerous races and is closely related to several Asian species. They are all dusky coloured with bright under tail coverts, and inhabit open country and cultivations avoiding true forest although not the forest edge. One of these, the Red-whiskered Bulbul *Pycnonotus jocosus*, has been successfully introduced to Fiji, Australia (Sydney and Melbourne, since the 1880s) and Florida (Miami, since 1960).



Red-whiskered Bulbul *Pycnonotus jocosus*. (*N.W.C.*).

The Striated Bulbul *Pycnonotus striatus*, a common montane forest species from Nepal to Burma, is olive but its upper and underparts are striped with white. In the same area is found the Finch-billed Bulbul *Spizixos canifrons* which has a short thick finch-like bill distinctively coloured pale yellow, looking almost white in the field. It is also unusual in having a forward pointing crest. The other member of the genus is found in eastern and central parts of China and on Taiwan.

Five species in *Hypsipetes*, usually regarded as a superspecies, occur on islands in the Indian Ocean. One of these, the Black Bulbul *Hypsipetes (Microscelis) madagascariensis*, also occurs in Asia. There are numerous black, black and white, and grey forms which all have a bright red bill, legs and feet as do other species in *Hypsipetes*. A close relative, the Brown-eared Bulbul *H. amaurotis*, inhabits islands and coasts of eastern Asia from the Philippines to Hokkaido.

The Asian species (5) in *Criniger* show a wide variation in colour, pattern, and size and shape of tail, but all have a conspicuously coloured throat. The African members (4 species) are a much more uniform group. They all inhabit forests, are often crested, and coloured either olive, yellow or brown. Some are found as high as 1,500–3,000 m.

Movements. The majority of forest bulbuls are suspected to be sedentary but some are nomadic. Ringing studies in Gabon and in Asia have shown that both the Green-tailed Bristle-bill *Bleda eximia* and the Large Olive Bulbul *Pycnonotus plumosus* are remarkably sedentary (Brosset 1981a, McClure 1974). Brosset also showed, in contrast, that the Yellow-whiskered Bulbul *Andropadus latirostris* was nomadic. Ringing studies have shown that the Brown-eared Bulbul migrates within the Japanese islands and some forms of the Black Bulbul migrate to winter in considerable numbers in north-east Burma.

Food. Small fruits and berries form the bulk of the food of many bulbuls (e.g. the African species in *Andropadus*, *Thescelocichla*, *Chlorocichla* and *Ixonotus*). Some feed on buds and the nectar of flowers and several genera are strictly insectivorous (e.g. *Bleda*, *Criniger*, *Phyllastrephus*, *Baeopogon*, *Nicator* in Africa). Insectivores usually search the foliage for their food but may catch flying insects in the manner of flycatchers (e.g. Finch-billed Bulbul). In the Gabon Brosset (1981b) found the Yellow-whiskered Bulbul omnivorous, although fruits were its staple diet, and feeding at all levels of the vegetation. In contrast, the sympatric Green-tailed Bristle-bill was a specialized insectivore only feeding in a narrow horizontal layer of the forest vegetation.

Behaviour. Forest bulbuls are characteristically secretive and skulking whereas those found in gardens and parklands are much more bold and conspicuous. Many species are gregarious and noisy, especially when feeding, but are territorial in the breeding season. Recent studies have revealed interesting exceptions and there may be others. In the Gabon, Brosset (1981c) found that the Green-tailed Bristle-bill lived in family units made up of a pair and yearlings of the previous breeding season. These family units associated daily with mixed parties of insectivorous birds. He found that they had two periods of feeding activity during the day, were long lived (often for more than 10 years) and that their populations were stable. In marked contrast the sympatric Yellow-whiskered Bulbul, an apparent aberrant case, was solitary outside the breeding season and gregarious during the breeding season when males formed leks (see LEK), the females alone brooding and feeding young. There was no defended territory even by the breeding females which often occupied nests close to each other. The life expectancy of this bulbul was small and the population showed considerable fluctuations during the 10 year period of the study. Feeding at fruiting trees took place several times throughout the day.

In at least 2 African species (the Spotted Greenbul *Ixonotus guttatus* and the White-tailed Greenbul *Thescelocichla leucopleura*) several helpers contribute to the nest construction and/or feeding of nestlings.

Voice. The chances that a chattering noise, throaty babbling or melodious whistle heard in the tropical forests is due to a bulbul are high. Although these calls are very varied they are an important means of field identification, although initially difficult to learn. Apart from calls several bulbuls have extremely beautiful songs which are rich in quality and powerful, for example in Africa the West African Nicator *Nicator chloris* and in Borneo the Yellow-crowned Bulbul *Pycnonotus zeylanicus*. Brosset found males of the Yellow-whiskered Bulbul singing only at leks during their restricted mating season.

Breeding. Brosset studied the breeding of 11 species of bulbul from 8 genera and found that their nests were not concealed but rather placed in open situations at heights less than 6 m above ground. Bulbul nests are not substantial structures and their loose texture allows the tropical rains to drain quickly through them. They are cup shaped, made of twigs, stems and dead leaves and lined with grasses and fungi (*Marasmius*), the mycelium of which serves to consolidate the structure. Some species of *Hypsipetes* place their nests 8–15 m above the ground.

Most species of bulbuls have a clutch size of 2 but it is 3 for the Yellow-whiskered Bulbul and 1 for the West African Nicator. Some Asian species have clutches of 4 or 5. The ground colour of the eggs ranges from white, pinkish white or cream coloured, to brown or green. They are heavily marked and blotched with various shades of brown, dark olive and purple. Incubation for those species studied is in the range 12–14 days and nestling period 13–14 days but 11 or 12 days in the Lesser Icterine Greenbul *Phyllastrephus icterinus*.

White-cheeked Bulbul *Pycnonotus leucogenys*. (*M.W.*).

The breeding seasons of some bulbuls are restricted to a short period (e.g. Yellow-whiskered Bulbul) during which clutches that fail are quickly replaced and fledged young are quickly abandoned. In some years Brosset found that the Yellow-whiskered Bulbul did not breed. Other species of bulbul (e.g. Green-tailed Bristle-bill) have a prolonged breeding season, do not replace clutches that are lost, and family units stay together for several months. A.I.I. and L.G.G.

BULLA: see SYRINX.

BULLFINCH: substantive name of *Pyrrhula* spp. used without qualification, in Britain, for *P. pyrrhula*; applied in the West Indies to species of *Loxigilla* and *Melopyrrha* (see FINCH; AVICULTURE).

BUNTING: substantive name of Old World species of Emberizinae, a subfamily of the Emberizidae (Passeriformes, suborder Oscines); in the plural, general term for the subfamily. In North America, most of these birds have the substantive name 'sparrow' or 'finch', the name bunting being used mainly for brightly coloured species of the subfamily Cardinalinae (see CARDINAL-GROSBEAK).

Systematic characteristics. The Emberizinae are frequently grouped together with the Carduelinae (see FINCH) into a single expanded family Fringillidae. The cardueline finches, however, are clearly of Old World origin, whereas the Emberizinae are a New World group that has spread via one or a few colonizations to the Old World where adaptive radiation has proceeded almost entirely within the confines of the single genus *Emberiza*; the 3 other Old World genera, *Miliaria*, *Melophus* and *Latoucheornis*, are all monotypic. Two further genera, *Calcarius* (the longspurs) and the monotypic *Plectrophenax*, are circumpolar and, properly speaking, not typical elements of either the New or Old World avifauna. The situation among the New World Emberizinae is far more complex, and despite the modern tendency towards the recognition of broadened genera within the subfamily, as many as 60 genera can reasonably be distinguished on present evidence. Of these, 4 genera restricted to the Galapagos Archipelago and Cocos Island are treated in a separate article (see DARWIN'S FINCHES), and many other Neotropical genera have been little studied and are only uncertainly placed within the Emberizinae.

The buntings of the Old World form a group which is clearly distinct from ecologically similar, sympatric species such as finches (Fringillidae), sparrows (Passeridae) and weaverbirds (Ploceidae). They number 42 species: the circumpolar Snow Bunting *Plectrophenax nivalis* and Lapland Longspur *Calcarius lapponicus*, the typical buntings *Emberiza* spp., the Corn Bunting *Miliaria calandra*, the Crested Bunting *Melophus lathami* and, finally, the rare and enigmatic *Latoucheornis siemsseni* from China. The large genus *Emberiza* is best represented in the Palearctic Region, which has 28 breeding species; an additional one, the House Bunting *E. striolata*, is shared by the Palearctic and Afro-tropical Regions, and the other 8 are Afro-tropical. The most familiar is probably the Yellowhammer *E. citrinella*, which inhabits western Eurasia to Iran and central Siberia. The Corn Bunting is a Palearctic species closely allied to the genus *Emberiza*, but is differentiated on account of its large size, bill structure, moult pattern (complete post-juvenile) and certain aspects of its behaviour. The Crested Bunting inhabits northern India and the Indo-Chinese countries, and is the only member of the subfamily in tropical and subtropical Asia. The male differs from all other buntings by having a long, pointed crest, and also has an unusual plumage for a bunting, being glossy blue-black, unstreaked and unspotted, with chestnut wings and tail; the female is streaked, however, has no crest, and resembles many other buntings.

The systematic position of some New World groups is so uncertain that it is very difficult to compare the Emberizinae of the Old World with those of the New, but the species are certainly far more numerous and diverse in the Western Hemisphere. Most closely related and physically similar to the Old World forms are principally Nearctic genera such as the juncos *Junco* spp. and the many streaky-brown plumaged sparrows of *Zonotrichia* and *Ammodramus*. Three species in *Zonotrichia* deserve special mention: firstly, the Song Sparrow *Z. melodia*, whose life history and behaviour were the subject of the seminal field study conducted by Mrs M.M. Nice in the late 1920s and 1930s, and whose population biology has since been studied both widely and in great detail; secondly, the White-crowned Sparrow *Z. leucophrys*, which has been a key species for studies focusing on the physiological ecology of birds; and thirdly, the Rufous-collared Sparrow *Z. capensis*, which is found over a huge geographical range from Mexico southwards, and which is possibly the best-studied of any predominantly Neotropical emberizine. The largest and most colourful emberizines of the New World are the ground-feeding towhees *Pipilo* spp., and among the smallest are the tiny grassquits *Tiaris* spp. which can frequently be seen clinging to seeding grass-stems along the roadsides of Caribbean islands. One of the most numerous genera in terms of species is *Altapetes*, the stout and predominantly olivaceous brush-finches which, as their name indicates, inhabit brushy areas from Mexico south to the Guianas and Brazil in the east, and to Peru, Bolivia, and north-western Argentina in the west.

Characteristics. In physical characteristics the emberizines are rather homogeneous, being small birds with legs of medium length and big feet equipped for scratching. Their size averages about 15 cm, but some species are a good deal smaller and others attain around 20 cm. Some are attractively coloured and patterned but the plumage is rarely brilliant, being brownish, greyish or olivaceous as a rule, streaked or disruptive in pattern, and sometimes including various combinations of other colours. Certain species have a short crest, the Crested Bunting alone has a long, pointed one. The tail is fairly long in many species, sometimes graduated or slightly forked. The wing, which has 9 obvious primaries (although a vestigial and hidden 10th, outer primary may be present), is long and pointed in most migratory species, rounded and short in most sedentary species. The bill is short, or relatively so, conical and attenuated, and some typical *Emberiza* spp. are provided with a hump in the roof of the mouth for crushing seeds. In the Reed Bunting *E. schoeniclus* the shape of the bill varies geographically to a remarkable extent, from very small, slight and attenuated to globular, massive and parrot-like in shape, these variations being correlated to the type of reed bed that the bird inhabits. Among small, omnivorous passerines, larger beak size is frequently held to be correlated with the inclusion of larger and/or harder seeds in the diet, but in the case of the Reed Bunting it is the smaller-beaked races that feed on seeds in winter whereas the larger-beaked forms subsist at this time on insect prey which they obtain by crushing reed stems.

Habitat, distribution and populations. The emberizines are predominantly terrestrial, or dwell in bushes and thickets, but their habitat preferences vary greatly. Many species inhabit grasslands or weedy and bushy areas in open or fairly open regions; some, especially Neotropical species, frequent open woodlands or the edges of forest, usually avoiding the denser and higher growth. With these few restrictions, buntings can be found anywhere and in all sorts of climates, from the hottest or most arid to the coldest and most humid, from the seashore to the very high and barren plateaux of the Andes, and from virtually one end of the earth to the other. Some American species inhabit Tierra del Fuego or the high Arctic; the Snow Bunting breeds at the tip of northern Greenland, farther north than any other land bird. In suitable habitats populations of particular species can reach extremely high densities. Thus among sedentary populations of Song Sparrows which have been studied on the salt marshes of San Francisco Bay, California, and on small Mandarte Island off the British Columbia coast, 20 or more breeding pairs may be present on every hectare of favoured habitat.

Food. The great majority of emberizines can be classified as omnivorous. During much of the year most species subsist predominantly on seeds, mainly secured by foraging on the ground. But during the breeding season many buntings rear their young largely or entirely on arthropod prey.

Behaviour. In many aspects of their behaviour, there is enormous specific variation. Many species collect together in large flocks outside the breeding season, but others are rarely seen in groups of more than 2 or 3. The Snow Bunting and the House Bunting are so confiding that they nest by preference in occupied dwellings when available, whereas other buntings are amongst the most wary and furtive of birds. In a majority of species, at least among the better studied Holarctic forms, males defend territories against conspecifics during the breeding season, and, indeed, the role of territorial behaviour in the life of birds was first elucidated largely through studies on the Reed Bunting and Song Sparrow. In the Sharp-tailed Sparrow *Ammodramus caudacutus*, however, territorial behaviour may be absent and males overlap greatly in their home ranges. Mating systems vary from the monogamy and occasional bigamy of most species studied, through the highly polygamous behaviour of some populations of Corn Buntings, to the apparent complete promiscuity recorded for the Sharp-tailed Sparrow in which relations between the sexes are limited to copulation alone.

Yellowhammer *Emberiza citrinella*. (*D.A.T.*).

Voice. The song can be loud, rich and musical, or so feeble as to be scarcely audible to man, being very high pitched and similar to the buzz of an insect.

Breeding. The nest of typical buntings and New World sparrows is cup-shaped, but is domed in many Neotropical members of the group, e.g. the grassquits *Tiaris* and the bullfinches *Loxigilla*. Grasses, fine roots and sometimes moss and lichens are normally the chief material; a few hairs and sometimes feathers are added to the lining where they can be found. The nest may be in a bush or tree, usually not high above ground; or it may be built on the ground. The choice of site seems to be less important than secure support and concealment. The Reed Bunting may build among reeds and sedges in shallow water; some species nest in holes in trees or on the ground or in crevices among boulders. The eggs may be immaculate or marked with blotches and scribbles, and clutch sizes vary from 2–7 or rarely more. The larger clutches tend to be found among species and populations inhabiting higher latitudes, and the smallest clutches in tropical forms. Incubation, from 11–14 days, may be either by the female alone or shared by both sexes, whereas care of the young is normally carried out by both parents, being restricted to the hen alone in only a few species. The young may leave the nest in as little as 8 days and fledge at 12–14 days. Among the typical buntings of the Holarctic Region which have cup-shaped nests frequently situated on the ground, nest predation may be high, but this is offset by the willingness of most to replace lost clutches. Adult mortality of these species normally lies within the range 35%–55% per annum.

BUPHAGINAE: see OXPECKER.

BURGOMASTER: sailors' name for the Glaucous Gull *Larus hyperboreus* (see GULL).

BURHINIDAE: see under CHARADRIIFORMES; THICKKNEE.

BUSH-BIRD: substantive name of *Thamnistes* spp. (see ANTBIRD).

BUSH-CREEPER: substantive name, in Africa, of *Macrosphenus* spp. (for subfamily see BABBLER).

BUSH-CROW: substantive name sometimes used for *Zavattariornis stresemanni*, a crow-like African bird of uncertain affinities (see under CROW (1)).

BUSH-HEN: name used in Australia for *Amaurornis ruficrissus* (see RAIL).

BUSH-QUAIL: substantive name sometimes used for the Indian gamebirds of the genus *Perdicula* (see PHEASANT).

BUSH-SHRIKE: substantive name of some species of Malaconotinae; in the plural, general term for the subfamily (see SHRIKE).

BUSH-SKULKER: *Turdoides fulvus* of Africa (for subfamily see BABBLER).

BUSH-TANAGER: substantive name of *Chlorospingus* spp. (see TANAGER).

BUSHTIT: substantive name of *Psaltriparus* spp., of the New World (see TIT).

BUSH-TYRANT: substantive name of the tyrant-flycatchers of the genus *Myiotheretes* (see FLYCATCHER (2)).

BUSKING: the aggressive display of the male Mute Swan *Cygnus olor* in which he advances across the water towards an intruder with his neck drawn back and his wings arched, proceeding with a jerky movement because during this display, as opposed to normal practice, he paddles with both feet in unison.

BUSTARD: the most usual substantive name of species of Otididae (Gruiformes, suborder Otides); in the plural, general term for the family. This is a phylogenetically independent, relatively homogeneous Old World family of medium-sized to large terrestrial birds (*c*. 40–130 cm). There are 22 clear species, but 3 of these (see below) are divisible to comprise up to 5 further species; the number of genera (treated here as 8) is also debatable.

Characteristics. All species are rather long-legged and long-necked, with stout (but often tapering) bodies, rather flattened heads and straight, short bills. Flight is powerful and sustained, the wings are broad and long, the tail broad and fairly short. The tarsi are covered in hexagonal scales and the feet have 3 short, broad toes with flattened nails (hallux absent). The back plumage of all species is essentially cryptic, but the sexes are usually strikingly dimorphic, either in size (males much bigger) or in (breeding) plumage (males more boldly marked, chiefly on head, neck and belly). Certain species have ornamental plumes (crests, moustachial bristles, ruffs, etc.), exaggerated or exposed in display; often also swollen subcutaneous tissue in the neck, and inflatable gular sacs or distensible oesophagi in the larger species. Females and young remain cryptic in both colour and behaviour. Bustards lack a uropygial gland, but have dense, friable powder-down, tinged pink in the absence of light; they frequently dust themselves but never bathe in water.

Habitat. They are typically birds of warm, dry, open landscapes, occupying habitats that range from semi-desert (1–3 species) through arid scrub, rolling grassland and savanna (most species) to quite dense bush with scattered clearings (2–3 species). Despite the use of farmland by some Palearctic species (though more readily outside the breeding season), birds are sensitive to disturbance and deterioration of habitat, and generally disappear in the face of expanding agriculture.

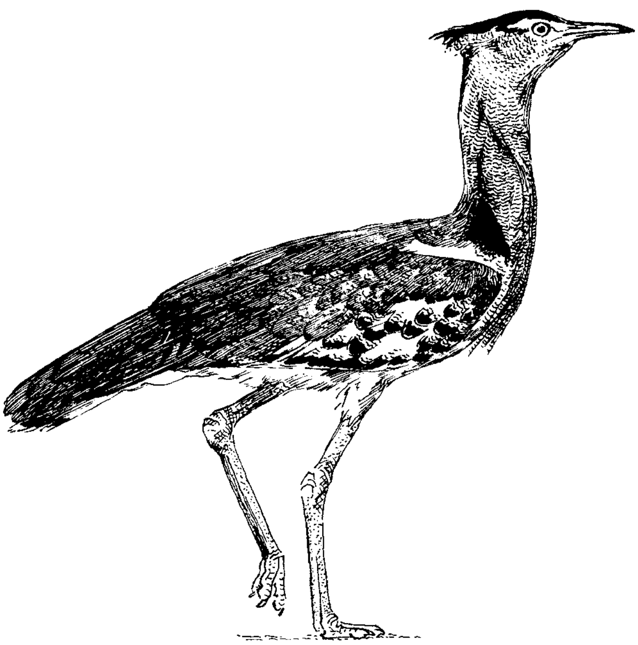
Distribution. The family belongs principally to the Afrotropical Region, within which there are 2 main areas of speciation: southern Africa below the Zambesi, and eastern Africa in the triangle formed by the Horn and the Nile above Lake Victoria. In the former area there occur exclusively the Blue Korhaan *Eupodotis caerulescens*, Karroo Korhaan *E. vigorsi*, Rüppell's Korhaan *E. rueppellii*, Black Korhaan *E. (Afrotis) afra*, and Ludwig's Bustard *Neotis ludwigi*; in the latter, Little Brown Bustard *E. humilis*, Hartlaub's Bustard *E. (Lissotis) hartlaubi* and Heuglin's Bustard *N. heuglini*. The Kori Bustard *Ardeotis kori* occurs in both, but nowhere else; the Red-crested Bustard *E. (Lophotis) ruficrista* (here including '*E. savilei*' and '*E. gindiana*') occurs in both, with a third population straggling across the Sahel; the White-bellied Bustard *E. senegalensis* (here including '*E. cafra*') has a distribution similar to *E. ruficrista* but with a fourth, scattered population in central Africa. Two species, the Black-bellied Bustard *E. (Lissotis) melanogaster* and Denham's Bustard *N. denhami* (here including '*N. cafra*' and '*N. burchelli*') are widely distributed across the Afrotropical Region, and 2 more, the Arabian Bustard *A. arabs* and Nubian Bustard *N. nuba*, are largely restricted to the Sahel region alone, although the former also has small populations in the south of the Arabian peninsula and (possibly still) in north-west Africa.

Not counting this small overlap by *A. arabs*, the Palearctic and Oriental regions hold 3 species each, Australasia one. The Great Bustard *Otis tarda* has a highly fragmented distribution extending from Portugal to Manchuria; that of the Little Bustard *Tetrax tetrax* is largely similar, but stops west of the Tien Shan range. The Houbara *Chlamydotis undulata* occurs sparingly throughout the arid zones of the region (Canary Islands, North Africa, the Middle East, and the cold deserts of the USSR). The Bengal Florican *Houbaropsis bengalensis* is confined to the extreme north-east of the Indian subcontinent, also Cambodia; the Lesser Florican *Sypheotides indica* is very thinly distributed across India into Nepal; and the Great Indian Bustard *A. nigriceps* is now largely confined to western India. Its closest relative, the Australian Bustard *A. australis*, occurs in the remoter parts of Australia, and also southern New Guinea.

Populations. All bustards are long-lived with slow reproductive rates, and therefore cannot rapidly recolonize landscapes from which they have been exterminated. Most Afrotropical species probably maintain their populations, but those with restricted ranges may be at risk; *A. kori* has declined sharply in southern Africa. All non-Afrotropical species are subject to serious and chronic depletion. The most endangered is probably *A. nigriceps*, with reputedly far fewer than 1,000 birds remaining; the floricans, which are now reduced to tiny pockets of habitat; and *T. tetrax* is dying out in all parts of its range save Iberia. In many of the countries where it occurs *O. tarda* is also on the brink of extinction: its long-term survival depends on the conservation policies of a handful of nations. This may also ultimately be true of *C. undulata*, which in recent years has been massively persecuted by hunters throughout its range. Reckless shooting, habitat destruction and introduced animals are blamed for the disappearance of *A. australis* from areas where it was once abundant.

Movements. Most Palearctic populations are at least locally migratory (but highly site-faithful as breeders), with the most pronounced and regular movements occurring in (to and from) the USSR. The Oriental and Australasian species are resident or seasonally nomadic, though *S. indica* may also undertake regular local migrations. Some Afrotropical species show fairly distinct but vaguely understood seasonal movements, notably for example *A. arabs* and *N. denhami* in West Africa, but patterns possibly vary not only between years and species but between localities and geographical regions as well as within species.

Food. Bustards feed opportunistically on a wide range of food items, varying with the season and local conditions. Vegetable food includes green shoots, leaves, flower-heads, seeds, pods, berries and, for Afrotropical species, *Acacia* gum. The chief animal prey is insects (Orthoptera, Coleoptera, mantids, termites, larvae, etc.) but also (e.g.) molluscs,



Kori Bustard *Ardeotis kori*. (*C.J.F.C.*).

arachnids and myriapods. Vertebrate prey consists of small reptiles, frogs, small mammals and the eggs and nestlings of ground-nesting birds. Bustards forage in a cautious, attentive walk through the vegetation, with frequent pauses not only to seek or take food items but to lift head to observe surrounding landscape; the bill is also used to probe and dig for food. Drinking occurs occasionally, but generally appears unnecessary.

Behaviour. Where persecuted, bustards can be wary and retiring; where not, they are often easily approached, especially on horseback or in a vehicle. Many species are gregarious, some even while breeding. The mating systems are barely studied, but probably often complex. *A. nigriceps* is considered polygynous, one male consorting with 3–5 hens; congeners seem likely to behave similarly. In *O. tarda* a non-territorial lek system seems to prevail, in which an elite of males establishes the right to display freely and copulate promiscuously with any females within the general lek area. Males of both floricans, who advertise their presence by leaping several metres into the air, calling, and parachuting down, appear to be promiscuous; this is probably also true of the 3 savanna-dwelling korhaans in southern Africa (*E. ruficrista*, *E. melanogaster* and *E. afra*), which like the floricans all have extensive black on their underparts, give spectacular aerial displays, and live solitarily; by contrast, the open-country species (*E. vigorsi*, *E. rueppellii*, *E. caerulescens* and *E. senegalensis*) lack black underparts and aerial displays, live gregariously, and appear to breed in group territories. The terrestrial self-advertising displays of the larger species are striking and unusual: *Ardeotis* and *Otis* both cock their tails forward and inflate highly distensible gular sacs, the latter also contorting its wings to make huge white rosettes; *Chlamydotis* puffs its long white ruff over its head, and struts in circles and long runs as if decapitated. In these 3 genera, copulations appear to involve lengthy and complex preceding rituals.

Voice. *Otis* and *Chlamydotis* are largely silent at all times, but *Ardeotis* species may emit deep booming sounds during display. Males of *T. tetrax* have a short rasping snort in the breeding season, and their wings produce a powerful sibilance. The floricans and small Afrotropical species have penetrating, repetitive calls consisting of froglike croaks, belches, clicks, whistles, etc.

Breeding. Breeding seasons (sometimes governed by rains) may be relatively protracted, except in *O. tarda* and *T. tetrax*. The female scrapes a shallow depression on bare ground, and (in most if not all species) assumes sole responsibility for incubation and care of the young. The smooth, subelliptical, usually dull-coloured but (in some species) glossy eggs number 2–6 in Palearctic species and *S. indica*, 1–2 in the others; incubation generally lasts 3–4 weeks. The young are precocial and nidifugous, and fed initially bill-to-bill; they fledge at *c.* 5 weeks. Sexual bimaturism probably occurs in all species that are sexually dimorphic in size. N.J.C.

BUSTARD-QUAIL: synonymous with BUTTONQUAIL.

BUTCHER-BIRD (1): popular name in Britain and North America for *Lanius* spp. (see SHRIKE). The name relates to the habit of forming a 'larder' of the prey.

BUTCHER-BIRD (2): substantive name of members of the genus *Cracticus* of the Cracticidae (Passeriformes, suborder Oscines).

Characteristics. The 6 (sometimes 7) species, ranging from 20–40 cm in length, are smaller than the other members of the family. All are rather large song-birds, with stocky bodies and large heads supporting a heavy bill, hooked at the tip. Their plumage is sombre, black, grey and white with a tendency for browns to occur in the plumage of juveniles; a recognizable brown variant *rufescens* of the Black Butcher-bird *Cracticus quoyi* occurs in Queensland.

Habitat. Butcher-birds are most widespread in woodlands, but some of the tropical species also live in rain-forest and mangrove fringes. The 2 southern forms, the Pied *C. nigrogularis* and the Grey *C. torquatus*, adapt well to farmland clearing and are common around Australian homesteads. They do less well in urban areas.

Distribution. The genus is confined to Australia and New Guinea. In most of Australia the Pied Butcher-bird occupies the inland and the Grey, including the race *argenteus* (Ford 1979), the wetter coastal areas, with substantial overlap of range. Clearing has favoured the spread of the Pied towards the coast. Two species, the Black-headed *C. cassicus* and the White-rumped *C. louisiadensis*, are confined to New Guinea. Two mangrove/rain-forest species, the Black and the Black-backed *C. mentalis* occur in both Australia and New Guinea.

Populations. Little is known about the density of the northern species. The Grey Butcher-bird in Western Australia holds a breeding territory of 30–40 ha but the density may be greater in eastern Australia.

Movements. There is no evidence of movement by any butcher-bird.

Food. Butcher-birds feed on large insects, crustacea, reptiles, small mammals and young birds. They are not related to the true shrikes (Laniidae) but have the shrike-like habit of impaling prey on thorns or wedging it in tree forks. The birds seek food by perching a few metres above the ground and pouncing on small animals when they see them.

Behaviour. In some species the breeding group contains more than 2 birds but detailed studies are lacking. At many nests a simple pair is found. The nests of the Black Butcher-bird are often close to those of the Trumpet Manucode *Manucodia keraudrenii*. Apparently the manucode chooses this arrangement and may gain protection from the aggressive nature of the butcher-bird.

Voice. All butcher-birds have loud songs, with which they proclaim the possession of their territory throughout the year. The song of the Pied Butcher-bird contains many almost pure tones, and is considered by Australians to be one of the most beautiful in the country. The only blemish on this reputation is that singing begins at dawn and the species is often known as the 'Bushman's Clock'.

Breeding. Butcher-birds build large cup-shaped nests of sticks lined with grass in tree forks up to 15 m or higher. Clutches range in size from 2–5 eggs, the southern species laying slightly larger clutches than the northern ones. The incubation period is 20–23 days and the nestling period 28-31 days. Breeding butcher-birds are very pugnacious and sometimes attack humans. S.J.J.F.D.

Ford, J. 1979. A new subspecies of Grey Butcherbird from the Kimberley, Western Australia. Emu 79: 191–194.

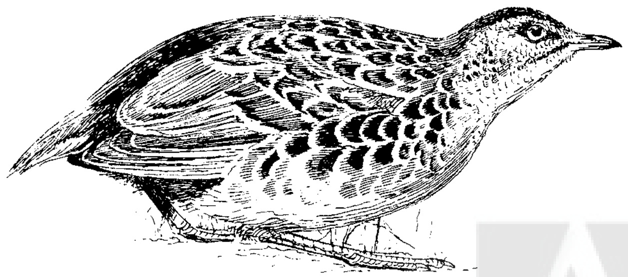
BUTEO: sometimes used in North America as a vernacular term for *Buteo* spp., there included under the general term 'hawk' although in Britain called 'buzzards' (see HAWK).

BUTEONINAE: subfamily, used by some authors for the larger members (buzzards and eagles) of the family Accipitridae (see ACCIPITRIFORMES; HAWK).

BUTT: an earthwork—usually one of a series in line—erected for the concealment of persons waiting to shoot driven birds, notably Red Grouse *Lagopus lagopus scoticus*.

BUTTERBALL: a name applied in North America both to the Bufflehead *Bucephala albeola* and to the Ruddy Duck *Oxyura jamaicensis* (see DUCK).

BUTTERFLY FLIGHT: a slow flapping flight used in aerial display by many birds.



Little Buttonquail *Turnix sylvatica*. (*C.J.F.C.*).

BUTTONQUAIL: substantive name, alternatively 'hemipode', of species of Turnicidae (Gruiformes, suborder Turnices); often used without qualification for the sole European species; in the plural (alternatively 'hemipodes'), general term for the family. The latter and the Australian monotypic family Pedionomidae (see PLAINS-WANDERER) together form the suborder. This small Old World group of only some 15 species is also considered to be allied to the sandgrouse and the pigeons.

Characteristics, habitat and distribution. The buttonquails or hemipodes are terrestrial grassland birds inhabiting mainly the tropics and subtropics, and remarkably resembling true quails *Coturnix* spp. (Phasianidae) in general appearance, plumage pattern, habitat preference, and mode of life. They are 11–18 cm in length. The family is characterized by having only 3 toes on the foot, a hind toe being absent. In flight the wings appear much rounded and the short tail is barely visible. The bill is like that of a quail but generally rather small and slender. A crop is missing. The oil gland is feathered; the feathers have an aftershaft.

Buttonquails live very secretively in arid or marshy grass and brush country, savannas, and more open woodland. When disturbed, they prefer to run for cover, but, if forced to take wing, they fly straight and fast, with whirring wings for 150 m or more before dropping back to the ground and disappearing into cover.

The typical genus of the family includes 13 species, 6 of which inhabit the Australasian Region. The other *Turnix* species are found in Africa, Madagascar, and the warmer countries of Asia, only one extending to Europe (in its extreme south-western part). This widely distributed (mainly Indo-African) Buttonquail (also called Striped or Little Buttonquail or Andalusian Hemipode) *Turnix sylvatica* is a bird with greyish-rufous, variably blotched and streaked upper parts, and pale below except for the rufous breast flanked with dark spots; its Philippine race is the smallest representative of the genus. In this species the sexual dimorphism in coloration is much less conspicuous than in the Barred (or Common) Bustard-quail *T. suscitator* of India and eastern Asia, in which the female acquires a black throat and chest in nuptial plumage. Many females of this species are trapped by the use of female decoy birds and then kept to be pitted against each other.

Several species have similar black markings below, e.g. the Madagascar Buttonquail *T. nigricollis* and the Black-breasted Buttonquail *T. melanogaster*, a very rare bird of the rain-forest scrubs of Queensland. One of the finest and largest species is the brightly coloured Ocellated (or Spotted) Buttonquail *T. ocellata* of Luzon (Philippines). In the Yellow-legged (or Indian) Buttonquail *T. tanki* the hen is distinguished by a broad orange-rufous nuchal collar; it has a breeding distribution from India to Manchuria and is migratory in the northern part of its range. The similar Spotted (or Red-backed) Buttonquail *T. maculosa*, ranging from Australia, New Guinea, and Melanesia to the Lesser Sunda Islands and Mindanao, seems to be its eastern counterpart. Some of the smaller Australian species are remarkable for their stout bill, e.g. the Redchested Buttonquail *T. pyrrhothorax*, which, like *T. maculosa*, has spread northwards, leaving two small island populations on Sumba and Luzon.

The second, and quite different, genus is monotypic. The little Lark-quail (often misnamed Quail-plover) *Ortyxelos meiffrenii* inhabits very dry sandy scrub country in the tropical grassland belt from Senegal to East Africa. It has sandy-rufous upper parts, rather long black and white wings, and strong jerky flight; it resembles a tiny courser *Cursorius* on the ground and a bushlark *Mirafra* on the wing.

Movements. According to local climatic conditions, buttonquails are sedentary, nomadic or migratory.

Food. The food consists of small invertebrates (termites, ants and other insects, spiders, snails), grass-seeds, grain and green shoots. The birds pick off items from the surface of the ground as well as scratching with feet alternately. Water is taken with a 'bibbling' action of the mandibles, similar to sandgrouse, without raising the head at each mouthful as do most birds.

Behaviour. Little information is available in regard to behavioural characters, but dusting and sunning are recorded regularly in captivity. Buttonquails are usually seen singly, in pairs or in small family parties, but some species tend to keep together in coveys of 15–30 birds.

The female is larger and more brightly coloured than the male, is extremely pugnacious against rivals of the same sex, and takes the leading part in courtship.

Voice. In the breeding season the female utters a loud drumming or booming call, only the hen being provided with a specialized vocal organ—an inflatable bulb of the oesophagus and an enlargement of the trachea.

Breeding. The nest is placed on the ground in a shallow depression scratched among grass, in a tussock, or beneath the shelter of a low bush or herbage. It is built of dry grasses and dead leaves, and varies from a more or less well-made cup to a substantial domed structure with a side entrance, sometimes with a short covered runway leading to it. In some species both sexes bring material, which they jerk in plover-like manner over their shoulders towards the nesting place, and work in turn from inside. The eggs are commonly 4 in number (in *Ortyxelos* only 2), short ovate to pyriform, rather glossy, pale greyish to buffish in ground colour and profusely freckled, dotted, and blotched with chestnut, dark brown, slaty-grey, or other shades. In captivity some females lay each day until a clutch is completed and then can start a new clutch within a couple of days. The male performs the duties of incubation and later of rearing the young, although the female may occasionally assist during a few days after laying. The behaviour of birds breeding in captivity and evidence from field observations strongly suggest that the hen lays several sets of eggs to be attended by different males.

Besides these and other peculiarities in the breeding behaviour, the buttonquails show a rather special kind of nidifugous development. Their incubation period of only 12–13 days is by far the shortest among birds with young hatching in a similarly advanced state, and even ranks near the lower limit known in the nidicolous group. The downy chicks leave the nest soon after hatching, are very agile and follow the male parent, by whom they are brooded and fed, the food being presented in the tip of the bill. When being hand reared, chicks must be hand fed for at least 7–10 days even though they begin feeding on their own on the second or third day. Presumably the male feeds the chicks for the same period of time. They begin to flutter when about 1 week old, and after another week they can fly and look after themselves, although the family keeps together for 1 or 2 more weeks, and finally at the age of 6–7 weeks they attain the size and weight of adults.

During this short growing period, characterized by a steady gain in weight, two moults are accomplished. At the end of the second week most of the natal down is replaced by juvenile feathers, and at the same time, when the bird is scarcely half-grown, a complete moult of the juvenile plumage begins. This is completed at the age of about 10 weeks, and results either in the adult postnuptial plumage or directly in the nuptial one. In the rapid succession of plumages and in many other features the buttonquails present a remarkable convergence towards the gallinaceous type of development, which implies a very early ability to fly. They differ, however, in that the adaptation of the growing wing to continuous use is attained in a less specialized manner; all the juvenile quills grow out nearly together, the only important modification being that the inner primaries are considerably reduced in size, particularly the innermost one, which remains almost vestigial. This primary is the first to be shed, the process taking place before the outer juvenile quills are fully grown. Sexual maturity too is reached early, at least in birds reared in confinement; these may begin to lay in the third to fifth month of life. The breeding season is prolonged and some species nest opportunistically in all months. These birds seem to be very short lived. Captive records of several species would indicate normal life span of only 2 to 3 years.

BUZZARD: substantive name of *Buteo* spp. (Accipitrinae); also used, in combination, for the honey-buzzards *Pernis* spp. (Perninae)—for both these subfamilies of the Accipitridae see HAWK. In America, where true buzzards are named 'hawks' (which they of course are), 'buzzard' is a popular misnomer for members of the Cathartidae (see VULTURE (2)), and is sometimes also applied to the Caracara *Caracara cheriway* (see under FALCON).

C

CACATUINAE: see PARROT.

CACHALOTE: substantive name of *Pseudoseisura* spp. (see OVENBIRD (1)).

CACIQUE: substantive name of species in 4 tropical genera (*Cacicus*, etc.) of the Icteridae (see ORIOLE (2)).

CADGE: term used in FALCONRY.

CAECUM: a blind tube branching from the junction of the small intestine and large intestine, usually paired ('caeca') but in some taxonomic groups single or absent (see ALIMENTARY SYSTEM).

CAGE BIRD: term applied to a variety of smaller birds (mostly psittacine and passerine) commonly kept in captivity, especially those which are totally domesticated, such as the Budgerigar and the Canary. The Budgerigar *Melopsittacus undulatus*, first brought alive from its native Australia by John Gould in 1840, has become the most popular of all pet birds, on account of its friendly and affectionate personality, bright colours and ability to mimic the human voice. An immense variety of colour mutations has been established.

A close second in popularity is the Canary *Serinus canaria*, from the Azores, Madeira and Canary Islands. First imported into Europe during the 16th century, it now exists in a diversity of varieties, colours and plumage patterns. In the UK the most popular breeds are the Border, Gloster, Norwich and Yorkshire Canaries (bred for their 'type') and the Roller which is bred solely for its exquisite song. Hybrids between the Canary and British finches such as the Goldfinch *Carduelis carduelis* and the Greenfinch *C. chloris*, are known as mules and are bred for song and exhibition.

Two small finches which are totally domesticated are the Bengalese, whose origin lies with one of the mannikins *Lonchura striata*, and the Zebra Finch *Poephila guttata* from Australia. Both these birds, which are bred in a variety of colour mutations, are ESTRILDID FINCHES (Estrildidae) while the Canary is one of the true finches (Fringillidae).

Another Australian species, more recently domesticated, is the Cockatiel *Nymphicus hollandicus*. Increasingly popular as a cage pet in the UK, this little cockatoo has long been cherished in the USA. A handsome long-tailed bird, it is grey with striking orange cheeks. It is being bred in a variety of mutations, such as White (Lutino), Pied and Pearl. It breeds freely in cage or aviary and young birds make affectionate pets, quickly becoming tame and learning to mimic.

In the 19th and early 20th centuries many British species were kept as cage birds, especially for their song. Legislation has now restricted the species which can be kept in captivity, and these are all aviary-bred (and closed-ringed, as proof of captive breeding). Mainly finches are kept (e.g. Goldfinch, Greenfinch and Bullfinch *Pyrrhula pyrrhula*) and these have been bred in captivity for a number of generations. A few mutations have been established, such as the Lutino Greenfinch.

There are several hundred cage bird societies in the UK, all of which stage at least 2 shows a year, the main show season being from October until December. The majority of exhibits are Budgerigars and Canaries, Zebra and Bengalese Finches and the species of British birds permitted under the Wildlife and Countryside Act (mainly finches); exotic birds, including parrots, are also exhibited. The majority of members of cage bird societies keep domesticated species but keepers of exotic birds are also catered for. In the USA the situation is different; societies are less local and more specialized, generally catering for breeders of budgerigars, canaries, parrots or finches rather than for the whole range of cage birds. See also AVICULTURE. R.L.

CAHOW: name for a species of petrel *Pterodroma cahow* breeding in small numbers on Bermuda, where it was rediscovered in recent years after having been thought to have become extinct (see PETREL).

CAIN AND ABEL SYNDROME: 'Cain and Abel' strife describes the sibling aggression frequently found in broods of owls and raptors, herons and various seabirds. The aggression is associated with food shortage and often results in a smaller sibling being killed and in some cases eaten (see CRONISM) by older chicks (see BROOD REDUCTION).

CAIQUE: substantive name of the Neotropical *Pionites* spp. (Arini) see PARROT.

CAIRININI: see DUCK.

CALAMUS: the hollow proximal portion of the shaft of a feather, below the vane (see FEATHER).

CALCIUM METABOLISM: see ENERGETICS; METABOLISM; NUTRITION.

CALFBIRD: one name for *Perissocephalus tricolor* (also 'Capuchinbird')—for family see COTINGA.

CALIDRITINAE: see SANDPIPER.

CALLAEIDAE: a family of the PASSERIFORMES, suborder Oscines; WATTLEBIRD (2). The editors of the *Check-list of Birds of the World*, vol. 15, have deliberately retained this traditional spelling, although a purist would prefer 'Callaeatidae', or possibly 'Callaeadidae'.

CALL-NOTE: see VOCALIZATION.

CALYPTOMENINAE: see BROADBILL.

CALYPTURA: substantive name now commonly used for *Calyptura cristata*, the smallest (and probably the rarest) of the COTINGAS, known only from a restricted area in south-eastern Brazil.

CAMAROPTERA: substantive name used for some members of the African warbler genus *Camaroptera* (see WARBLER (1)).

CAMOUFLAGE: see COLORATION, ADAPTIVE.

CAMPEPHAGIDAE: a family of the PASSERIFORMES, suborder Oscines; CUCKOO-SHRIKE.

CAMPO: term used in South America for a habitat consisting of grassy plains with scattered bushes and low trees.

CANARY: *Serinus canaria* (see AVICULTURE; CAGE BIRD; FINCH; VOCALIZATION).

CANASTERO: substantive name now regularly used for the species of the furnariid genus *Asthenes*, small birds with long, pointed and markedly graduated tail-feathers (see OVENBIRD (1)).

CANCELLATE: marked with cross lines, as on the webs between the toes of some water birds (see LEG).

CANNON-NETS: see TRAPPING.

CANOPY: the branching parts of trees, forming the tree layer in woodland. Where the canopy is continuous, the trees being close together, it is said to be 'closed', while an 'open' canopy is found where the trees do not touch each other.

CANOPY FEEDING: term used to describe hunting method of the Black Heron *Egretta ardesiaca* in which the wings are held forward over the head (see HERON). Also used to describe feeding in the canopy or upper layer or a forest, usually by itinerant parties of birds.

CANVASBACK: *Aythya valisineria*, a North American species of pochard (see DUCK).

CAP: an area of distinctive colour, in some plumage patterns, covering part of the top of the head, and sometimes down to the nape (see TOPOGRAPHY).

CAPERCAILLIE: name (of Gaelic origin, and sometimes spelt 'capercailzie') of *Tetrao urogallus*, and can be applied also to *T. parvirostris* (see GROUSE).

CAPITONIDAE: see under PICIFORMES; BARBET.

CAPITONOIDEA: see under PICIFORMES.

CAPON: a castrated domestic fowl.

CAPRIMULGI; CAPRIMULGIDAE: see below.

CAPRIMULGIFORMES: an order, alternatively 'Caprimulgi', comprising 2 suborders: Steatornithes and Caprimulgi, and 5 families: Steatornithidae (OILBIRD), Podargidae (FROGMOUTH), Aegothelidae (OWLET-FROGMOUTH), Nyctibiidae (POTOO), Caprimulgidae (NIGHTJAR). The nightjars are known in America as 'night-hawks' and 'goatsuckers'. The owlet-frogmouths are sometimes called 'owlet-nightjars', and the potoos 'tree-nightjars'. They are all cryptically plumaged and nocturnal.

CAPUCHINBIRD: one name for *Perissocephalus tricolor* (also 'Calfbird')—for family see COTINGA.

CARACARA: substantive name of most species of Daptriinae; used without qualification, in the USA, for *Caracara plancus*; in the plural, general term for the subfamily (see FALCON).

CARBOHYDRATE METABOLISM: see ENERGETICS; METABOLISM; NUTRITION.

CARDINAL: substantive name best restricted to *Cardinalis cardinalis* Northern Cardinal, and *Cardinalis phoeniceus* Vermilion Cardinal; used without qualification in the USA for the former species (also known locally as 'Cardinal Redbird', etc) (see CARDINAL-GROSBEAK). The name is misapplied to some other reddish birds, e.g. certain South American tanagers (Thraupinae); and it is used in the Old World for *Foudia madagascariensis* (for family see WEAVER).

The Northern Cardinal *Cardinalis cardinalis* occurs naturally from parts of temperate North America south into Middle America and on certain adjacent islands; it has been introduced successfully into the Bermudas and south-western California—also Hawaii, where it breeds all the year round and has become a pest to fruit-growers. It is about 15–20 cm long, varying somewhat geographically, and weighs 35–50 g. The bill is large and stout, nearly conical. Males are mainly some variant of conspicuous scarlet-orange to deep scarlet. Females have more muted coloration, the reds being mixed with browns and buff. Numerous subspecies have been named, mainly on the basis of geographical variation in depth of coloration.

Habitat. Woodland edges and gardens with a mixture of clearings and young trees, bushes or vines.

Movements. It is usually sedentary, but some individuals are highly migratory.

Food. Like the subfamily, it is mainly vegetarian, feeding on seeds and berries, but some insects are taken seasonally.

Voice. The song, which may be heard throughout the year, is a series of melodious frequently repeated whistles, varying in pitch. The female has also a song, which is a subdued version of that of the male.

Behaviour. The male Cardinal elongates his body in courtship song and may slip sideways along a branch until he reaches the female, the performance ending in copulation.

Breeding. Nest sites vary from on the ground to high in a tree, but are typically about 1–5 m from the ground. The nest is in a shady situation such as within a young evergreen, a hedge, or a tangle of vines. It varies from flimsy to compact, and is quite large for the size of the bird. There are usually 3 eggs, very pale blue, finely spotted with browns and lavender. Only the female incubates (12–13 days) and broods; the male feeds her, usually away from the nest. The young leave the nest in 9–10 days, and for some time thereafter the male tends and feeds them while the female may begin building a new nest. The pair-bond is maintained for successive broods through the season and, in some known instances, has persisted for as long as 3 years. R.S.P.

For references see CARDINAL-GROSBEAK.

CARDINAL-GROSBEAK: in the plural, general term for the subfamily Cardinalinae (Emberizidae; Passeriformes, suborder Oscines). The subfamily was known formerly as 'Richmondeninae' and 'Pyrrhuloxiinae'. There is still some doubt about the position of some genera within it and difference of opinion about generic limits, but a tentative list of those that should be included is: *Spiza* (1 species), *Pheucticus* (4, including '*Hedymeles*'), *Cardinalis* (3, formerly *Pyrrhuloxia*), *Caryothraustes* (2), *Rhodothraupis* (1), *Periporphyrus* (1), *Pitylus* (1), *Saltator* (12), *Guiraca* (5, sometimes included in next genus), *Passerina* (7). In English terminology, the commonest substantive name is 'grosbeak', but others are 'cardinal' (see above), 'bunting', 'saltator' and 'dickcissel'. See also GROSBEAK; FINCH; and for American usage, see BUNTING.

Cardinalinae are thick-billed 'seed-crunchers'; they differ in structure of palate, tongue and jaw musculature from the more slender-billed Emberizinae, which are 'seed-peelers' (Ziswiler 1965). The Dickcissel *Spiza americana* takes an intermediate position between this group and the American 'sparrows' (Emberizinae) and icterids (Icteridae). Typically cardinal-grosbeaks are 'buntings' of medium to large size (lengths 15–20 cm); and the males are usually brightly coloured. The group is confined to the New World and is predominantly tropical in distribution—but with 5 genera represented among birds breeding north of the Mexican border. Apart from the Cardinal (see above) the North American members of the subfamily include the Dickcissel (the male a brownish bird with yellow breast and black bib), the Rose-breasted Grosbeak *Pheucticus ludovicianus* (the male mainly black and white, apart from the rosy-red breast patch), the Blue Grosbeak *Guiraca caerulea* (the male dark blue all over, except for tan wing-bars), the Indigo Bunting *Passerina cyanea* (the male all blue) and the Painted Bunting *Passerina ciris* described as 'the most gaudily coloured American bird'; the male has red underparts and rump, green on the back, and blue on the head and wings; the female is green above and yellowish-green below. The remaining genera are represented only in the Neotropical Region, but—except for *Periporphyrus*—as far north as Middle America and the West Indies (Streaked Saltator *Saltator albicollis* on some of the Lesser Antilles). CARDUELINAE: see FRINGILLIDAE; FINCH.

CARE OF SICK, INJURED OR ORPHANED BIRDS: wild birds are frequently found in need of care as a result of accidental damage caused typically by collision with road vehicles, flying into overhead power cables or uncovered surfaces of glass, or after attack by cats or other predators. Less often they are discovered in poor condition through sickness. Seasonally, orphaned young, which have lost one or both parents, must either be fostered or allowed to die. For the special problem caused by oil at sea, see OIL-POLLUTION.

Sickness. (See DISEASE; ECTOPARASITE; ENDOPARASITE) Reasons for sickness can be varied and include bacterial and fungal infection, infestation by parasites, poisoning and nutritional diseases. Many drugs are available for treatment; the majority, however, are specific and early diagnosis of the cause of illness by a veterinary surgeon is therefore essential. Broad spectrum antibiotics (such as terramycin) will control most harmful bacteria and can be used as a precautionary treatment. As a counter to dehydration, initial fluid replacement can be effected by administering a glucose/saline solution orally, or by subcutaneous injection, at about 4% body weight twice during the first 12 hours.

Most importantly, the bird should be placed in a clean cardboard box (roughly 3–4 times its length) and made comfortable if necessary in a 'nest' of replaceable soft tissue. The top of the box should be covered with lightweight cotton material (or similar), secured around the top with clothes pegs and placed somewhere uniformly warm, so that the interior temperature attains about 25–30°C. If suitable food and water is within easy reach, the bird will feel secure and the relatively high body temperature of about 41°C will be more easily maintained.

Force feeding will often be necessary in the early stages of confinement and can either take the form of small, easily digested meals at regular intervals until an improvement in the condition occurs or, in cases where difficulty in accepting solid food is experienced, liquid, or liquidized solids, can be gently pumped directly into the crop using a soft polyvinyl chloride or rubber tube connected to a suitable syringe. Care must be taken to avoid the glottis (the opening to the trachea at the base of the tongue) and a suitable lubricant, such as liquid paraffin, will ease the passage of the tube into the oesophagus.

Jackdaw *Corvus monedula* with anchor strap in place and wing 'splint' about to be applied to immobilize broken left wing. (*Photo: I. Buchanan*).

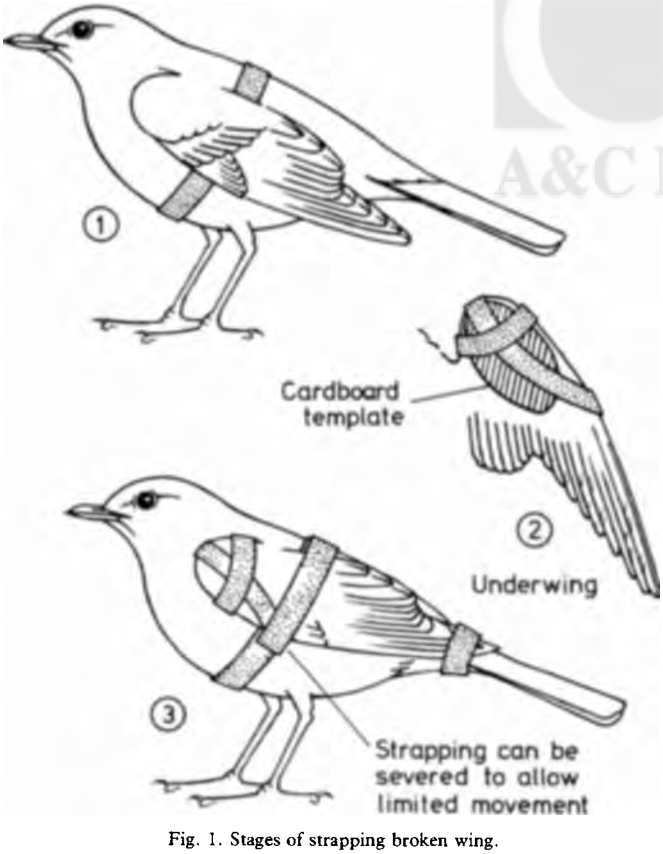

Fig. 1. Stages of strapping broken wing.

Regular removal of soiled material from beneath birds which are unable to stand is essential and their legs, feet and anal region must be bathed as required.

The presence of ectoparasites, many of which are very sensitive to temperature change, may be more obvious on sick birds and, in fact, numbers of lice may increase. Insecticides should be applied cautiously but pyrethrum, derived from the natural plant, is usually quite safe.

Injury. Most serious injury involves structural damage to wings and legs, and only experience will determine when treatment will be effective. Generally, however, simple fractures on small and medium-sized birds can be successfully repaired by immobilizing the damaged member in its correct position for 2–3 weeks whilst natural healing occurs. Personal experience has led to a system of treating wing damage which allows total, or partial, immobility in stages. This is obtained by first placing a strip of adhesive tape 1 cm wide completely around the body of the bird, in front of the thighs and behind the shoulder joints: this to be used as a basis for further attachment. Next, using the undamaged wing as a pattern, a stiff, cardboard template, cut to the shape of the forward part of the wing, is made. Small quantities of cotton wool padding attached to the card with adhesive tape will allow the true contours of the damaged wing to be followed accurately and this can then be fixed in position. Finally, a further strapping across the face of the wing and another securing the wing tips to the base of the tail will complete the operation (see Fig. 1). After 2 weeks, the outer strapping can be cut through below the wing to allow limited movement from the shoulder for a few days before total removal.

To limit unnecessary movement and to facilitate healing, a cardboard box of suitable size can be used for housing the patient as described above, and low perches, from which the bird can easily jump, will enable it to keep clean. Fresh water and food should be supplied in small, heavy, earthenware or similar dishes. Broken legs can be splinted in a variety of ways. For birds of Starling *Sturnus* size (20–25 cm) and above, a plaster of Paris cast can be formed, using specially prepared bandages, moistened and formed to the contours of the leg; these rapidly dry to form a rigid cast. Care must be taken not to apply more than necessary or the limb will become very cumbersome. Splints made from plastic tube, split longitudinally, or carefully rolled cylinders of light cardboard, suitably padded and attached with adhesive tape, are usually very effective alternatives. More complicated fractures can be dealt with successfully but involve the special expertise of a qualified veterinary surgeon.

Orphaned young. Genuinely orphaned young birds (as opposed to those regularly 'rescued' just after leaving the nest when they appear naive and helpless) require regular attention, and both adequate food and suitable accommodation are important. Three distinct phases should be considered: the period which would naturally be spent in the nest (particularly nidicolous species), the subsequent period of learning from the parents (e.g. birds of prey), and the final release to the wild.

Warmth and a feeling of security are of paramount importance, and most small young will readily settle in a nest of soft tissues, covered lightly with a dark, heavy linen cloth as a false brooder. The inevitable cardboard box will add shelter and security. Heat from an overhead lamp or, preferably, controlled bottom heat to maintain 25–30°C will reduce the amount of energy expended in keeping warm. Food should be provided at least hourly, roughly throughout the daylight period, and as a crude guide the following items can be used effectively. Small, insectivorous birds will readily accept tiny snippets of lean, raw beef, supplemented when possible with small mealworms and freshly killed winged insects. For those species which add fruit to an insect diet (e.g. white-eyes *Zosterops*), small pieces of strawberry, banana or other soft fruit should be offered. A mixture of finely crushed, dry brown bread, raw egg yolk, cod liver oil, abidec and grated apple, made to form a moist yet crumbly mixture, offers an invaluable addition to the basic diet for most insectivorous/vegetarian species, covering a range as diverse as Skylarks *Alauda arvensis*, Jackdaws *Corvus monedula*, thrushes *Turdus* and sparrows *Passer*. Where available, pro-nutro, manufactured by Hind Bros in South Africa, mixed to a cream, can be used almost universally for small birds and that or similar products are very useful for the pigeon family Columbidae. Special blends of food can be readily obtained for raising most young birds (Sluis mixtures from Royal Sluis, Holland, are ideal) but short term, in an emergency, a mixture of finely chopped hard boiled egg yolk and lean beef, moistened with glucose solution will feed almost everything.

To encourage young birds to feed themselves, food can be left with them in the box for a few days prior to fledging. If this is offered to them at the regular feed times, making obvious movements when selecting items from the dish, they will soon explore for themselves. In general, it is not necessary to give young birds water, as sufficient moisture will be contained in the food, but many welcome a few spots at feed times and pigeons will regularly drink heartily.

Release. A period spent after 'leaving the nest' in an outside aviary, where natural food can be obtained by the patient, either in competition with or at least in close proximity to similar species, will greatly assist a successful release. Earthworms, beetles, mealworms, soft fruits, seed mixtures, even live fish and naturally occurring insects can all be offered where appropriate so that skills can be acquired. Release is generally best effected in a suitable area where food and cover are available and, where post-breeding flocks aggregate, such areas should be chosen.

Although an emotive subject, euthanasia is sometimes inevitable and can be achieved by administering drugs, always under the control of a veterinary surgeon, but often it is more humane to use immediate, physical means. Small birds, thrown hard against a pavement or wall, will die instantaneously; and for larger birds, a blow at the base of the skull with a suitable length of metal or hard wood will be equally effective. It must be stressed that any such action should only be used to prevent further suffering and must be carried out with conviction: a half-hearted attempt may prolong suffering. C.A.J.C.

Christie, C. 1976. And Then They Fly Away. London.
Cooper, J.E. & Eley, J.T. (eds.). 1979. First Aid and Care of Wild Birds. Newton Abbot. (Rev. edn. 1984).

Yglesias, D. 1962. The Cry of a Bird. London.

CARIAMAE; CARIAMIDAE: see under GRUIFORMES; SERIEMA.

CARIB: substantive name of *Eulampis jugularis* and *Sericotes holosericeus* (for family see HUMMINGBIRD).

CARINA: see below.

CARINATE: having a keel (carina) on the sternum, the converse of RATITE (see also SKELETON, POST-CRANIAL).

CAROTENOID PIGMENTS: see COLOUR.

CAROTID ARTERIES: the main vessels passing up the neck to the head; the various different arrangements have been used as taxonomic characters (see VASCULAR SYSTEM).

CARPAL: name of small bones of the 'wrist', the carpal joint being the articulation of the manus with the radius and ulna and forming the forward pointing prominence of the folded wing (see SKELETON, POST-CRANIAL; WING).

CARPOMETACARPUS: the main bony structure of the 'hand' in birds, formed by the fusion of carpal and metacarpal elements (see SKELETON, POST-CRANIAL; WING).

CARRYING: transportation of various objects by birds. These are principally: (*a*) items of food for the bird's own consumption at another spot or to give to its mate (during courtship or on the nest) or young (see COURTSHIP FEEDING; FEEDING HABITS; PARENTAL CARE); (*b*) nesting materials (see NEST BUILDING); (*c*) nest refuse, including the shells of hatched eggs and the faeces of the nestlings (see PARENTAL CARE). There are also a few known instances in which birds transport their eggs or young.

Most birds carry objects grasped in the bill. Food is often carried inside the mouth, or farther down the alimentary canal and regurgitated. Only some raptorial birds carry prey or other objects in their talons (and not to the exclusion of use of the bill for lighter weights). Lovebirds *Agapornis* spp. carry nest material among the feathers on the rump. The larger penguins *Aptenodytes* spp. waddle about with the single egg or small chick resting on the tarsi, the position in which it is incubated or brooded. The Black Vulture *Coragyps atratus* sometimes moves its eggs about the laying area. Some aquatic birds habitually carry their young on their backs when swimming, e.g. swans *Cygnus* spp. and grebes (Podicipedidae). A few birds with nidifugous young occasionally transport their young in flight; for example, the Woodcock *Scolopax rusticola* does so, holding the small chick between its legs; other species in which the same behaviour has been recorded include the American Woodcock *S. minor*, the Common Sandpiper *Actitis hypoleucos*, and the White-browed Coucal *Centropus superciliosus* of Africa.

There is also the incidental transportation of, notably, plant pollen and

Swift *Apus apus* carrying food-ball for its young. (*Photo: H. Schouten*).

seeds (see POLLINATORS; SEED DISPERSAL); and the role of vector of parasites and infective organisms (see DISEASE; ECTOPARASITE; ENDOPARASITE; VECTOR). See photo PARENTAL CARE.

CARTILAGE: see SKELETON, POST-CRANIAL.

CARUNCLE: see INTEGUMENTARY STRUCTURES.

CASIORNIS: substantive name now regularly used for the 2 species of tyrant-flycatchers of the genus *Casiornis* (see FLYCATCHER (2)).

CASQUE: an enlargement on the upper surface of the bill, in front of the head, as in most species of hornbills (Bucerotidae)—or on top of the head, as in cassowaries (Casuariidae). Compare HELMET; SHIELD, FRONTAL; and see BILL; HORNBILL.

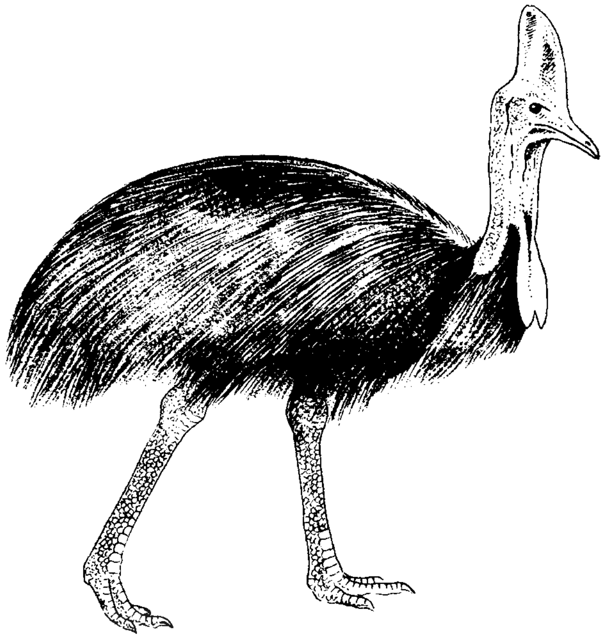
CASSOWARY: substantive name of the 3 species of the Casuariidae (Casuariiformes); in the plural, general term for the family. Cassowaries are large, heavy-bodied 'ratites' whose closest relatives are the emus (Dromaiidae) of Australia, the 2 families together composing the order Casuariiformes (see also EMU; RATITES). A cassowary is known from the Pliocene of Australia (Rich 1976). Three species are clearly recognizable, *Casuarius casuarius*, *C. unappendiculatus* and *C. bennetti*, and numerous subspecies have been described.

Characteristics. Cassowaries have coarse, bristle-like, drooping plumage, black in colour in the adult. The featherless head and neck are surmounted by a pronounced bony helmet, or 'casque', that rises from the top of the skull. Observations have recently been made on captive *casuarius* by P.J. Curry showing that the bird uses its casque as a shovel, turning over loose sand and debris. The casque's use in this way for finding fallen fruit and other food items in the litter on the forest floor seems a more plausible interpretation of its function than the traditional view that it is used to force a path through the dense forest. A conspicuous feature is the presence of wattles of coloured flesh hanging from the bare, or partly bare, neck; but they are lacking in the smallest species *bennetti*. The bill is short, strong, and laterally compressed. In the very reduced wings the remiges are reduced to bare shafts; the tail lacks characteristic rectrices. The legs are stout and powerful, the innermost of the 3 toes (numbers 2, 3, and 4 in the fundamental digital series) being armed with a long, sharp claw—a deadly weapon in combat, when the bird leaps feet first at its adversary. There have been various human fatalities among New Guinea natives as a result of an encounter with a cornered cassowary, and one case of a European boy similarly killed in Queensland. The body length of *unappendiculatus* of New Guinea ranges between 132 and 165 cm and the weight of an adult female while laying was 58 kg. The Australian form of *casuarius* stands about 150 cm high. Females are larger than males.

Distribution and habitat. Cassowaries have a restricted range in the Australo-Papuan area (New Guinea, Aru Island, Ceram, New Britain, Jobi and the eastern seaboard of north-eastern Australia from Cape York south to about Cardwell). The habitat occupied by each species appears to depend upon which other cassowary is sympatric with it (Davies 1976), but the scanty literature suggests that typically *bennetti* is a high altitude bird, *casuarius* a bird of medium altitudes and savanna woodland and *unappendiculatus* a bird of lowland rain-forests. White (1975, 1976) discusses the probable exotic status of *casuarius* on Ceram and *bennetti* on New Britain. It is clear that an extensive export trade in cassowaries has operated from New Guinea for at least 500 years, and the present distribution of the 3 species cannot be accepted as a natural phenomenon.

Food. Crome (1976) gave a detailed account of the food of North Queensland birds. They ate the fruits of 75 species of forest plant, those of the Myrtaceae and Lauraceae being most frequent. The main breeding period coincided with the peak availability of fruits of the Lauraceae. In New Guinea insects and plant tissues are also consumed.

Behaviour. Studies of the biology and breeding habits of the Australian Cassowary *C. c. johnsonii* have been made by Crome and by White (1913). The birds were found to occur largely singly or in pairs, but on occasion as many as 6 were seen together. Territories were found to be occupied during the laying season, apparently varying in extent from 1–5 km^2 (Rockingham Bay district of Queensland). During this time the birds were quite aggressive. Cassowaries were found to rest, from about noon to 4 p.m., in regular sunny spots, and to have fixed runs or tracks through the undergrowth. From time to time they were seen crossing creeks at regular points; they swim readily. Eggs were found in the nest from the middle of June until about the end of August, with a record for as late as the middle of September. Sightings of young chicks in June indicate that breeding may sometimes begin early in the dry season. The broods of 3–4 young birds, brown and initially striped, remained in company with the adult for about a year.



Cassowary *Casuarius casuarius*. (*K.J.W.*).

Voice. The call-notes—deep booming or croaking sounds—are more often heard than the birds are seen. Their wary habits and tendency to remain in cover provide abundant protection for such otherwise conspicuous birds.

Breeding. The egg sizes of *C. c. johnsonii*, perhaps the largest form, are given by White (1913); the averages of 5 separate clutches varied from 12.4 × 9.3 to 14.2 × 9.6 cm. The eggs vary in colour from pale to dark green, and are said to be darker in fresh than in incubated specimens. The shell texture may be smooth or rough, depending on the individual bird. As in the other ratites, incubation (for *c.* 30 days) of the eggs, which are laid in a clearing on the forest floor, is the province of the male, as is the care of the young, lasting *c.* 4 months.

Young cassowaries are frequently kept by the natives of New Guinea, being reared in enclosures until large enough to be eaten.

CAST; CASTING: same as PELLET.

CASTLE-BUILDER: name sometimes applied to species of spinetails (Synallaxinae)—see OVENBIRD (1)).

CASUAL (SPECIES): see VAGRANT.

CASUARII; CASUARIIDAE: see under STRUTHIONIFORMES; CASSOWARY.

CATACROMYODIAN: see SYRINX.

CATAMBLYRHYNCHINAE: FINCH, PLUSHCAPPED.

CATBIRD (1): substantive name, in North America, of *Dumetella carolinensis* and *Melanoptila glabrirostris* (see MOCKING-THRUSH).

CATBIRD (2): substantive name, in Australia, of *Ailuroedus* spp. and *Scenopoeetes dentirostris* (see BOWERBIRD).

CATBIRD (3): substantive name of the Abyssinian Catbird *Parophasma galinieri*, variously regarded as a flycatcher or a babbler (for family see MUSCICAPIDAE).

CATERPILLAR-BIRD; CATERPILLAR-SHRIKE: names sometimes applied to species of Campephagidae or, in the plural, used generally for the family (see CUCKOO-SHRIKE).

CATHARTIDAE: see CATHARTIFORMES; VULTURE (2).

CATHARTIFORMES: an order, comprising the sole Recent family Cathartidae (see VULTURE (2)). In Wetmore's system treated as a suborder Cathartae of the order Falconiformes, but as a suborder of the order Ciconiiformes by Ligon and König.

König, C. 1982. Zur systematischen Stellung der Neuweltgeier (Carthartidae). J. Orn. 123: 259–267.

CAUDAL: pertaining to the tail, or the region of the tail; or (relatively) nearer the tail.

CELL: in its special sense, a unit mass of living matter. Except in the simplest (unicellular) forms of animal life, a very large number of cells make up an organism, constituting its various tissues (see TISSUE). A cell usually has a nucleus, in which are found the chromosomes carrying the genes for the different heritable characters (see GENETICS). Cells multiply by a process of division (mitosis) in which every chromosome is split into two, one half going with each daughter nucleus. The final division leading to the formation of a germ-cell or gamete (whether spermatozoon or ovum) is a reduction-division (meiosis), in which the number of chromosomes is halved in each resulting 'pronucleus' (yielding the 'haploid' instead of the usual 'diploid' number). See also BLOOD.

CENSUS: term usually restricted to estimates of territory-holding populations. Non-territory-holding populations are often more mobile and visible, and their numbers are best estimated by a direct COUNT; this is particularly so in gregarious species.

There are several census methods currently in use e.g. mapping, transects, point counts. The choice of the most appropriate method depends on the nature of the species, its habitat and the information required. A mapping census is appropriate for an accurate census of a defined area, but a transect or point count may be sufficient to discover the approximate relative abundances of the species.

Mapping censuses. The first known mapping census was carried out in Kent, England, by the Alexander brothers in 1909. They marked the positions of summer visitors on a 6 inch map (1 : 10560) and repeated the census a second year to compare results. Few other workers used this rather laborious census technique, one exception being A.B. Williams (quoted in Kendeigh 1944) who mapped separately the birds seen on each visit to his study area and then made a composite map incorporating the data recorded on all his visits. The need to know absolute densities of breeding birds was not acute at that time and it was another 15 years before Enemar (1959) published his detailed account of mapping censuses of birds in a Swedish wood.

After further tests, this technique was adopted by the British Trust for Ornithology between 1962–1964 for their long term National Common Birds Census. This monitors year to year changes and trends in the breeding population levels of certain common birds. The rules for mapping censuses were later standardized internationally by the International Bird Census Committee (1969).

The mapping method requires a series of visits to be made to a defined study plot. On each visit, using a series of symbols, the position and activity of each bird is recorded on a large scale map (usually 1 : 2500). Each visit requires a separate map. The registrations for each species are then transferred to species maps, ideally one map for each of the common species. The resulting series of registrations often cluster into groups, each one indicating the approximate location of a bird's territory. These are delimited using a set of rules of analysis. Figure 1 illustrates a visit and species map. This method can only detect individuals which are holding territory; in some bird populations a non-breeding element may be present.

The symbols or registrations on the visit sheet (Fig. 1) indicate the locations of birds detected on that census. The letters refer to different species, e.g. WR = Wren *Troglodytes troglodytes*, R = Robin *Erithacus rubecula*, CH = Chaffinch *Fringilla coelebs*. Letters in circles are song registrations. Two song registrations joined by a dotted line indicate that both birds were seen or heard singing at the same time, while a continuous line means the same bird recorded in two different places. An underlined registration means that the bird was calling, not singing. An asterisk indicates a nest and BB indicates a fight. The registrations for each species on the species sheet are given a letter referring to the visit on which they were recorded.

Recent work has shown that intensive surveys over a few weeks in the main period of territorial establishment are quite comparable to the normal extended census (O'Connor 1980). The influence of weather factors has also been shown to be too weak to bias a season's results, although observations made on very cold or very wet days are certainly inadequate (O'Connor and Hicks 1980).

Other methods. Mapping censuses are most efficient for certain territorial non-colonial species. Nest counts, brood counts or direct counts of individuals or pairs, without delimiting into territories, are

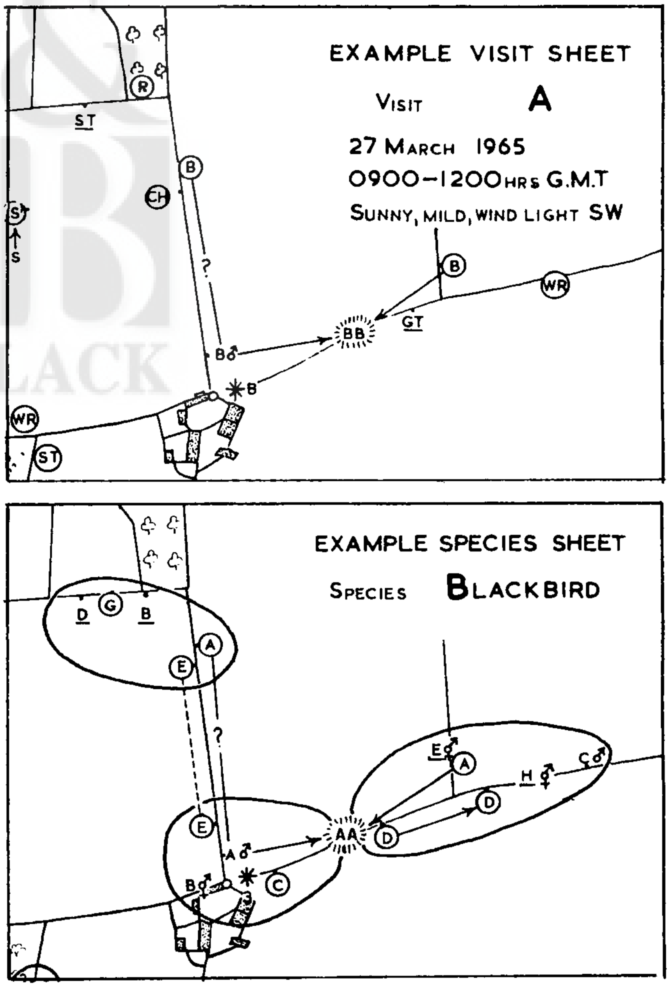

Fig. 1. Sections of visit map (*above*) and species map (scales 1 : 2,500) from a Common Birds Census plot. (Courtesy British Trust for Ornithology).

necessary for herons, ducks, geese and some waders. As an example, the national Heronry census in Britain, which started in 1928, relies on occupied nest counts made ideally in the second half of April. There are considerable problems still associated with censusing certain species, particularly seabirds, because of the difficulty of distinguishing between breeding and non-breeding individuals, the huge numbers involved and the likelihood that the whole population is not present in the breeding colony at any one time. Assessment of the size of seabird and flamingo colonies has been attempted by photography. This works best with colonies of conspicuous birds like Gannets *Sula bassana* on flat, rocky ledges and for species building relatively large nests like the Kittiwake *Rissa tridactyla*. Counts made from photographs of auk colonies may be up to 20% lower than direct counts, due to birds being obscured by rocky outcrops and by other birds. Photographs taken periodically of ranges of cliff may show up gross changes in the extent of seabird colonies.

Transects. For the first 60 years of the present century the transect type of census was usually employed. Finland, for example, has a history of line transect censuses dating back to 1916. They involve recording the numbers of birds of each species encountered along a length of habitat. The results, however, may be biased by inconsistencies in speed of walking, weather, type of habitat and conspicuousness of the species, as well as seasonal differences in the activities of different species. Therefore standardization is important. For valid comparisons, the transects need to be carried out at similar times of day, at the same time of the year and in similar weather conditions.

Some workers have used the line transect system to work out relative densities of breeding birds, e.g. Järvinen and Väisänen (1975). This method is sometimes called the complex line transect. It consists of dividing the birds recorded into those seen within 25 m on each side of the observer and those outside that distance. Densities obtained by this method are likely to be underestimates.

The advantage of the transect over the mapping census is that it enables workers to cover much larger areas of homogeneous habitat. This is particularly relevant in northern regions where the breeding season is also much shorter than further south. Enemar and Sjostrand (1967) showed that line transects increased the chances of detecting the scarce species which made up less than 10% of the populations detected on the mapping census, thus enabling a better measure of population trends and fluctuations to be obtained. There was however no advantage to be gained for commoner species.

Point counts. These may be considered a modification of the line transect technique. The birds are counted from a certain number of spots in a studied habitat in a constant time interval. Yapp (1962) called these 'time quadrats' and used them in conjunction with line transects as a check on his measures of relative abundance.

The method has since been developed in France by Blondel *et al* (1970). The observer visits spots twice in a season, in conditions good for bird song. One visit is made before the main arrival of summer visitors and one after. The higher of the two counts for each species is retained as the IPA (Indice Ponctuel d'Abondance) for a particular species in that spot in one breeding season. The observer stops at each spot for 20 minutes and then moves to another spot, ensuring that there is no chance of hearing the same birds. By noting habitat features, an analysis of the habitat preferences of birds is also possible. The rules for this and the transect method have been standardized by the International Bird Census Committee (1977). Densities have been arrived at by comparing the results with densities derived from a mapping census of the same area to obtain correction factors. There is however much variation and the results have to be treated with caution. The Point Count is most useful in habitats of limited extent such as broad-leaved trees in conifer forests. CENTROPODINAE: see CUCKOO.

CEPPHINI: see AUK.

CERE: the fleshy covering of the proximal portion of the upper mandible in some orders of birds (see BILL).

CEREBELLUM: part of the hindbrain (see NERVOUS SYSTEM).

CEREBRAL HEMISPHERES: parts of the forebrain (see NERVOUS SYSTEM).

CEREOPSIS: generic name sometimes used as English name of *C. novaehollandiae*, otherwise the Cape Barren Goose (see under DUCK).

CEROPHAGY: eating wax (see HONEYGUIDE).

CERTHIIDAE: a family of the PASSERIFORMES, suborder Oscines; TREECREEPER (1).

CERVICAL: pertaining to the neck.

CERYLINAE: see KINGFISHER.

CHACHALACA: substantive name of some species of Cracidae (see CURASSOW).

CHAETURINAE: see SWIFT.

CHAFFINCH: substantive name of 2 species of *Fringilla*; used without qualification for *F. coelebs* (see FINCH).

CHAJA: name commonly used in parts of South America for the Crested Screamer *Chauna torquata* (see SCREAMER).

CHALAZA: the pair of twisted strings of albumen suspending the yolk of an egg along its long axis (see EGG).

CHAMAEINI: see BABBLER.

CHAPARRAL: an environment, consisting of dense shrubs and stunted trees, characteristic of parts of North America.

CHAPARRAL-COCK: name applied to the Greater Roadrunner *Geococcyx californianus* (see CUCKOO).

CHARACTER DISPLACEMENT: divergence of the characters of closely related species in an area of geographical overlap. The probable existence of this phenomenon was first brought to light by Vaurie (1951) from a study of 2 overlapping nuthatches *Sitta tephronota* and *S. neumayer* in south-western Asia. It appeared that where they overlap they differ more in wing-length, bill-size and in the prominence of a black post-ocular stripe than they do in the areas where they are separate, and it was a reasonable explanation that competition between them had intensified their differences in the area of overlap thereby facilitating their coexistence. The theory has been applied to other cases, including some involving song differences, for instance between the Chiffchaff *Phylloscopus collybita* and Willow Warbler *P. trochilus*; but more detailed research into particular cases has tended to throw doubt on any such simple explanation of the interspecific differences in question. For instance, in some cases climatically related trends of variation may tend to produce results similar to those to be expected from character displacement. Each supposed case needs very careful examination. D.W.S. (1).

Vaurie, C. 1951. Adaptive differences between two sympatric species of nuthatches (*Sitta*). Proc. X Int. Orn. Congr.: 163–166.

CHARADRII; CHARADRIIDAE: see CHARADRIIFORMES; PLOVER (1).

CHARADRIIFORMES: an order, comprising 3 suborders: Charadrii, Lari, Alcae; 18 families: Jacanidae (JACANA), Rostratulidae (PAINTED SNIPE), Haematopodidae (OYSTER-CATCHER), Ibidorhynchidae (IBISBILL), Recurvirostridae (AVOCET), Dromadidae (CRAB-PLOVER), Burhinidae (THICKKNEE), Glareolidae (COURSER, PRATINCOLE), Charadriidae (PLOVER (1)), Scolopacidae (SANDPIPER, PHALAROPE), Pluvianellidae (MAGELLANIC PLOVER), Thinocoridae (SEEDSNIPE), Chionidae (SHEATHBILL), Stercorariidae (SKUA), Laridae (GULL), Sternidae (TERN), Rynchopidae (SKIMMER), Alcidae (AUK).

The Charadrii are equivalent to the former order Limicolae—the 'waders' of British and 'shore-birds' of American usage. They are birds of from small to moderate size, ground-living and usually ground-nesting; they mostly frequent the vicinity of water, either inland or on the sea coast. Most of them prefer open situations, relying for safety on cryptic coloration, wariness, and mobility; some live in marshes, and a few in woodland. They can run swiftly for short distances and fly strongly; the phalaropes habitually swim. Their bills show a variety of specialized forms adapted to probing in soft ground and so on. A long bill is often correlated with long legs. In some the front toes are more or less webbed; the hind toe is small or absent except in the specialized 'lily-trotting' foot of jacanas. Most of them are markedly gregarious except when breeding; and many perform long migrations. The great majority of the species are comprised in 2 large cosmopolitan families, Charadriidae (plovers) and Scolopacidae (sandpipers, snipe etc.). Some of the smaller groups are also worldwide in distribution, while others are more restricted—sometimes to the tropics or some part thereof, the phalaropes to the far north (except as migrants), and the sheathbills to the far south.

The Lari comprise the gulls and allied groups, birds of from fairly small to rather large size, web-footed and often with predominantly white plumage. They frequent sea coasts, inland waters, and marshes. They are highly gregarious and breed colonially, using a variety of nesting sites. The skuas are parasitic in their feeding habits. The suborder is cosmopolitan in distribution and some species are notable migrants. The Alcae are highly specialized for swimming under water; they are exclusively marine and restricted to the Northern Hemisphere.

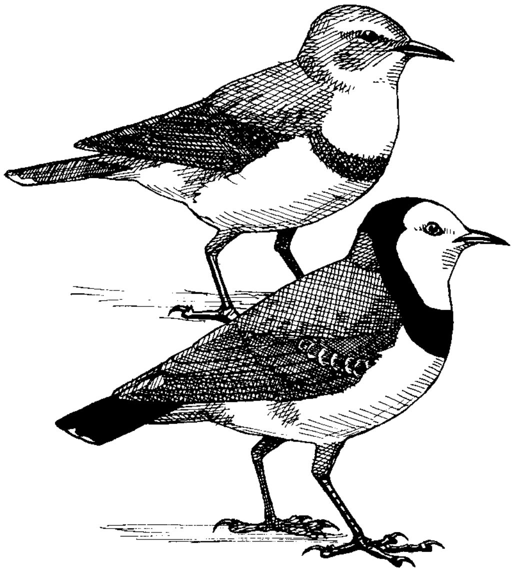
CHARDONNERET TRAP: see MARKING.

CHARM: see ASSEMBLY, NOUN OF.

CHAT (1): substantive name, in whole or part, of some species of Turdinae (see THRUSH); in the plural, general term for a subgroup ('chat-thrushes') of this subfamily, and more particularly for some of the genera, e.g. stonechats and whinchats *Saxicola* spp., wheatears *Oenanthe* spp., redstarts *Phoenicurus* spp., robin-chats *Cossypha* spp., cliff-chats *Thamnolea* spp., sooty chats or ant-chats *Myrmecocichla* spp. The name refers to the harsh 'chacking' notes of many of these birds.

CHAT (2): substantive name, in America, of certain species of Parulidae, e.g. *Icteria virens* and *Granatellus* spp., likewise 'Ground-chat' for *Chamaethlypis poliocephala* (see WARBLER (2)).

CHAT, AUSTRALIAN: substantive name for a small family, Ephthianuridae (Passeriformes, suborder Oscines), confined to Australia and Tasmania, consisting of 2 genera, *Ephthianura* (4 species) and *Ashbyia* (1 species); formerly included in the 'Australian wren-warblers' Malurinae (see WREN (2)). The possibility that the Ephthianuridae are actually more closely related to the Meliphagidae (honeyeaters) is currently being investigated with the use of biochemical techniques.



White-fronted Chat *Ephthianura albifrons*, female and male (front). (*N.W.C.*).

Characteristics. The 5 species are small (10.5–13.0 cm) songbirds with relatively long wings and short tails, and fine, slightly decurved bills. Sexual dimorphism is pronounced in *Ephthianura*, slight in *Ashbyia*. The adult males of the former are strikingly coloured and patterned: black, white and grey in the White-fronted Chat *E. albifrons*; black, white and red in the Crimson Chat *E. tricolor*; black, orange and yellow in the Orange Chat *E. aurifrons*; black and yellow in the Yellow Chat *E. crocea*. The adult male Gibberbird *Ashbyia lovensis* is greyish-brown above and dull yellow beneath with a buff breast-band. In all species the females and immatures are duller. There are indications that the adult male Crimson Chat goes into an eclipse plumage after the breeding season. The family has yet to be defined in anatomical terms; it is known, however, that all species have a brush-tipped tongue as in the HONEYEATERS.

Habitat. The typical habitat of each of the 5 species differs markedly, though there may be some overlap in this respect, particularly during eruptive movements. The Crimson Chat prefers shrub- and tree-savanna of the arid and semi-arid interior. The Orange Chat also lives chiefly in the arid zone, but favours samphire around saltlakes, and saltbush and cottonbush on stony plains. The Yellow Chat inhabits grassy swamps in northern and north-eastern Australia, and has recently been discovered well inland, in reedy swamps in the Great Artesian Basin. The Gibberbird, the most arid-living of the 5 species, frequents the sparsely-vegetated stony gibber plains of the Lake Eyre and associated drainages. The White-fronted Chat occurs mainly in southern districts, where it is found in wetter habitats than those of the other species, such as estuarine and lacustrine marshes and swamps, and damp pasture.

Movements. All species show some degree of seasonal movement. In the White-fronted Chat, the Tasmanian populations are more or less sedentary, whereas those of the mainland are partly migratory, some individuals moving north (inland) in the winter. The Yellow Chat was once thought to be sedentary and confined to certain subcoastal districts. The recently-discovered populations of the interior, however, appear to move from one artesian swamp to another, across many kilometres of open gibbers. The Crimson Chat and Orange Chat are strongly nomadic in the arid and semi-arid zones, moving and breeding opportunistically in response to good seasons and occasionally erupting towards the periphery of the continent in large numbers. The Gibberbird undertakes limited NOMADISM within the limits of its gibber habitat, exceptionally wandering southwards into wetter districts in very small numbers.

Food. Mainly small insects (including ants, wasps, bees, beetles, bugs, grasshoppers, caterpillars) and spiders are taken; less often, seeds. In addition, the Crimson Chat has been reported as taking nectar from flowers; indeed, its ability to cross deserts containing very little insect life may be attributable to its ability to use nectar as a source of energy. It has recently been suggested, however, that the brush-tongue of the Ephthianuridae is an adaptation for drinking dew and other tiny sources of water.

Behaviour. Generally gregarious, travelling and breeding in flocks of varying density. This tendency is not always obvious in the Gibberbird, because of the often well-dispersed nature of the groups. On the other hand, the Crimson Chat and Orange Chat, during periods of eruption, may occur locally in their hundreds.

Whereas the Gibberbird is almost entirely terrestrial, the other 4 species are less so, feeding largely on the ground but perching regularly in bushes or reeds. Most species are tame, often absurdly so. The Orange Chat, however, tends to be extremely wary, allowing no close approach, and it is usual to see, far off, a brightly-coloured male keeping watch from the top of a bush while the rest of the flock is feeding out of sight on the ground.

Voice. None of the Ephthianuridae is a noted songster. Their limited repertoires include a series of silvery notes (Crimson), a *tang* like a plucked violin string (White-fronted), a metallic *tang* and a mellow *cheek cheek* (Orange), an attractive descending trisyllabic call (Yellow) and an alarm of 5–6 high piercing notes (Gibberbird).

Breeding. Loosely colonial, and territorial insofar as the male protects the receptive female, eggs and fledglings but not the resources of the territory. The nest is cup-shaped, of dry grass, plant stalks and twigs; in the Gibberbird placed on the ground, in the other species low in shrubs or herbage. The eggs of all species are similar, having a whitish ground with spots of black, reds, browns and greys, reminiscent of the eggs of many honeyeaters. Clutch size is usually 3, less often 4. Incubation lasts 12–14 days, and the young are in the nest 14–15 days. In the Crimson Chat, the female builds the nest, and both sexes incubate and care for the young. All species except the Yellow Chat have been recorded putting on the 'broken wing' display to lure intruders away from nest and fledglings (see DISTRACTION BEHAVIOUR). In the breeding season, male Crimson Chats indulge in a diving display-flight from a perch, while male Gibberbirds perform a song-flight, mounting in steps to more than 30 m above the gibbers, then falling directly to earth. CHAT, PALM: see PALMCHAT.

CHATTERER: substantive name formerly used for some medium-sized species of COTINGAS, and sometimes for the family as a whole; and now used for some African BABBLERS of the genus *Turdoides*.

CHAT-TYRANT: substantive name now regularly used for the chat-like tyrant-flycatchers of the genus *Ochthoeca* (see FLYCATCHER (2)).

CHECKLIST: a systematic and comprehensive list of the species (and, frequently, subspecies) occurring in a certain geographical area; less usually, a list of the species in a family or order. Checklists usually summarize available information on the status and distribution of all the forms dealt with, but do not include biological data such as behaviour, ecology etc.

CHEEK: see TOPOGRAPHY.

CHEER: *Catreus wallichi* (see PHEASANT).

CHEMICAL REPELLENTS: see REPELLENTS, CHEMICAL.

CHEST: the THORAX; if used to designate a surface area, practically synonymous with breast (see TOPOGRAPHY).

CHEWINK: alternative name for the Rufous-sided Towhee *Pipilo erythrophthalmus* (see BUNTING).

CHICK: see under YOUNG BIRD.

CHICKADEE: substantive name, in North America, of some *Parus* spp. (see TIT).

CHIFFCHAFF: *Phylloscopus collybita*, a well-known Palearctic warbler, so named from its simple repetitive song (see WARBLER (1)).

CHILIA: substantive name sometimes used for the South American furnariid *Chilia melanura* (see OVENBIRD (1)).

CHIN: see TOPOGRAPHY.

CHIONIDAE: see CHARADRIIFORMES; SHEATHBILL.

CHIPPING: see HATCHING.

CHI-SQUARE TEST: see BIOSTATISTICS; STATISTICAL SIGNIFICANCE.

CHITINOUS: made of the hard horny substance ('chitin') of which the external skeletons of insects are composed (see PELLET).

CHLOROPHONIA: generic name used as substantive name of *Chlorophonia* spp. (see TANAGER).

CHLOROPSEIDAE: name used by Wetmore for a family equivalent to the Irenidae less *Irena* (see LEAFBIRD).

CHOANA: a funnel-shaped passage; especially one of the interior nares (see NARIS; SMELL).

CHORD: see MEASUREMENT.

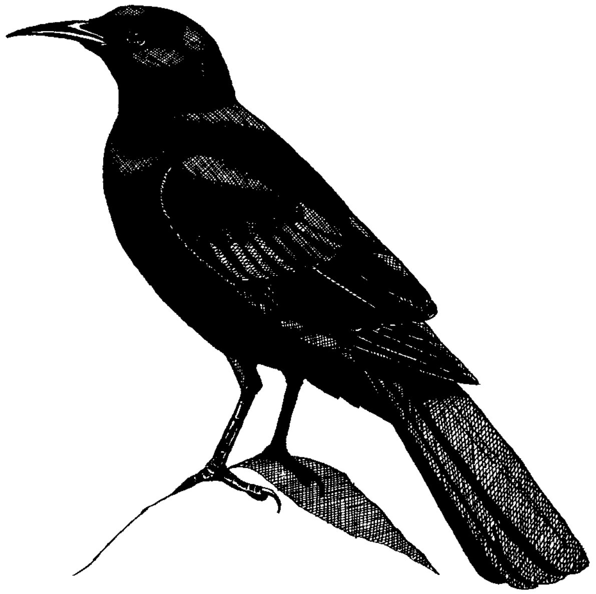
CHORDATES: see ANIMAL KINGDOM.

CHORDEILINAE: see NIGHTJAR.

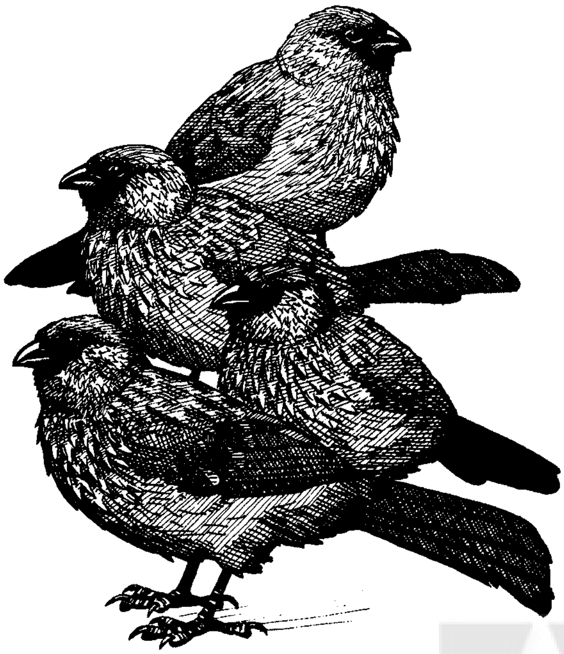
CHOUGH (1): substantive name of *Pyrrhocorax* spp., used without qualification, in Britain (but sometimes 'Cornish Chough'), for *P. pyrrhocorax* (see CROW).

CHOUGH (2): substantive name, as White-winged Chough *Corcorax melanorhamphos*, of one of the 2 members of the endemic Australian family Corcoracidae (Passeriformes, suborder Oscines), the other being the Apostlebird *Struthidea cinerea*. Until recently both were regarded as forming the subfamily Corcoracinae in the family Grallinidae, now restricted to the MAGPIE-LARK and one other species (Schodde 1975).

Characteristics. The White-winged Chough is 47 cm long, sooty black with a conspicuous white wing patch on the primaries that shows clearly in flight, a long curved bill like its namesake *Pyrrhocorax* (CHOUGH (1))



White-winged Chough *Corcorax melanorhamphos*. (*N.W.C.*).



Apostlebird *Struthidea cinerea*. (*N.W.C.*).

and long strong legs. The Apostlebird (28.5–35 cm long) is basically grey coloured with brown wings and a black tail. The strong bill is reminiscent of a sparrow's *Passer* but much larger. The eye colour changes with age in both species.

Habitat and distribution. Both *Corcorax* and *Struthidea* are confined to the eastern half of the Australian continent, neither of them reaching Western Australia or Cape York peninsula. *Corcorax* is common in the dry sclerophyll woodlands of the tablelands along the Great Dividing Range and inland to the Darling River; but is less frequent near the coast. *Struthidea* largely overlaps *Corcorax* but is found further inland and reaches the Northern Territory; it is less frequent on the tablelands or near the eastern seaboard than *Corcorax*. Both species seem to have adapted well to agricultural settlement and *Corcorax* has colonized the numerous large plantations of exotic pines planted commercially in southern Australia.

Throughout the breeding season *Corcorax* and *Struthidea* confine their activities to an area of some 20 ha surrounding the nest, which is defended against trespass by conspecifics and can therefore be regarded as a territory. For the rest of the year the birds forage over an area of several km^2; large aggregations form where food is locally abundant as on a cereal stubble after harvest. Both species are more at home on the ground than in the air and most of their travelling is done on foot. They tend to ascend trees by a series of leaps.

Food. *Corcorax* spends much of the day searching under branches, leaves, cowpats and tussocks for insects which form the major part of its diet, with seeds important in the winter. This search is accomplished by a sideways sweeping of the bill: the feet are never used for raking. *Struthidea* with its dumpy strong bill is pre-eminently a seed-eater although insects are also an important part of its diet.

Behaviour. Groups of *Corcorax* average 6 (2–20) whilst those of *Struthidea* average 9 (3–19) members, though its English name suggests the 12 Apostles. Many aspects of the group life of both species are similar. The units generally grow by the retention of offspring although fragmentation of a group after the death of the dominant male may result in the formation of a new unit by unrelated individuals. All members of the group may help to build the nest, to incubate the eggs and to feed and care for the nestlings and fledglings. No correlation between feeding rate and group size was found in *Corcorax* (Rowley, 1978a). Groups of from 4–8 birds reared similar numbers of nestlings (1.0–1.3 p.a.) whilst smaller groups were very unsuccessful and groups larger than 8 fledged most young. Only half of the young that left the nest lived to become a year old; during that time survival was better in groups of more than 6 birds than in smaller groups. Another apparent advantage of living in a large group is that after one brood has left the nest it may be cared for by part of the group whilst the others produce a second brood, reuniting later.

Display. *Corcorax* displays by waving its part-opened wings and spread tail, alternately. *Struthidea* lacks any wing marking and displays by bobbing its head up and down and waving its tail.

Voice. *Corcorax* has a series of single and double pipes and whistles which are quite unlike anything uttered by *Struthidea*, but both species have a similar creaky or rasping alarm call; *Struthidea* utters a series of calls rendered as *ch-kew, ch-kew, creechew creechew* . . .

Breeding. Both species build very similar nests of mud (as do MAGPIE-LARKS) 2–15 m above the ground on horizontal branches. These open bowls appear to be solid mud but contain up to 7% by weight of fibre. A piece of fibre (grass-stem or bark) is selected by the builder and taken to a mud source where it is dabbled until coated thoroughly; this is carried to the nest where it is trowelled into place with the bill and then settled by a rapid scissoring action of the mandibles. The side walls are seldom raised more than 2 cm per session since they need to harden before being added to. Such nests may last for years and are often reused (Rowley, 1978b). The 2 species usually nest from spring into the early summer but have been recorded responding to rainfall at other times by nest building and breeding. The normal clutch size is 2–5 but occasional multiple clutches (up to 10 eggs) have been recorded. Incubation lasts 19 days and the nestlings fledge when 23 (*Struthidea*) or 23–28 (*Corcorax*) days old. Fledglings are dependent on the adult group for food for several months. I.R.

CHRISTMAS BIRD COUNT: see BIRD-WATCHING.

CHROMATOGRAPHY: see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA.

CHROMOSOME: see CELL; GENETICS.

CHRONOCLINE: term introduced by G.G. Simpson for the gradation of a form in time, going back towards an ancestral type.

CHRONOMETER, BIOLOGICAL: see RHYTHMS AND TIME MEASUREMENT.

CHUCK-WILL'S-WIDOW: *Caprimulgus carolinensis* (see NIGHTJAR).

CHUKAR: *Alectoris graeca* (see under PHEASANT).

CHURRING: sustained low trill or reel, e.g. Nightjar's.

CHYME: the semi-fluid partly digested food leaving the gizzard for the duodenum (see ALIMENTARY SYSTEM).

CICADA-BIRD: Australian name of *Coracina* (*'Edolisoma'*) *tenuirostris* (see CUCKOO-SHRIKE).

CICONIAE; CICONIIDAE: see below.

CICONIIFORMES: an order, alternatively 'Gressores', and formerly also 'Herodiones', comprising 3 suborders: Ardeae, Scopi, Ciconiae; 5 families: Ardeidae (HERON, BITTERN), Scopidae (HAMERKOP), Ciconiidae (STORK), Balaenicipitidae (SHOEBILL), Threskiornithidae (IBIS, SPOONBILL).

The Ciconiiformes are mainly large birds, characteristically with long legs and long bills, adapted for wading in shallow water or marshes and mostly living on fish or other animal prey.

CINCLIDAE: a family of the PASSERIFORMES, suborder Oscines; DIPPER.

CINCLODES: substantive name now regularly used for the ground-living furnariids of the genus *Cinclodes* (see OVENBIRD (1)).

CINCLOSOMATINAE: see TIMALIIDAE; RAIL-BABBLER.

CIRCADIAN: term applied to a biological rhythm of about a day, i.e. *circa* 24 hours (see RHYTHMS AND TIME MEASUREMENT).

CIRCAETINAE: see HAWK.

CIRCANNUAL (CIRCENNIAL) RHYTHMS: endogenous annual rhythms persisting under seasonally constant environmental conditions with a period of approximately (*circa*) one year (*annus*).

CIRCINAE: see HAWK.

CIRCULATION: see HEART; VASCULAR SYSTEM.

CISTICOLA: substantive name often used for some members of the large genus *Cisticola* (see WARBLER (1)).

CLADE: see CLADISTICS.

CLADISTICS: Method of biological classification, also applicable in biogeography. The basic principles of cladistics were set out by Willi Hennig (1966). The keys are his definition of relationship (Fig. 1) and his discussion of how relationship is recognized. Relationship in Hennig's sense, by closer common ancestry, is evinced only by shared derived characters (synapomorphies) inherited from that ancestry. Shared primitive characters (symplesiomorphies), inherited from a more remote ancestry, are irrelevant or misleading in the search for relationship. For example, the teeth and long bony tail of ARCHAEOPTERYX are irrelevant to its relationship with birds, for lizards, salamanders and fishes also have teeth and long bony tails. Feathers and a furcula, however, are synapomorphies unique to *Archaeopteryx* and birds. The third type of character, those unique to any one species or group, Hennig named autapomorphies. The three terms autapomorphy, synapomorphy and symplesiomorphy describe the distribution of characters relative to a particular problem: feathers are an autapomorphy when one is interested in what (featherless) group is most closely related to birds, a synapomorphy when one is interested in the relationships of *Archaeopteryx*, and a symplesiomorphy if the problem is one of relationships within birds.

From these ideas, Hennig derived definitions of three types of group. Monophyletic groups contain all and only the descendants of a common ancestor (ABCD, BCD or CD in Fig. 1), and are characterized by synapomorphies or evolutionary novelties. A paraphyletic group is created when one or more parts of a monophyletic group are removed because of autapomorphies (e.g. Reptilia—those amniotes remaining when birds and mammals are removed; Invertebrata—metazoans lacking vertebrate characters). All 'ancestral groups' are paraphyletic. Polyphyletic groups are those whose defining characters are assumed not to have existed in the latest common ancestor of the group: they are characterized by convergence or non-homology (e.g. a group of all winged animals).

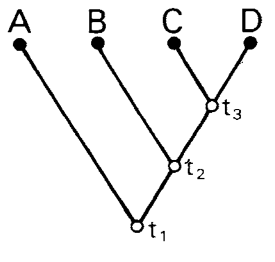

Fig. 1. Hennig's definition of relationship. Two species (e.g. C and D) are more closely related to each other than to a third (A or B) if they share an ancestral species (at t_3) not shared with the third.

Cladists argue that classifications should contain only monophyletic groups. Paraphyletic groups, which are permitted or recommended in evolutionary classifications, should be avoided because they have no historical reality (they cannot become extinct, for example), and no defining characters. Reptiles, for instance, can be defined only by listing characters they lack, such as feathers, hair and homothermy.

Cladistic analysis consists of evaluating the distribution of characters, and ordering homologous characters in 'transformation series' from primitive to derived. Ontogenetic transformation is the only unambiguous method of ordering the polarity of such series, but ancillary methods such as outgroup comparison are available. That cladogram is accepted which is congruent with the distribution of the greatest number of characters rated as synapomorphous. The cladist method is epitomized by 'search for the sister group'—sister groups are species or groups which are each other's closest relatives, such as C and D or B and C + D in Fig. 1.

In forming classifications, cladists recommend that the cladogram be directly translated into the classification; in other words, that sister groups be given equal rank. A cladistic classification of Fig. 1 would be:

- taxon ABCD
  - subtaxon A
  - subtaxon BCD
    - infrataxon B
    - infrataxon CD
      - species C
      - species D

The structure of the cladogram determines the relative rank of the taxa, but not their absolute rank. Hennig proposed ranking by age, for example that groups originating in the late Palaeozoic be ranked as orders, but this practice is not general. Various devices and notations have been proposed to simplify cladistic classifications (Wiley, 1981).

Cladistic analysis is now accepted by many evolutionists as the best approach to systematics. The principal remaining difference between cladists and non-cladists is that the latter wish to retain paraphyletic groups, since they are held to be consonant with evolutionary theory in allowing divergent groups higher rank than their sister groups (e.g. class Aves versus order Crocodilia). Modern developments in cladistics tend to divorce systematics from evolutionary theory, by drawing a distinction between cladograms (summaries of character distribution) and trees (character distribution plus ancestry and descent) (Nelson and Platnick, 1981).

In biogeography, application of cladistics has resulted in the development of vicariance biogeography, in which species cladograms are used to specify the historical interrelationships of geographic areas (Nelson and Platnick, 1981). C.P.

CLASS: a primary taxonomic category; all birds, including those known only from fossils, constitute a single 'class' of animals, the Class Aves (see ANIMAL KINGDOM; AVES; TAXON): even so, birds are reduced to the rank of a subclass of the Class Reptilia by some authors (Wolters 1975–82). A class is divided into 'orders', but these may be grouped in intermediate categories such as subclasses and superorders.

Subclasses. The division of the Class Aves into subclasses has no practical application to the taxonomy of geologically recent birds, all the orders of which fall in the subclass Neornithes; the most ancient of the fossil birds, the Archaeornithiformes of the Jurassic, are placed by Wetmore in his only other subclass, the Archaeornithes. There are, however, other possibilities, particularly adhered to by palaeontologists, e.g. by Brodkorb (1963): Class Aves, Subclass Odontoholcae (with Hesperornithiformes, tooth-billed birds), Subclass Ornithurae (all orders known as Neornithes).

Superorders. Wetmore divides the Neornithes into the superorders Odontognathae, Ichthyornithes, Impennes, and Neognathae. Of these, the first and second include only fossil birds; the third includes only the Sphenisciformes (penguins); and all other recent (and some fossil) birds are assigned to the Neognathae. So far as birds of today are concerned, therefore, use of the superordinal category involves nothing beyond the question whether the penguins differ more fundamentally from all other recent orders than these differ from each other—a point on which many disagree with Wetmore. At present the systematic arrangement of birds is in a state of intensive re-consideration at all levels and with all kinds of experimental, biochemical methods and cladistic re-interpretations, the end of which is not yet in sight.

CLASSIFICATION: the grouping of organisms into categories or taxa and the subsequent grouping of these into a system, usually hierarchical; also the finished product of the grouping. The work of classification is known as taxonomy or systematics. Both names at present are usually considered synonymous and in common usage are often interchangeable. In fact, since A.P. de Candolle (1813), the term taxonomy has been formerly more regularly applied to the classification of plants, whereas the term systematics has remained more directly based on the title of Linnaeus' *Systema Naturae* (1735 and subsequent issues) and has been for a long time the exclusive term in zoology. In modern literature taxonomy more often refers to the analytical, systematics to the more synthetic part of the work of classification. Nomenclature, the naming of categories, is a practical, not an essential part of classification (see SYSTEMATICS; TAXON; TAXONOMY; NOMENCLATURE).

Theories of classification. The primary goal of classification is to see order or rather reveal basic systems, if present, in the multitude of forms of life that occur and have occurred on earth. It does not aim merely to provide a general reference system for universal scientific use; instead it is an expression of basic biological theories. For it has not always been self-evident that the diversity in nature can be theoretically classified and there are still various philosophical approaches to classification known as essentialism, empiricism, nominalism, and evolutionism. All classifications start with noting differences, hence with discriminating between groups. At first, these groups were based on easily observable differences in outward appearance, which in birds mean particularly bill and feet, leading to groups such as 'birds with curved beaks', order XIV of Linnaeus, including Hoopoe *Upupa*, Treecreeper *Certhia*, Hummingbird *Trochilus*. This was followed by more biological classifications such as that by Carl Illiger (1811) who arranged birds into: *Scansores, Ambulatores, Raptatores, Cursores, Grallatores, Natatores.* With acceptance of the existence of organic evolution, the notion of relationship as the basic principle in classification has replaced that of appearance or structure and through this arose the difference between the *artificial* (based on similarities) and *natural* (based on relationships) classification systems. At present nearly all classifications of birds are intended to be natural and attempt to reflect the evolutionary history of birds.

Methods of classification. For a long time linear sequences of hierarchically arranged categories could meet the needs of classificatory work. Linnaeus recognized 6 taxonomic categories in which to arrange the organic and inorganic world in his *Systema Naturae* (1735): *regnum, classis, ordo, genus, species, varietas.* The now generally used category 'family' was introduced in ornithology by F.M. Daudin not before 1800. It should be stressed that these categories are not natural categories; according to most present-day authors the only 'natural' entities in nature are individuals and (at their best) species. Therefore the number of categories recognized is theoretically unlimited and this is acceptable as long as the principle of hierarchy is adhered to. The following taxonomic categories, arranged according to hierarchy, are at present in wide use: *regnum* (Animals), *phylum, subphylum, superclass, class* (Birds), *subclass, cohort, superorder, order, suborder, superfamily, family, subfamily, tribe, genus, subgenus, superspecies, species, subspecies.*

Usage of categories and recognition of characters on which distinctions are based are subject to the personal judgement of the taxonomist. There are no special specific, generic, familial etc. characters; all those in use are a matter of comparison and tradition. In the better known animal groups, such as birds, most recent authors tend to incorporate any distinctive character in the complex of data used to discriminate between taxonomic categories, irrespective of whether these characters are of a morphological, structural, genetic, biochemical, physiological, ethological or ecological nature. In this way classification has become a matter of the study of the living bird rather than exclusively that of the cabinet specimen. The need to do this was fully explained in *The New Systematics* (1940, editor Julian S. Huxley), which heralded the revival of systematics as a biological science. The different methods of classification used today and described below reflect basic differences in classification theory.

Evolutionary systematics. Several attempts have been made to reduce the traditionally subjective aspects of classificatory work. One of these is the mainly neo-Darwinian evolutionary systematics which judges on 'weighted phenetic similarities' in the context of evolutionary relationship. This method was followed by nearly all bird taxonomists during the first half of this century and by a majority for many years after the publication of Mayr's *Systematics and the Origin of Species* (1942).

Phylogenetic systematics. More recently the so-called phylogenetic systematics has given a strong impetus to classificatory work and achieved notable results. This kind of approach is based on the theory of CLADISTICS (the description of the course of evolution through clades, which are delimitable monophyletic units) developed by the entomologist Hennig (1950, English translation 1966). Basic to this theory is the search for those points in evolution where clades start to diverge, a method which is only possible by rigid distinction between primitive or original similarities (symplesiomorphies) versus progressive or derived similarities (synapomorphies). All forms sharing a certain derived character must have branched off together, i.e. in the same clade, from other related forms which have kept the same character in an original, relatively primitive state. Basically this is the same reasoning as that of the classical comparative anatomists of the decades around the turn of the century. The strict application of the method means that all groups sharing a derived character must be placed in a taxonomic category of the same hierarchical value as the 'sister group' of related forms which retains the character in its primitive state—a procedure that sometimes produces apparently absurd results. The method has been most efficiently applied in birds by Cracraft relating to cranes and rails (1973) and the ratites (1974), by Feduccia (1977) relating to perching birds, and by Raikow (1978) relating to New World nine-primaried songbirds. The rigid application of the theory of cladistics to classification has been severely criticized by Mayr (1974, reprinted 1976).

The method results in a system of cladistics, named cladograms, with fixed points at the supposed beginnings of divergence between clades, the whole resembling the branches of a tree of descent. The main drawback is that, as in the heyday of comparative anatomy, no one can be sure which characters are analogous (similar structure and function but not same origin) and which are homologous (same origin but not necessarily similar structure and function). Hence the course of evolution remains as difficult to trace as ever, and the reality of the branching points may be illusory. Moreover, a cladistic system may be representative of the possible phylogenetic history of one or more organs or structures rather than of the organisms themselves (birds).

Numerical taxonomy. To avoid a classification based on one or a few characters, the choice of which is subjective, several authors have suggested that as large a number of characters as possible should be taken into consideration and quantified; those organisms scoring the highest number of similarities are likely to be most closely related. In birds this was practised not very successfully for osteological characters by Verheyen (1961), but in general zoology (and bacteriology) it received balanced mathematical (in later years computerized) treatment by Sokal and Sneath (1963), and became known as Numerical Taxonomy. The method, which uses measurable phenetic characters known as Operational Taxonomic Units (OTU's), results in the construction of so-called phenograms. These are static, not evolutionary or phylogenetic, illustrations of observable degrees of similarities and differences. Numerical taxonomy was applied to birds among others in the methodologically most interesting works by Schnell (1970) on gulls and Robins and Schnell (1971) on North American grassland sparrows.

On the whole, numerical taxonomy has not yet provided new insight in avian systematics; probably it will not, as the number of bird species is small and, compared with other animals, the structural resemblances among birds are larger than the differences among them, so that the human brain can still master the details of similarities and distinctions and weigh their importance in phylogenetic history. This also applies to the recognition of characters of great adaptive plasticity, such as bill, feet and wings, which often obscure the results of numerical taxonomy, and to 'the role of adaptive mechanisms in the origin of higher levels of organization', to cite a title by Bock (1965).

To avoid the trap in numerical taxonomy of the subjective choice of taxonomic characters used, and to help combine the advantages of numerical taxonomy and cladistic analysis, a new method has been proposed by Estabrook (1972) and others: the method of *character compatibility*. This method is based on the old concept of the occurrence of character combinations, particularly applied in plant taxonomy, and works with Evolutionary Units (EU's) rather than with species or other taxa. Hence, though theoretically it can fall into the same trap as that of orthodox comparative anatomy, it is less liable in practice to do so. The method is complicated and has been applied to birds, e.g. by Strauch (1978) in a review of the phylogeny of Charadriiformes.

Evaluation of methods. Present classifications of birds at their best are based on mixtures of evolutionary and phylogenetic systematics, the ultimate results of which are neither very satisfactory nor notably unsatisfactory. Avian systematists lack the fossil information available more prolifically for mammals. As a result, knowledge of the relationship of higher systematic groups (categories from families upwards) has proved in particular to be more imperfect than had been realized, so that numerous changes of insight and opinions of basic importance can be envisaged in the near future. This not only refers to details (e.g. suggested close relationship of flamingos (Phoenicopteridae) with stilts and avocets (Recurvirostridae)), but also to methods of theoretical approach, for which see the numerous outstanding papers in recent issues of the journal *Systematic Zoology*. Mention should also be made of the biochemical papers by Sibley and Wilson and their collaborators, dealing with DNA-hybridizations and differences in the rates of change in evolution of proteins and morphological structures, respectively (see references under DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA). All these recent studies mark a renewed interest in macro-classification as applied to the biology of birds.

Current systems in practice. To quote Landsborough Thomson, 'One must not seek to stereotype systematic thought and thus deter progress; but with such diverse views on the part of specialists, it is for most purposes of ornithology desirable to standardize—at least for a time—one particular system.' That followed in the present work down to familial level, and set out at the beginning of the volume, is a combination of the arrangements and linear sequences by Wetmore (1960), Stresemann (1959), Sibley, Ahlquist and collaborators (1970, 1972) and Storer (1971). Quite a number of other lists have been published in recent years. The most elaborate and well-balanced is that by Morony, Bock and Farrand (1975); the most unorthodox and wholly cladistic is that by Wolters (1975–1982). No classification can be final, as our knowledge of the course of evolution cannot be otherwise than imperfect; hence classification and sequences will always be liable to change and will remain in a happy stage of continued progress. Wolters, H. 1975–1982. Die Vogelarten der Erde. Hamburg.

CLAVICLE: a paired bone ('collar bone') of the pectoral girdle, the two clavicles in birds being fused to form the furcula ('wishbone' or 'merrythought')—see SKELETON, POST-CRANIAL.

CLAW: for those on the toes, see LEG; also MOULT; for those sometimes borne on the manus, see WING.

CLEIDOIC: term descriptive of the totally enclosed condition of eggs of the type produced by birds. Such an egg represents a virtually sealed physiological system (except for some gaseous exchange) during the period of incubation, a condition that makes certain adaptations necessary, e.g. as regards EXCRETION. See DEVELOPMENT, EMBRYONIC; EGG; EXCRETORY SYSTEM; NUTRITION.

CLIMACTERIDAE: a family of the PASSERIFORMES, suborder Oscines; TREECREEPER (2).

CLIMATIC ADAPTATION: an adaptation serving to fit the species for occupation of a particular climatic region, or to optimize on the opportunities and limitations of such. It includes breeding modifications, seasonal movements, etc. (see ADAPTATIONS, ENVIRONMENTAL).

CLIMAX COMMUNITY: a biotic community representing the maximum ecological development possible in the particular environment (compare SERAL COMMUNITY).

CLIMAX VEGETATION: see HABITAT.

CLIMBING: see LOCOMOTION, TERRESTRIAL.

CLIMOGRAPH: an ecological method of combining experimental data and field observations in the form of a contoured diagram expressing the effects of temperature and humidity, acting together, in the range of a species under study (see ECOLOGY).

CLINE: a term introduced by Huxley for a geographical gradient in a phenotypic character within the range of a species, for example the increasing darkness of plumage from east to west found in many European bird species; sometimes, but less satisfactorily, used for the aggregate of populations showing such variation. A cline has itself no status in nomenclature. It may include forms to which subspecific names have been attached, although where the gradation is continuous (as happens in the absence of barriers) the validity of such subspecies becomes questionable (see SUBSPECIES; and DEME). Nevertheless, the forms at the extremities of a cline may show striking differences when directly compared with each other, and this may be true also of intermediate forms taken from points sufficiently far apart in the clinal range; in such cases the use of subspecific names may have a practical convenience in providing taxonomic points of reference. Notations have been suggested for the designation of clines in terms of their geographically extreme forms, but this procedure seems to import a concept too rigid for the reality. The fact is that different characters may show clinal variation independently of each other, and sometimes in different directions, e.g., some from east to west and others from north to south.

Huxley, J.S. 1938. Clines: an auxiliary taxonomic principle. Nature 142: 219–220.

CLIPPING: rendering a captive bird temporarily incapable of flight by cutting the primary feathers of one wing; these feathers are replaced at the next moult (compare PINIONING).

CLOACA: the combined terminal opening of three physiological systems (see ALIMENTARY SYSTEM; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; EXCRETORY SYSTEM). This single opening in birds (and reptiles) contrasts with mammals, wherein the ailmentary system has a separate terminal opening to the exterior.

CLOCK, BIOLOGICAL: see RHYTHMS AND TIME MEASUREMENT.

CLOSE RINGING: see CAGE BIRD; CONSERVATION; MARKING.

CLOSE SEASON: period of protection, covering the breeding season, for birds shot for sport.

CLOUD: see MIGRATION; NAVIGATION; WEATHER AND BIRDS.

CLOUD-SCRAPER: substantive name of some *Cisticola* spp. (see WARBLER (1)).

CLUB: term generally applied to a gathering of non-breeding seabirds on the edge of a breeding colony. Although club sites vary from day to day with, for example, prevailing wind and tidal conditions, they are essentially traditional, offering a sufficient area for congregation, a good vantage point, and ready access and exit. In the great majority of cases, those attending are non-breeders of both sexes, whether immature or adult, also failed breeders. At any colony, the size and composition of the club will vary with the availability of immature birds to join it, depending in turn on factors such as season and the colony's previous breeding success.

Apart from loafing and comfort activities, club members typically perform a wide repertoire of sexual and territorial behaviour, including copulation. The club thus serves as a place where birds may encounter others of comparable age and status, and provides a venue for mate attraction and in some cases at least, preliminary pair formation. Often, as in, for instance, the Gannet *Sula bassana* and Guillemot *Uria aalge*, the males defend temporary sites within the club from which they advertise for females.

CLUMPING: see ROOSTING.

CLUTCH: a set of eggs, i.e. the complete number laid by one female and incubated simultaneously (written c/1, c/2, c/3 etc.) (see CLUTCH-SIZE; EGG; LAYING; also ECOLOGY). For exceptions see BROOD-PARASITISM.

CLUTCH-SIZE: number of eggs laid in a discrete group within a clearly defined, often elaborate NEST. The number of eggs laid varies markedly for a number of reasons.

Natural selection; optimal and most productive clutch-size. It is presumed here that the clutch-size of any species is the product of natural selection, adjusted so as to maximize the parents' contribution to future generations. Three main factors contribute to the clutch-size evolved by any species. Firstly, in species which feed their young, an increase in brood-size means that the parents have to work harder to provide food for them. In practice, however, any increase in feeding rate is not proportional to the increase in brood-size, so that the individual young in large broods receive less than those in small broods. As a result, compared with young in small broods, the young in large broods either fail to fledge or leave the nest lighter in weight and with a lower chance of survival. The outcome is that birds starting off with very large clutches may actually raise fewer young than those with smaller clutches.

Secondly (and this may apply particularly to nidifugous birds such as Anseriformes, Galliformes and most Charadriidae) any increase in clutch-size makes the nest or brood more conspicuous so that losses from predation outweigh the advantages of laying the larger clutch.

The combination of these two factors will dictate the *most productive clutch-size* (that which produces the largest number of surviving young per nest). Nevertheless, a third factor will also influence the clutch-size evolved; this relates to the survival of the parents. Compared with parents of smaller clutches, the parents of the most productive clutches may suffer higher mortality because they have to work harder to feed the larger broods and either put themselves at greater risk from predation or are less able to lay down reserves for moulting and surviving the winter. If this is the case, natural selection will favour an *optimal clutch-size* (that which yields the largest number of surviving young in the parents' life-time); this will be somewhat smaller than the most productive clutch-size.

The number of eggs laid in a clutch varies considerably, both between and often within species. The mechanism by which the number of eggs in a clutch is determined physiologically is not fully known (see LAYING).

Inheritance of clutch-size. All evolutionary arguments have as their basis the assumption that the feature concerned is heritable. Heritability of clutch-size has not been studied widely in birds, but has been shown to exist in the Great Tit *Parus major*. In this species, the female and, by inference, the male both contribute to the clutch-size of the daughter. (Perrins and Jones 1974; van Noordwijk *et al* 1980).

The relationship between food and clutch-size. The production of a clutch of eggs may impose considerable demands on the laying female. In extreme cases such as some of the tits Paridae, some ducks Anatidae, and game-birds Phasianidae, the weight of a complete clutch may exceed the weight of the female herself. The production of such a clutch obviously requires very considerable amounts of extra food, and it seems possible that clutch-size is related to the food supply available to the laying hen. Such a relationship has been demonstrated for 2 migrant species. The Red-billed Quelea *Quelea quelea* migrates short distances between breeding areas. Its body reserves of fat and protein (the latter mainly in the flight muscle) decrease to such a low level during laying that the female's clutch is almost certainly limited by the level of her reserves. The Lesser Snow Goose *Anser caerulescens caerulescens* and other geese which breed in the high Arctic, arrive on the breeding grounds when these are still largely snow-covered. They lay their eggs and sometimes undertake much of the incubation before feeding is possible, relying on the food reserves with which they arrived. In the Lesser Snow Goose these reserves affect the size of the clutch; in the Barnacle Goose *Branta leucopsis* there is evidence that the breeding success is affected by the winter feeding conditions. But in many cases there are good reasons for believing that clutch-size is not controlled by food supply. Firstly, if a bird loses its clutch to a predator during or shortly after laying it, the bird may quickly lay a repeat clutch; the total number of eggs may be considerably in excess of the normal clutch. Secondly, in a few experiments where extra food has been provided early in the breeding season, the laying date, but not the clutch-size, has been altered (see BREEDING SEASON).

Hence it seems likely that the clutch-size of most birds is related to the amount of food the parent birds can collect for their brood, not the amount that is available for the laying hen (but see *Food Supply* below).

Phenotypic variation in clutch-size. Not only are there differences between individuals in the clutch-size laid, but individual birds lay clutches of different size under different circumstances (see ii below). A number of observers have recorded that large clutches may produce more survivors than clutches of average size, an observation which, at first sight, contradicts what has been said above. But evidence suggests that the larger clutches are laid under circumstances when the birds are likely to be able to raise large broods (Perrins and Moss 1974). Two types of circumstance may be involved, though they are not easily separated.

Firstly, clutch-size may vary with the 'quality' of the individual female herself. If more 'able' females (perhaps ones which are better at foraging) lay larger clutches than less 'able' females, large clutches will result in a larger number of surviving offspring than the normal clutches of less able females. The evidence for such an effect comes from experiments in which females who have laid clutches of different sizes are, artificially, given broods of the same size; among these females (who now have broods of the same size) those who laid the largest clutches are most successful at raising young.

Secondly, individual birds may respond adaptively to small changes in the environment; they may lay larger clutches in good habitats (see (vii) below) than in poor ones. There is some recent evidence that birds can respond to the quality of the territory; Magpies *Pica pica* lay larger clutches in territories where breeding success (by other pairs in previous years) has been more successful than they do in territories where breeding success has been lower in earlier years. Such responses will lead to the observation of large clutches yielding higher numbers of surviving young than smaller clutches.

Birds, then, do not simply inherit the ability to lay a clutch of a fixed size; more likely they can be thought of as inheriting the ability to lay a clutch which varies within certain limits and, at the same time, the ability to vary that clutch by 'recognizing', and responding adaptively to, certain environmental features which affect the ease with which the brood can be raised.

Variations in clutch-size. Clutch-size varies both between and within species. Indeed, the same individual bird may lay clutches which differ markedly in size in different years or at different stages of the season. The main features with which variations in clutch-size are associated are listed below:

(i) Taxonomic groupings. Perhaps the most striking variation observed is that between different taxonomic groups (see Lack 1968). While doubtless this can be partly explained by the tendency for birds in each group to be ecologically similar, the differences in clutch-size between different groups are very marked: at the low end are the Procellariiformes in which all species, from the smallest storm petrels (Hydrobatidae) to the largest albatrosses (Diomedeidae) lay only a single egg. At the other extreme are the game-birds, whose precocial or nidifugous young leave the nest soon after hatching and fend for themselves, although they are usually guarded by the hen. Although a few species such as the Argus Pheasant *Argusianus argus* have small clutches (only *c.* 2 eggs), most have much larger clutches. The European Grey Partridge *Perdix perdix*, which in Finland lays clutches of *c.* 19 eggs, has possibly the largest clutch of any nidifugous bird.

Within-species variation in clutch-size can also be correlated with taxonomy, being much larger in some groups than others. Within the Charadriidae, for example, each species has a very constant clutch-size (commonly 4), whereas in other groups such as the owls, the clutch-size of many species varies markedly (see ix below).

(ii) Body-size. Within any given taxonomic group there is a tendency for the smaller species to lay the larger clutches. For example most ducks (Anatinae) lay 7–9 eggs while most geese and swans (Anserinae) lay only 5–6. In some orders, a number of the largest species may lay only a single egg although smaller species have larger clutches (e.g. eagles (Accipitridae); penguins; cranes; auks).

(iii) Egg-size. Egg-size tends to be inversely related to clutch-size, those birds which have large clutches tending to have small eggs and vice-versa. Such a generalization only really holds within taxonomic groups, because different groups have large differences in clutch-size and relative egg-size. A negative correlation between egg-size and clutch-size also holds between individuals of the same species and even between different clutches of the same individual. This has the interesting implication that the bird 'knows' how many eggs will be laid in a given clutch when the first egg is ovulated.

(iv) Nest-type. Many hole-nesting birds lay larger clutches than closely related species which nest in open sites. For example, in the sub-family Anatinae, hole-nesters have an average clutch of 10.4 eggs compared with other species whose average clutch is 5.0. In hole-nesting passerines in Central Europe the average clutch is 6.9 compared with 5.1 for open-nesting species. In general, the hole-nesters also tend to have young that develop more slowly; in the passerines quoted above, hole-nesters fledge at a later age (17.3 days) compared with open-nesters (13.2 days). The difference is believed to be associated with the relative safety of nests in holes. Since nests in such sites are less liable to be found by predators, it has proved advantageous to lay larger clutches and take longer over raising them. In contrast, open-nesting species have smaller clutches with faster development and they tend to have more broods within a season. The hole-nesting Blue Tit *Parus caeruleus* lays a clutch of 11–12 eggs in good habitats in Europe (this is an average figure; individuals may exceptionally lay as many as 18 or 19 eggs); this is the largest clutch laid by any nidicolous species.

(v) Nest-size. Within species, variation in clutch-size has sometimes been related to the size of nest. In a small number of hole-nesting species the female appears to modify the size of her clutch in relation to the size of the hole, laying larger clutches in larger sites; presumably, this is in response to the ability to raise a brood in a certain size of nest. There is some evidence that exceptionally large broods may be stressed, inasmuch as they have difficulty preventing themselves from overheating.

One feature of nest-size which needs explanation relates to the open cup-shaped nest which is so characteristic of many species of passerine. No species seems normally to lay a clutch larger than 6 or 7 eggs in such a nest.

(vi) Latitude. Clutch-size varies markedly with latitude, increasing from the tropics northwards. This holds both when comparing closely related species, and even different populations of the same species, over a wide latitudinal range. Although the variation has been attributed to longer days, enabling birds to find more food in the north, this can at best be only a partial answer. For example, owls have larger clutches in temperate areas than in the tropics, yet most of these birds feed at night and the nights get shorter with increasing latitude. Further, the Snow Bunting *Plectrophenax nivalis* lays increasingly large clutches even beyond the Arctic Circle, although the amount of daylight available to parents for collecting food can hardly differ in such areas in mid-summer.

The most convincing explanation of this phenomenon has been provided by Ashmole (1963) and Ricklefs (1980), that clutch-size is related to the abundance of food per bird. The argument is that in the tropics there is a relatively stable environment, and in the equable non-breeding season, mortality is low. Consequently, populations of all species remain near to the food limit. Furthermore, the spring 'flush' of food is relatively small. As a result of both these factors, parent birds at low latitudes are not able to get large quantities of extra food to raise young, so large clutches are not productive. In contrast, the higher latitudes have a harsher environment outside the breeding season, hence fewer birds in spring and larger spring flushes of food; these factors combined lead to very rich supplies of food per pair and permit the raising of large broods.

(vii) Habitat. Within the tropics, clutches of closely-related species tend to be larger in savanna and grassland habitats than in rain forest. The explanation put forward is the same in principle as that given for latitude, that there is more food available per bird in habitats in which seasonal fluctuations are most marked (Lack 1968). The 'carrying capacity' of savanna outside the breeding season is lower than that of rain-forest, but in the breeding season parents can raise larger broods in savanna because there is more food available per pair.

The above refers to differences in clutch-size between closely related species. In addition, some studies have shown that clutch-size of the same species tends to vary in different habitats. The reasons for this may be related to the density of breeding pairs (see below) or to the quality of the habitat. At least in some areas, pairs breeding in marginal habitats lay smaller clutches, but whether they are poorer quality birds or whether the habitat is a poorer one for raising young is usually not known. Again, the assumption is that natural selection has favoured the laying of smaller clutches in circumstances where it is difficult to raise large broods.

(viii) Density. Clutch-size may vary inversely with breeding density. However, breeding density may affect reproductive output in a number of ways other than by affecting clutch-size. Non-breeding individuals may be more common at high than at low density. This may be either because more birds fail to obtain territories at high densities or, as in the Red Grouse *Lagopus lagopus*, because only the males with the largest territories can obtain a mate.

The reproductive output of the Great Tit is also related to density, but in this case the relationship arises because both clutch-size and the proportion of second broods (see below) decrease as density increases. As a result, there is a strong correlation between reproductive output per pair and breeding density.

The reduction in clutch-size with increasing density tends to be small and is by no means fully compensatory; a doubling of the density does not lead to a halving of the clutch-size. As density increases, the number of eggs per unit area of habitat increases steeply. Hence the most likely explanations for the lowering of clutches at high densities are:

(a) that at high densities the parents find it more difficult to form the eggs, or

(b) that the nests are at greater risk from predation under these circumstances, or

(c) that it is harder to find food for the young at high densities. Natural selection has favoured reducing the clutch under these circumstances since, by so doing, the chances of raising some successful young are increased.

(ix) Age. Clutch-size may vary with the age of the laying hen. The most common situation is perhaps that found in passerines where one-year old, and sometimes 2-year old birds lay smaller clutches than older birds. In some cases there are parallel variations in breeding ability, older birds being more successful than young ones. In multi-brooded species, the annual production of young of the older females may be larger both because they lay more eggs in a clutch and because they make more nesting attempts. For example, in the European Blackbird *Turdus merula*, older females raise on average 6.3 young per season compared with the 3.4 of one-year old birds. The difference arises only partly because of clutch-size (0.4 eggs larger in older birds); the older birds make an average of 3.1 nesting attempts per year compared with the 2.3 of young birds.

Often the male selects the territory and provides food for his mate during laying. It might be expected that older males would be more successful at such activities and that the females would lay larger clutches in response to the increased 'living standards' provided by the older males. Studies in North America on the Common Tern *Sterna hirundo* showed that the female laid a larger clutch if the male brought her an above average quantity of food; it is not known whether the males which brought more food were older than the others.

There are few convincing data demonstrating that when a breeding female becomes 'old' her clutch-size decreases; but this is true for the Hawaiian Goose *Branta sandvicensis*, at least in captivity.

(x) Season. Many birds show no seasonal variation in clutch-size, but among those that do there are perhaps two main trends. In certain species, especially those that are largely single-brooded, clutch-size may decrease as the season proceeds (Fig. 1a). This may be related to either of two factors. There is evidence for some species that the food supply for the young may be less abundant later in the season so that the parents who lay later may find it harder to raise large broods than those that lay earlier. Secondly, and probably inter-related with the first, the birds that breed later may be less efficient, or may be younger birds, and lay smaller clutches accordingly.

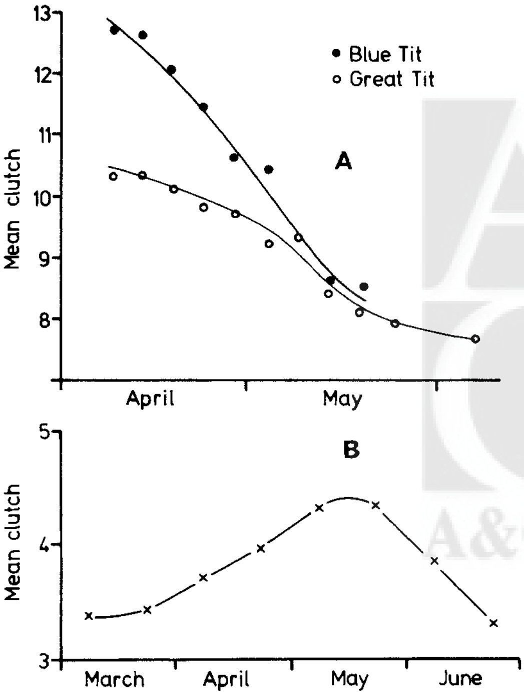

Fig. 1. Seasonal variation in clutch-size. (a) Blue Tit *Parus caeruleus* and Great Tit *P. major*. (b) Blackbird *Turdus merula*. Note the much longer laying season in the Blackbird. (From Lack 1966, Snow 1958).

In other species, such as the European Blackbird, the clutch-size increases during the early part of the season and then declines (Fig. 1b). This trend seems to be related to the food supply, the high clutches in mid-season coinciding with the maximum abundance of woodland caterpillars. Species which lay more eggs in the middle of the season than at either end tend to be multi-brooded.

(xi) Food supply. There is little evidence for most birds that food supply influences clutch-size. However, in certain game-birds it has been suggested that food supply affects not only clutch-size, but also egg quality (and through this, hatching success and subsequent survival). Certain owls, in particular the Tawny Owl *Strix aluco*, Short-eared Owl *Asio flammeus*, and Snowy Owl *Nyctea scandiaca*, lay larger clutches when their small mammal prey are more abundant than when prey are scarce. It is not known whether the female owls lay more eggs because they themselves can obtain more food or because the increased clutch is an adaptive response to the fact that larger numbers of young can be raised on the plentiful supply of food.

(xii) Islands. In a few cases, there is evidence that clutch-size of an island form is lower than on the adjacent mainland. For example, the Coal Tits *Parus ater* on the island of Corsica lay clutches which are about 2–5 eggs smaller than those on the adjacent mainland of France. A number of species breeding in the British Isles have slightly smaller clutches than their European counterparts. Little Owls *Athene noctua*, which were introduced to Britain from Europe in the late 19th century, apparently now lay a smaller clutch than those in nearby Europe, although it seems the reduction in clutch took a few years to occur.

The reason for such differences is not known. However, in some cases islands have a smaller range of species than adjacent mainland areas, but (and perhaps because of this) higher densities of the species which are present. Hence possibly, this situation is a special case of a density effect on clutch-size (see viii above).

(xiii) Non-breeding. One possible clutch-size is zero! For obvious reasons it is difficult to assess the frequency of non-breeding birds. However, in some of the owls and other birds-of-prey, many or even most pairs may fail to breed in years of unusually low prey populations.

In certain other species, such as some of the flamingos, whole populations may not attempt to breed in some years. The reasons for such failures may be related to food supply, though the details are not known.

(xiv) Type of young. The type of development of the young might be expected to affect clutch-size and yet does not appear to do so in most species. Newly hatched young birds fall roughly into two types; those which hatch well-feathered and able to leave the nest and those which are quite incapable of such activity (see YOUNG BIRD). The former (nidifugous or precocial) young hatch with well-developed legs and brains and with their eyes open. In the case of the waders (Charadriidae) the young, and hence the eggs, are relatively large. Presumably, because of the problems associated with incubating such large eggs, the clutch is small, only 2–4. It might therefore be thought that nidifugous young would be associated with large eggs and small clutches. However, clutch-size is quite large and egg size relatively small in some other groups with nidifugous young, e.g. rails, game-birds, ducks, so that there is no correlation between the state of development of the young at hatching and clutch-size.

Reproductive rates and other reproductive tactics. A very large number of species lay a single clutch each year and raise a single brood, but there are a number of ways in which the reproductive rate of birds may be increased.

(i) Multiple broods. A larger number of birds, especially passerines, have more than one brood in a year (see BREEDING SEASON).

(ii) Hatching synchrony. In many birds, incubation does not start until about the time the clutch is completed. As a result all the young hatch at about the same time (synchronously). If food is scarce, all the young will be equally deprived and, if conditions are very bad, they all become weakened and perish. In other species, the female may start to incubate before the clutch is complete and the young will hatch asynchronously over a period of days. Because the young are very different in age and hence in size, the smallest young cannot compete for food on equal terms with its larger siblings. If the food supply is insufficient for the whole brood, the youngest die without depriving their larger brood-mates of food. Hence even when food is scarce, one or two young may be successfully raised. In species which exhibit asynchronous hatching, clutch-size may not vary greatly with conditions, but the brood size is adjusted to match the available food supply. Asynchronous hatching occurs mainly amongst nidicolous birds which catch animal prey; perhaps in these species it is difficult at the time of laying for the female to 'predict' what the level of food supply will be when the young hatch. The main groups which exhibit marked asynchrony in hatching are the cormorants, herons, birds-of-prey, owls and swifts. Other species, such as the House Sparrow *Passer domesticus*, hatch some young together but the last one or two hatch a little later. In the Great Tit early broods tend to hatch synchronously and later ones asynchronously. Such a pattern appears to match the caterpillar food supply which seems to be more predictable early in the season than it is later on (see also GROWTH).

(iii) Polygamy. In a number of species one sex may take two or more partners of the opposite sex; this may be done either sequentially or concurrently (see MATING SYSTEM). Usually it is the male which takes two or several females; less commonly the female may have more than one mate.

In many cases, the advantage to the sex which has several mates is obvious in that more young can be raised per year. The advantage, if any, to the sex which has to share a mate is less obvious since raising young on its own may result in fewer young being raised than when assisted by a mate. Usually, such mating systems involve species with an unbalanced sex ratio, hence possibly the choice for the more common sex may be to accept a polygamous situation or run a high risk of not finding a mate at all.

(iv) Double nesting. In a few species the pair is apparently monogamous but the female may lay two clutches, one of which is incubated by the male while the female herself incubates the other. Species for which this habit are known include the Mountain Plover *Charadrius montanus*, the Spotted Sandpiper *Actitis macularia* and the Red-legged Partridge *Alectoris rufa*; all nidifugous.

(v) Multiple nestings. The nesting pattern is even more complicated in a number of tinamous, the Ostrich *Struthio camelus* and possibly the Rhea *Rhea americana*. In the Ostrich and the tinamou *Crypturellus variegatus* the female lays eggs for a succession of different males, leaving the male to incubate (though in the case of the Ostrich, each nest has a dominant female which shares the incubation). In the tinamous *Crypturellus boucardi* and *Nothoprocta cinerascens* the females go around in small groups laying a 'clutch' jointly before moving on to another male. Such pattern shortens the length of the laying period and hence the risk from predation. The details of these nesting patterns are very poorly known.

(vi) 'Insurance' eggs. In a number of species which raise only a single chick, 2 eggs are laid. For example in the Brown Booby *Sula leucogaster* on Ascension Island, the White Pelican *Pelecanus onocrotalus* and the Lesser Spotted Eagle *Aquila pomarina* 2 young are almost never raised.

The most likely explanation for such apparently wasteful behaviour is that a proportion of all eggs fail to hatch for one reason or another, and if the energy requirements for manufacturing a second egg are not great, the parents can increase their chances of raising a chick by laying a second egg. It does not matter which egg hatches.

In some of the penguins the eggs within a clutch (usually 2) may be of quite different sizes; normally only one of the young survives. Such a strategy may combine the advantages of asynchronous hatching and having insurance eggs (see PENGUIN *Eudyptes*).

(vii) Parasitic birds. Although this subject is covered elsewhere (see BROOD-PARASITISM) it is mentioned here in relation to reproductive output. Since eggs are usually laid at the rate of only one or two per nest, the term clutch-size is not strictly appropriate. The number of eggs laid per season by parasitic birds is not well known. Individual Cuckoos *Cuculus canorus* may lay up to 25 eggs per season (though this was under unusual circumstances where nests of the host were made freely available to the Cuckoo), while the Cowbird *Molothrus ater* may lay 30 or more, possibly in runs of 5 or 6, followed by a gap of a few days; presumably this reflects the ancestral situation when the clutches were laid and incubated by the birds themselves. These numbers of eggs are far higher than the numbers laid by most species and perhaps serve to emphasize the influence of parental care.

(viii) Mound-builders. One group of birds, the megapodes or mound-builders, incubates its eggs by laying them in sand warmed by one means or another (see MEGAPODE). The number of eggs laid by a female is not known for most species, but in the Mallee Fowl *Leipoa ocellata* 72 recorded 'clutches' varied between 5 and 33 with a mean of 18.6.

Rates of evolution. Some of the ways in which birds maximize their reproductive output have evolved over long periods of time, while others may be quite recent. For example, 5,000 years ago few North Temperate birds were breeding where they are today. Hence local differences in clutch-size must have evolved since that time.

Indeed, selective pressures can lead to changes on a much shorter time scale than this. It has been shown for the Great Tit that observed selective advantages could lead to changes of 1.5 eggs per clutch in as little as 10 years (van Noordwijk *et al* 1980). Although some larger species which lay a small clutch do not seem able to alter its size rapidly, this is not likely to hold true for smaller species with larger clutches. Clutch-size should be considered as a dynamic feature, capable of rapid changes if environmental conditions alter. C.M.P.

CNEMOPHILINAE: see BIRD-OF-PARADISE.

COB: special term for a male SWAN.

COCHLEA: part of the ear (see HEARING AND BALANCE).

COCHLEARIIDAE: a monotypic family of the CICONIIFORMES (suborder Ardeae) recognized by some authors (e.g. Wetmore, Peters) for the Boat-billed Heron *Cochlearius cochlearius*, which in this work (following Mayr, Amadon and Bock) is treated as a member of the Ardeidae (see HERON).

COCHOA: substantive name generally used for the 3 species of *Cochoa* of south east Asia, a distinctive genus within the Turdidae (see THRUSH).

COCK: a male bird; applied without qualification to the male of the domestic fowl—compare HEN. Special terms apply to the males of some species, e.g. DRAKE, GANDER, COB, TIERCEL, BLACKCOCK. The names of certain species have also a special use as terms for the male, e.g. RUFF, and formerly MALLARD.

COCKATIEL: the Australian Parrot *Nymphicus hollandicus* (Cacatuinae) (see PARROT).

COCKATOO: substantive name of the species of the Cacatuinae; in the plural, general term for the subfamily (see PARROT).

COCK-FIGHTING: also called 'cocking', the sport of pitting male domestic fowls against each other in combat; the 'game-cocks' used are specially bred and trained for the purpose (see DOMESTICATION). Betting on the results is a major element. The word 'cockpit' originally signified an enclosure where the 'mains' were held. The sport originated in ancient times in Asia, where the natural spurs on the tarsi were often made more deadly by fitting them with iron spikes. It spread to Greece in classical times, later to Rome, and thence to other parts of Europe, and eventually to the New World. It has been prohibited by law in Great Britain since 1849, and it is now generally banned in many countries, including Canada and the United States. In eastern Asia, female Barred Bustard-quail *Turnix suscitator* are caught and kept for fighting, as also are male Quail *Coturnix coturnix*; and the Russians have a fighting breed of domestic goose.

COCK-OF-THE-ROCK: substantive name of *Rupicola* spp. (see under COTINGA).

COCK'S NEST: see NEST, COCK.

COEREBIDAE: a family of PASSERIFORMES, suborder Oscines; see HONEYCREEPER, also BANANAQUIT; CONEBILL.

COEVOLUTION: reciprocal evolutionary change in 2 (or more) interacting species, whereby each becomes adapted to the interaction. Coevolution may involve an animal and a plant (e.g. a hummingbird (Trochilidae) and a plant which it pollinates) or 2 animals (e.g. a predator and its prey). The interaction may be immediately beneficial to both parties, as in the first of these examples, or immediately beneficial to only one of them, as in the second; both qualify as examples of coevolution, but in practice the term is most often used for interactions that are mutually beneficial. Mutualism is sometimes used as a general term for this kind of interaction. In birds, such interactions mainly involve nectar-eaters (see POLLINATORS) and fruit-eaters (see SEED DISPERSAL). A very different and complex case involves colonially nesting oropendolas and caciques (Icteridae), the nest-parasitic Giant Cowbird *Scaphidura oryzivora*, and several kinds of insects (see BROOD-PARASITISM), and there may be other complex interactions of this kind so far undiscovered.

COHORT (1): a taxonomic category sometimes interpolated between subclass and superorder (see CLASSIFICATION).

COHORT (2): in population studies, a term used for a group of individuals of similar age within a population, especially a year-class.

COITION: see COPULATION.

COLD: see ADAPTATIONS, ENVIRONMENTAL; WEATHER AND BIRDS.

COLD SEARCHING: see HOT SEARCHING.

COLETO: name, in the Philippine Islands, for *Sarcops calvus* (see STARLING).

COLIIDAE: see below.

COLIIFORMES: an order comprising only the Coliidae (see MOUSEBIRD).

COLLAR: a band or patch of distinctive colour, in some plumage patterns, at least partly encircling the neck (see TOPOGRAPHY).

COLLECTING: see CONSERVATION; MUSEUM.

COLONIALITY: spatio-temporal clumping of nests. At present, there are no objective (nor even widely accepted) criteria as to how clumped nests must be to constitute a true colony, but most are beyond question. The term 'loose colony' is sometimes used for rather more dispersed nests that are still judged to be in a clump relative to the density of nests in the general vicinity (Lack 1968). In other colonies, by contrast, the spacing can be extremely close—often the area that a parent can defend without physically leaving its nest.

Coloniality has evolved independently many times in the Class Aves. Currently, about one-eighth of all avian taxa nest in colonies and there is no major taxonomic restriction to the practice.

Species categorized as 'colonial' often exhibit solitary nesting also, sometimes near major colonies. The reasons for this variability are not known, but it offers a convenient point of research leverage via intraspecific comparisons. Various suggested advantages of coloniality may be tested by studying colonial versus solitary pairs of the same species under the same ecological pressures.

Mixed-species (or 'heterospecific') colonies, though very common, have been little studied. The vague proposition that such colonies are best viewed as 'super-organisms' suffers both from a lack of evidence and from theoretical flaws (specifically, an apparent misunderstanding of natural selection). At present, it seems most reasonable to assume that individuals join colonies to promote their own selfish interests and not on behalf of some higher-level 'systems' function. This does not preclude the likelihood that there may be certain advantages in having a variety of neighbouring species (e.g. nesting near a pugnaciously defensive species), while other advantages (e.g. the selfish herd effect) may be independent of the neighbour's taxonomic identity.

Though many studies address the subject of colony substructure, no general principles have emerged. In a few species, it has been shown that older, experienced breeders occupy the central (safer) territories, giving an age-related 'organization' to the colony. Many more studies have shown merely that the placement of nests (within and between species) is non-random. Perhaps this is due to competition for sites.

The ecological features and life-history of species may show the reasons for clump-nesting. Lack pointed out that most colonial bird species are nidicolous and that most forage in flocks. Darling (1938) noted that there is often high within-colony synchrony of nesting activity, which can make both direct and indirect contributions to individual breeding success. The inter-relation of three characteristics, synchrony, offspring vulnerability during an extended nestling period, and social foraging, is a main topic in the literature of bird coloniality.

The evolutionary question of why clumped nesting arose is a subset of the larger problem of animal group-living in general, with the important difference that bird nests are sedentary. Thus a colony can be regarded as a 'flock' of individuals that must leave a sizeable component of their inclusive fitness in one place throughout the nesting period (see FITNESS). This stationary component (eggs and young) constrains the behavioural options of the parents.

There are several automatic disadvantages associated with any form of group membership (Alexander 1974): (1) increased competition for mates, (2) increased competition for food and space, (3) increased

King Penguins *Aptenodytes patagonicus*. The nests are spread just out of reach of each other. The eggs are incubated on their feet. (*Photo: N. Rankin*).

Quelea *Quelea* nests in Uganda. (*Photo: F. Pölking*).

conspicuousness to predators, and (4) increased risk of disease and ectoparasite transmission. For colonial birds, Hoogland and Sherman (1976) added (5) increased risk of misdirected parental care (resulting from cuckoldry, brood mixing, and possible brood-parasitism). In the many species where colonial nesting has evolved, there must have been one or more benefits of sufficient magnitude to override these disadvantages. There are many proposed benefits for coloniality: here, 7 of the most important are summarized.

Limited nest sites. One simple reason for nest clumping can be that a discontinuous habitat gives the birds no alternative to crowding together. Although simple in principle, this factor probably applies mainly to seabirds nesting on oceanic islands (e.g. albatrosses Diomedeidae). This factor is seldom separable from others (e.g. nesting on remote islands discourages land predators). In non-marine habitats there may be difficulties in judging whether 'suitable' nest sites are discontinuous or not.

Predator detection. An individual's survival chances can be enhanced when there are more eyes watching for danger. This does not necessarily imply any degree of true cooperation: in maintaining vigilance to protect self and offspring each bird inadvertently protects its neighbours by providing useful information. Such information may be communicated via specialized warning signals or automatically by escape behaviour. In foraging flocks of various species, it has been shown that group members generally learn of approaching predators more quickly, more reliably, and at a lower expenditure of watchfulness than solitary birds. Animals in colonies apparently enjoy similar benefits (Hoogland and Sherman 1976); they can use the information for trying to repel the predator, for giving mobile young time to hide or flee, and/or for saving themselves.

Group resistance. Many colonial birds perform collective defensive behaviour to repel intruders and predators. Presumably, the effectiveness of such mobbing attacks is increased by the additional birds in a colony (Kruuk 1964, Hoogland and Sherman 1976). Even if the predator is not driven away outright, it may be distracted enough to reduce its hunting efficiency, thus allowing other lines of defence (e.g. egg crypsis) to work (Tinbergen *et al* 1963).

Numerical swamping. Perhaps the most universal antipredator benefit of colonial nesting is from the reduced risk to each bird's eggs and young, as there are alternative targets for predators: the colony functions as a 'selfish herd' (Hamilton 1971). The fact that predation is often heaviest at colony edges may explain why many colonies are densely packed. (Kruuk 1964, Patterson 1965). On the other hand, colonies are far more conspicuous than a concealed nest (Horn 1968).

Most of the mathematical advantage from this sort of 'hiding behind conspecifics' is gained by the first few dozen pairs (depending on the number and type of major predators). But that advantage continues to be available to the later-joining pairs and the colony may continue to grow for this reason alone. Also, the critical group-size for numerical swamping may be higher for bird colonies than for fully mobile mammal groups because of the extended period of vulnerability to predators.

Cooperative foraging. If individuals feed more efficiently as members of a flock, colonial nesting may be advantageous in helping birds form flocks more easily. There are various ways in which flock-membership can improve individual foraging success (see FLOCKING), including most of the general group-living anti-predator advantages mentioned above (e.g. early detection). In addition, some birds hunt cooperatively. Thus cormorants and pelicans drive schools of fish into shallow water where they are concentrated and more easily captured (Bartholomew 1942).

Various kinds of information about food types, locations, and abundances may also be shared among the members of a feeding flock (see Information Centre Hypothesis, below). Murton (1971) showed that subordinate Woodpigeons *Columba palumbus* watch dominant flock-mates closely and switch food preferences when the dominants do, apparently benefitting from the older birds' experience. In flock-feeding experiments with Great Tits *Parus major*, it has been shown that flock-mates move nearer to a successful individual and search that area for small hidden food concentrations. This type of interaction, known as SOCIAL FACILITATION or local enhancement, is probably very common among flock-feeding birds and may promote coloniality indirectly, via recruitment.

Travel minimization. If the food supply exists in unpredictable but relatively rich patches, exclusive defence of small individual territories may not be profitable. Horn (1968) showed that clumping of nests in the geometric centre of such a zone of patches minimizes the travel/search distance for each bird. Because the patches contain more food than an individual can use anyway, tolerating colony-mates at the food supply incurs no significant cost.

Information centres. In addition to the simple geometric advantage just described, colonial birds may be in a position to monitor the hunting success of neighbours and then follow them to favourable foraging sites. Ward and Zahavi (1973) called such assemblages 'information centres' and proposed that this function was the primary factor promoting the origin and evolutionary maintenance of most bird colonies and roosts. Direct evidence, however, supporting the hypothesis—much less this contention—is in very short supply. Horn actually observed 3 cases of such a system in Brewer's Blackbirds *Euphagus cyanocephalus*: adults that had been feeding on low-yield upland prey followed neighbours who had brought larger aquatic prey to their nestlings.

Several of the same ecological factors are required for this model as for cooperative foraging. Food must be clumped, unpredictable, and locally abundant. In addition, the birds must tolerate close-feeding neighbours: if feeding territories are defended effectively, it is hard to see what advantage is gained by following.

Finally, the adaptive significance of laying synchrony within bird colonies presumably varies from case to case. If predation pressure be significant, it seems likely that pairs breeding in synchrony with their neighbours will obtain more group anti-predator benefits (via detecting, mobbing, and/or swamping) than pairs breeding out of synchrony. Similarly, the group benefits associated with foraging can be more available to birds whose neighbours face similar food demands simultaneously. Mere demonstration of higher reproductive success as a function of synchrony is not, by itself, sufficient for assigning adaptive significance to any of these potentially contributing factors.

The proximate cause of nesting synchrony in colonies is not clearly understood. Although mutual reproductive stimulation by breeding neighbours (the so-called 'Fraser Darling Effect') has been demonstrated in the laboratory (Lott *et al* 1967), its importance to wild populations remains equivocal. COLONIZATION: see RANGE CHANGES.

COLONY: a number of birds breeding gregariously, the term vaguely including the location and the nests. For special terms see ASSEMBLY, NOUN OF.

COLORATION, ADAPTIVE: embraces those visual phenomena that subserve survival or reproductive functions in the various relationships between predators and prey, between members of the same or the opposite sex or of a social group, or between parent and offspring. The term may thus be used to include not only modifications of colour, but all aspects of form, adornment, pattern, posture, activity, and background that together determine an animal's appearance in nature and are of value in the struggle for existence. Animal coloration must always be considered in relation to the behaviour associated with it, and to the effect of this upon a potential observer. (For the physical basis of coloration see COLOUR.)

Coloration characteristics fall broadly into two groups; those promoting concealment (cryptic) and those enhancing conspicuousness (phaneric). The former, making for effacement, hinder detection; the latter, acting as advertisements, facilitate identification. The optical-psychological principles upon which recognition of a bird (or of any other solid object) depends include: differences of hue and tone between object and background; differential effects of light and shade, or of relief, that convey the appearance of solidity; shape, or surface-continuity framed by a characteristic contour; cast shadow; and movement. The effectiveness of cryptic and phaneric coloration is due to the suppression or exaggeration, respectively, of these visual characters.

Cryptic coloration. The biological role of cryptic coloration is limited to predator-prey relationships, either affording protection against enemies (procryptic) or facilitating capture of food (anticryptic). Among birds procryptic coloration is common, and anticryptic rare. Again, cryptic coloration may afford either general concealment or special disguise; instances of the latter are rare in birds. The two categories intergrade in a type of coloration known as 'background picturing'.

General resemblance. Every major habitat provides examples of birds that wear cryptic plumage—white in snowlands, e.g. Snowy Owl *Nyctea scandiaca*, Ptarmigan *Lagopus mutus* in winter dress; ochre, buff, or sandy-grey in deserts, e.g. sandgrouse, thickknees, wheatears *Oenanthe* spp., larks; green in the rain-forest canopy or dense foliage, e.g. toucanets (Ramphastidae), some parakeets and conures (Psittacidae), fruit pigeons (Treroninae); variegated browns among grass and reeds, e.g. many waders (Charadrii), crakes (Rallidae), bitterns (Botaurinae), buntings (Emberizidae), grass warblers *Cisticola* spp. (Sylviinae). Of special interest in this connection are species and races of desert larks (*Ammomanes, Mirafra, Spizocorys*) with plumage closely matching the particular ground on which they occur—whether black lava, red or brown earth, or white sand. Such birds have clearly defined habitat preferences, and are reluctant to leave their own terrain for adjoining ground of a different hue (see LARK).

Obliterative shading. Graded coloration, ranging from darkest on the back to lightest on the under parts, neutralizes relief and thus renders the solid body as an apparently flat surface. Obliterative shading forms a basis for the coloration of nearly all cryptic birds, whether or not they carry a superimposed pattern; it reaches its highest perfection in various terrestrial birds of open country, such as bustards, thickknees, buttonquails, francolins *Francolinus* spp., and sandgrouse.

Disruption. In its concealing role, pattern prevents or delays recognition by attracting an observer's attention to itself and away from the form that bears it. Such a distractive effect depends upon the colours being characteristic also of the background (Woodcock *Scolopax rusticola*, Grey Partridge *Perdix perdix*) and embodying strongly contrasted tonal elements that transgress anatomical form and contour and so visually break up surface continuity (Turnstone *Arenaria interpres*, Killdeer *Charadrius vociferus*, Cream-coloured Courser *Cursorius cursor*). Many birds carry dark head-markings so disposed as to coincide with and include the otherwise conspicuous eye. Such coincident elements may take the form of horizontal stripes, e.g. Bobwhite *Colinus virginianus*, Quail *Coturnix*

Willow Grouse *Lagopus lagopus* male in winter plumage. (*Photo*: *E.J. Hosking*).

Lava Gull *Larus fuliginosus* blending with background in Galapagos. (*Photo: E.J. Hosking*).

Grey-breasted Seedsnipe *Thinocorus orbignyianus* incubating. (*Photo: G.L. Maclean*).

Ringed Plover *Charadrius hiaticula* chick showing protective colouring. (*Photo: R.J. Chandler*).

coturnix, Snipe *Gallinago gallinago*, Whimbrel *Numenius phaeopus*, Dotterel *Eudromias morinellus*; or of vertical bars, e.g. Woodcock; or of a combination of both, e.g. Ringed Plover *Charadrius hiaticula*.

Immobility, and shadow concealment. Effective concealment is possible only when it is accompanied by cryptic quiescence. Immobility and the squatting posture, as a reaction to danger, are most highly developed in various cryptic ground-nesting birds of several groups—some female ducks and game-birds, snipe, woodcock, plovers (Charadriidae), coursers *Cursorius* spp., bustards, nightjars, larks; also in highly cryptic nidifugous young, such as Ruffed Grouse *Bonasa umbellus*, Stone-curlew *Burhinus oedicnemus*, Lapwing *Vanellus vanellus*, Ringed Plover, Oystercatcher *Haematopus ostralegus*, and Little Tern *Sterna albifrons*. The crouching posture also serves to obscure or reduce the tell-tale shadow cast by the body.

Background picturing. Disruptive patterns afford concealment in relation to a generalized background. The coloration of species that rest or nest in a specialized habitat may be correlated more closely with the environment; in such species the disruptive design is scenic, and tends to reproduce the background configuration against which it is likely to be displayed—whether of heath, grass, or reed. Such colour schemes are always rendered more effective by appropriate cryptic postures, for example, prone in Owl Parrot *Strigops habroptilus*, Ptarmigan, and Golden Plover *Pluvialis apricarius*, vertical and frontal in Bittern *Botaurus stellaris* and Little Bittern *Ixobrychus minutus*.

Special resemblance. In a few highly specialized cases, cryptic coloration exerts its effect by disguise rather than concealment—colouring, form, and posture combining to produce a more or less exact resemblance to some familiar object of the habitat. Various nightjars afford the best examples among birds. In their usual prone position on the ground, many species resemble fallen bits of wood; frogmouths (Podargidae), which nest on a horizontal tree-fork, adopt an oblique posture and so simulate a broken branch; while the Grey Potoo *Nyctibius griseus*, which lays its single egg on top of a broken tree-stump, incubates in a stiffly erect posture. All these birds close the eyes when in the presence of an intruder, and remain motionless. Nestlings of the Bar-winged Flycatcher-shrike *Hemipus picatus* face one another with their bills pointing upwards and nearly meeting, their coloration and attitude causing the lichen-garnished nest with its contents to resemble a snag on the branch.

Phaneric coloration. Conspicuousness, the basis of all phaneric characters, depends upon the exaggeration of those visual attributes—colour, relief, form, and movement—that tend to be suppressed in cryptic species. Brilliant hues and textures alien to the environment are widely developed, notable examples being seen among gallinules *Porphyrio* spp., macaws (Psittacidae), turacos, toucans, kingfishers, woodhoopoes, glossy starlings *Lamprotornis* spp., tanagers (Thraupinae), and the males of many ducks and game-birds. Countershading is replaced by self-coloration, which reaches the height of conspicuousness in uniformly white or black birds, e.g. swans *Cygnus* spp., pelicans, egrets *Egretta* spp., spoonbills (Plataleinae), cockatoos (Cacatoeinae), and crows *Corvus* spp. Colours and patterns are generally displayed constructively (crest, breast, ruff, tail, and so on); and the contour is often conspicuously framed with a marginal pattern (tail of Ruffed Grouse, throat of King Bird-of-paradise *Cicinnurus regius*). Frequently, the eye is made prominent in its setting of feathers, e.g. owls, white-eyes *Zosterops* spp., or ornamental skin, e.g. many vultures (Aegypiinae), storks, cranes, game-birds, hornbills, and toucans. Eye-spots are displayed (Argus Pheasant *Argusianus argus* and peacock pheasants *Polyplectron* spp.) and reach their most extravagant appearance in the huge paired ocelli, each formed by a purple-red gular sac framed in a broad circle of white feathers, in the Blue Grouse *Dendragapus obscurus*. Adornments (plumes, fans, ruffs, wattles, inflatable air-sacs, and the like), and above all specialized activity (including orientated postures, antics, dances, and utterance of sounds both vocal and instrumental) contribute further to the impact made upon the observer.

Phaneric (unlike cryptic) coloration subserves a wide range of biological functions, both interspecific and intraspecific—in relations between enemies and prey (warning, adventitious warning, bluff, BATESIAN MIMICRY, and deflection); between rival males (threat and distance recognition); between opposite sexes (sex recognition and epigamic display); between members of the same or different species (social, and specifically distinct signals); and between parent and offspring (feeding releasers and indicators).

Warning coloration and adventitious warning. Warning characters (proaposematic) are associated with deterrent or noxious attributes that render a species relatively unacceptable to predators (see PALATABILITY OF BIRDS AND EGGS). In another category (allosematic) are certain relatively defenceless birds that habitually nest close in association with aggressive aposematic aculeate hymenoptera such as *Polybia*, *Polistes*, *Apis*, *Azteca*, *Oecophylla*. The insects tolerate the presence of the birds (which build pensile or covered nests) but not other intruders; thus the birds secure themselves from attack by most enemies. Such nesting associations are known among tropical birds of widely different groups—caciques (*Cacicus*) in South America; mannikins (*Lonchura*), estrildid or weaver-finches (*Uraeginthus*), and striped swallows (*Hirundo*) in Africa; bayas (*Ploceus*) in Malaya; and bush-warblers (*Gerygone*) in Australia (see also NESTING ASSOCIATION).

False warning coloration. Bluffing characters (pseudaposematic) include so-called 'terrifying actions'—fluffing of feathers, spreading wings, demonstrating with claws or bill—as in the intimidating displays of young owls and hawks, and Batesian mimicry. Instances of the latter are rare among birds e.g. *Oriolus* ('*Mimeta*') and *Philemon* in Indonesia (see MIMICRY). In an aggressive (pseudepisematic) rather than a protective role are the wonderfully detailed mimetic resemblances that the eggs of various cuckoos bear to those of the foster-parents (see BROOD-PARASITISM).

Deflection displays. These serve to deflect the attention of enemies away from the more to the less biologically valuable or vulnerable members (incubating parent, or nestlings) of a social group. Inter-individual deflection (parasematic) operates both in the relations between the sexes and in those between parents and offspring. In the former category is the conspicuous appearance of various male ducks and pheasants, and the delayed moult of certain male ptarmigan *Lagopus* spp., which diverts attention from the incubating female; in the latter, the so-called 'injury-feigning' behaviour of the brooding parent, whose movements and posturing (falling, lying on one side, leg-trailing, wing-dragging, wing-flapping, or quivering) advertise its whereabouts at a distance from the nest. Such displays are known to occur in many avian orders—Gaviiformes, Anseriformes, Galliformes, Gruiformes, Charadriiformes, Columbiformes, Strigiformes, Caprimulgiformes, Passeriformes; they do not appear to have been recorded in any other class of animal (see DISTRACTION BEHAVIOUR).

Social signalling characters. Social recognition, or guide-marks (proepisematic), such as those displayed in flight on the wings, tail, and rump of many waders (Charadrii), serve to ensure contact between members of a flock, or to release and direct following behaviour. The patterns have few components and are striking and distinctive. In cryptic nidifugous young (Lapwing, Ringed Plover, Egyptian Plover *Pluvianus aegyptius*) a white nuchal band, when displayed, assists the parent to locate and reassemble the brood. The predominantly white plumage of many sea birds—gannets, albatrosses (Diomedeidae), gulls, and some terns—is socially advantageous as a signal of the whereabouts of a locally and sporadically plentiful food-supply (fish shoals, etc.). In a different category are the specifically distinctive characters that serve to prevent confusion with members of closely related species. Notable examples are the almost heraldic colour-schemes of toucans, the speculum in ducks, and the head and neck characters of penguins and auks.

Threat and distance recognition. Threat characters are directed against rivals, usually of the same sex (antepisematic), and associated with combat, actual or potential. Under this head are included close-range aggressive threat, in which the characters displayed indicate a readiness to fight (Blackcock *Tetrao tetrix*, Junglefowl *Gallus gallus*, and Ruff *Philomachus pugnax*); and recognitional threat, which advertises the presence of a potential competitor at a distance. Characters (both visual and auditory) used in the latter context are generally significant in relation to territorial defence (monogamous, and some polygamous, territorial species); by deterring a rival from intrusion, they obviate the need for combat.

Courtship and display. Characters that promote the meeting and mating of the sexes and subsequent phases of the reproductive cycle (epigamic) are discussed elsewhere (see DISPLAY).

Feeding indicators and releasers. Adornments with a releasing and directing function connected with the feeding of nidicolous young are found in several orders. Nestlings that are directly fed by parent or fosterer (e.g. Passeriformes, Cuculidae) commonly have the gaping display enhanced by wide bill flanges and a brilliant mouth-lining (see TONGUE). Red, orange, and yellow (the colours displayed by ornithophilous flowers) are frequent in these quasifloral displays, which may, as in the Bearded Tit *Panurus biarmicus* (white projections set on a background of red and black and surrounded by the yellow gape), be detailed and elaborate. The mouths of various nestlings reared in dimly lit surrounding are bordered with white (Jackdaw *Corvus monedula*, glossy starlings *Lamprotornis* spp.). In some species of which the young are nidifugous, or thrust their heads into the parent's mouth to obtain food, the parent carries the relevant ornaments. Thus the red spot on the gonys of the adult Herring Gull *Larus argentatus* releases and directs the pecking response; while in the Gannet *Sula bassana* and Cormorant *Phalacrocorax carbo* the mouth-lining of the adult displays conspicuous colour—black in the former, yellow in the latter (see RELEASER). H.B.C.

Armstrong, E.A. 1947. Bird Display and Behaviour. (2nd edn.). London.
Cott, H.B. 1957. Adaptive Coloration in Animals. (2nd edn.). London.

COLOUR: in birds especially that of the feathers (see FEATHER; PLUMAGE). The colours are due to the reflection of some but not all the components of the incident white light. When all the components of white light are reflected the bird will appear white. Colours can be removed from incident white light—(a) by the physical nature of the reflecting surface, giving structural colours, and (b) by certain chemical attributes, giving pigmentary colours. Some colours are due to a combination of these two methods. The removal of some parts of the spectrum by these methods results in the reflection of the remaining parts.

Structural colours. Those of birds are due either to interference, giving iridescent colours that change with the viewing angle, or to the scattering of light, giving non-iridescent structural colours. The structure responsible for iridescence is present in barbules that are flattened for part of their length and twisted so that one of the flat sides comes to face the observer. Barbule torsion is accompanied by loss of the hooklets and flanges; this reduces the mechanical strength of the vane, and so fully iridescent colours are not found in flight feathers. It was formerly thought that all iridescent colours were due to interference in the thin outer layer of the barbule keratin. It has now been found that in some feathers, including those of hummingbirds, highly refractive melanin granules beneath the barbule surface are responsible for the interference.

Non-iridescent structural colours, produced by the scattering of the shorter waves in white light by very small particles (Tyndall scattering), do not alter with the angle of vision. If the diameter of the particles is less than the wavelength of red light, more of the short-wave components of white light will be reflected and the structure will appear blue. In non-iridescent blue feathers the scattering particles are actually minute air-filled cavities within the barb keratin. Such feathers appear blue in reflected light, but dull brown in transmitted white light owing to the background of melanin.

Pigmentary colours. These are widespread in the bill, 'soft parts' and feathers of birds. The commonest pigment of birds is melanin which usually occurs as granules, is insoluble in most solvents (but can be dissolved in alkalis), and has no characteristic absorption bands. Melanin is not always black (eumelanin), but may be brown, red-brown, or even yellow (phaeomelanin). Eumelanin occurs in crows, the Blackbird *Turdus merula*, some gallinaceous birds, and many others; brown or red-brown phaeomelanin gives the dull colours of many birds showing protective coloration, and yellow phaeomelanin, the yellow colour of the down in domestic chicks. Melanin formation in birds may be influenced by sex, age, and season (see PLUMAGE, ABNORMAL).

Carotenoids are organic compounds consisting of carbon and hydrogen (carotenes) or carbon, hydrogen and oxygen (xanthophylls). They are soluble in organic solvents, are characterized by their behaviour on a chromatographic column, and by their absorption spectra. They are responsible for the colour of many red and orange feathers. Egg yolk has two carotenoids, lutein and zeaxanthin, and the red wattles of the Pheasant *Phasianus colchicus* contain astaxanthin. Growing feathers of Canaries *Serinus canaria* can be made red by feeding with paprika, which contains capsanthin.

Like other animals, birds are unable to synthesize carotenoids, and they obtain them directly or indirectly from plants. The bright red yolk of the Gentoo Penguin *Pygoscelis papua* is due to astaxanthin in the crustacean diet, and the pink of flamingos to a similar pigment derived from blue-green algae and aquatic invertebrates. Carotenoid deposition is often selective; thus feathers have only xanthophylls, whereas bill and skin may have both carotenes and xanthophylls.

Haemoglobin, the red tetrapyrrole respiratory pigment of vertebrates and some invertebrates, is not normally seen as an external colour in birds. It does, however, colour the wattles of the Turkey *Meleagris gallopavo* and the bare head and neck of some vultures (Aegypiinae). There are also other tetrapyrrole pigments, e.g. the protoporphyrin of most egg-shells (Kennedy and Vevers 1976); a fragment of domestic hen eggshell shows absorption bands when seen in transmitted light, and also the typical red fluorescence of porphyrin in ultraviolet light. Porphyrin also occurs in the feathers of owls and bustards and in the pink down of some birds.

The bright red wing-feathers of turacos are coloured by turacin, a copper porphyrin, which is extracted by dilute ammonia to give a purple-red solution. The green feathers of some turacos contain turacoverdin, the relationship of which to turacin is not completely understood. See also TURACO.

Two types of pigment, of unknown composition, occur in certain parrots. In one type the pigment is pale yellow in visible light and fluorescent yellow-gold, sulphur-yellow, or green in ultraviolet light. The fluorescence disappears in alkali, but is not affected by acid. The crest of some cockatoos *Cacatua* spp. is coloured by one of these pigments.

The second type consists of non-fluorescent red or yellow pigments, chemically quite distinct from carotenoids, found in the Budgerigar *Melopsittacus undulatus* and some other parrots.

Combined effects. Some colours are due to the combined action of two or more pigments, or of pigment and structure. Thus in many green feathers the outer layers of the barbs contain yellow pigment that filters some of the short-wave rays out of the incident white light. Below this filter, box cells containing minute air spaces scatter the remaining short waves; as a result, the feather appears green. If the filter pigment is dissolved out the feather becomes blue, as in ordinary Tyndall scattering. When the filter is carotenoid it can probably be bleached out under natural conditions, e.g. in the tropical magpie *Cissa*, which is green in subdued forest light, but blue when living in open sunny country.

Olive-green is caused by the juxtaposition of tiny black and yellow pigment spots. Thus in the Greenfinch *Carduelis chloris* and in some tits there is melanin in the barbule tips and yellow carotenoid in the barbs and barbule bases.

Purple occurs as a mixture of Tyndall scattering and red pigment, e.g. in the Blossom-headed Parakeet *Psittacula cyanocephala*, in which the barbs have a structure producing scattered blue, and the barbules contain red pigment.

Colours may be modified by a structural attribute which alters the surface texture. Short feathers growing out perpendicularly from the body produce the appearance of velvet, e.g. the nape feathers of Teal *Anas crecca*. Twisting of the barbs to expose their flat shiny surfaces gives an effect of lacquer, e.g. in some *Pitta* spp. Powder particles on the feather surface reflect light at numerous surfaces, giving the dull, greyish colours of some pigeons and cranes.

Cosmetic coloration. Some birds adorn their plumage with coloured secretion from the preen gland (see OIL GLAND). The Great Indian Hornbill *Buceros bicornis* rubs its bill on the outlet of this gland and transfers the yellow secretion to some of the white wing feathers. The pigment (a carotenoid) bleaches in air and light, and is frequently renewed. Such cosmetic coloration may also account for the pink suffusions seen on the breast of the Black-headed Gull *Larus ridibundus* and the White (or Rosy) Pelican *Pelecanus onocrotalus* during spring (Stegmann 1956). These colours are known to disappear quickly in most museum skins. G.V.

COLOUR DYING: see MARKING.

COLOUR PHASE: see PLUMAGE.

COLOUR RINGING: see MARKING.

COLOUR STANDARDIZATION: involves the integration of (1) language or symbols, (2) either colours of which the names are widely understood or else colour samples in an atlas or chart, and (3) the variables in biological materials being described. The result should be comprehensible to persons other than the describer. Standardization can be done at different levels. One is by use of generally understood colour terms, in combination with modifiers as needed, as is done in most non-technical works on ornithology. Another consists in comparing biological materials with colour samples on a chart or in an atlas, these being designated by words or symbols. The latter can be more precise, but the reader of descriptions prepared in this manner must have access to an equivalent copy of the chart or atlas in order fully to comprehend the descriptions.

In practice in taxonomy, and in view of the range of variation in most biological materials, one compares specimens or series of them—not colour descriptions of each; describing is an aftermath of comparing. The specimens then become the points of reference, not named colours in an atlas (although the describing may be in terms from an atlas—see TYPE SPECIMEN). To utilize the results of such comparisons to the full one must again refer to the same or equivalent specimens.

In written descriptions that are intended to be meaningful to the majority of readers, it is desirable to use as few colour terms as possible. For most persons, such a list probably does not exceed 50 terms. An analysis of all terms used in all descriptions in several standard works reveals that a larger list is unnecessary.

The following includes the *colours* that are in widespread accepted use, the *names* being those in general use except that certain 'pure' or 'spectral' colours are more accurately designated; after a 'spectral' colour is listed, any of its 'impure' derivatives that are included here follow in parentheses: ruby (rose, dusky brown, pink), scarlet (blackish brown), scarlet-orange (chestnut, brownish red, fuscous, rufous, flesh, sepia, tawny, cinnamon), orange (brownish olive, buffish brown, smoke-grey), orange-yellow (olive, buffish yellow, cream, straw-yellow), yellow, yellow-lime, lime, lime-green, green, emerald, turquoise-cobalt, cobalt (pearl-grey), cobalt-ultramarine, ultramarine, ultramarine-violet, violet (sooty black), violet-magenta, magenta.

Such colour terms can be modified, as required and where logical, by terms of 'lightness'—pale, light, medium, dark, deep. Or they can be modified by combination with neutrals; pale greyish, light greyish, etc. Note that *black* and *white* are absolutes; attempts to modify them, such as 'greyish white' or 'brownish black' are incorrect. Metallic colour names widely used in ornithology are: bronzy, coppery, golden, leaden, silvery. They combine colour and texture. The following terms or phrases, which refer to texture alone or are used in combination with colours, are also widely used in ornithology: burnished, dull, glossy, hoary (or frosted), iridescent, having a sheen, silky, velvety, waxy.

If one departs from generally understood terms and uses a chart or atlas, the standard used should always be clearly indicated. Many coloured descriptions have been based on Ridgway's *Color Standards and Color Nomenclature* (Washington, D.C. 1912), now a rare book. A more workable standard, but using symbols instead of words, is the Villalobos-Dominguez and Villalobos *Atlas de los Colores* (Buenos Aires. 1947); it includes a concordance of symbols and Ridgway names. Palmer, R.S. 1962. Handbook of North American Birds, vol. 1. New Haven, Conn., and London. (See Introduction, at pp. 4 and 8, with colour chart.)

COLOUR VISION: see VISION.

COLUMBIDAE: see below.

COLUMBIFORMES: an order, alternatively 'Columbae', comprising 3 families: Columbidae (PIGEON), Raphidae (DODO, extinct), Pezophapidae (Solitaire, extinct, see under DODO).

COLUMELLA AURIS: the ear ossicle, alternatively 'stapes' (see HEARING AND BALANCE; SKULL).

COLY: alternative name for MOUSEBIRD.

COLYMBIDAE: together with 'Colymbiformes' (alternatively 'Colymbi'), discarded familial and ordinal names formed from the generic name *Colymbus* Linnaeus 1758, applied to the Gaviidae (see DIVER).

COMB: see INTEGUMENTARY STRUCTURES.

COMBASSOU: substantive name, alternatively 'indigo-bird' or 'indigo-finch', of *Hypochera* spp. (see WHYDAH (1)).

COMET: substantive name of *Polyonymus caroli* and *Sappho sparganura* (see HUMMINGBIRD).

COMFORT BEHAVIOUR: general term for a complex of basic, highly stereotyped maintenance activities concerned with the care of the plumage and covering associated behaviour (see also ROOSTING). Such phenomena are broadly similar throughout the whole class Aves, the main differences, especially between aquatic, terrestrial and arboreal birds, being related to structure and habits. In original or ritualized form they often occur as pre-flight or other displays, and are also a source of so-called 'DISPLACEMENT ACTIVITIES'.

Feather maintenance. It is essential that the plumage, especially the wings, be kept in sound order, both for the primary purposes of insulation and flight and for use in e.g. display and camouflage. This is achieved by routine maintenance, including repair of the feather structure, dressing with preen-oil and other organic liquids, and the removal of unhygienic or damaging substances, both those originating from the bird itself (e.g. excess or stale preen-oil, other lipids, carbonic and other exudates shed via the skin and feathers) and from the external environment (e.g. dirt, ectoparasites). In several cases, special movements are used to care for the more inaccessible parts, especially the head and undersurface of the primaries. The main patterns of feather care in the majority of birds include bathing, drying, oiling, preening and plumage-scratching. These appear to form a homogeneous functional group to which the activities of DUSTING, ANTING, SUNNING or even SMOKE-BATHING could be subsidiary.

Bathing. It seems best to restrict this term to cases of true bathing in water involving special movements used deliberately to wet the plumage, either 'spontaneously' in routine feather care sessions or in direct response to the soiling of the plumage; in non-passerines particularly, these bathing movements may be accompanied by 'washing' actions—the rolling of the head over flanks and back, plumage-scratching, and vigorous preening (see below). Most species bathe but a few groups that dust themselves do not (see DUSTING).

There are 7 methods of bathing shown by passerines and other land-birds: (1) stand-out bathing (so-called 'splash-bathing') while settled on land at the edge of the water; (2) stand-in bathing while standing or crouching in the water itself (practised by most taxa); (3) in-out bathing while jumping repeatedly into the water and out again (babblers); (4) flight-bathing on the wing by a series of dips and rises (swifts and swallows); (5) plunge-bathing by diving from a perch onto the surface of the water, sometimes repeatedly (kingfishers and tyrant flycatchers); (6) rain-bathing by deliberate exposure to precipitation (parrots, woodpeckers and larks); and (7) foliage- and dew-bathing against wet vegetation (hornbills).

In typical stand-in bathing, the bird e.g. a Robin *Erithacus rubecula* ruffles its feathers and wets the plumage by repeatedly dipping head and breast into the water while shaking the body from side to side and flicking both wings rapidly up and forward, this being the limit of the movements performed by the stand-out bather. It next wallows with head raised and rear-end submerged, tail fanned, while flipping water across its back with one wing at a time. Feather ruffling and the shaking of head, wings and body also occur in the other bathing methods, but the details are hard to follow. Specialist rain-bathers have characteristic postures with feathers ruffled, wings fully extended horizontally, and tail spread. Most families or subfamilies use one of these methods exclusively, but some two or even more. For example: as well as stand-in bathing, pigeons will rain-bathe, adopting a posture similar to that used in SUNNING; vireos will stand-in bathe briefly at times during spells of plunge-bathing into shallow water; wrens will in-out bathe at times instead of or before their more usual stand-in bathing, apparently when cautious or testing the depth of the water; and babblers will foliage-bathe as well as in-out bathe. True rain- and especially foliage-bathing seem to be employed by many taxa as an alternative, if subsidiary, bathing method to their main one. However, rain-bathing is often confused with a bird's attempt to dry itself when caught in the rain (see below)—though a special RAIN-POSTURE may be adopted. Some species that normally stand-in bathe will sometimes make incomplete, often clumsy, attempts to bathe in the rain or in wet vegetation.

Blackbird *Turdus merula* juvenile bathing. (*Photo: E.J. Hosking*)

Many seabirds and waterbirds, e.g. penguins, divers, grebes, gannets and boobies and most other pelecaniform birds, and waterfowl, swim-bathe while floating in deep water. Some, e.g. gulls and certain rails, also stand-in bathe in shallow water. Highly aerial seabirds, such as frigatebirds and certain terns, are solely flight-bathers. The swim-bathing of grebes, typified by the Great Crested Grebe *Podiceps cristatus*, is of two main types. When surface-bathing, the bird performs a series of ducking-and-rubbing actions, dipping head, neck, and forebody under water and rubbing the head against the flanks, and also a series of wing-thrashing actions, beating the partly open wings against the water; it may also shuffle the folded wings in the water, and 'barge-swim' with rear-end submerged and wings extended below the surface. When dive-bathing, the grebe makes a series of kick-dives to submerge entirely with feathers ruffled and wings loosely open; between dives, it floats immobile, low in the water, wallowing or soaking. The surface-bathing of the Anatidae (swans, geese, and ducks) is basically similar to that of grebes, with head-ducking and wing-thrashing sequences; there is no barge-swimming, but waterfowl often somersault. Dive-bathing in the Anatidae, however, takes the form mainly of sudden total submergences with the wings open; especially when a number of birds take part, it is interspersed by flapping over the surface and by short flights—as if the birds are fleeing from a predator ('dashing-and-diving'). The surface-bathing of gulls too is basically similar, that of penguins apparently rather less so, but no dive-bathing has been described for either group. Gulls have a sideways rolling action (so-called 'plunging') and penguins a special 'body-thrashing'. The Brown Booby *Sula leucogaster*, like most other sulids, often starts a bathing session with a series of shallow flight-plunges; when surface-bathing, it interrupts the usual activities of head-dipping, wing-shuffling, etc. by banging the carpal joints of the wings against the water and also by rolling laterally with wings fully extended onto its side or back. It may roll from side to side or at times turn a complete somersault.

In many cases, a bird bathes just to dampen its plumage evenly as much as possible without actually soaking it. The main aim then would seem to be to facilitate the oiling and preening which typically follow. At times too, a bird will bathe in order to cool itself. A distinction needs to be made between ordinary routine or standard bathing, performed fairly frequently (in grebes, several times a day) and a thorough bathe, performed less often (in grebes, perhaps just once a day). The thorough bathe of a grebe consists of prolonged, intense surface-bathing and dive-bathing; it is followed by a session of long and thorough feather care, special attention being given to the wings. Even so, such a bathe must fall short of a real drenching which would destroy the waterproofing and buoyancy of the plumage. In landbirds however, a thorough bathe can involve a really good soaking—providing that the feathers are not damaged or flying efficiency totally impaired. A passerine indulging in such a bathe will on occasion turn itself into a mass of dishevelled, watersoaked feathers, repeatedly exposing and closing its feather tracts, forcing water into the apteria and squeezing it through the tracts, thus rinsing the skin and feather bases most efficiently. In all cases of such bathing, the bird needs the opportunity and sufficient time afterwards to groom itself thoroughly in safety, so the frequency and timing of such sequences has to be strictly controlled.

Pied Shag *Phalacrocorax* ('Hypoleucos') *varius* wing-drying posture. (*Photo: G. Moon*).

Drying. All birds make deliberate movements to remove surplus water from the plumage quickly, both during and after bathing, accidental wetting from precipitation, etc.; these drying movements may continue intermittently during the oiling and preening session that typically follows. In grebes, waterfowl, and many other non-passerines, the drying actions after bathing are basically the appropriate comfort-movements (e.g. body-shaking, wing-flapping) performed more frequently or more intensely than usual and often interspersed by head-rolling and rapid preening (so-called 'wiping') and by other feather care actions—see below. Some birds (e.g. ducks, gulls) shake themselves in flight, and, especially in those species that leave the bathing area to oil and preen, normal flight also facilitates drying. Diving birds when feeding perform drying movements from time to time during pauses and lulls on the surface and at the end of the diving session. Cormorants and darters adopt a characteristic spread-wing posture after diving for food or bathing, perching thus often for long periods; similar attitudes being found also in a number of other large birds when wet; however, such behaviour may well have other functions besides drying, including thermoregulation (see HEAT REGULATION; SUNNING). Passerines do not wing-flap but, in addition to wing-oiling type and other preening actions (see below), perform various shaking movements to dry themselves; of these last, the most distinctive is 'whirring', a rapid vibration of the tail and wing tips simultaneously, together with a general ruffling of the plumage. The passive use of air currents and the heat of the sun at times is probably widespread in birds as auxiliary means of drying.

Oiling. In species with a functional OIL GLAND, the plumage is typically anointed with the fatty secretion (preen-oil) of that gland immediately following bathing and initial drying. The oil is obtained, a few or several times, during the first minutes of the oiling and preening bout: the bird reaches back and squeezes the nipple of the gland between the mandibles; it may also push the bill and chin across the gland or its associated tuft of feathers or down, and in the case of species with long necks (e.g. grebes), rub or roll the head on it. Oil is then distributed over the plumage mainly by rubbing and preening with the bill and by rubbing and rolling with the head (so-called 'oil-preening'); also by scratching with the foot. In most taxa, the head is oiled indirectly by contact with other parts of the plumage, including the wings. In passerines the bird also gets oil on the bill directly, then transfers the oil to one foot by scratching the bill and finally to the head feathers by scratching all over the head rapidly, moving the head under the foot while so doing. The undersurface of the primaries also presents problems of access for efficient oiling and preening. Many non-passerines oil this area by lowering the carpus, raising the wing-tip, and turning the head round to it over the back for treatment with the bill as in normal preening. Grebes rub the primary tips alternately on the oil gland direct by persistent wing-twitching after a thorough bathe. Passerines oil the under surface of the wings with the bill or with the bill and head together, extending one wing at a time sideways and forwards, carpus uppermost, and often alternating from wing to wing rapidly. Wing-oiling type movements also help to dry the wings (see above). Typically, oiling follows on directly from bathing and drying; in some taxa however (e.g. boobies) there may be a further oiling and preening session long after the initial bathing-drying-oiling-preening sequence, perhaps stimulated by secretion of fluid from the nasal-glands.

Powdering. In those taxa with powder-down patches and tracts (see PLUMAGE), the material produced permeates the plumage, aided by preening, and appears to supplement preen-oil or, in those birds lacking a functional oil gland (e.g. many pigeons), to replace it. After fouling the feathers of head and neck with slime from their fish prey (eels, etc.), bitterns and herons rub the affected parts on the powder-down patches, then scratch off the slime and powder using the pectinated claw, apply preen-oil, and finally preen thoroughly.

Preening. True preening (so-called 'nibble-preening'), the arrangement, cleaning, and general maintenance of the plumage using the bill, is the basic and most important activity of feather care. It occurs frequently, in short or more prolonged bouts, throughout the day especially during loafing, either as the climax of the bathe-dry-oil-preen sequence or independently. In the latter case, it may be done as routine or in response to the soiling or disarrangement of the feathers or because of irritation. When preening without prior bathing, some birds e.g. grebes, wildfowl, and waders (Charadrii) will deliberately wet the bill by dipping it in the water periodically during the bout. Longer preening sessions in particular tend to be structured, certain areas of the plumage being treated in fixed sequence.

Two main sets of bill actions are used in preening: (1) with the mandibles opening and closing, the cutting edges operating against each other (nibbling); (2) with the mandibles closed or passively open, and operating as a single unit (stroking). The first set is especially important for working in preen-oil, re-arranging the plumage, repairing split webbing, and removing waste matter. Nibbling (mandibulating) is the most thorough and accurate preening method: an individual feather or small group of contour feathers is seized in the mandibles and passed between them, working from base to tip; or attention is concentrated at or near the calamus of the feather and on the adjacent area of skin. In birds with fine or small bills, especially passerines, nibbling often consists of repeated tiny peckings with the tips of the mandibles, but birds with large or broad bills have less precise and delicate movements. Waterbirds may perform particularly vigorous nibbling actions during bathing (so-called 'washing' in Anatidae) or during oiling and the initial phase of the subsequent preening ('snapping' and 'biting' in gulls). Drawing or 'feather-stripping' is related to nibbling, and often alternates with it, single feathers or groups being pulled through the bill in one movement. The stroking actions are less skilful than the others, which they supplement, and are used to dry the feathers, smooth them down, and apply preen-oil. When stroking, the bird moves the closed bill rapidly down the feathers, usually in the direction of the alignment of the plumage. A more vigorous treatment of whole areas, with closed or partly

Bar-tailed Godwit *Limosa lapponica* preening. (*Photo: J.B. & S. Bottomley*)

Robin *Erithacus rubecula* preening. (*Photo: J.B. & S. Bottomley*)

open bill, is termed 'stropping' in grebes; similar movements occur in gulls and penguins, while the 'wiping' of penguins involves the head also and is associated particularly with drying. Quivering is a trembling action of the closed bill down the feather; this and stroking are used to preen the primaries, particularly in passerines.

As well as the bill, the head and foot are employed subsidiarily in preening, especially for drying and oiling. The head itself is preened by scratching (see below) and by being rubbed against other parts of the plumage. In some taxa, one individual may preen another (see ALLOPREENING); though this is often thought to be primarily of social significance, it must also function in feather care at times—especially if reciprocated and confined to the head and other areas inaccessible to the bird's own bill. Parents may preen their helpless young.

Red-footed Falcon *Falco vespertinus* scratching. (*Photo: P. Munsterman*).

Plumage-scratching. This is effected by one foot at a time, usually while the bird supports itself on the other though some species will scratch in flight, and is of two types: (1) simple head-scratching, so-called 'basic scratching' or 'scratching reflex', an immediate response to sudden irritation on the head-parts; and (2) scratch-preening, so-called 'extended scratching', a supplementary form of preening, usually of the head-parts, but in some cases also of other areas. The first type may occur at any time, and is by far the more common, the second mainly during bouts of feather care. The head-oiling of most passerines provides a good example of scratch-preening; in those taxa with a pectinated claw, this preening comb is used for prolonged scratch-preening (true combing). Hummingbirds with particularly long bills will scratch-preen the dorsal plumage, wing, and vent, while others confine their attention to head, bill, hindneck, chin, and upper throat; in all cases, the scratch-preening movements tend to be slower and more deliberate than those of simple head-scratching. Some parrots use similar movements for scratch-preening the face, employing the toes like fingers, or rub the face against the clenched toes. The Budgerigar *Melopsittacus undulatus* scratch-preens its vent area using the upper part of the toes, the joint between them, and the tarsus.

There are two methods of scratching the head: direct or 'underwing' scratching, with the foot brought straight up to the head without involving the wing; and indirect or 'overwing' scratching with the foot brought up above the humerus after the wing has been lowered. In simple head-scratching, each species typically uses one method only, and that is usually characteristic of related species up to the family or subfamily level; in only a few groups, e.g. the American wood-warblers (Parulidae), differences exist at the genus level. No direct-scratching species, however, has ever been seen to use the indirect method for either simple head-scratching or scratch-preening. Indirect-scratching species may use the direct method but mainly during ontogeny or in flight. Other variation in scratching method may be related to the type of plumage-scratching involved, the indirect method being used for simple head-scratching and the direct at times for scratch-preening—especially of areas other than the head, as in hummingbirds. Avocets and stilts scratch the head indirectly but the bill directly.

Care of skin and bare parts. The skin and feet are attended to by use of the bill mainly during routine feather maintenance, particularly bouts of true preening. Many birds will examine the feet and pick off dirt at other times too. Waders deliberately clean the feet in water before going to the nest. The eyes are cleaned and also protected during feather care sessions by use of the nictitating membrane (see VISION). Dirt or other sources of irritation in the eye itself or on the surrounding area elicit an immediate shoulder-rubbing response; this should not be confused with rather similar movements used by grebes and waterfowl during bathing and oiling and by penguins for drying after bathing. Grebes and other water birds will clean the bill by dipping it in the water; ducks and other waterfowl also submerge the bill and blow air through the nostrils, probably both to clear the nasal passages of mucus and to get rid of dirt. Similar 'sneezing' behaviour has been recorded in penguins. Such activities are often supplemented by head-shaking (see below) as is the special throat-touching movement of the grebes whereby water is drained from the bill after diving. The bill is also cleaned by scratching with one foot, by seizing or pecking hard objects, or (in gulls) by being plunged into the ground. After bathing and at other times, many landbirds wipe the bill and gape-flanges on a perch or other firm surface in a species-characteristic way, either by stropping it from side to side with a sharpening-like action or by rubbing one side several times and then the other. Many taxa lubricate the bill with preen-oil, more or less incidentally during oiling spells; passerines (at least) also anoint the feet similarly and will deliberately treat the tarsi with bill-quivering movements.

Comfort movements. Term now sometimes used to cover the whole field of what is here called 'comfort behaviour' but best restricted mainly

Dunlin *Calidris alpina* wing-stretching. (*Photo: M. Holliday*).

to various shaking and stretching actions. Others, relating to the bare parts, are mentioned in the section above. All are often associated with feather-maintenance activities, occurring during loafing breaks, but often occur quite independently. As well as putting the feathers in order and stretching muscles, the main comfort movements may well prepare the muscular and circulatory systems for activity.

Shaking. The head-shake, usually a brief mainly lateral movement, seems common to all birds. Wildfowl also have a distinctive head-flick in which there is a rotary component of head and neck with the bill rising vertically; in most other groups, this action seems incorporated into high-intensity head-shaking—as with the head-fling of grebes. The body-shake is more complex, involving the rapid ruffling up and lowering of the contour feathers often with rotation of trunk, neck, and head to a greater or lesser extent. In grebes, body-shakes occur on the water only, as the bird lifts itself by paddling with the feet (rise-and-shake); wildfowl have similar swimming-shakes but also perform standing-shakes in shallow water or on land. Some birds e.g. falcons and gulls, will body-shake on the wing (flying-shake or so-called 'aerial rousing'). When wing-flapping, the bird beats the wings deliberately a number of times. The wing-flap is most characteristic of non-passerines such as grebes (the rise-and-flap) and wildfowl (swimming-flap, standing-flap); in some, e.g. gulls and waders, it may be prolonged and vigorous, the bird even rising from the ground meanwhile. The closed wings may also be vibrated in a wing-shake, and many groups have a lateral tail-wag. Wildfowl also incorporate tail-wagging and wing-shaking into the body-shake, and tail-wagging into the wing-flap. Body-shaking, tail-wagging, and wing-flapping especially act as feather-settling movements; they are also drying ones (see above).

Stretching. The one-wing stretch seems common to all birds, the wing being extended sideways and downwards or backwards until it is nearly or fully open, held still briefly, then folded away again. In many species, there is also a co-ordinated stretching of the corresponding leg (wing-leg stretch)—but both can occur independently. Passerines and near-passerines especially accompany these movements with a sideways fanning of the tail. In the both-wings stretch, the wings are lifted together above the back—typically while still remaining flexed or only partly open at the carpal joints. Passerines often follow this with the two-leg stretch as they straighten the tarsal joints and lift the body. Wildfowl lack this movement but combine the both-wings stretch with a forward extension of the neck, etc, and grebes with a neck-stretch, head-rotating, and a head-stretch (chin-brace); in penguins, the sequence of activities is even more complex. The term 'full-stretch' seems therefore better suited for such co-ordinations. In addition to the two standard wing-stretches, plovers and many other waders have a vertical wing-raising posture in which the fully extended wings almost touch; at times this appears to be a comfort movement but it serves as a social signal as well, especially before and immediately after flight. Finally, many birds have a movement in which the mandibles are deliberately opened then closed. It is still argued whether this represents a jaw-stretch or a true yawn (see YAWNING). In wildfowl it appears to be a jaw-stretch, in the Ostrich *Struthio* and in penguins a yawn, while in grebes and at least some pelecaniform birds there is both a jaw-stretch and a distinctive yawn.

Snipe *Gallinago gallinago* loafing. (*Photo: F. Pölking*).

New Zealand Kingfisher *Halcyon sancta* juvenile wing-stretching. (*Photo: G. Moon*).

Resting postures. Adult birds usually rest and sleep while standing on one or both legs; some cursorial and wading birds, including plovers and storks, will also at times squat half-down, taking their weight on the tibio-tarsal joints. Aquatic birds, such as divers and grebes, normally loaf only while floating on the water, except when incubating; a few highly aerial species, such as terns and swifts, will rest on the wing even through the night. Young birds often rest by squatting right down on the belly, as do adults of certain groups such as gamebirds (Galliformes), gulls, pigeons, and babblers, when feeling safe from danger, or when ill. In the most typical of the full resting postures, the bird relaxes, ruffles its contour feathers, fluffing them over the folded wings, and turns the head round and inserts the bill 'behind the wing'; one leg may be drawn up into the plumage. A minority of groups merely draw the head in close to the body in a hunched attitude (e.g. pigeons), rest the bill on the foreneck (e.g. storks), or insert it into the side of the neck (e.g. herons, grebes—the latter in the well-known 'pork-pie' posture with the opposite foot stowed away up in the flank 'pocket' under the wing). See also ROOSTING.

COMMENSALISM: the rare situation where species A benefits from the presence of species B, but where B is indifferent to the presence of A, neither gaining nor losing from the association, e.g. sparrows *Passer* spp. nesting in the bases of nests of larger species. Commensalism differs from Symbiosis or Mutualism, in which both species benefit from the association.

COMMISSURE: the line of apposition of the closed mandibles, as viewed laterally (see BILL).

COMMON BIRDS CENSUS: see CENSUS.

COMMUNITY: a natural assemblage of species, the term being usually restricted to assemblages occurring in defined habitat types; frequently further restricted to assemblages of related species, e.g. the bird community of oak woodland. Community ecology is concerned with the patterns that characterize such assemblages and with the interactions, especially competitive, between the species. There has been a rather general consensus among ecologists that interspecific competition is fundamental for the interpretation of community patterns (e.g. MacArthur 1972, Cody 1974; and see COMPETITION); but for a critical re-assessment of the role of competition, and of the probable importance of chance factors in determining community structure (and indeed of the reality of any such 'structure'), see Connors and Simberloff (1979) and Wiens (1983).

Wiens, J.A. 1983. Avian community ecology: an iconoclastic view. *In* Brush, A.H. & Clark, G.A. (eds.). Perspectives in Ornithology. Pp. 355–403. Cambridge.

COMPETITION: the interaction which occurs when two or more individuals, of the same or different species, use a resource (food or nest sites, for example) in short supply.

Competition may either be by 'exploitation'—as the limiting resource is simply used up; or by 'interference'—behavioural interactions in which individuals or species pre-empt valuable resources for their exclusive use, by direct aggression or display.

The interactions are intra-specific when individuals of a single species are involved, or inter-specific when two or more species utilize the same limiting resource. Inter-specific competition cannot occur without intra-specific competition.

The abundance of a species in a habitat may be markedly reduced by inter-specific competition, and in the extreme, it may be excluded altogether by a superior competitor or competitors. The combined competitive effects of several species on another species are sometimes referred to as diffuse competition.

COMPETITIVE EXCLUSION: the exclusion (usually from a particular habitat) of one species by another, competitively superior species, in cases where each is exploiting the same environmental resource(s). Ecologically less similar species may still compete, without one excluding the other. The precise conditions determining competitive exclusion or competitive coexistence can be stated mathematically. They depend not only upon how similar the species are in their ecologies, but also on their abundances in the absence of competition. See also ECOLOGY.

COMPLEX: in taxonomy, a neutral term used when the precise status and interrelationships of a group of forms is in doubt.

COMPROMISE BEHAVIOUR: see AMBIVALENCE.

CONCHA: part of the ear (see HEARING AND BALANCE; OWL).

CONDITIONING: see LEARNING.

CONDOR: substantive name of the 2 species of Cathartidae that are placed in *Vultur* and *Gymnogyps* respectively (see VULTURE (2)). See photo FLIGHT.

CONDYLE: an articulating process on a bone (see SKELETON, POST-CRANIAL).

CONEBILL: substantive name of the 10 species of *Conirostrum* and of *Oreomanes fraseri* (Giant Conebill) (Passeriformes, suborder Oscines). The systematic position of this small group of Neotropical birds is problematical; they are here placed together with *Coereba* in a family Coerebidae (see HONEYCREEPER, BANANAQUIT), but future research may well lead to a different arrangement. The typical conebills are small (10–14 cm) warbler-like birds with short, pointed bills. Their plumage is not brilliant, mostly grey or bluish above and paler, with chestnut brown and buff tints, below, and black or white head markings in some species. They fall into two groups ecologically, one group inhabiting swampy tropical forest, including mangroves, and the other group subtropical to temperate woodlands in the Andes. They are not well known ecologically, but are evidently mainly gleaners of insects from arboreal vegetation, some species at least being also partly frugivorous. Unlike the Bananaquit, those species whose nests are known build deep open cup nests. The Giant Conebill, a considerably larger bird (length *c.* 18 cm), is found in very high-altitude *Polylepis* woodland in the Andes, where it forages by searching the tree trunks for insects concealed beneath the bark.

D.W.S. (1)

CONFIDENCE LIMITS: see BIOSTATISTICS.

CONGENERIC: of two or more species, meaning that they are, or should be, placed in the same GENUS.

CONGRESSES, INTERNATIONAL: gatherings for scientific discussion and for establishing personal contacts and, on occasion, for reaching agreement on courses of action. International Ornithological Congresses are now held at intervals of 4 years. Continuity is provided by an International Ornithological Committee of 100 members, meeting during the course of each Congress; this body fills vacancies in its own number, decides general questions concerning the regulation of Congresses, chooses the country in which the next is to be held and elects a President for the succeeding Congress. A small Permanent Executive Committee makes recommendations to the International Ornithological Committee and deals with matters arising in the interval between Congresses; the constitution of this body is governed by the rule adopted in 1954—Acta XI Congressus Internationalis Ornithologici: 42, Decision 3 (pub. Basel, 1955).

The following International Ornithological Congresses have been held, under the Presidents named.

I 1884 Vienna: Dr Gustav Radde (Austria)
II 1891 Budapest: Prof. V. Fatio (Switzerland)
III 1900 Paris: Dr Emile Oustalet (France)
IV 1905 London: Dr R. Bowdler Sharp (Great Britain)
V 1910 Berlin: Prof. Anton Reichenow (Germany)
VI 1926 Copenhagen: Dr Ernst Hartert (Germany and Great Britain)
VII 1930 Amsterdam: Prof. Einar Lönnberg (Sweden)
VIII 1934 Oxford: Prof. Erwin Stresemann (Germany)
IX 1938 Rouen: Prof. Alessandro Ghighi (Italy)
X 1950 Uppsala: Dr Alexander Wetmore (USA)
XI 1954 Basel: Sir A. Landsborough Thomson (Great Britain)
XII 1958 Helsinki: Prof. Jacques Berlioz (France)
XIII 1962 Ithaca, N.Y.: Dr Ernst Mayr (USA)
XIV 1966 Oxford: Dr David Lack (Great Britain)
XV 1970 The Hague: Prof. N. Tinbergen (Great Britain), Dr Finn Salomonsen (Denmark)
XVI 1974 Canberra: Prof. Jean Dorst (France)
XVII 1978 Berlin: Prof. D.S. Farner (USA)
XVIII 1982 Moscow: Prof. L. von Haartman (Finland)

The 19th Congress is due to be held in Ottawa in 1986 under the presidency of Prof. Klaus Immelmann (West Germany).

Each Congress is followed by the publication of a special volume of *Verhandlungen, Proceedings, Comptes Rendues* or *Acta*, edited by its General Secretary. The proceedings of the 3rd and 4th Congresses constituted volumes of the former international journal *Ornis*. The Presidential Address at the 8th Congress gave the history of the earlier meetings.

The International Congresses of Zoology, held at intervals of 5 years, are also of interest to ornithologists in a more general way. They are important in that they constitute the final authority on questions of zoological NOMENCLATURE and appoint the standing International Commission on that subject. (A.L.T.) B.C.

CONNECTIVE TISSUE: a general term for a variety of fibrous and other tissues of the body, including ligaments and tendons (see also under MUSCULATURE).

CONSERVATION: measures, including legislation, preservation and management of habitat, control of environmental pollution, education and research, to promote the wellbeing and survival of wild birds. Their purpose is to achieve as wide a variety of species, and the greatest number of each, compatible with and appropriate to the ecological conditions existing in an area, and to guard against the extinction of species or races. During the second half of this century they have replaced an earlier approach which relied on legal protection for individual species or groups of species.

This protectionist approach was based on the assumption that birds could co-exist with Man, provided they were safeguarded against excessive persecution and exploitation. Since then land pressures have enormously increased. Initially, expanding towns, motorways and airports were responsible, but recent intensification and mechanization of agriculture and forestry have made extensive areas of remaining countryside inhospitable to wildlife. A more flexible approach is needed and one which, since all change cannot and indeed should not be stopped, allows for the integration of wildlife. Because of the mobility of birds (see MIGRATION), and world trade in birds (alive and dead), plumage and their eggs (see UTILIZATION BY MAN), international aspects also apply.

Legislation. Different approaches have been adopted but all emanate from one of two fundamentally different attitudes. Either birds are considered as something to be hunted as quarry, which is the possession and right of the owner or occupier of the land, or as being within the public domain, regardless of the ownership of the land on which they may be found.

British legislation. This evolved from the former approach. Thus in the Middle Ages birds such as the Grey Heron *Ardea cinerea* were protected as quarry for falconry, a royal sport (see FALCONRY). Continuing interest in hunting led to the concept of a special group of huntable species referred to as GAME-BIRDS. The development of game preservation and the need for further protection of owners' rights was reflected in the Game (Scotland) Act 1772 and the Night Poaching Act 1828. A series of Acts then followed, which were still principally aimed at upholding the rights of owners and occupiers, and only indirectly benefiting birds. This narrow British definition of game is not easily understood in other countries, where all birds shot for food are regarded as game and covered by legislation.

The second half of the 19th century saw a change in attitude and increasing public concern towards wild birds in general. A number of Acts extended protection to a wider variety of species. The privilege of owners and occupiers of land was retained by local exemptions, and it was not until the mid-20th century that a really effective and comprehensive Act was achieved. The Wild Birds Protection Act 1954 started with the concept that all wild birds and their eggs should be protected. There were exceptions for hunting and in the interests of agriculture, science and education. This enlightened and straightforward approach, already adopted in 1914 in the Netherlands and 1929 in Prussia, not only facilitated enforcement, but represented an important educational advance with acknowledgement by Government that wild animals represented a common heritage. The 1954 Act continues to this day to underlie protection for wild birds in Britain. Modified in 1967, in 1981 it was incorporated, with further changes to bring it into line with the European Community Directive (see below), into the Wildlife and Countryside Act.

Legislation outside Britain. By contrast this was based on the alternative approach to birds which, with other wild animals, are part of the public domain. In the USA protection of birds is divided between federal (national) government and state governments. Federal government legislates when the matter is deemed by Congress to be of interstate, national or international concern.

This system includes provision for hunting certain species for sport, but not commercially. Migratory birds that are considered to be game—most ducks (Anatidae), some rails (Rallidae), and a few waders (Charadrii) and doves (Columbidae)—are subject to licence and annual regulations by the Federal Fish and Wildlife Service. Non-migrating game, such as the Turkey *Meleagris gallopavo*, grouse (Tetraonidae) and quail (Odontophorinae) are covered by state regulations.

To achieve its purpose legislation must be effectively enforced. Understandably wildlife laws come low down the priority list of overworked police forces, who find it difficult to act without specialist knowledge of wild birds and their eggs. In the United States, Canada, Australia, New Zealand and certain other countries, the task of investigation and enforcement is largely undertaken by federal and state wildlife enforcement agencies, whose officers have special responsibilities and training in wildlife legislation, conservation work and species identification. Most European countries lack these specialist services and as in Britain, rely on voluntary bodies, such as the Royal Society for the Protection of Birds and the Royal Society for the Prevention of Cruelty to Animals, who either undertake prosecutions themselves, or co-operate with police by carrying out much of the preliminary investigation work and providing the expertise.

International action. An increase in knowledge of migratory movements led to the realization that birds could not be regarded as the property of one country alone. The first international convention between two countries was the Migratory Bird Treaty of 1916, which provided reciprocal legislation for the protection of migratory birds between the United States and Canada; this was extended in 1937 to include Mexico.

In Europe the international aspect of bird protection was first raised at Vienna in 1868, when a meeting of German agriculturists and foresters resolved to procure international agreements for the protection of birds and other animals useful to agriculture and forestry. Although efforts were made to bring the proposal into effect, it was not until 1902 that an International Convention for the Protection of Birds useful to Agriculture was signed in Paris. This accorded protection to birds enumerated as useful and to their nests, eggs and young, while other species were pronounced harmful and exempted from protection. Various methods of taking and killing birds were prohibited, and also the sale of protected birds during the close season.

During the first two decades of the 20th century, an increase in field observations, and experience of the dire results of commercial exploitation of certain species, led in 1922 to the founding by Dr T. Gilbert Pearson of the United States of the International Council (then Committee) for Bird Preservation (ICBP)—the first international organization concerned with the preservation of wildlife.

In 1925, Professor Einar Lönnberg of Sweden drew attention to the urgent need for international co-operation for the protection of the Anatidae, pointing out that Scandinavian countries bred the birds and countries further south shot them. His efforts led to active co-operation between European countries and to the passing of the Wild Birds (Ducks and Geese) Protection Act 1939 in the United Kingdom, and similar protective measures in other European countries, and eventually to the establishment of the International Wildfowl (now Waterfowl) Research Bureau (IWRB).

In addition to these exclusively bird-orientated organizations, international conservation was strengthened by the formation in 1948 of the International Union for the Conservation of Nature and Natural Resources (IUCN), the World Wildlife Fund (WWF) in 1961 and the United Nations Environment Programme (UNEP) in 1972. The IUCN represents government and non-government organizations and an important part of its output has been the Red Data Books listing rare species (see ENDANGERED BIRDS). The ICBP and IWRB act as specialist advisory bodies to IUCN. WWF is primarily a fund-raising body giving major financial support to IUCN and ICBP. The UNEP, which relates to the total environment, also gives funds for conservation work. In 1980, IUCN, WWF and UNEP jointly published a World Conservation Strategy.

In 1935, at a meeting of ICBP in Brussels, representatives of the Finnish, Swedish and Norwegian Governments produced a draft convention for the international protection of birds. It was eventually agreed that an entirely new convention was not practicable, and proposals should be incorporated in the revision of the Paris Convention of 1902. Although now restricted to Europe, it took 12 years before the requisite number of countries ratified in 1963. More recently there was renewed impetus for international co-operation, and in 1979 three international instruments were agreed: the European Communities Directive on the Conservation of Wild Birds; the Council of Europe Convention on the Conservation of European Wildlife and Natural Habitats (the Berne Convention); and the Convention on the Conservation of Migratory Species of Wild Animals (the Bonn Convention). Of other conventions perhaps the most important was the Convention on the Conservation of Nature and Natural Resources in Africa.

Protection of habitats. As the human population of the world continues to grow, the necessity to preserve habitats for wild birds becomes increasingly urgent. It is now known that most species of birds will flourish if an adequate ecological base, including cover, food, water and the necessary conditions to satisfy behavioural needs is provided for them, with freedom from disturbance. In many countries a start has been made with the establishment, both by governments and voluntary bodies, of national parks, nature reserves, refuges and sanctuaries. Internationally the first major action directed specifically to safeguarding habitats for birds was the Convention on Wetlands of International Importance signed in Ramsar, Iran, in 1971. Since then both the European Community Bird Directive and Berne Convention have provided for habitat protection, particularly of those more sensitive to outside influences and of importance to migratory species as staging, wintering or breeding sites.

It is now realized that the protection of sites is not sufficient by itself and that without management many will deteriorate. To guard against unwanted changes, most reserves are now subjected to a management plan which lays down objectives and a programme of research and estate work. With increasing experience gained from site work and the accumulation of ecological information, management work is now highly successful, and there are numerous examples of sites which have had their scientific value considerably increased. For example, when the Minsmere Reserve on the east coast of England was acquired by the Royal Society for the Protection of Birds, it was not rated as of outstanding importance since much of the area had been transformed into agricultural land. An intensive management programme has won it national status and inclusion as one of the British internationally important wetland sites under the Ramsar Convention. This enrichment of habitat and re-creation of lost sites is one of the most exciting and important recent achievements of Conservation.

In addition to major site management, considerable efforts have been made to produce diversification within the main habitats. These include the best siting and density of nestboxes; the artificial provision of food in frosty weather or where the natural food is polluted; and different treatments of woodland clearings and fringes. In Scandinavia, substantial increases of breeding range of the Goldeneye *Bucephala clangula* have been achieved by provision of suitably designed nestboxes, and in America Wood Duck *Aix sponsa* have been locally much increased by provision of raccoon-proof nestboxes. The attraction of ducks to artificial decoy ponds has a long history in Europe (see DECOY), and recently pools to encourage wildfowl have been constructed in large numbers in North America with some incorporating artificial islets giving cover for nesting wildfowl. Floating rafts have also been used to extend the breeding area of the commercially exploited guano cormorants on islands off Peru (see GUANO).

Research. A considerable body of empirical knowledge now exists on management techniques. This has not yet been assessed or related scientifically to fundamental studies in ethology, ecology and population dynamics. Studies with this object in view are now in progress in several countries.

Conservation will also benefit from a wide range of applied and fundamental research. Certain projects are more immediately valuable and offer practical solutions to urgent problems. An autecological study of a diminishing species may reveal the cause of the decline and enable action to reverse it. Thus in the United States it has been shown that the survival of the rare Kirtland's Warbler *Dendroica kirtlandii* depends on burnt areas to stimulate regeneration of pines, on which the species is largely dependent.

General studies of broad geographical distributions with population estimates, such as numerous recent national bird atlas projects (see ATLAS), provide basic material on which national conservation programmes are based, and long term surveillance studies give early warning of unsuspected problems. In Britain these take many forms e.g. the Common Birds Census, run by the British Trust for Ornithology, which calculates an annual index of abundance for widely distributed farmland and woodland plots; the Beached Bird Survey of the Royal Society for the Protection of Birds which records the number of dead birds and the proportion oiled that wash ashore over measured stretches of coast; the annual census of heronries started in 1928. North America conducts annual surveys of waterfowl to allow calculation of permitted hunting levels for the forthcoming season. Research will also establish whether claims of damage by birds are valid.

Black-headed Gulls *Larus ridibundus* and Common Terns *Sterna hirundo* nesting on artificial island. (*Photo: E.J. Hosking*).

Difficult and controversial issues arise in connection with proposals for introduction not only of exotic species, but of species perhaps native to similar habitats not far away, and even in some cases formerly indigenous at the place in question (see NATURALIZED BIRDS). So much harm has been done by thoughtless introductions, and the indirect consequences of such interference are so unpredictable, that most authorities at present take an ultra-cautious attitude towards any such projects. In principle there may be no logical objection to introductions in a world where so much other human interference is unavoidable, but its practice in the present state of ignorance about possible repercussions can rarely be justified. Artificial attraction of birds and artificial increase of their numbers may also have dangers, but these tend to be more easily controlled if need arises. Recently there has been a growing interest in research into captive breeding and reintroduction of species in an attempt to re-populate areas. In Britain the Wildfowl Trust has successfully bred the Hawaiian Goose *Branta sandvicensis* in captivity, and reintroduction to the wild is underway. In the United States, Canada and other countries a massive captive breeding programme involving the Peregrine *Falco peregrinus* is in progress and the first successful breeding of pairs reintroduced into the wild was recorded in 1980. In contrast, in certain instances e.g. where large gulls compete for nesting sites with terns, the gulls' numbers may have to be reduced.

Environmental pollution. A country possessing excellent, well enforced bird legislation and large numbers of nature reserves may still find itself faced with a conservation disaster caused by a widely dispersed man-made environmental pollutant. The most recent alarming example was the serious widespread effect, particularly on birds of prey and fish-feeding birds, of persistent organochlorine pesticides such as DDT and dieldrin (see TOXIC CHEMICALS). In some instances pollution may have its origin outside the immediate control of the country affected. Pollution of the seas by oil from shipping operations and disasters and mining operations (see OIL POLLUTION) is an example. In such circumstances conservationists have to press for international action through agencies such as the United Nations and the Organization for Economic Co-operation and Development.

Education. Effective conservation of wildlife in the modern world requires considerable finance and deployment of resources. Governments and peoples will not support this expenditure unless they understand the necessity for it and believe it to be worthwhile. Educational activities aimed at both adults and children are now promoted in many countries. These include television and radio programmes, work in schools involving field courses and the publication of books and magazines. Nature trails and public viewing 'hides' or 'blinds' on reserves enable large numbers of people to observe and study at close range rare and shy birds without disturbing them or affecting the scientific interest of the site.

Voluntary bodies have played an outstanding role in this work. In North America the National Audubon Society and many affiliated state and local Audubon societies continue to be extremely active in promoting public awareness and participation. In Britain the development of public interest is clearly reflected in the growth of the Royal Society for the Protection of Birds, whose adult membership has increased from 5,000 in 1940 to 375,000 in 1984. Its Young Ornithologists' Club is also expanding with a membership now standing at over 80,000.

Elsewhere in many countries of the world, new voluntary societies are being formed and established ones are gaining in strength. To encourage such growth in Europe, a Working Group of European Bird Protection Societies (WEBS) was formed in 1976 to exchange experience and ideas. I.P.

CONSPECIFIC: of two or more subspecies or other forms, meaning that they belong to the same species (or should be so regarded, although considered by others to be specifically distinct)—see SPECIES.

CONSUMMATORY ACT: 'an act which constitutes the termination of a given instinctive behaviour pattern or sequence' (Thorpe 1951), bringing about a sudden drop in motivation—compare APPETITIVE BEHAVIOUR; BEHAVIOUR, HISTORY OF; SPECIFIC ACTION POTENTIAL.

CONTACT CALL: a noise made by a bird as a means of keeping in touch with others of its species (see FLOCKING).

CONTINGENCY TABLE: see BIOSTATISTICS.

CONTOUR FEATHER: the predominant feather type, characterized by the presence of vanes, which, at least in their distal parts, are firm and flat. Includes remiges and rectrices. Sometimes highly modified (see FEATHER; PLUMAGE).

CONTROL (1): deliberate action by man to limit or reduce the numbers of a wild species, where potential increase or existing abundance is thought to be detrimental to human interests; a negative aspect, so to speak, of CONSERVATION. See EMU WAR; QUELEA CONTROL.

CONTROL (2): recovery and release of a bird already marked (see MARKING).

CONTROL (3): standard of comparison for checking inferences deduced from experiment (Concise Oxford Dictionary). A classic ornithological example is the experiment by Keeton (1971) to test whether magnets mounted on pigeons *Columba livia* could affect their homing behaviour. Individual birds were released alternately from 2 treatment groups, chosen randomly from a flock housed in a single pen. Birds in the 'experimental' group wore a magnetic bar glued, just before release, to the back at the base of the neck. The 'control' group wore a brass bar of identical size, weight and placement, the important 'control' factor being that brass has no magnetic properties. The birds were liberated at various sites and their orientation to home observed. Under overcast conditions the magnet-bearing birds were significantly more disorientated than the brass-bearing birds, indicating that the magnets were a confusing factor. One possible interpretation of the results, therefore, was that, under certain conditions, pigeons can use magnetic cues in homing (see also NAVIGATION). E.K.D.

Keeton, W. 1971. Magnets interfere with pigeon homing. Proc. Nat. Acad. Sci. 68: 102–106.

CONURE: substantive name of the species of several Neotropical parrot genera, e.g. *Aratinga* (Psittacinae, Arini) (see PARROT).

CONVERGENCE: evolution on lines tending to produce similarity between unrelated or only distantly related forms as a result of adaptation to a like mode of life—the antithesis of radiation in its evolutionary sense (see ADAPTATIONS, ENVIRONMENTAL; EVOLUTION; RADIATION (1)). Examples of modes of life leading to convergent adaptations are running (in place of flight), aquatic habitat, aerial pursuit of insect prey, and raptorial feeding habits; but there are many others.

Convergence is all the more important as a phenomenon of avian evolution because it is superimposed on a high degree of uniformity in basic structure within the class. For that reason it is confusing to taxonomists, who have difficulty in distinguishing between characters that are primary, and therefore of phylogenetic significance, and characters that are secondary in that they are the result of special adaptations (as contrasted with the general adaptations common to all birds).

Convergence can be extremely subtle in its manifestations, producing similarity not merely in a few characters but in a whole series of characters, even of minute detail, that are advantageous for the particular mode of life. The resemblance may indeed have so many facets as to arouse scepticism concerning the absence of a close relationship. This is a frame of mind induced by the misleading process of enumerating points of similarity as if they were quite independent instead of being items in a 'constellation of characters' contributing to a single adaptation.

At the same time it has to be realized that phylogenetic relationship and convergent adaptation need not be mutually exclusive. Convergence may occur between forms that had diverged not very far back in the evolutionary process.

CONVERSION TABLES: for factors for converting between the British and the metric systems see Tables at the end of the volume.

CO-OPERATIVE BREEDING: the phenomenon of non-breeding birds attending the nests of breeding members of their species and carrying out some or all of the behaviour patterns associated with nesting, including nest-building, incubation, and feeding of the nestlings. The presence of non-breeders at the nests of many species of Central American birds was pointed out by Skutch (1961), who coined the term 'helpers at the nest' to describe the supernumeraries. Subsequently this behaviour has been found to be widespread among birds, particularly those of terrestrial ecosystems at tropical and sub-tropical latitudes.

Occurrence. Co-operative breeding is most frequent among passerines, where it has been recorded, at least casually, for 32 families and sub-families, but it also occurs in groups as diverse as rails, kingfishers and bee-eaters, swifts and woodpeckers, suggesting that the behaviour has evolved independently on many occasions (Brown 1978). It occurs almost invariably in species where groups of more than two birds defend common territories throughout the year and in such cases it is normal for non-breeding members of the group to participate in feeding the nestlings and, less frequently, in incubation.

Co-operative breeding is also found among many colonial birds, particularly those nesting in holes (e.g. bee-eaters, kingfishers) where the non-breeders may participate in breeding activities at several different nests during the same season. The same applies in the case of territorial groups where more than one pair breeds. In some species where groups hold territories outside the breeding season but individuals pair to breed, failed breeders may become helpers at adjacent nests.

The extent of co-operative breeding varies widely in different species, from those in which only a small proportion of nests are attended by non-breeders, with usually no more than one at each (e.g. todies *Todus* spp. and long-tailed tits *Aegithalos* spp.), to species in which several non-breeders are nearly always present at each nest, (e.g. the babblers *Turdoides* spp., Whitewinged Chough *Corcorax melanorhamphus* and Mexican Jay *Aphelocoma ultramarina*). In the former case the non-breeders are generally males and this sex also predominates where larger groups occur. This bias apparently results from the earlier dispersal of females from their natal group, with a consequently higher mortality.

Among species in which stable, territorial groups persist over several years, co-operative breeding forms one of a number of behaviour patterns typical of prolonged adaptation to a group-territorial existence. These include allopreening, roosting clumped together, giving communal vocalizations, and maintaining sentinels while feeding. Species which have reached this stage generally exhibit little or no sexual dimorphism, produce no distinctive song and frequently appear to suppress any signs of courtship behaviour, courtship displays and mating being carried out infrequently and well away from other group members.

Evolution. Among group-territorial species, groups frequently arise through the deferred dispersal of young reared within the territory, so that breeders and non-breeders are closely related. This observation has led to speculation that KIN SELECTION may have played an important role in the evolution of co-operative breeding. Among colonial species which exhibit co-operative breeding, however, breeders and helpers are not necessarily closely related and a satisfactory evolutionary explanation for this type of co-operative breeding is not yet forthcoming. For the group-territorial Florida Scrub Jay *Aphelocoma coerulescens* Woolfenden and Fitzpatrick (1978) have pointed out that by helping to increase the number of young reared within the territory, non-breeding males increase their own chances of 'budding-off' a new territory to become breeders themselves. With such a strong selection pressure operating on the individual it appears that kin-selection may be unimportant. Where territorial boundaries are relatively inflexible, moreover, non-breeders may compete with one another for the privilege of eventually breeding in the parental territory, creating a selection pressure against the rearing of further young within the territory. This may account for the fact that in some species where co-operative breeding is normal the actual production of fledglings per pair is no higher than for similar species where helpers are not found (Gaston 1978).

Environmental correlates of co-operative breeding are difficult to define. Virtually all co-operative breeders are sedentary, however, and those in which co-operative breeding is obligatory, with several helpers at each nest, are often medium-sized passerines feeding by searching on the ground. They are found particularly in savanna and seasonal rainfall areas of the tropics. In a few genera co-operative breeding occurs among island populations, but not among continental species (e.g. mockingbirds *Mimus*, Seychelles Brush Warbler *Bebrornis sechellensis*). Demographic factors are probably responsible for the origin and maintenance of group territories and hence co-operative breeding, being the result of high population densities existing close to the carrying capacity of the habitat. If the dispersion of food supplies in space and time favours the defence of year-round territories, then where adult survival is high there is little scope for young birds to establish new territories. Under these conditions the best option for young birds is apparently to remain in the parental territory to await the best moment to establish a new territory or take over a vacant one, while perhaps contributing at the same time to their own inclusive FITNESS by assisting their parents in rearing further offspring.

The relative dearth of co-operative breeding species in cool temperate climates is apparently related to the high proportion of migrants and the unpredictable winter mortality of residents, making the deferment of breeding a chancy business. In Britain the only species known to exhibit co-operative breeding regularly, the Long-tailed Tit *Aegithalos caudatus* and the Dunnock *Prunella modularis*, both belong to genera particularly associated with high altitudes in the Himalayas, an area with a high concentration of co-operatively breeding species. In both cases the occurrence of co-operative breeding in the temperate Palearctic may result from pre-existing behavioural adaptations common to all members of the genus. A.J.G.

CO-ORDINATE: term used in taxonomy to mean 'of equal nomenclatural status' (see GROUP (1); NOMENCLATURE).

COOT: substantive name of *Fulica* spp.; used without qualification in Britain for *F. atra*; has also been misapplied to gallinules *Porphyrio* spp. (see RAIL).

COPPERSMITH: *Megalaima haemacephala* (see BARBET).

COPPERTAIL: substantive name of some *Metallura* spp. (for family see HUMMINGBIRD).

COPRODAEUM: name sometimes applied to the part of the cloaca into which the rectum opens (see ALIMENTARY SYSTEM).

COPULATION: the sexual act, leading to fertilization of the ova of the female by spermatozoa from the male (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM); also termed 'coition'. This usually occurs with maximum frequency a day or two before the first egg is laid, although the precise interval varies with species, clutch-size, and other factors.

Although the Anatidae have penes, the males of most species of birds have no specialized intromittent organs. Furthermore, copulation involves bodily contact with another individual, which is avoided at other times. For these reasons many, and perhaps most, copulation attempts are unsuccessful, the principal cause of failure being a sudden changeover to aggressive or fleeing behaviour in one of the partners (see PAIR FORMATION; DISPLAY).

Redshanks *Tringa totanus* about to mate. (*Photo: P. Munsterman*).

Normally, of course, the male mounts the female, but reversed mounting occurs as a usual sequel to copulation in many species. Homosexual mounting has been observed in a number of cases. Such phenomena are, as might be expected, more frequent in species in which the sexes are alike in colour; but it is probable that in most species each sex can show the sexual behaviour characteristic of the other if appropriate conditions arise.

Red-necked Phalaropes *Phalaropus lobatus* mating. (*Photo: H. Schouten*).

In a successful copulation the tail of each bird is displaced laterally, and the feathers round the cloacae are turned back so that the engorged lips of the two cloacae can come into juxtaposition. Copulation usually occurs on the ground or on a perch, but some species may copulate on the water (e.g. Anatidae) and a few even on the wing (Apodidae). R.A.H.

COQUETTE: substantive name of *Lophornis* spp. (see HUMMINGBIRD).

CORACII; CORACIIDAE: see below, and ROLLER.

CORACIIFORMES: an order comprising 4 suborders, Alcedines, Meropes, Coracii, Bucerotes; 10 families: Alcedinidae (KINGFISHER), Momotidae (MOTMOT), Todidae (TODY), Meropidae (BEE-EATER), Coraciidae (ROLLER), Brachypteraciidae (GROUND-ROLLER), Leptosomatidae (CUCKOO-ROLLER), Phoeniculidae (WOOD-HOOPOE), Upupidae (HOOPOE), Bucerotidae (HORNBILL). The classification adopted here differs in minor detail only from that used by Wetmore and Peters. Among structural points, there is a tendency for the 3 forward toes to be connected together; syndactyly is most marked in the Alcedinidae and Meropidae.

Very many members of the order are birds of brilliant plumage. Other striking features often present include long tails, crests, and large bills. Most of the species are partly arboreal, but many find their food (largely animal) on the ground—some in the air (bee-eaters) or in the water (some kingfishers). They usually nest in holes, some excavating burrows for themselves (KINGFISHERS, TODIES, MOTMOTS, BEE-EATERS); the nesting habits of the HORNBILLS are especially remarkable. The eggs are white or slightly tinted. The young at hatching are blind, helpless, and (except in hoopoes) naked.

The order as a whole is cosmpolitan, but of the families this is true only in respect of the Alcedinidae; of the rest, 2 families are Neotropical and the others confined to the Old World. In some cases the distribution is very restricted, e.g. to the West Indies (Todidae) or to Madagascar and the Comoros (Leptosomatidae).

CORACOID: a paired bone (not present in mammals) of the pectoral girdle (see SKELETON, POST-CRANIAL).

CORCORACIDAE: a family of the PASSERIFORMES, suborder Oscines; MAGPIE-LARK.

CORDON-BLEU: substantive name of some waxbills *Estrilda* spp. (see ESTRILDID FINCH).

CORELLA: substantive name for the 2 Australian smaller white cockatoo species, *Cacatua sanguinea* (Little Corella) and *C. tenuirostris* (Long-billed Corella) (see PARROT).

CORMORANT: substantive name of some species of Phalacrocoracidae (Pelecaniformes, suborder Pelecani); used without qualification in the British Isles for one of the species found there, *Phalacrocorax carbo*; in the plural, general term for the family. The substantive name for other species of Phalacrocoracidae is 'shag'; used without qualification in the British Isles for the other species found there *P. (Stictocarbo) aristotelis*; in the plural, alternative general term for the family, which includes *c.* 34 species in 5 genera or sub-genera, although some authors have recognized only 1–3 genera. Several groups of allopatric forms are treated either as species or as superspecies. Some authors prefer to place the darters as a subfamily Anhinginae in the Phalacrocoracidae (see DARTER).

Characteristics. Cormorants are medium to large in size (0.5–1.0 m long), found on both salt and fresh water. The bill is of moderate length, cylindrical and hooked. The neck is long and S-shaped. The short legs are set far back and the large feet are totipalmate. The wings, relatively short, are strong and the tail very stiff. The plumage is predominantly dark, and in fresh adult plumage has a bronze, greenish or bluish sheen. Many species have white throats, forenecks, breasts and abdomens, and may have individually variable amounts of white in patches and bars above and below the wings and on the back. Some have black or white crests, and have white nuptial plumes irregularly distributed with concentrations on the head, neck, rump and thighs. A few species have large pale grey areas, and one a brown head and upper neck. In most species the wing coverts are grey with a black margin. A few also have a black terminal spot on the wing coverts. Immatures may be brown where the adults are black, white or grey. The plumage of juveniles is dark, silky, and adult-like. In all ages the dark plumage may fade to sandy brown.

Facial colours, including the bill, the mouth lining, and the naked parts of the throat, may be bright yellow, orange, red, purple, violet, blue, green and/or black. The iris may change from brown in juveniles to green or blue within a year, but in some species it remains brown. The tarsi of cormorants are less scutellated than those of shags. All cormorants and some shags have black feet, while other shags have pink, red or yellow feet. Most species of shag have seasonally a shaggy tuft of black feathers as a crest on the forehead. Modified barbs on the contour feathers allow air to escape and water to penetrate the body plumage, thus reducing buoyancy (see SWIMMING AND DIVING). Ingested pebbles also reduce buoyancy, and may serve to adjust the centre of gravity. Cormorants swim low in the water. Ashore the water is shaken and aired out of the plumage. Secretions from the OIL GLAND help the plumage shed rain and spray. Most species spread their wings to dry, but not sub-antarctic forms of *Leucocarbo*. In addition to drying, the spreading of wings may have several other functions, including thermoregulation and grooming.

Sustained flight consists of steady wing-beats and an occasional glide. During an onshore wind cormorants may even soar. Flocks may form V's and lines flying low over the water, occasionally rising as if trying to look for prey or get their bearings. Cormorants fly with their heads held high and shags with their heads held low.

Distribution. The cormorants may be divided into 3 genera or subgenera, *Phalacrocorax*, *Hypoleucos*, and *Microcarbo* (= *Halietor*). *Phalacrocorax* includes *carbo*, *lucidus* and *capillatus*. *P. carbo* is the most

Shag *Phalacrocorax aristotelis*. (*J.B.*).

widespread in the family and occurs from the North American and Arctic shores of the North Atlantic across North Africa and Eurasia to Australasia and its sub-antarctic islands. *P. lucidus*, which occurs in Africa south of the Sahara, has been treated either as a species or as a sub-species of *P. carbo*. *P. capillatus* is restricted to some of the Asian shores of the North Pacific. The 3 forms are very similar in plumage and bare part colours. As adults they have a median erectile crest on the nape and upper hind neck.

Hypoleucos includes 2 large species, *auritus* in North America and *varius* in Australia and New Zealand; and 3 small species that form a superspecies with *auritus*; *olivaceus* in South and Middle America, *fuscicollis* in southern Asia, and *sulcirostris* in Indonesia and Australasia. They are relatively slender and have long bills, bodies, tarsi and tails.

Microcarbo consists of 6 small species or subspecies that occur in an arc around the Indian Ocean. *Microcarbo* is characterized by a short stubby bill, a broad body, short tarsi, and a long tail.

The shags may be divided into 2 genera or sub-genera, *Leucocarbo* and *Stictocarbo*. *Leucocarbo* includes 14 species, mainly around the southern oceans, and the flightless *L. harrisi* of the Galapagos, frequently considered to be in a separate monotypic genus, *Nannopterum*. *Leucocarbo* is robust with sturdy short broad wings. *L. bougainvillei* and *L. capensis* are the main producers of GUANO.

Stictocarbo includes 8 species of world-wide distribution. It is slender with long wings and short tail. The bill is long and thin with a small hook. It nests on small ledges and in alcoves of steep coastal cliffs.

Movement. Movement is mainly in response to weather-induced shortages of food. Inland populations move to avoid frost and drought. Coastal populations disperse following failures of cold, nutrient-rich, oceanic currents, and insular populations are mainly sedentary.

Food. Cormorants and shags feed on a wide variety of fish, crustaceans and cephalopods. They dive from the surface, often taking a forward leap; underwater they use their feet for propulsion and their wings and tail for balance. The catch is commonly brought to the surface before being swallowed. Large flocks (up to 2,000 individual *Phalacrocorax auritus*), moving line abreast, may co-operate in driving shoals.

Voice. Usually cormorants and shags are silent, but when breeding there are individual, sexual, age and species differences in their calls. The Bank Cormorant *Phalacrocorax neglectus* of South Africa has a loud, melancholy cry when disturbed. Visual signals are complex with marked differences between genera and species.

Breeding. Cormorants nest in colonies, sometimes densely packed, on rocky islets, cliffs and in trees, often with other kinds of waterbirds. They are at least seasonally monogamous, though some species breed more than once each year. The male selects the nest site, and the female builds the nest with material gathered by the male. The pair take turns guarding the nest and its contents; in some species, the female forages during the morning and the male during the afternoon. The modal clutch size is 3 or 4. The pale blue or green, usually unmarked eggs are incubated on the feet. The chicks are naked when hatched after about 4 weeks incubation. After a week they are covered in black, grey and/or white down. They squeal for food with a closed bill and beg silently for water with an open bill. Very small chicks take fluid from their parents' lower bill; when larger they take solid bits of regurgitated food from their parents' throats. They leave the nest after about 4 weeks and fledge when about 7 weeks old, but are fed sometimes for several months afterwards. First breeding is generally deferred until about 2–3 years old.

Fishing with cormorants is an ancient kind of aquatic 'falconry', formerly pursued in many parts of the world. Its origins are in Asia where it is still practised, with its highest development in Japan (see DOMESTICATION). See photos COMFORT BEHAVIOUR; FLIGHTLESSNESS; SWIMMING AND DIVING. (A.L.T.) G.F. CORNCRAKE: *Crex crex*, sometimes called 'Landrail' (see RAIL).

CORNEA: part of the eye (see VISION).

CORNEOUS: horny.

CORONARY VESSELS: see HEART.

CORONET: substantive name of *Boissonneaua* spp. (for family see HUMMINGBIRD).

CORPUSCLE, RED: see BLOOD.

CORPUS LUTEUM: (plural 'corpora lutea')—see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

CORPUS STRIATUM: part of the forebrain (see NERVOUS SYSTEM).

CORRELATION: statistical (not necessarily causal) association between two (or more) phenomena, one tending to vary directly or inversely as does the other. The degree of correlation may be expressed as a coefficient of which the values range from +1 (complete direct association) to −1 (complete inverse association), lower values than unity representing weaker associations and zero representing none at all. See further under BIOSTATISTICS; STATISTICAL SIGNIFICANCE.

CORRIDOR: term used for MIGRATION on a narrow front.

CORTEX: for that of the cerebral hemispheres (part of the forebrain) see NERVOUS SYSTEM; for that of the adrenal gland see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

CORVIDAE: a family of the PASSERIFORMES, suborder Oscines; CROW (1).

COSMETIC COLORATION: see COLOUR.

COSMOPOLITAN: distributional term applied to species or higher taxa found in all the main zoogeographical regions—or at least in most of them, and certainly in both Old and New Worlds and in both Northern and Southern Hemispheres (see DISTRIBUTION, GEOGRAPHICAL).

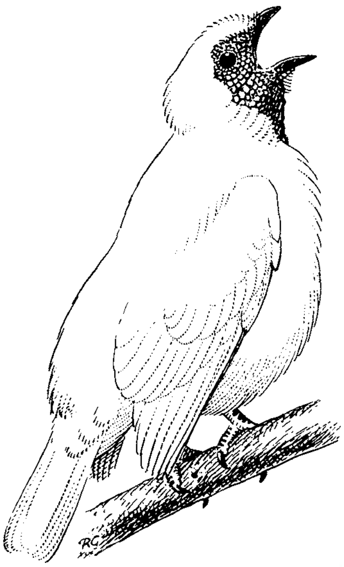
COSTAL: pertaining to the ribs (see SKELETON, POST-CRANIAL).

COT; COTE: a shelter for domesticated birds (or other animals), especially doves, i.e. 'dovecots'.

Hornell, J. 1947. Egyptian and medieval pigeon houses. Antiquity 21: 182–185.

COTINGA: substantive name of some species of Cotingidae (Passeriformes, infraorder Tyranni); in the plural, general term for the family. This Neotropical group contains about 65 species and is allied to the manakins (Pipridae) and tyrant-flycatchers (Tyrannidae). Several genera which were formerly included in the Cotingidae, especially *Tityra*, *Pachyramphus* (becards), *Rhytipterna* and *Laniocera* (mourners), are now placed in the Tyrannidae. It is by no means certain that the family Cotingidae, as currently recognized, is monophyletic; it is extremely diverse, and may consist of several lineages that were independently derived from an ancestral 'tyranniform' stock during the long period of isolation of South America from the rest of the world (see NEOTROPICAL REGION). The cock-of-the-rock *Rupicola* is sometimes placed in a separate family Rupicolidae on the basis of the major artery of the thigh (sciatic in *Rupicola*, femoral in the other cotingas examined).

Characteristics. Cotingas range from 9–45 cm in length, and are very varied in external appearance, although typical cotingas are alike in possessing rather broad bills somewhat hooked at the tip, rounded wings, and short legs. A few depart radically from this general form, notably the purpletufts *Iodopleura*, which have relatively long, pointed wings and resemble small swallows, and the Swallow-tailed Cotinga *Phibalura flavirostris*, which has pointed wings and a long forked tail and, like the purpletufts, feeds in part by aerial hawking for insects. Some species are



Bare-throated Bellbird *Procnias nudicollis* male. (*R.G.*)

of undistinguished appearance, with little difference between the sexes; in others the males have plumage of brilliant or unusual colours (e.g. very deep reds and purples), curiously modified feathers on the wing and the head region, peculiar fleshy wattles, or patches of brightly coloured naked skin; in most of these species the females are inconspicuously coloured.

Outstanding among the cotingas are the 2 species of cock-of-the-rock *Rupicola*, in which the male is brilliant orange or red with a helmet-like crest concealing the bill; the 3 species of umbrella-bird *Cephalopterus*, with black umbrella-like crests and long pendent wattles (feathered in 2 species, nearly bare in the third) hanging from the upper breast; the 4 bellbirds *Procnias*, the males of which have extensible wattles springing from the base of the bill (*P. alba*, *P. tricarunculata*), a 'beard' of fleshy black wattles on the throat (*P. averano*), or a bare green throat (*P. nudicollis*); and the 7 species of *Cotinga*, in which the males are mainly of various shades of brilliant blue. Crimson or plum-coloured throats are a feature of several genera that in other respects are quite dissimilar. In several species one or more of the outer primaries are peculiarly modified, being notched, attenuated or twisted.

Distribution. The family is nearly confined to the tropics; the northern limit is in southern Mexico, well within the tropics, but in the extreme south a few species reach latitudes of 28–31° S in south-eastern Brazil.

Habitat. Many species inhabit lowland primary forest; others occur in montane forest, and a few Andean species live at temperate levels at the upper edge of forest or even higher, in the zone of bushes and stunted woodland. The larger forest-inhabiting species are especially vulnerable to destruction and degradation of primary forest; at least 2 species in eastern Brazil (*Xipholena atropurpurea* and *Cotinga maculata*) have suffered severely from destruction of the coastal forests and are considered endangered.

Movements. Most species are sedentary but several undertake well-marked altitudinal migrations, breeding in montane forest and moving down to the lowlands in the off-season, and in the extreme south 2 species are known only as breeding migrants (*Phibalura flavirostris* and *Procnias nudicollis*) and so presumably move north, to a warmer climate, in the non-breeding season. Some lowland forest species undertake movements which may to some extent be regularly seasonal, probably in response to the changing availability of the fruits on which they depend.

Food. Most cotingas are frugivorous, and some, e.g. the bellbirds, are extreme fruit specialists, feeding not only themselves but their young wholly or predominantly on fruits. The greater part of the diet of the large cotingas of tropical forest is provided by a limited number of plant families (especially the laurels Lauraceae, incense family Burseraceae, and palms Palmae). Probably there has been a long period of coevolution between the cotingas and trees of these and some other families. The largest cotingas, generally known as fruit-crows, have a mixed diet of fruits and large insects. Most cotingas typically pluck fruits on the wing, in short sallies from a perch, and insects are usually seized from the leaves and branches in a similar way. The short-winged, heavy-bodied fruit-eaters of the Andes (*Pipreola* spp.) take fruit from a perch, and all species will do so on occasion when suitable perches are available. As already mentioned, the purpletufts and Swallow-tailed Cotinga make aerial sallies after flying insects.

Behaviour and voice. Some cotingas, in which sexual dimorphism is not very marked, live in pairs (e.g. *Carpornis* and *Pipreola* spp.), but many species, and probably all the larger ones, are polygynous. In these species lasting pairs are not formed, the sexes associate briefly for mating, and the females carry out all nesting duties single-handed. In the males of such species display behaviour, and the ornamentation associated with it, reaches extremes of elaboration. In the Guianan Cock-of-the-rock *R. rupicola* the males gather to display at traditional LEKS. Each male clears a court on the forest floor, and during the breeding season the greater part of the day is spent at or near the court. Screaming Pihas *Lipaugus vociferans* also display in leks; the males (dull-coloured like the females) are much more widely spaced than the cock-of-the-rock and advertise themselves by very loud ringing calls from perches in the middle strata of the forest. Male bellbirds utter extremely loud, metallic calls from special display perches, either in the tree-tops (for long-range advertisement) or low down in the forest under-storey (for the later stages of courtship). Individual males are widely spaced, but form discrete groups ('dispersed leks'). In the Calfbird *Perissocephalus tricolor*, one of the large fruit-crows, the males display communally in small leks on branches below the forest canopy, advertising themselves by loud mooing calls associated with extravagant postures. Analogous displays occur in the Red-ruffed Fruit-crow *Pyroderus scutatus* and umbrella-birds. In 2 genera in which the males have white wings (*Xipholena*, *Carpodectes*), males make conspicuous display flights above the forest canopy, when their wings are visible at a great distance. The displays of some of the little known species, e.g. the Crimson Fruit-crow *Haematoderus militaris*, are unknown.

Breeding. The breeding of many of the cotingas is unknown. Some of the Andean species build substantial cup nests, which they place in trees or bushes, but most species whose nests are known build very specialized and peculiar nests, which seem to be adapted primarily to escape predation by their inconspicuousness or inaccessibility. Thus the large fruit-crows, bellbirds, pihas, and Pompadour Cotinga *Xipholena punicea* build relatively tiny platforms or saucer-shaped nests of interlocking twigs or coiled tendrils. All of these, so far as known, have single-egg clutches, probably because such nests cannot safely accommodate more than one egg or well-grown young. The cock-of-the-rock attaches a more substantial nest of mud and plant fibres, cemented together with saliva, to vertical rock faces in caves or over streams; its clutch is of 2 eggs. The nest of the White-browed Purpletuft *Iodopleura isabellae* is a tiny cup attached with cobweb to a slender horizontal twig high in a tree, reminiscent of a hummingbird's nest. Cotinga eggs are typically olive or pale brown in ground colour, irregularly spotted and blotched with darker browns and ashy colours. Incubation periods are long (27–28 days in the Guianan Cock-of-the-rock, 26 days in the Calfbird, 25 days in the Purple-throated Fruit-crow *Querula purpurata*, 23 days in the Bearded Bellbird *Procnias averano*), and fledging periods long but very incompletely known (42–44 days in the Andean Cock-of-the-rock *R. peruviana*, 33 days in the Bearded Bellbird, 32–33 days in the Purple-throated Fruit-crow). There is no information on the number of nesting attempts that a female may make per year, but it is probable that the reproductive rate of all the larger cotingas is generally low. Moult seasons follow a well-marked annual pattern in most species, and it is a general rule that in those species in which the female alone attends the nest the males begin their annual moult well in advance of the females. COTINGIDAE: see under PASSERIFORMES; suborder Deutero-Oscines; infraorder Tyranni; COTINGA.

COTYPE: see TYPE SPECIMEN.

COUA: substantive name of *Coua* spp.; in the plural, general term for the subfamily Couainae (see CUCKOO).

COUAINAE: see CUCKOO.

COUCAL: substantive name of *Centropus* spp.; in the plural, general term for the subfamily Centropodinae (see CUCKOO).

COUNT: a method of studying the distribution and the trends in population of a species by making synchronized counts on a widespread sample of sites of the numbers of individuals present in successive years. For the most part the term is used in respect of studies undertaken outside the breeding season, the commonest subjects being the wintering flocks of gregarious species. Studies of breeding populations are usually referred to as 'censuses', but the distinction between the two terms is ill-defined (see CENSUS). The word 'census' is also used to describe an autumn or winter count in which the sample of sites is more comprehensive than usual.

The counting technique has been applied to several groups of birds, including game-birds (Galliformes), waders and gulls (Charadriiformes). It has also been used intensively over many years in the study of wildfowl (Anatidae), a field in which many of the developments and refinements have been pioneered. The current investigation, whereby the European populations of migratory ducks, geese and swans are kept under annual review, is certainly the most ambitious and sustained of the projects attempted hitherto; the remainder of this article is therefore devoted to this one study.

Organized counts of wildfowl were first made in Britain in the late 1930s, mainly around London. These lapsed in 1939, but were restarted in 1948 on a much wider scale. By the mid-1950s some 500 sites throughout the Kingdom were being covered regularly on a set date each month between September and March, and this still continues. Occasional counts have also been made in many other less important areas, bringing the total number of British sites for which data are now available to about 3,000.

Several other European countries began making similar counts of wildfowl during the 1950s, and in 1967 these national investigations were incorporated in a common programme under the aegis of the International Waterfowl Research Bureau. The countries already making the monthly counts were encouraged to continue, using the same prearranged dates throughout, whilst those not yet involved were invited, as a first step, to participate in a single mid-January 'census'. By the 1980s some 6–7,000 sites were being covered annually, and over the years records have been amassed from more than 14,000 different places in Europe, northern and central Africa and south-west Asia. A total of 57 countries have contributed. Counts on a rather smaller scale have also been made in November of the years 1969–1973, and more recently in March.

The great majority of the records have come from northern and central Europe, where virtually all the more important resorts have been covered in at least some of the years since 1967. In these northern districts the populations of most species are dispersed in relatively small flocks over a large number and variety of wetland habitats; counts are therefore required from a correspondingly large sample of sites. These have been undertaken to a very great extent by volunteer observers, working in their spare time and at their own expense. In southern Europe, Africa and Asia the wetlands are scattered more sparsely, but are often much larger in extent; the wintering wildfowl tend, therefore, to concentrate in certain well-defined areas. In the absence of local observers, these major centres have been covered by mobile teams of visiting ornithologists; aerial surveys of some of the more inaccessible wetlands have also been made, both in northern Europe and the regions further south.

Both the national and international wildfowl counts are directed primarily towards the common Palearctic species, with special emphasis on the dabbling and diving ducks (*Anas* and *Aythya* spp.). These are the easiest to count effectively, because by day they congregate to roost or feed on the larger and more open sheets of water. In Britain and north-west Europe the counts are believed to include a substantial proportion of their total populations, perhaps as much as 75% in some species. The sea-ducks (*Clangula, Melanitta* and *Somateria* spp.) are much more difficult, and effective methods of counting their populations are still being sought. Counts from the shore in Morocco and Portugal, and aerial surveys along the coasts of France, Scotland, the Netherlands, Denmark and Sweden have produced local winter totals, and counts of moulting Eiders *Somateria mollissima* have helped to substantiate the size of the Baltic and White Sea populations; radar has also been used to assess the numbers of Long-tailed Ducks *Clangula hyemalis* and scoters *Melanitta* passing on migration through the Gulf of Finland. Nevertheless the information on all these species is far from complete. The geese also require special treatment, in their case a separate effort is made to count the entire north-west European population of each species on at least one occasion each winter. The timing and tactics of these 'censuses' varies from species to species, depending on their daily habits and their distribution at various stages of the winter.

International counts of waders were started as a parallel study in 1966, and have developed along similar lines. The most intensive counts so far have been made around the coasts of northern and western Europe, but surveys have also been conducted in several important areas of western and southern Africa, and in parts of south-west Asia. In Britain, the period of greatest activity was between 1969 and 1975, when the British Trust for Ornithology organized a series of monthly counts throughout the year on all major estuaries. Although directed primarily at the waders, the 'Birds of Estuaries Enquiry' of the BTO and the Royal Society for the Protection of Birds encompassed all species of water birds, including many which had not been counted before. Since 1975 the work has continued on a reduced scale.

The prime purpose of the counts is to provide a scientific basis for the long term conservation of both wetlands and waterfowl. The projects in which the data are currently being used are:

1. to identify the areas of habitat which are of special importance to the various species;
2. to estimate the total numbers of each species in each of the main wintering areas;
3. to formulate the criteria by which habitat importance can be judged, at both national and international level;
4. to compile maps showing the numerical distribution of the species during January, and other months for which data become available;
5. to monitor trends in the north-west European populations of selected species, especially those subjected to heavy hunting pressure.

These studies have already produced a wealth of information; in particular they have shown that the numbers and distribution of the species are subject to constant change. The monitoring of these changes, and the availability of up-to-date information on the local, national and continental situation continues to be a major conservation requirement.

COUNTERSHADING: or OBLITERATIVE SHADING: contrast between dark-plumaged upperparts and light underparts which reduces the effect of shadow cast by the bird, so that it does not stand out from its background.

Allen, G.M. 1925. Birds and their Attributes. Francestown, USA.

COUNTERSINGING: singing in rivalry with another male within hearing; or 'duetting' between male and female of a pair (see VOCALIZATION).

COUNTING: term loosely applied to manifestations of a number sense. Experiments on this number sense or 'counting' ability of birds and other animals have been carried out for over 50 years, but it was not until comparatively recently that the difficulties of the task came to be fully realized. The fact that a bird discontinues ovulation and commences incubation when a certain number of eggs are in the nest (not when a certain number of eggs have been laid) is certainly not evidence for counting ability: the bird may merely be reacting to certain visually observed proportions of egg to nest, or it might be responding to the growing amount of stimulation received through the brood patches.

During the course of some of the early work on counting by mammals, results were obtained that suggested not merely counting, but mathematical ability of a high order. It was eventually shown, however, that the animals could give these results only when they could see the trainer and when the trainer himself knew the answer. In some cases there seems to be no doubt that the trainers actually believed that their pets were displaying intelligence of the highest order. Yet in the end it became abundantly clear that when the horse or the dog was giving its answer, by stopping its stamping or barking when the correct number had been reached, it was not giving evidence of a counting ability at all but had merely been extremely sensitive to minute, probably involuntary, signs and signals which the owner made. These 'clever' animals could never actually solve any problems by themselves; they merely obeyed their master's signs, which—given at the proper moment—stopped the stamping or barking by which they were spelling out their answers. The classic example of this was the horse 'Clever Hans'; and, ever since, mistakes of this kind in animal psychology have been called 'Clever Hans errors'. Precautions at least as rigid, to exclude such errors, are required when dealing with birds.

The study of the counting abilities of birds was explored by the elaborate experiments of Köhler and his school, in which extraordinary precautions were taken to avoid errors of the 'Clever Hans' type. In these experiments, and during training for them, the observer and the animals were always separated by a partition so that the experimenter was never seen by the bird although, while at work, he was able to watch it through the view-finder of a cine-camera fitted into the wall. When a deterrent was required in conditioning there was only one degree of punishment and this was always the same—namely a light touch on the back by means of a mechanically operated stick—so that it was impossible for the experimenter inadvertently to give signs by means of the punishing apparatus. In many of the experiments the bird was left entirely to itself and the result recorded automatically by a cine-camera, so that all possibility of an investigator inadvertently giving cues was ruled out. By such methods Köhler and his associates demonstrated that birds have what he calls an 'unnamed number' concept. The experiments were of two main types, simultaneous presentation and successive presentation. The first problem was presented to birds in a number of different ways, starting with only two groups of edible units (e.g. grains of corn, fruit, pieces of biscuit), the two groups differing by one unit only. In this way a Raven *Corvus corax* and a Grey Parrot *Psittacus erithacus* were taught to open that box which had the same number of spots on the lid as there were on the key card presented to them. These birds thus eventually learned to distinguish between five groups indicated by 2, 3, 4, 5, and 6 black spots on the lids of small boxes, the key being one of these numbers (i.e. a group of one of these numbers of objects) lying on the ground in front of the boxes. As a control, every other factor was changed in a random manner from experiment to experiment.

In presenting the numbers successively many different methods were employed. At first birds were trained to eat only 'x' grains out of many offered in a heap in circumstances such that the configuration of the heap gave no cue. Another task was to take only 'x' number of peas which were discharged from a chute into a cup one after another at randomly varied intervals ranging from 1 to 60 seconds. In this experiment the pigeon never sees more than one pea in the cup. It always has the same view and there is no visible cue for distinguishing the last 'allowed' pea from the first 'forbidden' one.

Another experiment involved opening the lids of boxes standing in a long row until 'x' baits had been secured. Since the baits were arranged in the boxes in 20 or more different distributions from one experiment to the next, the number of lids actually to be opened in order to get the required number was constantly changing. For instance, if the bird is to be trained to take 5 baits it may have to open any number of boxes between 1 and 7. The bird thus learns to open lids for up to 'x' baits, so that the number of lids it has to open to get 5 (when 'x' = 5) changes with each experiment. One Jackdaw *Corvus monedula* could learn 4 problems of this kind at the same time. It learned to open black lids until it had secured 2 baits and green lids until it had secured 3, red lids up to 4, and white lids up to 5. Similar results were obtained from Budgerigars *Melopsittacus undulatus* with a bell indicating 2 and a buzzer indicating 3. In these experiments—since, as far as can be seen, all external cues were successfully excluded—we can assume that only an inner token can be responsible for a bird ceasing action when the required number was reached. It is as if the bird is doing some inward marking of the units it is acting upon. This supposition is strengthened by the fact that sometimes these supposed inward markings show themselves in external behaviour in the form of intention movements. Thus a Jackdaw, given the task of raising lids until it had secured 5 baits, which in this case were distributed in the first five boxes in the order 1, 2, 1, 0, 1, went home to its cage after having opened 3 lids only and consequently having 4 baits. The experimenter was in the act of recording 'One too few. Incorrect solution', when the Jackdaw returned. It then went through a remarkable performance: it bowed its head once before the first box it had emptied, made 2 bows before the second box, 1 before the third. It then went farther along the line, removed the fourth lid (the box with no bait) and then the fifth and took out of this the last, fifth, bait. Having done this it left the rest of the line of boxes untouched and went back to its cage as if regarding the experiment as over. It appears from this 'intention' bowing, repeated the same number of times before each opened box as on the first occasion when it found the baits in them, that the bird remembered its previous actions. It seems as if it became aware that the task was unfinished and so returned and commenced again 'picking up' in vacuo, with intention movements, baits that previously it had actually picked up. When, however, it came to the last 2 boxes, which by mistake it had omitted to open on its first trip, it performed the full movements and thus completed the task.

The simplest explanation Köhler has to offer for this intention marking is that it may consist in equal marks—as if we were to think of or give 1 nod of the head for 1, 2 for 2, and so on. This is called thinking unnamed numbers, and for the great majority of experimental results at present available it is not necessary to suppose that the bird does the marking by unequal or qualitatively different marks in a fixed order, as we do when we think of the words for 1, 2, 3, 4, 5, or, alternatively, a phrase of 5 different syllables. Lögler (1959) has shown that a bird trained to open a box with, say, 3 spots on a lid as a result of seeing 3 flashes of light, will then go, without further learning, to the same box when it hears 3 sounds of varying pitch or 3 random alternations of sound and light. There is good evidence for the ability of birds to transfer the idea of number from one quality to another and also to combine successive and simultaneous recognition of number. This is a big advance on anything previously established, but it still remains a special solution only, i.e. the bird having been trained, say, to open box No. 3 when it sees 3 spots, box No. 4 when it sees 4 spots, and box No. 6 when it sees 6 spots, will not necessarily go and open box No. 5 when it hears 5 blasts of a whistle—provided, of course, that it has not been taught the number 5 before. In other words, there is as yet no evidence that animals have a power of expanding their general concept of number to other numbers of a series, i.e. that they can do arithmetic and have the general power of abstract dealing in numbers.

A possible example of counting by birds is described by Egremont and Rothschild (1979). Chinese fishermen on the Li-Kiang river use Cormorants *Phalacrocorax carbo* to catch fish, the traditional procedure being to prevent the Cormorant from swallowing fish by means of a neck ring. After a bird has brought 7 fish to its master, the neck ring is loosened so that the bird can eat the eighth fish it catches itself. Apparently the birds refuse to move after the seventh fish unless the neck ring is loosened, suggesting that perhaps they can tally up to 7 counts, independent of the time between them. COUROL: alternative name for *Leptosomus discolor* (see CUCKOO-ROLLER).

COURSER: substantive name of all but one species of the subfamily Cursoriinae (Charadriiformes, suborder Charadrii, family Glareolidae); in the plural, general term for the subfamily. For the other subfamily, the Glareolinae, see PRATINCOLE. The coursers consist of 9 species in 3 genera. The largest genus, *Cursorius*, has 2 species in India and 3 in Africa. The genus *Rhinoptilus* has one Indian species (Jerdon's Courser *R. bitorquatus*, now almost certainly extinct) and 3 African species. The aberrant Egyptian Plover *Pluvianus aegyptius* belongs to a monotypic genus and is confined to the larger rivers of tropical Africa.

Characteristics. Coursers are plover-like in size and shape, but are rather longer-legged and have a strongly curved culmen. They are between 20 and 30 cm long and weigh 75–100 g. The toes are short, the hind toe is absent and the claw of the middle toe is pectinate (except in *Pluvianus*); the legs are whitish in most species, but yellow in the Three-banded Courser *Rhinoptilus cinctus* and reddish in the Bronzewing Courser *R. chalcopterus*. The tail is square. There is no obvious sexual dimorphism in any courser.

The genus *Cursorius* is characterized by a long bill (about half of the length of the head), a plain rufous forecrown, plain brown dorsal plumage, a broad white line behind the eye bordered below by a black line, and a dark brown band or patch across the lower belly (except in the Cream-coloured Courser *C. cursor*). The immature plumage is boldly patterned dorsally. The Cream-coloured Courser and Burchell's Courser *C. rufus* of northern and southern Africa respectively have a blue-grey hindcrown.

The genus *Rhinoptilus* is characterized by a short bill (33% of the length of the head), one or more chest bands in black, brown or rufous, bordering broader areas of rufous, white or greyish-brown, and the crown scalloped or broadly streaked with brown and buff. The Three-banded Courser and the Double-banded Courser *R. africanus* have the dorsal plumage boldly patterned in black, brown and buff.

The Egyptian Plover is atypical of coursers in being grey above and buff below with the crown, the centre of the back, a conspicuous chest band and a line through the eye, black. The eyebrow is pure white and, as in *Cursorius*, reaches to the nape. The bill is about 44% of the length of the head. The Australian Dotterel *Peltohyas australis* is a courser-like plover of the central Australian arid zone, formerly included with the Glareolidae, but now unequivocally shown to be a member of the family Charadriidae.

Relationships within the subfamily Cursoriinae are not easy to work out, but it has been suggested, using feather lice (see ECTOPARASITE) as evidence, that the evolutionary trend has been from *Rhinoptilus* through *Cursorius* to *Pluvianus*. Adult plumage patterns seem to confirm this idea. Chick plumage patterns, usually a good source of systematic information, are too variable among coursers to be of any systematic use. The nearest relative of the coursers is the Australian Pratincole *Stiltia isabella* (see PRATINCOLE) which has features of both coursers and pratincoles.

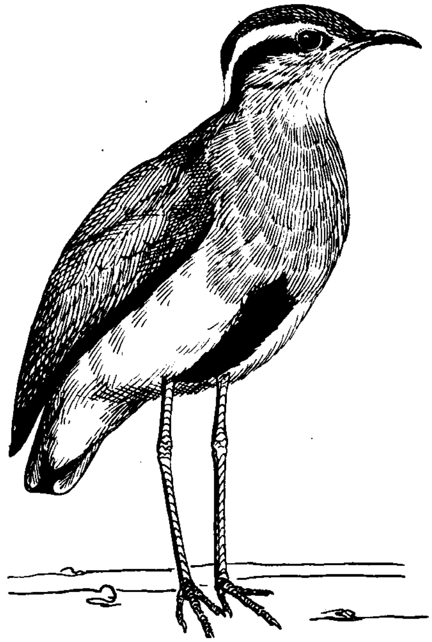
Habitat. Coursers are birds of dry, rather flat savanna, grassland and desert. The Egyptian Plover inhabits sandbars and shores of large rivers.

Distribution. The subfamily Cursoriinae is distributed throughout the non-forested parts of Africa, the Middle East and India.

Movements. The true coursers are mostly nomadic, especially in the more arid areas; those of savannas tend to be more sedentary. No courser appears to be migratory. The Egyptian Plover appears to be more or less sedentary.

Food. Coursers feed largely on insects picked up from the ground, while members of the genus *Cursorius* apparently also eat seeds. The Egyptian Plover feeds on small arthropods found by turning over stones, probing in sand, scratching in damp sand with both feet together; they may be caught in the air by a run, or merely picked from the surface of the sand or a plant. It has also been said to pick food from the mouths of basking crocodiles (see CROCODILE BIRD), but if it ever does so, it has not been seen doing so in recent times.

Behaviour. Coursers of the genus *Cursorius* tend to be gregarious, occurring in small parties of up to about 15 birds. Even during the breeding season, nesting pairs tolerate the close proximity of conspecifics. *Rhinoptilus* coursers are usually found in pairs, or small family parties. *Pluvianus* occurs in pairs when breeding but is said to form small flocks after breeding has ended and the water level in the rivers is high. Most coursers are fairly active at night, but only the Bronzewing Courser is truly nocturnal. When approached in open desert habitat, coursers will run a little way and then stop with neck stretched upright to look at the intruder.



Temminck's Courser *Cursorius temminckii*. (*C.E.T.K.*).

Voice. Coursers have unmusical growling or grunting calls, often uttered on the wing, but some *Rhinoptilus* species have attractive whistled contact and alarm notes that carry a considerable distance.

Breeding. All cursoriines nest on the ground. The true coursers may make a shallow scrape for a nest, or they simply lay the eggs on the bare soil. An exception is the Three-banded Courser which lays its 2 eggs in a fairly deep scrape in loose gravelly soil, partly filling the scrape to bury the eggs until less than half is exposed. The eggs are incubated in this partly buried state. Most coursers lay clutches of 2 eggs, but the Double-banded lays only one egg, and the Bronzewing often lays 3. The Egyptian Plover lays 2 or 3 eggs in a deep scrape on a sandbank; by day the eggs are completely buried under 2–5 mm of sand which is continuously wetted by the parents during the hottest hours of the day (from about 3–4 hours after sunrise to 2–3 hours before sunset) in order to keep the egg temperature from rising too high; water for this purpose is carried in the soaked belly plumage and never by regurgitation as has often been quoted in the past (see BELLY-SOAKING). Small chicks are also buried and wetted in this way.

Cursoriine eggs are cryptically coloured, off-white to yellowish brown in ground colour, finely and densely scrawled or irregularly spotted with dark brown and grey. Burial of eggs by both the Three-banded Courser and the Egyptian Plover is done with the bill and not with the feet as in other waders (Charadrii). Some coursers deliberately lay their eggs among dry antelope droppings for extra camouflage.

Incubation in the Double-banded Courser takes about 26 days (which is average for waders of this size), in the Egyptian Plover about 30 days. It is thought that the latter's long incubation period is facilitated by wetting the sand, which reduces evaporation from the eggs and allows the chicks to develop to a highly precocial condition by the time they hatch. All cursoriines feed their young until they are almost ready to fly, although the young pick up much of their own food after the first few days. The young can fly at 5–6 weeks of age. Coursers with eggs or chicks have no true distraction displays, but the Egyptian Plover has an injury-feigning display in the presence of a human intruder. See photo INCUBATION; PARENTAL CARE. COURT: alternatively 'arena' (and various special terms)—see LEK.

COURTSHIP: term used, in the study of bird behaviour, to cover a wide range of activities of which the function seems to lie in attracting a mate, maintaining the pair bond, and in facilitating copulation and parental activities (see PAIR FORMATION; also COPULATION; COURTSHIP FEEDING; DISPLAY; LEK; MECHANICAL SOUNDS; TERRITORY; VOCALIZATION). See photo DISPLAY.

Scottish Crossbill *Loxia scotica* male feeding female. (*Photo: E.J. Hosking*).

COURTSHIP FEEDING: the feeding of one member of an adult pair by the other. In sexually dimorphic species it is normally the male that feeds the female, but where the behaviour and plumage of the sexes is similar, the reverse sometimes occurs; further, in species where the female takes the active role in courtship, she may regularly feed the male.

The movements used by each species in courtship feeding are usually closely similar to those of juvenile begging and feeding the young. Thus in cardueline finches the male regurgitates the food, whereas in tits it is passed directly from his bill. Often the posture adopted by the female resembles not only the begging of the young, but also the female copulatory posture and the submissive posture. The movements may, however, become further ritualized, and elaborate ceremonials, such as the fish-flight in terns, may be incorporated (see RITUALIZATION). Billing and scissoring movements may be a further development of courtship feeding, or they may be independently derived from movements used in feeding the young or in aggression.

Courtship feeding is usually most frequent before or during the period of copulation and egg-laying, but often it continues during incubation. During egg-laying and incubation the actual food exchanged may be important as such, but in most species it seems to be primarily of symbolic and stimulatory significance—many cases of a female begging from a male although already carrying food herself have been recorded. Indeed, in many species elaborate ceremonials of billing, scissoring, and the like, in which no food is passed, occur as well as, or instead of, courtship feeding itself.

Courtship feeding does not, in general, occur in birds that do not form pairs. Presumably, where it does not have a nutritive function, it has a survival value relating to the pair bond. Its precise function varies between species. In some it is closely related to copulation, the male feeding the female while copulating, or just before or afterwards. In others it occurs at the same stage in the cycle as copulation, but not in immediate temporal relation with it (see also COPULATION). The food conveyed may be of direct importance to the female, and may also indicate the male's potential as a provider of food for the young. It may also have a function in reducing aggression between the partners, perhaps promoting habituation to the proximity of the mate and thus facilitating sexual and, later, parental behaviour (see PAIR FORMATION); in general it is commoner in sexually monomorphic species (i.e. where both sexes carry the releasers for aggressive behaviour). However, even when the peaks of courtship feeding and copulation occur at the same stage in the reproductive cycle, courtship feeding usually starts well before and lasts after copulation. In other species there seems to be no relation with copulation except that both occur in the breeding season; in such cases little can be said about the functions of courtship feeding except that it presumably plays a general role in promoting and maintaining the pair bond. Lack, D. 1940. Courtship feeding in birds. Auk 57: 169–178.

COVERT: also 'tectrix', term for any of the contour feathers that overlie, dorsally or ventrally, the bases of the remiges and rectrices; applied also to the auriculars (ear coverts), concealing the external auditory meatus. There are upper and under tail coverts, and upper and under wing coverts. In the wing, the upper coverts in particular form several distinct rows, designated (from distal to proximal) as primary, greater, median, and lesser coverts (see TOPOGRAPHY; WING).

COVEY: see ASSEMBLY, NOUN OF.

COWBIRD: substantive name of species in several genera (*Molothrus*, etc.) of Icteridae (see ORIOLE (2)).

CRAB-PLOVER: *Dromas ardeola*, sole member of the Dromadidae (Charadriiformes, suborder Charadrii, superfamily Charadrioidea). It is a very distinctive large shorebird, about 40 cm long; the sexes are identical, being white with black mantle and primaries. In immature birds the crown, neck, scapulars and tail are suffused with grey-brown. The large black bill is laterally compressed. The long legs are slaty-blue and the feet are partially webbed. The wings are long and pointed and the tail is short.

Habitat and distribution. The Crab-plover is a coastal bird, breeding in sand dunes and feeding on sandy and muddy beaches, coral reefs and reef flats. As a breeding bird it is endemic to the north-western Indian Ocean, breeding in the Persian Gulf, on southern coasts of the Arabian peninsula, and in Somalia. Out of the breeding season it occurs on most islands of the western Indian Ocean south to Madagascar and on continental Africa south to Natal; in the east it occurs in the Laccadives

Crab-plover *Dromas ardeola*. (*C.E.T.K.*).

and Maldives, Pakistan, peninsular India, Andamans and (rarely) in the Malay Peninsula. On islands of the Malagasy Region non-breeding birds can be found throughout the year.

Foods. Molluscs are eaten, but food consists mainly of crabs taken by both day and night; small crabs are eaten whole but the massive bill is used to break open larger ones.

Behaviour. Crab-plovers are frequently gregarious. In the non-breeding range they occur singly, in small parties and in large flocks, but birds from large roosting flocks generally disperse to feed more or less solitarily on extensive reef flats exposed at low tide. Both near breeding colonies and in the non-breeding range Crab-plovers are usually not very approachable, and when disturbed they are noisy; the call is a low fluty and musical chattering.

Breeding. The birds nest during the northern summer in burrows in colonies, sometimes numbering hundreds of nests, resembling rabbit warrens. Burrows, up to 2 m long, end in an unlined chamber in which is laid a single large white egg (unique in the Charadrii). The downy chick is nidicolous, but older chicks may emerge from their burrows at night. In the Seychelles, Crab-plovers sometimes arrive in autumn in family parties, with juveniles begging and being fed by their parents, suggesting prolonged parental care. (R.M.) C.J.F.

CRACIDAE: one of the families of the GALLIFORMES; comprising the curassows, guans, and chachalacas (see under CURASSOW).

CRACTICIDAE: a family of the Passeriformes, suborder Oscines (see BUTCHER-BIRD (2); CURRAWONG; MAGPIE (2)).

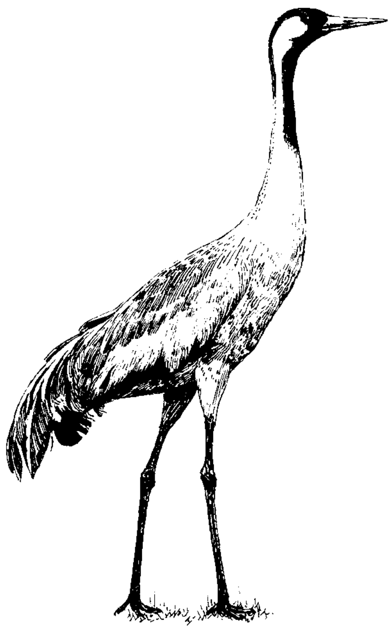
CRAKE: primary or alternative substantive name of many species of Rallidae (see RAIL).

CRANE: substantive name of the species of Gruidae (Gruiformes, suborder Grues); in the plural, general term for the family. Cranes form a homogeneous and phylogenetically very ancient family of large, stately and often very tall (up to 1.5 m) terrestrial and wading birds. There are 14–15 species in 4–5 genera (treated here as 15 in 4): 10 typical cranes *Grus*, Wattled Crane *Bugeranus carunculatus*, Demoiselle Crane *Anthropoides virgo*, Stanley or Blue Crane *A. (Tetrapteryx) paradisea*, Black-necked Crowned Crane *Balearica pavonina* and Grey-necked Crowned Crane *B. regulorum* (these two last, sometimes considered one species, probably represent a distinct subfamily). Recent studies of unison-calls suggest that the Siberian Crane *G. leucogeranus* is closer to *Bugeranus* than *Grus*.

Characteristics. All species are long-legged, long-necked birds with graceful tapering bodies and (except in *Balearica*) ornamental inner secondaries hanging over tail; bills are medium length (short in *Balearica*), straight and sharp. The hallux is raised. Flight is powerful and easy, the wings long and broad, the tail short. *Grus* and *Bugeranus* have bare patches on head and sometimes neck, coloured red, orange or black, the latter with a pair of feathered wattles either side of the chin; *Balearica* has a throat lappet, bare cheeks, bushy crown of bristly feathers and, with *Anthropoides*, elongated breast plumes. *A. virgo* has white post-auricular plumes. Most plumages comprise shades of grey, white, brown, blue and black. The sexes are similar, but males are slightly larger. In *Grus* (except *G. leucogeranus*) the trachea penetrates the sternum with 2 or more loops, assisting volume of calls; it is nearly straight in *Balearica*.

Habitat. Cranes show 3 partially distinct habitat requirements, for nesting, feeding and roosting. Nesting habitats are usually secluded and aquatic, e.g. bogs, marshes, floodplains, wet grasslands and swamps. Feeding habitats (throughout the year) generally extend also to dry uplands, savanna, cultivations and pasture; breeding birds may fly some distance to reach them. Roosting (also flight-feather moulting) sites are usually in remote areas with surface water. *G. leucogeranus* is considered the most aquatic species; the Cuban race of the Sandhill Crane *G. canadensis* is probably the least. The Whooping Crane *G. americana* uses (in winter) the most saline habitats. *Balearica* roosts regularly in trees.

Distribution. The family is represented on all continents except South America and Antarctica. The main area of speciation is central to eastern Asia, which (including north and east Siberia) holds 8 species. Of these the Common Crane *G. grus* breeds from north-east Europe to eastern Siberia, the Black-necked Crane *G. nigricollis* on the Tibetan plateau, the Hooded Crane *G. monacha* in central Siberia between Tomsk and Lake Baikal, the Japanese (or Manchurian) Crane *G. japonensis* in Ussuriland, Manchuria and western Hokkaido (Japan), the White-naped Crane *G. vipio* in Mongolia, Manchuria and the adjacent USSR, *G. leucogeranus* in northern Siberia (north-east Yakutia and the lower reaches of the Ob), *A. virgo* (apart from a tiny number perhaps still breeding in North Africa) from Bessarabia and eastern Turkey across central Asia to Mongolia and adjacent southern Siberia, and *G. canadensis* in north-east Siberia and (patchily) throughout the northern Nearctic, with outpost subspecies in Mississippi, Florida and Cuba. *G. americana* is thus the only purely Nearctic species, breeding in a single area in Canada. The Sarus Crane *G. antigone* occurs from the Indian subcontinent across south-east Asia into northern Australia; its close relative, the Brolga *G. rubicunda*, is confined to parts of Australia and southern New Guinea. In Africa, *A. paradisea* only occurs south of the Tropic of Capricorn, except for an outpost in Namibia; *Bugeranus carunculatus* is thinly distributed south of 5° S and in the Ethiopian highlands; *Balearica pavonina* occurs from West Africa across to Ethiopia; and *Balearica regulorum* replaces it from Uganda to the Cape.



Common Crane *Grus grus*. (*C.J.F.C.*).

Populations. The migratory species tend to occur discretely because birds show a high site-fidelity and philopatry, the young learning the migration routes from their parents; this increases the likelihood of local extinction. Although a few species (notably *G. canadensis* and *G. grus*) retain relatively large populations, probably all have declined considerably and 5–7 are now at risk. *G. monacha* and *G. vipio* each have a few (not more than 3) thousand individuals; *G. japonensis* and *G. leucogeranus* a few hundred; *G. americana* (see also under ENDANGERED BIRDS) less than 100 (more including captive stock). *Bugeranus carunculatus* and *G. nigricollis* have unknown populations, but the former is certainly small and diminishing, the latter possibly so. Two sedentary races of *G. canadensis* (in Mississippi and Cuba) are represented by tiny remnant numbers. The causes of declines are everywhere the same: habitat destruction and disturbance, with some hunting.

Movements. No crane is entirely resident. All Holarctic species are strongly migratory, apart from the Japanese population of *G. japonensis* and the 3 southern races of *G. canadensis*. Birds commonly fly in large V-formations, by day or night, sometimes at enormous heights. Routes are traditional and involve the use of particular staging areas. *G. grus* winters in Iberia, northern Africa, Sudan, and parts of Asia from Turkey across to China. *G. nigricollis* winters in western China; the 'Manchurian' population of *G. japonensis* winters in China, Korea and Japan, *G. monacha* and *G. vipio* in the latter two. The Ob River population of *G. leucogeranus* winters at one site in India but the present wintering grounds of the Yakutia population seem uncertain. The northern races of *G. canadensis* (including the Siberian birds) winter in the southern USA and Mexico; *G. americana* migrates to a small area of coastal Texas. Some *A. virgo* travel further south than any other Holarctic species to winter in north-east and north-central Africa (9–15° N); most, however, visit the

Indian subcontinent and parts of south-east Asia. All the remaining species show at least small local movements.

Food. Cranes are omnivorous, the diet varying with season and local conditions, but preferences for animal or vegetable diet appear also to vary between species (e.g. chiefly animal in *G. americana*, *A. paradisea* and possibly *Balearica*, chiefly vegetable in *G. leucogeranus*, *G. canadensis* and *Bugeranus carunculatus*). All species use the bill to probe and dig for rhizomes, roots and tubers of marsh plants (although *Balearica* also scratch for them with their feet); they also browse, graze and glean for above-ground vegetable matter, especially seed-heads of grasses and sedges, leaves, shoots, buds, fruit (including acorns), etc. Most species also exploit cultivations where possible or at certain seasons; maize is particularly important for *G. canadensis* in both autumn and spring. Animal food is highly varied, but insects (especially Orthoptera and Coleoptera) are always important; also worms, molluscs, crustaceans, crabs, fish (including eels), amphibians, and less commonly small reptiles, birds (eggs and chicks) and small mammals. Only *G. americana* is known consistently to maintain winter feeding territories, probably as a result of its dependence on animal food (blue crabs *Callinectes* and several genera of clam).

Behaviour and voice. Cranes are usually gregarious outside the breeding season, especially when roosting and moulting. All are strictly monogamous, some species evidently pairing for life (but the survivor remates when its partner dies). Pairing appears to occur in flocks of young birds between independence (end of the first year) and maturity (from 3 years onwards). The bond is maintained all year round, most obviously by unison-calling (duetting) and associated displays. The famous and beautiful dancing-displays of cranes (in which birds bow, leap in the air, run wildly and toss vegetation about) may also at times serve this purpose, but they can occur in isolated birds or flocks and seem only to reflect general excitement. Pairs hold large territories, but the traditional and often isolated nature of the nesting site restricts aggression. The rolling, sonorous and often musical calls carry very long distances, perhaps serving both to disperse and to contact pairs; flocks are often extremely noisy. In migratory species, the offspring accompany their parents throughout the winter (when they may still be fed), and are only driven away after arrival back at the breeding grounds the following year.

Breeding is seasonal in the 9 Holarctic species, somewhat more extended in *A. paradisea*, *G. antigone* and *G. rubicunda*, and considerably so in *Bugeranus* and *Balearica*. Nests (often bulky through repeated use, but with little or no material in *Anthropoides*) are always in the open (*Balearica* trample the surrounding area flat, but also sometimes build low in trees) and usually on marshy ground. The eggs are oval or subelliptical, and variable in colour, markings and gloss; usually 2 are laid (but up to 4 in *Balearica*) and one young reared. Incubation is by both birds and typically lasts *c.* 30 days (up to 40 in *Bugeranus*); the young are precocial and nidifugous. Intersibling aggression may lead to the death of the weaker chick, but parents may take charge of one young each, feeding them bill-to-bill. Fledging periods vary, but are shorter in Holarctic species (55 days minimum) and apparently longest in *Bugeranus* (105 days minimum). N.J.C.

CRANIAL: pertaining to the skull.

CRÈCHE: an assemblage pooling the still dependent young of several pairs of a species, e.g. Eider *Somateria mollissima*, Emperor Penguin *Aptenodytes forsteri*, Greater Flamingo *Phoenicopterus ruber*. The term seems particularly apt in those cases where only a few adult birds are usually present, although these may not have any special role as guardians. See also PARENTAL CARE.

CREEPER: element in substantive names used (some also as general terms) in several families of Passeriformes; although used alone by American ornithologists for *Certhia*, more often written as part of a compound word—for Certhiidae see TREECREEPER (1); for Climacteridae see TREECREEPER (2); for Rhabdornithidae see CREEPER, PHILIPPINE; for Salpornithidae see CREEPER, SPOTTED; for Tichodromatidae see WALLCREEPER; for Coerebidae see HONEYCREEPER; for Drepanididae see HAWAIIAN HONEYCREEPER; for Timaliinae (bush-creeper) see BABBLER; for Dendrocolaptidae see WOODCREEPER; for Formicariidae (antcreeper) see ANTBIRD; for Furnariidae (earthcreeper, streamcreeper) see OVENBIRD (1). The New Zealand Brown Creeper *Finschia novaezeelandiae* is now placed in the subfamily Mohouinae of the Acanthizidae; see WARBLER, AUSTRALIAN.

CREEPER, PHILIPPINE: in the plural, general term for the members of the endemic Philippine family Rhabdornithidae (Passeriformes, suborder Oscines). The 2 usually recognized species are the Plain-headed Creeper *Rhabdornis inornatus* of Luzon, Mindanao, Samar, Leyte and Negros, and the Stripe-headed Creeper *R. mystacalis* of these islands and Masbate, Panay, Bohol, and Dinagat.

Characteristics. *R. mystacalis* is about 15 cm long, brown above and white below, with a black mask, a white eyebrow, black striping along the sides, and white crown-streaks. Males tend to be greyer above than females (Parkes 1971). *R. inornatus* is larger and duller, with an unmarked crown. Both species have a straight bill, longest in races from the northern Philippines (Rand and Rabor 1960).

Habitat. *Rhabdornis* inhabits rain forest, forest edge and clearings. *R. inornatus*, the less common species, is most often found above 900 m. *R. mystacalis* is common at lower elevations, but may be uncommon to absent at higher elevations on some islands.

Food. Although both species will climb on trunks (duPont and Rabor 1973, M.D. Bruce), they forage primarily in the outer canopy. Here they perch crosswise on branches or walk along them, gleaning insects from leaves and twigs, probing among flowers, and occasionally eating small fruits.

Behaviour and breeding. Little is known of their biology. Both species usually forage either in single-species flocks of under 10 birds or in larger, mixed-species assemblages. Their nests are unknown, although *R. mystacalis* is suspected of nesting in holes in trees or hollow limbs. One call of the Stripe-headed Creeper is a high-pitched, squeaky *tsee-tsee-wit-see*.

Rhabdornis has been allied with *Sitta* (see NUTHATCH), *Certhia* (see TREECREEPER (1)), and *Climacteris* (see TREECREEPER (2)), but its resemblances to these climbing birds are superficial (Mayr 1963). It differs from them in leg musculature, and lacks such climbing adaptations as stiffened rectrices, elongated toes and reduced toe pads (Orenstein 1977). The genus has plumage and anatomical similarities to the babblers *Ptilocichla* and *Kenopia* (see BABBLER), but its true relationships remain uncertain.

As 'Creeper' is a misnomer for these birds, Rabor and Kennedy (MS) suggest that 'Rhabdornis' replace it as the substantive name for the family. R.O. and R.S.K.

CREEPER, SPOTTED: substantive name of *Salpornis spilonota*, sole member of the Salpornithidae (Passeriformes, suborder Oscines). Formerly included in the Certhiidae (see TREECREEPER (1)) or Sittidae (see NUTHATCH), *Salpornis* lacks *Certhia*'s stiffened rectrices, and differs from both families in nest type and details of leg musculature.

Characteristics. The Spotted Creeper is about 13 cm in length, with an elongate, thin, downcurved bill, pointed wings and a nearly square tail with 12 rectrices. It has short legs and long, partly fused toes with strongly curved claws. Adults are blackish-brown, heavily spotted with white above and mottled white, buff and brownish below, with a barred

Emperor Penguin *Aptenodytes forsteri* guarding crèche of young. (*Photo: J. Prévost*).

tail and white eyebrow. Immatures are duller.

Habitat and distribution. Spotted Creepers are locally distributed in the central Indian peninsula, and in Africa south of the Sahara to about 25° S. They are sedentary birds, usually found singly or in pairs in savanna or in semi-open acacia or miombo *Brachystegia* woodland, often in association with mixed foraging parties.

Food. A foraging Spotted Creeper flutters and clambers rapidly from the base of a tree to the upper branches, exploring bark fissures for beetles (e.g. Bostrychidae), ants, spiders and other arthropods. It holds its tail clear of the trunk. Flight between trees is undulating or gliding. The bird lands by 'tumbling' on to a trunk, with open wings.

Voice. Vocalizations include a rapid, shrill whistle *sweepy-swip-swip-swip* . . ., 5 or 6 high-pitched, croaking *kek*'s and a single *tseee*.

Breeding. *Salpornis* nests between August and May, at different times in different areas. The nest is a soft cup of leaf-stalks, bark, lichen and other materials, lined with hair or spider egg-cases and bound together with cobwebs, cocoons and vegetable down. Its walls may be built up during incubation. The nest is usually placed 3 to 13 m up near the fork of a horizontal branch. The 2 or, more usually, 3 eggs (*c.* 18.5 × 3.5 mm) are pale bluish to greenish, with dark markings tending to form a ring around the blunt end. Apparently only the female incubates, fed by the male. Both sexes brood the young. A nest tree may be re-used for several seasons. R.O.

CREPUSCULAR HABITS: see under NOCTURNAL HABITS.

CRESCENT-CHEST: substantive name now regularly used for the 4 species of TAPACULO of the genus *Melanopareia*.

CREST: a tuft of feathers on the crown of the head, which in many species can be raised or lowered (see DISPLAY).

CRIMSON-WING: substantive name of *Cryptospiza* spp. (see ESTRILDID FINCH).

CRISSUM: the area round the vent, with the under tail coverts (see TAIL; TOPOGRAPHY).

CROCODILE-BIRD: name designating an African bird (or birds) said by Herodotus and Pliny to pick food (leeches, débris) from the gums of basking crocodiles, even entering the open mouth; usually identified with either the so-called Egyptian Plover *Pluvianus aegyptius* (see under COURSER), or the Spur-winged Plover *Vanellus* ('*Hoplopterus*') *spinosus* (see PLOVER), and perhaps applicable to both these species and to some others. The subject is controversial, because many observers who have had ample opportunities have never seen the birds feed from, still less enter, the crocodile's mouth and are accordingly sceptical. The number of positive modern records of any reliability is indeed so small that one may doubt whether this particular action of entering the mouth is frequent. It is not in dispute, however, that both the species named above

Snowy Egret *Egretta thula* with raised crest defending feeding territory. (*Photo: J.B. & S. Bottomley*).

commonly associate with basking crocodiles and feed close to them or on their ectoparasites (tsetse flies, etc.). This latter habit is also shown by the Common Sandpiper *Actitis hypoleucos* while in Africa during the northern winter—and has likewise been recorded from Borneo. Many other species fearlessly keep company with basking crocodiles, even sleeping beside them or standing on them. The Water Dikkop *Burhinus vermiculatus* goes further in apparently having a nesting association with the crocodile, laying its eggs at the same time (when the river is low) and often incubating them within a few feet of the brooding reptile (see THICKKNEE).

As in other circumstances the crocodile regularly preys on waterfowl, this mutual tolerance is remarkable; one recalls the different reactions of antelopes and the like to lions when the latter are respectively hunting and resting. It seems likely that the birds are of more value to the crocodile as sentinels, giving early warning of the approach of danger, than in removing parasites. To some of the birds the crocodile's parasites are food, and to the nesting Water Dikkop its proximity may provide some protection against egg-eating predators. With other species of birds the relationship seems to be casual. A.L.T.

Meinertzhagen, R. 1959. Pirates and Predators. Edinburgh.

CROMBEC: substantive name of *Sylvietta* spp. (for subfamily see WARBLER (1)). See photo NEST BUILDING.

CRONISM: term (*Kronismus* in German) proposed by Schüz for the actual or attempted swallowing by the parents of their own dead or sickly young.

Schüz, E. 1957. Der Verschlingen eigener Junger ('Kronismus') bei Vögeln und seine Bedeutung. Vogelwarte 19: 1–15.

CROP: also called 'ingluvies' (see ALIMENTARY SYSTEM; CROP MILK).

CROP MILK: a secretion of the oesophagus, resembling mammalian milk in its composition, produced by all pigeons (Columbiformes) and among other bird orders at least by the Greater Flamingo *Phoenicopterus ruber* and the Emperor Penguin *Aptenodytes forsteri*, with which they feed their young after hatching.

In pigeons and doves the milk is produced in the crop, a sac-like distension of the oesophagus (see ALIMENTARY SYSTEM) normally used for food storage. During the last few days of incubation the epithelial cells of the dorsal and lateral crop walls begin to enlarge and cells containing milk slough off. This process is under the control of the pituitary hormone prolactin (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM) and occurs in both sexes. For the first few days after hatching the nestlings are given only milk and it seems important that at this time the milk is not contaminated with other food. Only when the crop is empty are the milk cells sloughed off and regurgitated to the young at frequent intervals. Thereafter the young begin to receive whatever else the parents are collecting. In the domestic pigeon milk production continues for about 16 days. Unlike other granivorous birds, pigeons feed very little animal matter to their nestlings, so that the secretion of a crop milk rich in fat and protein ensures that the young receive adequate nutrition during the period of maximum growth.

In the Emperor Penguin the secretion of oesophageal milk by the male enables the chick to double in weight after hatching while receiving no other food. This is the more remarkable since the male has by that time undertaken all the incubation without feeding for over 2 months.

Greater Flamingoes do not regurgitate predigested food for their young and appear to feed them solely on their milk for up to 2 months after hatching. Between them the parents produce 200 ml of milk daily, enabling the chick to grow from 100 g at hatching to some 2–4 kg. For the first few weeks the milk is dark red, due partly to the presence of the pigment canthaxanthin but also to large numbers of red blood cells.

The composition of different crop milks is shown in the Table. Pigeons' milk contains, at least qualitatively, most of the amino acids essential to growing chickens (see NUTRITION). Pigeons' milk contains no carbohydrate, whereas penguin milk has an appreciable quantity. Flamingo milk has an unusually high fat content. P.J.J.

Comparative composition of crop milks of pigeons, Greater Flamingo and Emperor Penguin, expressed as percent of dry weight.

	Pigeon[1]	*Greater Flamingo*[2]	*Emperor Penguin*
Protein	58.4	32.5	59.3
Fat	35.1	65.3	28.3
Carbohydrate	—	0.8	7.8
Minerals	6.5	1.4	4.6

CROSS: see HYBRID.

CROSSBILL: substantive name of *Loxia* spp. (see FINCH). See photo COURTSHIP FEEDING.

CROSS-FOSTERING: replacement of the eggs of one species by those of another (usually closely related), so that the young are reared by the 'wrong' parents.

CROTOPHAGINAE: see CUCKOO.

CROW (1): substantive name of many species of Corvidae (Passeriformes, suborder Oscines); in the plural, general term for the family, although also, in a more restricted sense, for the typical crows *Corvus* spp. Outside the typical genus, the most frequent substantive names are 'jay', and 'magpie' (varied to 'tree-pie' in one genus), while 'nutcracker', 'chough' and 'piapiac' are special names for one or two species in each case. Within *Corvus* 'raven' is applied to various large species, while 'rook' and 'jackdaw' are special names. The names 'crow' and 'jay' occur as misnomers for unrelated birds (see CROW (2) and JAY), while 'magpie' and 'chough' have other meanings in Australian ornithological usage (MAGPIE (1) and (2), and CHOUGH (1) and (2)).

It has been considered that the Corvidae were most closely related to the birds-of-paradise (Paradisaeidae), bell-magpies (Cracticidae), Old World orioles (Oriolidae) and the drongos (Dicruridae), but more recent studies of egg-white proteins suggest that their nearest relations are the shrikes Laniidae. The division into 2 subfamilies, the typical crows (Corvinae) and the jays and magpies (Garrulinae), is not now considered useful. There are some differences between authorities about the demarcation of both genera and species. Goodwin (1976) describes 23 genera and 113 species. The taxonomy and nomenclature followed here is that of Goodwin.

Characteristics. The crows, as a family, may represent the furthest stage so far reached in avian evolution; much in their behaviour suggests a highly developed mentality, and some species have a complex social organization. This is not to say that they show extreme specialization; on the contrary, they are characterized by great adaptability. They are certainly successful, as judged by the large number of species and the almost world-wide distribution.

They are large birds, by the standards of the Passeriformes (from 20–66 cm long), and they include the largest members of that order. The bill is stout, fairly long, and often with a small terminal hook. The nostrils are usually round, without an operculum, and shielded by bristles directed forwards. The legs and feet are robust, the tarsi are usually strongly scutellated in front and booted behind; in the choughs they are booted both in front and behind.

While the typical crows are either wholly black, including bill and legs, or black with some white, grey or brown, the jays and magpies often have bright colours, especially blues and greens; further, many of the jays and magpies have very long tails, and some of the jays are crested. The sexes are alike in plumage, or nearly so, and there is no marked seasonal change. Crows are mostly strong fliers.

Habitat. Apart from the two cliff-dwelling choughs *Pyrrhocorax*, the crows are found in woodlands of all types, though the *Corvus* species

Carrion Crow *Corvus corone*. (*C.J.F.C.*).

prefer open steppes, to which the landscapes modified by man, e.g. parkland, orchards, often approximate, and this assists their colonization by a number of species all over the world. The jays, on the whole, inhabit closed canopy woodland. A few species, e.g. Raven *Corvus corax* and Jackdaw *C. monedula*, occupy cliffs, quarries and even buildings.

Distribution. The family is almost cosmopolitan, but is most abundantly represented in temperate parts of the Northern Hemisphere. It is, however, unrepresented in New Zealand (apart from the introduced Rook *Corvus frugilegus*) and in most of the archipelagos of the Pacific Ocean; in South America the only representatives are jays.

The typical crows *Corvus*, a single genus, have an exceptionally wide distribution; they are absent from South America but are the only representatives of the family in Africa south of the Equator, in the Malagasy region and in Australia and Oceania. Both the choughs *Pyrrhocorax*, are Palearctic apart from an outlying colony of the Red-billed species *Pyrrhocorax pyrrhocorax* in Ethiopia. The nutcrackers *Nucifraga*, are Holarctic. The magpies are not necessarily a closely related group, those of the genus *Cissa* for example may be closer to the jays of the genus *Garrulus* than to the typical magpies of the genus *Pica*. Of the 5 genera now generally grouped as magpies, one has an Holarctic distribution, one is Oriental and Iberian and the remainder are all Asian, with several of the species confined to south-east Asian islands. Among the jays there are 8 New World genera and in South America they are the only representatives of the family; one genus is Holarctic, one is Palearctic. The ground jays of which there are 2 genera inhabit mainly high semi-desert areas in Asia. There are 3 monotypic genera whose relationship to other groups in the family is not clear, 2 are found in northern tropical Africa and one in south-east Asia.

Movements. Most members of the family are sedentary, but some may show weather movements, while a few perform regular migrations within the North Temperate Zone (see MIGRATION). Large scale autumnal movements of jays and nutcrackers are probably due to shortages of foods on which they are dependent and which are normally stored for winter and early spring use.

Food. Many of the species are practically omnivorous, taking both animal and vegetable food, and much feeding is done on open ground. Many have definitely predatory tendencies, some take the eggs and young of other birds; carrion is taken by some species, and some find their food among the jetsam of the sea or lake shore. Insects are taken, especially by the smaller species, and vegetable diet includes such items as acorns and the seeds of pine cones, and sometimes soft fruits. The birds are among those that hold food with the foot while tearing it with the bill. Some species, especially of jays, magpies and nutcrackers living in high latitudes or altitudes have the habit of hiding excess food for use in time of scarcity (see FEEDING HABITS; FOOD STORING).

Behaviour. Most, if not all, corvids are sociable, but there are different degrees of gregariousness among them, ranging from species like the Rook which nest in colonies and hold only a small territory immediately surrounding each nest, to those like the Carrion/Hooded Crow *Corvus corone* that maintain a large territory area throughout the year. In this species territorial integrity is vital to breeding success, because the most important predators on the eggs and young are other non-territory holding Carrion/Hooded Crows, but these are usually gregarious, living and feeding in a non-breeding flock. Many corvid species that nest in isolation, e.g. the Raven, use communal roosts under certain conditions. In several species additional birds, sometimes young of the previous season, are tolerated within the territory. This tolerance probably depends on the submissive behaviour of the additional birds and ranges from the 'helpers' of some of the New World jays, where several birds may assist with rearing the young and with territorial defence, to the 'third bird' which Carrion/Hooded Crows will allow within the territory outside the nesting season; these are males who give some assistance with territorial defence and may succeed to the territory if the holder is killed.

The sociability of corvids is most marked at special feeding sites such as rubbish dumps and during migration and at winter roosts. In the roosts the coming together at nightfall of birds from a wide area may facilitate the finding of food during the ensuing day's foraging. Among socially breeding species like the Rook and Jackdaw the territorial behaviour implies recognition of a number of individual territory holders and their mates, as these are not attacked in the vicinity of the territory, while total strangers are.

Territory serves a different purpose for the Nutcracker *Nucifraga caryocatactes*: it is not only the area within which they breed but also the area within which they store food in the late summer and autumn ready for the winter and early spring. They are dependent on these food caches as individuals and it may be because each bird remembers where its own food is stored, that the two nutcrackers appear to be the only corvid species in which the male takes a share in incubation, leaving the female free to visit her own food caches.

There are interspecific reactions between corvids, especially the typical crows. For example Rooks, Carrion/Hooded Crows and Jackdaws will mob a predator attacking or holding a member of these or related species. Again Jackdaws on a flight line to a winter roost may stop briefly to join a group of one of the other typical crow species on the ground (see TERRITORY; FOOD STORING).

Voice. Many of the calls are loud, and for the most part harsh and discordant. Nevertheless, some species have a not unmelodious subsong, or 'whisper-song' uttered by both sexes and audible only at very short range (see VOCALIZATION). Some show considerable powers of mimicry, both when wild and in captivity (e.g. Jay), although others are not known to do so in a wild state (e.g. Magpie) (see MIMICRY, VOCAL).

Breeding. The crows often breed colonially, but not necessarily so even in species that are markedly gregarious at other times. Some species pair for life. Courtship feeding is common, and the male continues to feed the female while she is sitting on the nest. Both sexes take part in building the nest. In almost all the species only the female incubates the eggs or broods the young, but the male helps to feed them and sometimes performs most of that task; food is brought in the throat. In some of the New World jays, help in feeding the young, and even in nest-building or in feeding the sitting female, may be given by non-breeding 'helpers', some of which are known to be immature.

The nest tends to be a bulky structure of coarse twigs, variously lined; it is usually open but in a very few species it is roofed over. It is placed in a tree or bush, or on a cliff or building or occasionally on the ground. The eggs number 2–4 in some tropical jays but in other species there may be up to 9 or more. The colour ranges from buff or cream to green or greenish-blue, and there is usually heavy blotching or spotting with brown or other colours and paler underlying markings. Incubation periods are recorded as 16–21 days. The young are hatched blind, helpless, and either naked or with sparse down. They may be fledged in 20 days, but in some of the larger species 5–6 weeks may be spent in the nest.

Typical crows. It is generally agreed that these are the most advanced members of the family; they have in fact been described as 'in many ways the most adaptable and highly evolved of all birds'.

They are nearly all large birds, none really small, and some are very large for passerines, ranging in size from the Raven (length 60–66 cm; wing 38–43.6 cm) to the Jackdaw (length 33–34.6 cm; wing 22.5–24.6 cm). The plumage is often entirely black, and with black bill and legs as well, but the feathers may show a metallic gloss, from purple to blue and bluish green. Some species have parts of the plumage brownish or grey, even white, but bright pigments are absent. They tend to be omnivorous and in part predatory. When feeding on the ground they walk, but they roost and nest on trees and cliffs, often in very inaccessible places. They are strong fliers, often indulging in aerobatics. They are intelligent and wary, and often highly gregarious. Many of their calls are loud and commonly harsh. R. Meinertzhagen placed all the typical crows in the genus *Corvus*, and this course has been followed by Amadon (1944) and by E.R. Blake and C. Vaurie, among others; such names as '*Coloeus*', '*Corvultur*' and '*Rhinocorax*' may therefore be relegated to the synonymy. Affinities within the genus are difficult to determine, and some of the decisions as to the validity of species may need revision.

The genus *Corvus* contains about 40 species and for the purpose of the present summary a geographical arrangement (ignoring slight overlaps of the boundaries of regions) is convenient.

Palearctic. The Rook is a rather distinctive representative, with the white bare skin of the face (in the adult), the relatively bland *caw*, and the highly social behaviour, including colonial nesting; the tall trees in which its 'rookeries' are built are often near human habitations. Similar in size is the Carrion/Hooded Crow, of harsher voice and more predatory habits, whose territorial requirements have already been referred to. It is at present usual to regard the all-black Carrion Crow and the partly brownish-grey Hooded Crow as conspecific—*C.c. corone* and 1 other race; *C.c. cornix* and 3 other races—because they replace each other geographically and interbreed freely where their ranges meet; but the intermediates are presumably selected against, as the main populations apparently remain pure (see HYBRIDIZATION, ZONE OF SECONDARY; SPECIATION; SPECIES). The Hooded Crow is a notable migrant, in huge daytime flocks, in northern Europe.

Smaller, and indeed small for the genus is the Jackdaw, with grey nape, generally nesting more or less colonially but nearly always in holes, a habit that is unusual in the genus; the site chosen may be in a tree, cliff, a building or in the ground. Larger and indeed the largest passerine species is the Raven, a bird now largely restricted to remote mountain areas but with a wide Holarctic range (extending also to Central America).

In the more easterly parts of the Palearctic Region the Jackdaw is replaced by *C. dauuricus*, sometimes called the Daurian Jackdaw, and there are 2 other members of the genus—the Jungle Crow *C. macrorhynchos* (also widespread in the Oriental Region) and the Collared Crow *C. torquatus*.

Nearctic (and Neotropical). In North America, in addition to the Raven, there is the widespread Common Crow *C. brachyrhynchos*, not unlike the Carrion Crow. Of more restricted distribution are the White-necked Raven *C. cryptoleucus*, the North-western Crow *C. caurinus*, and the Fish Crow *C. ossifragus*; the last is a shore-feeder of the Atlantic and Gulf coasts and some of the major river systems. In southern North America, Central America and the Caribbean the Raven ranges as far south as Nicaragua. The Sinaloan Crow *C. sinaloae* and the Mexican Crow *C. imparatus* are mainland species. The Cuban Crow *C. nasicus*, the Jamaican Crow *C. jamaicensis* and the Palm Crow *C. palmarum* are confined to islands.

Afrotropical (and Malagasy). The Pied Crow *C. albus* is a familiar bird throughout Africa south of the Sahara except in rain-forest and desert areas; and it is the only member of the family found in Madagascar. It is a large species, in which the glossy black plumage is relieved by white across the base of the hindneck and on the chest and upper belly. Also widespread in eastern and southern Africa, is the Black Crow (or Cape Rook) *C. capensis*, which lays eggs that are rather like the rare erythristic eggs of other crows; they have a buff, buffish white or pinkish ground colour, usually profusely spotted and marked with brown, brownish red or purplish grey.

The Brown-necked Raven *C. ruficollis*, of northern and north-eastern Africa (also south-eastern Asia), is sometimes treated as conspecific with *C. corax*. There are also the Fantailed Raven *C. rhipidurus* in north-eastern Africa and the Middle East, the White-necked Raven *C. albicollis* in East and South Africa, and the rather similar but larger Thick-billed Raven *C. crassirostris* in Ethiopia.

Oriental. The common crows of southern Asia are the widely distributed (also eastern Palearctic) Jungle Crow *C. macrorhynchos*, the House Crow *C. splendens* of India and adjacent countries, and the Slender-billed Crow *C. enca* distributed from Malaya to the Philippines. About 7 more species are spread through the islands of south-east Asia and the South Pacific, several restricted to particular islands. The most isolated of all is the Hawaiian Crow *C. tropicus*. Some of these species are apparently largely fruit-eating. The Long-billed Crow *C. validus* of the Moluccas has white irides, as have the Australian crows.

Australian. In Australia and Tasmania there is a group of related species all having white irides. They are the Australian Crow *C. orru* whose range extends north of Australia to New Guinea and the Moluccas and several other islands, the Little Crow *C. bennetti*, the Australian Raven *C. coronoides*, the Little Raven *C. mellori* and the Forest Raven *C. tasmanicus*. In New Zealand there are no indigenous crows, only the introduced Rook.

Choughs. The 2 species of *Pyrrhocorax* are birds of medium size for this family, with glossy black plumage. The red-billed *Pyrrhocorax pyrrhocorax* has a rather long decurved red bill and red legs. The Alpine Chough *P. graculus* has a longer tail, a much shorter and less curved yellow bill and orange to red legs, the depth of colour of both bill and legs varying considerably. They are both gregarious cliff-dwellers of strong acrobatic flight. The Chough still exists on the western coasts of the British Isles; it is almost absent from the Alps, but otherwise has a distribution roughly similar to that of the Alpine Chough. Both species inhabit the mountain areas from the Iberian Peninsula and the Atlas mountains eastwards to central Asia and China, but the Alpine Chough is found at higher altitudes and does not use maritime cliffs. Both species readily become tame when they are not molested; one of the Mount Everest expeditions recorded Alpine Choughs as in attendance at a camp at 8,100 m.

Nutcrackers. The Nutcracker is an inhabitant of coniferous forests in high latitudes and altitudes of the Palearctic Region. It is slightly larger than the Jay *Garrulus glandarius* and has chocolate brown plumage, boldly speckled with white; the size and profuseness of the white spots, the length of the tail and the length and thickness of the bill differ in different geographical races. The Nutcracker's most important foods are the seeds of *Pinus cembra* and allied species and hazel nuts. The habit of food storing, often in deep snow, is very well developed and the birds are dependent upon it (see FOOD STORING). Clark's Nutcracker *N. columbianus* inhabits corresponding country in western North America and has similar habits; it differs in appearance in having the plumage largely grey, with black-and-white wings and tail.

Magpies. The name 'magpie' has come to be applied to a number of species that are not pied at all but have some general resemblance to *Pica*, usually including the long tail.

The typical Magpie *Pica pica* is about 46 cm in length including its long graduated tail. The scapulars, underparts and the inner webs of the primaries are white, the rest black with green, blue, purple and bronze gloss. It is widely distributed in the Palearctic Region except in the treeless north. There are many geographical races within this area, varying a little in size and in the amount of white on the body and wings. The species is represented by the race *P.p. hudsonia* in North America where there is also the Yellow-billed Magpie *P. nuttalli*, generally considered to be a separate species.

In a monotypic genus, the Azure-winged Magpie *Cyanopica cyanus* is decidedly smaller than *Pica* but has the same general shape, with the long, graduated tail. The plumage is largely brownish-grey, with a deep black cap descending to the nape and with light blue wings and tail. The species is remarkable for its discontinuous distribution; it is found only at the extremes of the Palearctic Region, in the Iberian Peninsula in the west and in northern China, Mongolia, and Japan in the east. The Iberian population is subspecifically distinct from the group of races in the Far East, but the history of the distribution of the species as a whole is not known.

The magpies of the genus *Cissa* are about the same size as *Pica* but most of them have longer tails due to the very long central tail feathers. There are 8 species of the genus *Cissa*; Whitehead's Magpie *Cissa whiteheadi* is black and white with a comparatively short white-tipped tail; there are 4 blue and 3 green species in the genus. All live in southern Asia, mainly in the south-east and in islands as far east as Taiwan, Java and Borneo.

The genus *Crypsirina* contains 10 species also living in areas from India eastwards, some of them limited to a restricted island distribution. They are the 'tree-pies' and are less brilliantly coloured than *Cissa*, being mainly rufous-brown, and black with shades of grey; some have the tips of the central tail feathers widened to a racquet formation.

In Tenasserim, the Malay Peninsula, Sumatra and Borneo there is a monotypic genus *Platysmurus*. The single species is *Platysmurus leucopter-*

us, the Black Jay; a magpie-like black bird with a white wing patch and a comparatively short tail.

Typical jays. The Jay *Garrulus glandarius* is the original bearer of the common name. It is a medium-sized crow with pinkish-brown body plumage, white rump and wing patch, black tail, beautiful blue and black barred wing coverts, and a black-and-white erectile crest. It is essentially a woodland bird, feeding on acorns during much of the year but also taking quantities of caterpillars and other insects, on which the young are largely fed. It also takes the eggs and young of other birds in the nesting season. In winter and spring the adults subsist largely on acorns previously hidden. In the open it appears a heavy flier, but is agile among trees and its progression on the ground is by long hops. Its many races are widely distributed in the Palearctic Region, except the most northern parts and central Asia. It has 2 congeners, generally similar birds, the Lanceolated Jay *G. lanceolatus* in the Himalayas and the Purple or Lidth's Jay *G. lidthi* in the Ryukyu Islands.

The grey jays of the genus *Perisoreus* inhabit the northern coniferous forests of both Old and New Worlds; they are probably of Old World origin. The Siberian Jay *Perisoreus* (*'Cractes'*) *infaustus* is slightly smaller than *Garrulus glandarius* and of much less colourful plumage—mainly brown and grey, but bright rufous on the wing, rump, and sides of tail. It is a Palearctic species with a more northern range than *Garrulus*. It is replaced in Szechwan by *P. internigrans*. In northern America there is the similar Grey (or Canada) Jay *P. canadensis*, with a white forehead and black nape and lacking the reddish feathers.

American jays. There are over 30 species of American jays assigned to 8 genera. The Blue Jay *Cyanocitta cristata* is a familiar North American bird, distributed from southern Canada to the Gulf of Mexico. Its upper parts are bright blue, with white patches on wings and tail and it has a pointed crest. Its sole congener, Steller's Jay *C. stelleri*, ranges from Alaska to Nicaragua, mainly on the western side of the continent. The Scrub (or Florida) Jay *Aphelocoma coerulescens*, ranging from the north-western United States to Florida and Mexico, is predominantly deep blue and brownish above, with no white on the tail and no crest. It has 2 congeners, in Middle America.

The species of *Cyanolyca* (9), *Cyanocorax* (12), which includes the Green Jay *C. yncas* found from Texas to Peru, and *Cissilopha* (4) are all inhabitants of tropical America.

The Pinyon Jay *Gymnorhinus cyanocephalus*, sole member of its genus, has a breeding distribution restricted to mountain areas in the western United States. It is a stumpy bird with mainly blue-grey plumage, and is gregarious in its habits.

The Brown Jay *Psilorhinus morio* is a large jay living in Mexico and Central America; there are 2 colour phases, the lighter one having white-tipped outer tail feathers and lighter body colour, yellowish to cream on the underparts instead of brown. The 2 phases were at one time considered to be separate species. The 2 magpie-jay species *Calocitta formosa* and *C. colliei* live respectively from Mexico to Central America and in western Mexico and are considered to be conspecific by some authors. They differ in that *C. colliei* has a longer tail and black face, throat and upper breast; the forehead and crest are also black.

Ground jays. The group of ground or running jays, sometimes referred to as ground choughs, comprises 4 *Podoces* spp. and *Pseudopodoces humilis* in a monotypic genus. They live on the semi-arid plateaus of central Asia and are highly specialized members of the family. As the name implies, they are largely terrestrial and tend to run rather than take to the air. They are relatively small birds (20–25 cm long), fawn or pinkish fawn in colour except in one species which is silver grey, all have rather short glossy black and white wings and varying amounts of black and white especially on the head and tail; the legs are long in proportion. *Pseudopodoces* is the smallest of the group and looks more like one of the larks (Alaudidae) than a crow. It also departs from the family norm by nesting in crevices in walls or in rodent holes, and in having white eggs. The species of *Podoces* usually build nests in bushes, and they have spotted eggs.

Aberrant forms. There are 3 monotypic genera with affinities so obscure that their inclusion in the family at all has sometimes been doubted. They are quite unlike each other and are taken together here merely for convenience. It was only in 1938 that *Zavattariornis stresemanni*, sometimes called Stresemann's Bush-crow, was first described. It is confined to southern Ethiopia, where it inhabits the thorn bush and builds large domed nests. It is a relatively small crow (*c.* 30 cm long), mostly grey above, with blue-black wings and tail, and white below; a patch of bare skin round the eye is said to be blue in life.

The Piapiac *Ptilostomus afer* is a familiar bird in West Africa and eastwards to Uganda. It is smaller in body than a magpie *Pica* sp. and similarly has a long graduated tail; the legs and feet are notably strong. The plumage is glossy black, tinged with brown on wings and tail; the bill is reddish except at the tip while the bird is immature, but is wholly black in the adult. The birds are usually to be seen in small flocks, on the ground (feeding largely on insects) or in palm trees. They show but slight fear of man and are common about villages, often associating with sheep and goats, at times perching on their backs (as on those of large wild mammals, including elephants, in the limited parts of the range where such are common).

The Crested Jay *Platylophus galericulatus* has been classified with the shrikes Laniidae, and it is not certain that it should be considered a member of the Corvidae. It is about the size of a Blue Jay *Cyanocitta cristata*, dark olive brown and grey in colour with black face, throat and neck, and with a white crescent on each side of the neck; it has a long rather broad black crest and is found in tropical forests in Java, Sumatra, Borneo and the Malay Peninsula. Goodwin, D. 1976. Crows of the World. London.

Turcek, F.J. & Kelso, L. 1968. Ecological aspects of food transportation and storage in the Corvidae. Comm. Behav. Biol. Pt. A, 1: 277–297.

CROW (2): name misapplied to a variety of birds that are not members of the Corvidae. Thus, 'Bald Crow' is sometimes used for the two species of *Picathartes* (see under BABBLER); 'John Crow' (also 'Carrion Crow') is a popular misnomer in America for species of Cathartidae (see VULTURE (2)), and 'Rain Crow' for the Great Lizard Cuckoo *Saurothera merlini* in the West Indies (see CUCKOO); 'Piping Crow' is an alternative substantive name in Australia for *Strepera* spp. (Cracticidae—see CURRAWONG), and 'Wattled Crow' in New Zealand for *Callaeas* spp. (Callaeidae—see WATTLEBIRD (2)). See also FRUITCROW (Cotingidae); KING-CROW (Dicruridae); PARADISE CROW (Paradisaeidae); and 3 items below.

CROWN: see TOPOGRAPHY.

CROWN-BIRD: alternative name of the Crowned Crane *Balearica pavonina* (see CRANE).

CROW-PHEASANT: name, also 'Griffin's Pheasant', applied in India to a species of coucal, *Centropus sinensis* (see CUCKOO).

CROW-SHRIKE: name sometimes applied to *Strepera* spp. (see CURRAWONG).

CROW-TIT: substantive name sometimes used for *Paradoxornis heudei* (see PARROTBILL).

CRURAL: pertaining to the leg, especially the tibiotarsus (see LEG).

CRYPTIC: term applied to coloration or other characters that, by providing concealment or disguise, afford protection against enemies (procryptic) or facilitate capture of prey (anticryptic);—see COLORATION, ADAPTIVE; NATURAL SELECTION. The opposite is PHANERIC.

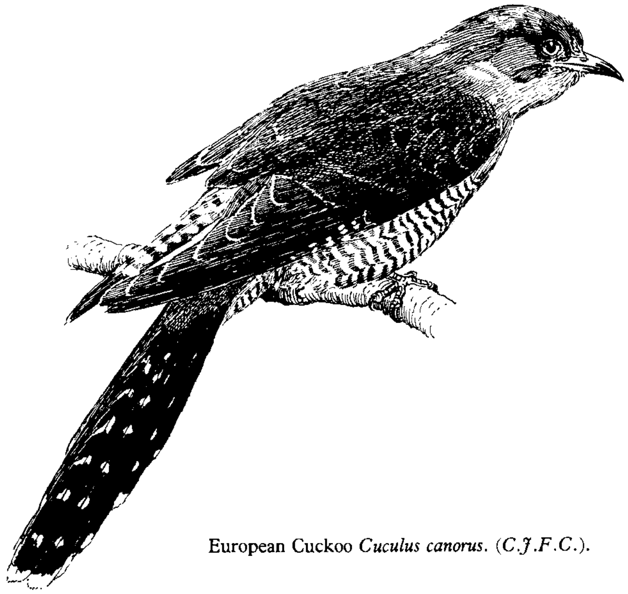
CRYPTIC SPECIES: alternative term (best abandoned, because of its ambiguity) for SIBLING SPECIES.

CRYPTOPTILE: term applied to the hypothetical early representatives of feathers in the remotest ancestry of birds; sometimes also to the first filaments appearing from the feather papillae in a young bird (see PLUMAGE).

CRYPTURI: see TINAMIFORMES.

CUBITAL: obsolescent alternative for 'secondary' in the terminology of wing feathers (see PLUMAGE; WING).

CUCKOO: substantive name of all species of Cuculidae (Cuculiformes); in the plural, general name for the family. Used without qualification in Britain, with equivalents in other languages in Europe,



European Cuckoo *Cuculus canorus*. (*C.J.F.C.*).

for *Cuculus canorus*. The common name in many European languages derives from the call of the European species. The family is large, with about 130 species in 34 genera. About 50 species lay their eggs in the nests of other species, which rear the young cuckoos (BROOD-PARASITISM). The other cuckoo species build a nest and rear their own young; a few are communal nesters.

Characteristics. Cuckoos vary considerably in size and appearance, but the species most often seen are slender, long-tailed, medium sized (20–30 cm) birds with two toes directed forward and two backward. In size the cuckoos vary from the small glossy cuckoos *Chrysococcyx*, which are about 15 cm long, to the coucals *Centropus*, the largest being nearly 90 cm. Most cuckoos have loose-webbed feathers and are variable in colour with most species being brown or grey, but some are all black, and others are brilliant greens, violets, or yellows. Many have brightly coloured bare areas of skin on the face, and some have a crest or long eye-lashes. Most have a slender straight or decurved bill not unlike other insect-eating birds, but some have a laterally compressed bill with a high arch. Most cuckoos have short legs, but the large terrestrial cuckoos are long-legged.

The closest relatives to the cuckoos are probably the turacos (Musophagidae). Aside from this, the relationships of cuckoos to other groups of birds are not known. The current systematic arrangement of cuckoos is based largely on breeding biology and geographic distribution, rather than on details of the feather tracts and moult and on skeletal and muscle anatomy. Within several subfamilies the anatomy varies among the species, and sometimes cuckoos within a subfamily are more different from each other than from cuckoos placed in different groups.

The subfamily Cuculinae, the brood-parasitic cuckoos of the Old World, includes the Cuckoo *Cuculus canorus*. Twelve other species occur in this genus, ranging through Europe, Asia, Africa, and Australia. Common species in other areas include the glossy cuckoos *Chrysococcyx*, the Koel *Eudynamis scolopaceus* of India, China, New Guinea, and parts of Australia, and the crested cuckoos *Clamator* of Africa, India, and the Mediterranean region.

The subfamily Phaenicophaeinae includes the typical nest-building cuckoos of the Old and New Worlds. They are slender, short-legged, insect-eating birds with long, graduated tails. In tropical Asia and the Malaysian region these cuckoos are often called 'malkohas'. The Red-faced Malkoha *Phaenicophaeus pyrrhocephalus* of Ceylon and part of southern India is probably the rarest of the cuckoos, and the continuing encroachment upon its primary forest habitat threatens its existence. In the New World the Phaenicophaeinae have developed the most diverse forms on the islands of the Caribbean, with the large lizard-eating cuckoos *Saurothera* of the Greater Antilles and the more widespread *Piaya* squirrel cuckoos resembling the Old World malkohas. The genus *Coccyzus* of the New World is the most successful in number of species.

The subfamily Crotophaginae includes the anis (*Crotophaga*, 3 species) and the Guira Cuckoo *Guira guira* of the New World. These are group-living cuckoos with group territories. Sometimes several pairs have nests within a group territory, and sometimes they have communal nests. They are short-winged, the bill is laterally compressed and deep, and the tail has only 8 feathers (10 in the other cuckoos).

The subfamily Neomorphinae includes several long-legged, terrestrial cuckoos, mainly of the New World. The Greater Roadrunner *Geococcyx californianus* is a familiar bird of scrub deserts in south-western North America. Roadrunners seldom fly except to a display perch, and they run in pursuit of lizards or in a scramble for cover. Hand-raised roadrunners have been followed all day on foot as they walked through the desert scrub. The brood-parasitic cuckoos of the New World, the Striped Cuckoo *Tapera naevia*, the Pheasant Cuckoo *Dromococcyx phasianellus*, and the Pavonine Cuckoo *D. pavoninus*, are associated with the nesting cuckoos in this group by their roadrunner-like appearance.

The subfamily Couinae includes 10 species of *Coua* on Madagascar. These are long-legged, pigeon-sized cuckoos often with bright colours of plumage and naked skin on the head. One of these, *C. delalandei*, is probably now extinct.

The subfamily Centropodinae includes about 26 species of coucals *Centropus* in the Old World, mainly in Africa and south-east Asia. They are terrestrial cuckoos with a long, straight hind claw, and they build a covered nest.

Habitat. Most cuckoos are birds of forest and woodland, often living in dense thickets where they are difficult to observe. Some live in open woodland, such as the Yellow-billed Cuckoo *Coccyzus americanus* of North America. Others live in open country with only scattered trees or shrubs, such as the South American Guira Cuckoo or the parasitic African Didric Cuckoo *Chrysococcyx caprius*. The Greater Roadrunner lives in desert scrub. A few coucals of the Old World tropics live in wet grassland and marshes.

Distribution. As a group, cuckoos are cosmopolitan with species on all tropical and temperate continents and on many islands. The species are most numerous in the tropics. Many genera are restricted to certain parts of the world. Three genera are known only from New Guinea (*Rhamphomantis*, *Caliechthrus*, and *Microdynamis*, all brood-parasites), and 2 only from the Philippines (*Dasylophus* and *Lepidogrammus*). The New World ground-cuckoos *Neomorphus*, found in tropical forest from Nicaragua south through Peru, Bolivia, and Brazil, are large terrestrial cuckoos. It is uncertain how many species are involved. Only one kind lives in any one region, but the kinds are morphologically distinct and may comprise several species. They are apparently isolated from each other by large rivers, especially in the Amazon basin. On the other hand some cuckoos are widespread; the typical cuckoos *Cuculus* have species in Europe, Asia, Africa, Madagascar, and Australia, and the genus *Coccyzus* occurs throughout the New World, including most Caribbean islands and the Galapagos Islands. The Caribbean islands have many distinct local races of the Mangrove Cuckoo *Coccyzus minor*. Islands near New Guinea have distinct species of the largest of the coucals *Centropus*. Records of strayed migrant North American *Coccyzus* in Europe and of Palearctic *Cuculus* in North America suggest the ability of these widespread birds to invade new regions.

Movements. Cuckoos that breed in temperate habitats usually migrate to warmer areas for the winter. They generally migrate by night, though they also move by day along the East African coast and they fly on to the coast of Britain by day. Several species migrate long distances. The Cuckoo of northern Europe and Asia migrates to Africa, apparently with non-stop flights of 3,000 km or more. Many then move further across the tropics into the temperate-zone woods of southern Africa. Cuckoos from the Iberian Peninsula winter in West Africa north of the Equator. The Shining Cuckoo *Chrysococcyx lucidus* of New Zealand migrates northward over 3,000 km of land and ocean to the Solomon Islands. A few cuckoos of temperate areas in southern Africa remain during the entire year, but their quiet ways in the non-breeding season make them difficult to find. Most cuckoos of temperate southern Africa migrate to north of the Equator. Some Indian birds of one of the same species, the Jacobin Cuckoo *Clamator jacobinus*, cross to east-central Africa for the winter.

Food. Cuckoos are mainly insectivorous. Many are specialists on caterpillars, particularly noxious-tasting hairy kinds that other birds seldom take. Cuckoos bite one end, mince the insect back and forth in the bill, and shake it vigorously at one end until the gut and its toxic contents come free. They beat both hairy and smooth caterpillars against a branch. Hairs are usually swallowed along with the rest of the caterpillar. Local seasonal outbreaks of eastern tent caterpillars in North America are often associated with an influx of Black-billed *Coccyzus erythrophthalmus* and Yellow-billed Cuckoos which then nest in the infested woods and feed the caterpillars to their young. Other insects taken by cuckoos include grasshoppers, mantids and locusts, including some large, brightly-coloured, apparently noxious species. Larger cuckoos such as the lizard cuckoos, roadrunners, and coucals take both insects and small vertebrates, including lizards and snakes. Coucals and some female parasitic cuckoos take the eggs and nestlings of other birds. The ground-cuckoos *Neomorphus* of tropical forests in the New World often feed on insects flushed by swarms of army ants, which they follow, and sometimes they follow peccaries, which may flush insects. The Old World ground-cuckoos *Carpococcyx* also feed on insects but appear not to have been described feeding with ant swarms. Two species of anis *Crotophaga* of the American tropics feed on grasshoppers and associate in flocks in pastures with feeding cattle. The couas *Coua* of Madagascar take some fruit but rear their young on large insects and centipedes. The Channel-billed Cuckoo *Scythrops novaehollandiae* and the Koel also feed largely on fruit; the young of these brood-parasites are fed mainly insects by their foster parents.

Behaviour. Most cuckoos are solitary and shy, remaining alone and quiet most of the year except when they breed. In the breeding season the males sing and defend a territory. The anis and the Guira Cuckoo are however highly social birds that live in flocks throughout the year. Smooth-billed Ani *Crotophaga ani* flocks defend a territory from other flocks throughout the year. From 8 to 25 birds may live in a flock. They often nest more or less communally, with more than one pair in the flock breeding, and more than one female sometimes using a nest. Non-breeding adults as well as the breeding pairs help to feed the young.

Voice. Cuckoos are noisy in the breeding season. The most often heard birds of African woodlands in the rainy season are cuckoos and doves. The details of songs vary among the species, but many cuckoos have series of *coos* or *kuks* on the same pitch or changing pitches. The parasitic glossy cuckoos *Chrysococcyx* of the Old World and the parasitic New World Striped Cuckoo *Tapera naevia* have whistled calls. The biggest known repertoire is that of the Greater Roadrunner; it includes dove-like coos, a bark, a whine, a whirr, a growl, and a vigorous bill clacking. The male European Cuckoo alone gives the familiar *cu-koo*; and the song of most cuckoo species is given only by the male. The female may have a distinct call, such as the bubbling sound or a growl in several species of the parasitic *Cuculus*. Young parasitic cuckoos sometimes sound like the young of their foster species, and young of the Yellow-billed Cuckoo sound like a hissing snake. Some parasitic cuckoos call both day and night and have earned local names such as 'brain-fever birds' for their monotonous repetition. Cuckoos also sing in the rainy season when they nest, sometimes just before a rainstorm, earning the name 'rain bird' for various species in the Caribbean, Africa, the Australasian Region, and Asia.

Breeding. Courtship behaviour of most cuckoos includes the feeding of the female by the male during the egg-laying period. Most nesting species of cuckoos build a simple platform nest of sticks in bushes or trees or on the ground in wooded country. Eggs are laid at intervals of 2–3 days. The eggs of most nesting cuckoos are uniform in colour, often glossy bluish or whitish. The incubation period is short (10 days), and incubation may begin with the first egg. The period to fledging is also short and the young grow rapidly from the helpless hatchling covered with a stiff hair-like down to the feathered fledglings in 6–7 days. Clutch size varies considerably; the Black-billed Cuckoo lays 2–6 eggs, one every 2 days. When it lays a large clutch of 5 eggs, the last egg may be laid the same day that the first laid egg hatches, and the last egg laid may not have time to hatch by the time the first-hatched young has fledged. Both male and female of this species help feed the young.

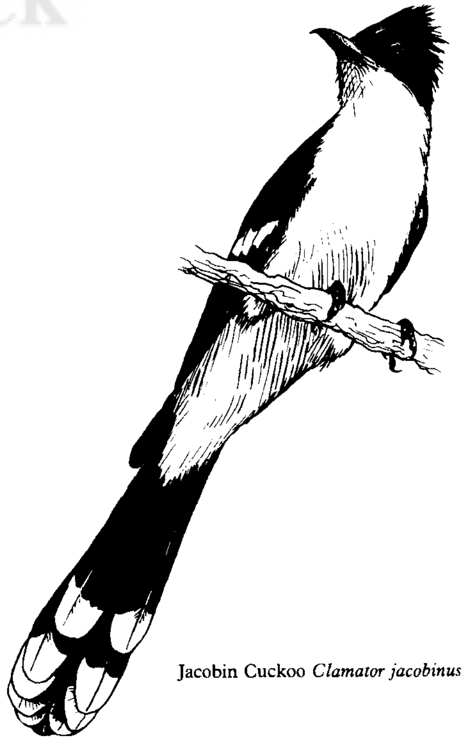
Most tropical nesting cuckoos have small clutches of 2–3 eggs, but anis may lay up to 7 eggs, and huge composite 'clutches' (up to 29 eggs have been recorded) result from several females laying in the same nest. In the communal nests of the anis the bluish eggs have a distinct whitish chalky layer on the surface. The socially dominant pair does most of the breeding in the group.

Breeding of the coucals differs from other cuckoos in that the nest is domed with a side entrance. In some species the female is larger than the male. The polyandrous female may have two or more mates, each with a different nest. The parental roles of the male and female are not well known.

In the parasitic cuckoos the female lays in the nest of another species, nearly always a song-bird, which then behaves as host or foster parent, incubating the egg and feeding the young. In some species the egg closely matches the egg of the host. The resemblance is an adaptation to parasitism; the eggs that most closely match the host eggs are more likely to be accepted by the incubating host. A few parasitic cuckoos have different kinds of egg, one female laying eggs of one colour and pattern, another laying another kind of egg. Eggs are usually laid in the nest of a host with similar eggs. The European Cuckoo *Cuculus canorus* has local populations each with several different morphs of eggs, some spotted and others of uniform colour. The female often removes and eats an egg of the host while she is investigating the host nests before laying her own egg. She lays her egg after holding it in her oviduct for a day, thus putting the embryo a day ahead of a fresh host egg in development. Eggs of parasitic cuckoos usually hatch before the eggs of the host, though not in a shorter time than in nesting cuckoos of the same size. When it hatches, the young European Cuckoo shoves the host eggs or chicks out of the nest. Thereafter it receives all the food brought to the nest by the foster parents, and may remain in or near the nest for up to 4 weeks. Evicting behaviour has also been seen in a few other species of *Cuculus* and in some glossy cuckoos *Chrysococcyx*. The New World Striped Cuckoo *Tapera naevia* upon hatching kills any other young birds in the nest, using a sharp hook at the tip of its bill, an adaptation otherwise known only in some honeyguides. In some other parasitic cuckoos, such as the Great Spotted Cuckoo *Clamator glandarius*, the young grow up together with the foster siblings.

The plumage of the young resembles the plumage of the host young in some cuckoos that grow up with them. The young of the Koel *Eudynamis scolopaceus* in India are dark, like their young crow nest-mates. Young Koels in Australia are pale; here they parasitize paler hosts and not crows. The juvenile plumage of the Drongo Cuckoo *Surniculus lugubris* in southern Asia is black with small white spots, much like the juvenile plumage of the local drongos. The significance of this resemblance is not known; Drongo Cuckoos parasitize small babblers not drongos, at least in Malaya. In the Philippine Islands the juvenile plumage of *S.* (*lugubris*) *velutinus* is a uniform rufous, much like the local Rufous Paradise Flycatcher *Terpsiphone cinnamomea.* Field studies are needed on these cuckoos.

No apparent pairs are formed by most parasitic cuckoos. Males sing and advertise themselves on a territory, but a male may mate with more than one female, and a female may mate with more than one male. A female lays her eggs in the territories of several males, and several females (often known by their distinctive eggs) may lay in the territory of the same male. In most species the female alone finds the nest, usually by watching the hosts as they are building, and lays after flying to the nest while it is unattended. The male and female of the Great Spotted Cuckoo and of the Jacobin Cuckoo associate more closely in pairs and work together to parasitize a nest. The male flies near the nest, the host chases



Jacobin Cuckoo *Clamator jacobinus.* (*K.P.*).

him off, and the female then slips quickly into the unattended nest to lay.

Parasitic cuckoos lay in a series, or 'clutch', an egg every other day, for 3 to 5 eggs, then rest for a few days until the next series. If host nests are unusually abundant, either in nature or in a field experiment, then the cuckoo may continue to lay on the alternate-day schedule for a few weeks.

The eggs of parasitic cuckoos are smaller in relation to the female's body size than are the eggs of nesting cuckoos. As the cuckoo foster species are usually much smaller birds than the cuckoos, the small eggs allow a female to parasitize a number of nests of the foster species. Small egg size and the success of females in tracking several nests allow many eggs to be laid in a season. Females of several species of parasitic cuckoos in Africa as well as the Cuckoo in Europe commonly lay as many as 20–24 eggs in a season.

Population structure. Certain colour patterns of mimetic cuckoo eggs are found over a wide region, while others are local. Because more than one kind of European Cuckoo egg occurs in some areas, it has been suggested that there may be several races living together but each mating only within its own race. This suggestion was made to explain why egg mimicry and polymorphism do not break down in areas where more than one kind of egg pattern occurs. Each egg race, or 'gens', would then breed true, behaving much like a biological species. In fact there appears to be no difference in the voice or other behaviour of cuckoos living in such mixed populations. The egg mimicry may instead be maintained by a sex-linked gene complex, with mother passing on to daughter her genetic code for egg colour and pattern. Cuckoos resemble other birds in that the female, and not the male as in mammals, carries the odd sex chromosome (female heterogamy). At the present time it seems likely that a sex-linked polymorphism, and not a splitting of local populations into non-interbreeding races or 'gentes', explains the variation in egg colour.

Some parasitic cuckoos are polymorphic in plumage. European populations of the Cuckoo include grey birds and brown birds; similar polymorphisms are known for a few other species in the genus *Cuculus*. Females alone are variable in these cuckoos. A possible explanation of plumage polymorphism is that the less common form is less likely to be recognized by the local hosts, and so is more likely to lay in a host nest.

Cuckoos tend to return to breed in the same general area where they were born, but not to exactly the same location. Most recoveries in a later breeding season of Cuckoos ringed in Europe as nestlings have been found 20–100 km from the site of birth. This is about the same distance as in the nesting Black-billed and Yellow-billed Cuckoos . A Cuckoo may be attracted to a habitat or to a host species like the one it grew up with, but we have no direct evidence on the nature of development of host recognition and host specialization in the Cuckoos.

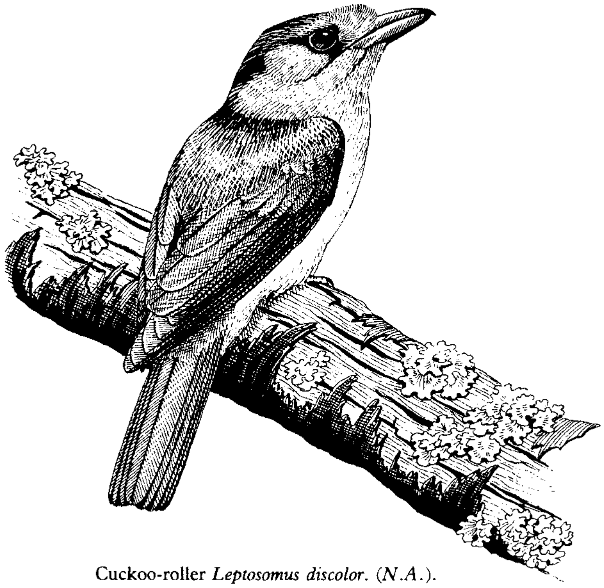
CUCKOO-FALCON: *Aviceda cuculoides* of tropical Africa and allies, 'falcon' being a misnomer (see HAWK).

CUCKOO-ROLLER (or COUROL): the names used for *Leptosomus discolor*, the single species in the family Leptosomatidae (Coraciiformes), perhaps correctly placed in a different superfamily from the GROUND-ROLLERS and ROLLERS.

Characteristics. The species is confined to Madagascar and the Comoro Islands. It may represent a first invasion of Madagascar by primitive roller stock (contrast with the ground-rollers). There are 3 subspecies (one endemic to Anjouan, another to neighbouring Grand Comoro). Excluding the last, it is *c.* 43 cm long, with a stoutish bill (broad at the base), long ample wings, a moderately long tail and very short legs. There is a pair of powder-down patches, one on each side of the rump. The greyish bloom characteristic of the plumage may be due to this powder-down. The feathers of the lores face forward and upward to conceal the base of the bill. There is also a short crest, adding to the apparent size of the large head.



Cuckoo-roller *Leptosomus discolor*. (*N.A.*).

The sexes differ conspicuously in colour. The adult male has the upperparts, except the hindneck, slaty, with iridescent green or copper, depending on the incidence of light; the underparts and hindneck ashy grey. The female and young male have the upperparts dark brown, with the crown and hindneck barred black and rufous; the underparts pale rufous, boldly spotted with black. The Grand Comoro form is only *c.* 38 cm long, the female with the tail bright chestnut-red instead of dark brown.

Habitat. Evergreen forest or virtually any type of woodland.

Distribution. Throughout Madagascar (including the dry southwest) and on all 4 Comoro Islands.

Populations. Not known to be anywhere endangered, but numbers must be diminishing everywhere, through habitat destruction. Those in the limited Comoro environments require special attention.

Movements. There is no satisfactory evidence of any regular movement.

Food. Large insects (including hairy caterpillars) and chameleons.

Behaviour. Usually solitary, occasionally in small parties; tame and confiding. Often circles with slow wing-beats over forest or woodland, frequently calling; or likewise when perched on a conspicuous stub at the top of a tree, the bird leaning forward with its throat puffed out.

Voice. The most usual call is an arresting, beautiful, loud *kwiii-yu, kwi-yu, kwi-yu, kwi*, the second and third notes not so long drawn-out, nor so loud, as the first; the fourth (final) note the shortest and least loud.

Breeding. The eggs are whitish tinged green, laid in a natural cavity in a tree. The clutch-size in Madagascar can be up to 5, although a cavity in the Comoros contained only 2 young. Incubation may be entirely by the female, but she is fed by the male, and he assists in the feeding of the young, which are covered in long white down. (A.L.R.) C.W.B.

CUCKOO-SHRIKE: substantive name of some species of Campephagidae (Passeriformes, suborder Oscines); in the plural, general term for the family (also known as caterpillar-birds). They have nothing to do with either cuckoos (Cuculidae) or shrikes (Laniidae). Various other substantive names are applied to different species without much consistency, some being compounds including the word 'shrike', e.g. 'grey-birds', 'trillers', 'caterpillar-shrikes', 'flycatcher-shrikes', 'wood-shrikes' (also used for Prionopidae), 'Cicada-bird', and 'Pied Shrike'.

The name 'cuckoo' perhaps derives from the grey coloration, sometimes conspicuously barred, and the name 'shrike' from the strong notched bill.

The family includes 70 species in 2 distinct groups: the colourful and lively minivets in the genus *Pericrocotus* and the rather drab and dull-coloured cuckoo-shrikes in 8 other genera; 3 of these (*Pteropodocys*, *Campochaera*, and *Chlamydochaera*) are monotypic; the remaining 5 are *Tephrodornis*, *Hemipus*, *Campephaga* (including '*Lobotos*'), *Lalage*, and *Coracina* (including '*Edolisoma*').

Characteristics. The minivets *Pericrocotus* spp. are a distinctive group, the size of wagtails *Motacilla* spp. and with a moderately long and graduated tail. In most species the male is a striking black and red, whereas the female is yellow or orange and black or grey. The cuckoo-shrikes of the other 8 genera vary in size from that of sparrows *Passer* spp. to that of pigeons *Columba* spp. (*c.* 14–40 cm) and the prevailing colours are light and dark grey, more rarely black and white. The wings are rather long and pointed, and the tail is moderately long and round; rictal bristles are well developed and in many species partially conceal the nostrils. The sexes differ in depth of colouring, the female being a pale and washed-out version of the male. The young often have a white nestling plumage, exchanged for a plumage resembling that of the female at the post-juvenile moult.

A notable peculiarity is that, in most species, the feathers of the back and rump are thickly matted, partially erectile, and equipped with rigid pointed shafts. These spine-like feathers are easily shed, and according to Gilliard, it is possible that they act as a mechanism of defence, as in the trogons and pigeons. The White-winged Triller *Lalage sueurii* of Australia is the only member of the family known to have 2 moults yearly; the normal postnuptial moult in the autumn produces an eclipse plumage, which in the male (but not in the female) differs strikingly from the breeding plumage.

Habitat. All the cuckoo-shrikes except one are arboreal, although some, e.g. the Pied Triller *Lalage nigra* of Malaysia, often drop down to the ground for a few moments when feeding. In central Australia however, the Ground Cuckoo-shrike *Pteropodocys maxima* frequents treeless plains, perches on fence posts, flies after insects like a swallow, and runs strongly on the ground unlike any other member of the family. A few species are restricted to the true forest, but the rest are more typical of the forest edge, secondary growth, gardens, and coastal vegetation. The minivets are birds of the tree-tops.

Distribution. The cuckoo-shrikes are an Old World and mainly tropical family, ranging from Africa across southern Asia and Malaysia to Australia and the western Pacific.

Several species of the genus *Campephaga* are inhabitants of Africa. For example, the *Campephaga phoenica* subspecies ranges from Senegal and the Sudan to Cape Province. The Wattled Cuckoo-shrike *C.* ('*Lobotos*') *lobata*, with the aberrant character, in the male, of a yellow wattle near the gape under each dark red eye, has a limited range in West Africa, and is little known. The Pygmy Triller (or Pied Shrike) *Hemipus picatus* occurs in India, and the Black-breasted Triller *Chlamydochaera jefferyi* is a montane species in Borneo with a restricted distribution from Mt. Kinabalu to Mt. Dulit.

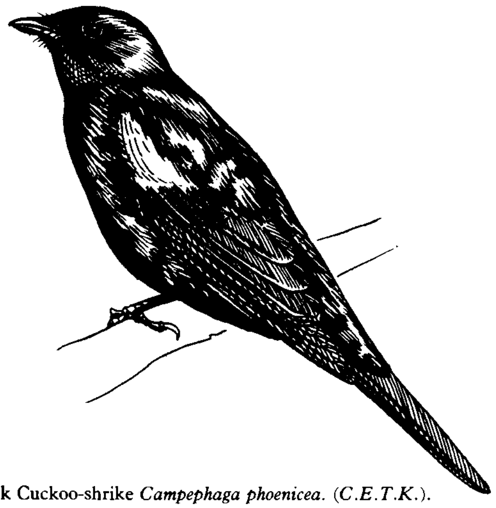
The minivets are absent from Africa and Australia but extend up into the far eastern Palearctic Region (eastern Siberia, China, Japan, the Ryukyus).

Movements. The only long-range migrant in the family is *Pericrocotus brevirostris* which migrates from the far eastern Palearctic Region to winter in the Oriental Region. Some species move locally, especially in Australia.

Food. The family is mainly insectivorous, but caterpillars, especially hairy ones, and some fruit are taken. The Black-breasted Triller is reported to feed only on fruit. The Pygmy Triller catches flying insects after the manner of flycatchers.

Behaviour. Minivets are gregarious in winter, collecting in flocks of a dozen or more individuals. Their bright tones harmonize well with the Burmese scene, where they are among the most characteristic birds. A feature of the montane forests, from the Himalaya to Borneo, is the mixed parties of birds, usually including babblers, warblers, flycatchers and others, with one or two species of cuckoo-shrikes or minivet.

Voice. The cuckoo-shrikes mostly have loud call-notes, either whistles or rather disagreeable squawks; the call of the Black Cuckoo-shrike is described as a soft double whistle. Minivet flocks communicate with soft and musical call-notes.



Black Cuckoo-shrike *Campephaga phoenicea*. (*C.E.T.K.*).

Breeding. In the courtship display of some of the large cuckoo-shrikes, the male lifts each wing alternately, without opening the feathers, perhaps half a dozen times, calling vigorously while doing so. The performance is repeated at intervals, and is a most distinctive field character.

Both sexes build the nest, but in many species only the female incubates. The nest is usually placed high up in the fork of a tree, or simply on a horizontal branch, and is difficult to see from below. It is a shallow little cup of fine twigs, roots and grasses, or moss and lichen, usually lined. The minivets build a shallow but massive little cup of fine twigs and roots, often matted with cobwebs and studded with lichens so that it resembles the twig on which it is placed. The clutch usually consists of 2–5 eggs (but 1 egg only in the Cicada-bird *Coracina tenuirostris*), usually pale green when fresh but apt to fade if exposed to light, marked with brown, grey or purple; the eggs of some minivets are white or greyish in ground colour.

Knowledge of breeding by cuckoo-shrikes of the genera *Coracina* and *Campephaga* is scanty. In general, however, development stages of all seem to be protracted, with incubation for *c.* 3 weeks and a nestling period of similar or greater length. The share of the sexes in building, incubation and tending the young evidently varies. B.E.S.

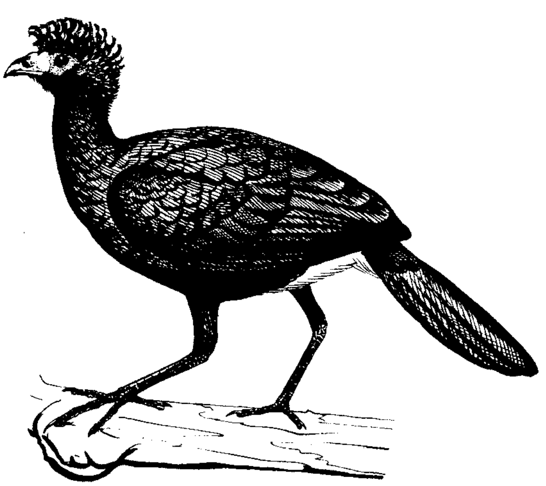
CUCKOO'S LEADER; CUCKOO'S MATE: popular name, in Britain, for the Wryneck *Jynx torquilla* (see under WOODPECKER). It refers to the approximately simultaneous appearance in spring of this summer visitor and the Cuckoo *Cuculus canorus*.

CUCULI; CUCULIDAE: see below.

CUCULIFORMES: an order, alternatively 'Cuculi', comprising 2 suborders: Musophagae, Cuculi; 2 families: Musophagidae (TURACO), Cuculidae (CUCKOO). They comprise mainly arboreal birds with short legs and rounded wings. The largest number of species occur in the tropics; those living in temperate and cold climates are migrants with long, pointed wings. The fourth toe can move sideways in turacos and backwards in cuckoos (zygodactylous foot). Anatomical characters and outward appearance of the birds are often reminiscent of gallinaceous birds and relationship has been suggested by several authors, but the systematic position of the order is still unclear. The cuckoos are especially notable for their breeding strategies, which range from normal parental care to various forms of social breeding and nest parasitism (see BROOD-PARASITISM).

CULMEN: the dorsal ridge of the upper mandible, from forehead to tip (see BILL).



Black Curassow *Crax alector*. (*C.E.T.K.*).

CURASSOW: substantive name of the big species (*Crax, Mitu, Nothocrax* and *Pauxi*) of the Cracidae (Galliformes); in the plural, serving as a general term for the family, other members of which are called guans (*Penelope*), piping-guans (*Pipile*) and chachalacas (*Ortalis*). The family is restricted to the warmer zones of the New World and is considered to be the most primitive group of living gallinaceous birds. In South America the curassows largely take the place of the Phasianidae which are very poorly represented and from which the curassows stand phylogenetically well apart; there is no hybridization between the 2 families.

Characteristics. In size curassows vary from 75–112 cm in length. Most true curassows (*Crax, Mitu, Nothocrax*) are conspicuously crested with curved feathers. In most genera the sexes are alike, but *Crax* is sexually dimorphic. They can be sexed by cloacal examination (adult males have a copulatory organ), or sometimes by the colour of the iris; e.g. in *Penelope obscura* the iris of the male is red, that of the female dark brown, whereas the contrary is true for *Crax blumenbachii*. The wings are short and round, and markedly concave. The bill is heavy and bent, frequently with a shiny coloured cere. Most true curassows (*Crax, Mitu*) have the base of the bill enlarged; *Pauxi* is adorned with a large helmet; *Oreophasis*, a guan, with a horn on the forehead. The legs are long and strong, the toes are heavy and fairly long and have bent claws.

Habit. The curassows are the most arboreal Galliformes. They usually stay in trees, either in the forest or at its edge. They run with great agility along the branches, jumping up and up until they reach the tree-top, whence they take off, half gliding, half fluttering.

Distribution and systematic characteristics. The range of the family extends from the southern United States to northern Argentina. There are 10 genera (2 of which *Mitu* and *Pauxi* are sometimes included in *Crax*) and 44 species. The status of many forms, whether species or races, is in doubt, especially when their distribution is allopatric, which is very common. There exist several monophyletic groups which can be combined into superspecies.

There are 14 species of true curassows. The Great Curassow *Crax rubra*, weighing approximately 4,800 g, ranges from Mexico to Ecuador; the male is black with a greenish or bluish sheen above, white on belly and sides, and has stiff, narrow crest-feathers strongly recurved at the tips, and the base of the bill ornamented with a large turgid yellow knob which increases in size during courtship; the plumage of the female is brown. The Red-billed Curassow *Crax blumenbachii* is a member of the same superspecies; it lives in south-eastern Brazil where it is endangered by deforestation and hunting. In the Amazonian Razor-billed Curassow *Mitu mitu tuberosa* the bill-adornment is not soft but consists of a hard, narrow brilliant red frontal comb. The plumage is black with a steel blue sheen, brown on the belly; birds of both sexes weigh about 3,500 g; the species is still relatively common in Amazonia. Recently, after a space of 300 years, the race of Razor-billed Curassow *Mitu mitu mitu* from north-eastern Brazil was rediscovered, a last remnant living in small forest pockets in Alagoas; it can be saved from extinction only by breeding in captivity.

In the Helmeted Curassow *Pauxi pauxi* both sexes have a solid fig-shaped casque on the base of the bill; the bluish-grey colour of this casque contrasts with the red of the bill itself; the bird is about 1 m long, weighs about 3,600 g and inhabits the mountain forests of Venezuela.

There are 12 species of guans, called 'jacu', 'camata', 'pava', etc. most of them similar in appearance, greenish olive to brown. The sexes are alike except that sometimes the colour of the iris is different in male and female; there is bare skin round the eyes and on the upper part of the neck, and the naked throat forms a conspicuous wattle, being yellowish red, strikingly visible while the bird is calling. A big species of guan such as *Penelope purpurascens* (Mexico to Ecuador) weighs about 1,900 g. *Penelope superciliaris* from Brazil weighs only 850 g.

There are 3 species and several subspecies of piping-guans, *Pipile* (also called *Aburria*) spp., known as 'cujubi', 'jacutinga' etc. They are all similar in colour, black with white spots on breast and wings and a white crest; the outer primaries are sharply attenuated (see under Behaviour below). The naked throat is shiny blue and red with a long wattle; the weight of *Pipile pipile cumanensis* is about 1,200 g. One species, *Pipile jacutinga*, from south-eastern Brazil (down to Misiones), which was still extremely common 50 years ago (e.g. in Santa Catarina), is now near extinction.

There are 9 species of chachalacas *Ortalis* spp. called 'aracua' in Brazil, an onomatopoeic name like 'chachalaca'. The Plain Chachalaca *Ortalis vetula* has, like other chachalacas, a bare bright red throat with a strip of feathers down its centre. The upper parts of the plumage are dark olive brown, the lower parts lighter, and the tail is greenish black, white tipped on the sides; the bird is 50 cm long and weighs about 550 g. It ranges from Texas and Mexico to Nicaragua.

Food. Curassows do not scratch for food as much as other gallinaceous birds, although they often come down to the ground to feed on fallen fruits and flowers. They like to feed on buds and tender leaves, and occasionally on small animals such as insects and frogs. They store food in the crop (*Crax, Mitu*) or in the greatly expandable oesophagus (*Ortalis, Penelope*). The larger species and the piping-guans have a muscular stomach. Stones of fruits pass through the alimentary tract whole or are spat out, but the larger species grind up hard seeds.

Voice. The voice is raucous (*Ortalis, Penelope*), whistling (*Pipile*) or booming with a strange muffled quality (*Crax, Mitu, Nothocrax*). In many species the voice is amplified and modified in pitch by means of an extended, looped trachea, the curve sometimes reaching to the abdomen. These modifications which resemble those in cranes, swans and the Capercaillie *Tetrao urogallus* may be present in both sexes (*Penelope*) or only in the males (*Ortalis, Crax, Nothocrax*). A system of air-chambers in the neck may also serve as a voice amplifier (*Crax*).

Behaviour. During the nesting season some species produce a loud noise with the wings, some guans wing-drumming, all piping-guans wing-whirring very strongly. To do this they fly from one treetop to another, a display that is difficult to see because the birds perform only very early in the morning, late in the evening or in moonlight.

Breeding. The Cracidae build their nests of dry twigs and leaves loosely woven together; the nest is quite small in relation to the size of the birds; the nest cup is at times relined with fresh material. The nest is placed a few metres high in trees, sometimes in branches overhanging water or even quite near the ground. A few species nest on the ground (e.g. *Penelopina nigra* of Mexico). Occasionally the nest of another bird is used as a base for building. The clutch consists of 2–3, rarely 4 eggs. These are large, white, with a rough shell (*Ortalis, Crax*) or smooth (*Penelope*). Incubation lasts 22 (*Ortalis*), 29 (*Crax*) or 34 (*Pauxi*) days. The young are hatched with well developed primaries and secondaries. They are led out of the nest by the female on their first day and hide in the branches. They are able to fly after 3 or 4 days, and they soon do not hesitate to take off from the end of a branch to fly to a neighbouring tree, following the female or both parents. The parents present food in their bills to the young and this is mostly of animal origin. The colouring of the chicks is light brown and black; at times a striped pattern appears. The bigger species do not breed until 2 years old.

Parents and offspring keep together for some months. Later they join with others to form flocks of 10–20 birds until the next breeding season. In *Crax*, *Pipile* and *Penelope* the same individuals appear to pair in succeeding years, thus forming continuous monogamous relationships. Chachalacas (*Ortalis*) are partly polygamous and form nesting colonies; males co-operate at times in nest building. Parental care varies with species, but little is known about it. In some curassows (*Crax*) the male takes part in feeding the young. The question of sex ratio has not been sufficiently clarified; a ratio of 1 : 1 has been noted in several species of *Penelope* and *Ortalis*, but females predominate in some *Crax* spp. Curassows have now been bred successfully in captivity. CURLEW: substantive name of *Numenius* spp.; used without qualification in Britain, for *N. arquata* (see under SANDPIPER). See photo VOCALIZATION.

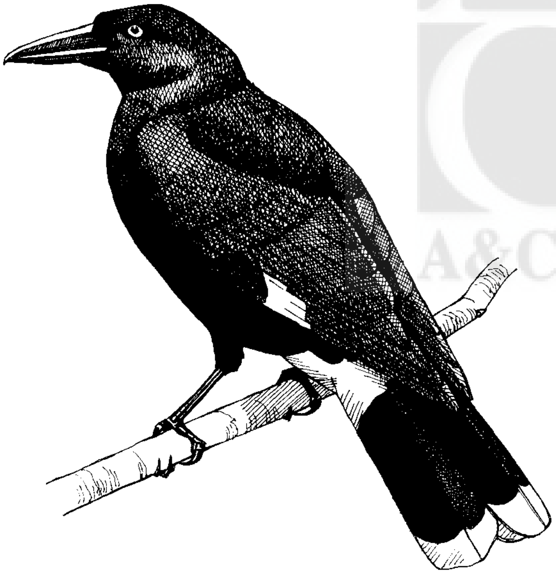
CURLEW, BEACH: name used in Australia for *Burhinus neglectus* (see THICKKNEE).

CURLEW, BUSH: name sometimes applied to the Stone-curlew *Burhinus magnirostris* of Australia and New Guinea (see THICKKNEE).

CURLEW, STONE: see STONE-CURLEW; THICKKNEE.

CURRAWONG: substantive name of the species of *Strepera*, family Cracticidae (Passeriformes, suborder Oscines).

Characteristics. Currawongs (also called bell-magpies or crow-shrikes) are large birds, about 50 cm in length, having a long tenth primary, tarsi almost completely sheathed in scales arranged in a kind of boot, and the bill long and straight with a sharp, slightly hooked point. The plumage is black, grey and white. Six species used to be recognized, but recently they have been grouped into 3, the Pied *graculina*, the Black *fuliginosa* and the Grey *versicolor*. A peculiarity of the *versicolor* group is the number of isolated forms and the tendency to an inconsistency in plumage characters where some forms have come secondarily into contact. Thus, there are currawongs with greyish plumage and white wing patches, and others which are black and white or greyish-brown and white, in varying degrees; but no clear-cut colour characters that separate the 2 groups.



Pied Currawong *Strepera graculina*. (*N.W.C.*).

Habitat. The birds frequent all types of forest and woodland from coastal rain-forest to montane woodlands and inland mallee woodlands.

Distribution. The Pied Currawong occurs in eastern Australia and Lord Howe Island, the Black is confined to Tasmania and the Grey occurs throughout Australia and Tasmania. The Grey has probably invaded Tasmania twice, the earlier immigration leading to the evolution of the Black Currawong and the later to one not yet fully differentiated from its mainland ancestor, although its plumage is already much darker.

Populations. There is no information about the density at which currawongs occur, nor about the rate of recruitment into the population. Numbers appear to be more or less stable at present and those of the Pied Currawong have been estimated to exceed a million (Readshaw 1968a).

Movements. Only the Pied Currawong undertakes recognizable movements. In winter, when breeding is over, the species forms large flocks which move extensively about south-eastern Australia harvesting phasmatids and other large insects that sometimes develop into plagues in the *Eucalyptus* forest (Readshaw 1968b).

Food. Currawongs feed on large insects, many of which they take on the ground. They will also eat small vertebrates and have no hesitation in taking arboreal insects when they are abundant. They will take orchard fruits and various wild berries.

Behaviour. During the spring and summer breeding season territories are strongly defended, mainly by pairs. Territorial boundaries are maintained during the non-breeding season, but at much lower intensity. Only Pied Currawongs form large winter flocks.

Voice. The Grey Currawong's calls are bell-like, but vary across their range. The Black and Pied Currawongs have different variations of a rollicking *currawong* call, from which the genus gets its name.

Breeding. The currawongs all build a large stick nest, usually placed high in a tree-fork and lined with bark fibre. The clutch varies from 2–4, but there is no information about the length of incubation or nestling periods. Nests of the Pied Currawong are sometimes parasitized by the Channel-billed Cuckoo *Scythrops novaehollandiae*. The fledged young of the Grey Currawong continue to be fed by their parents for some months, possibly until the next breeding season. S.J.J.F.D.

CUT-THROAT: *Amadina fasciata* (see ESTRILDID FINCH).

CYCLARHINAE: see under VIREONIDAE; PEPPER-SHRIKE.

CYGNET: special term for a young SWAN.

CYPSELI: name formerly used for the order APODIFORMES; SWIFT.

D

DABCHICK: alternative name for certain of the smaller Podicipedidae (see GREBE).

DACELONINAE: see KINGFISHER.

DACNIS: generic name used as substantive name of *Dacnis* spp. (see HONEYCREEPER(1)).

DAMBO: an environment, consisting of grassy land that seasonally becomes marsh, characteristic of parts of tropical Africa.

DAPTRIINAE: see FALCON.

African Darter *Anhinga rufa*. (*J.B.*).

DARTER: substantive name (alternatively 'Snake-bird' or 'Water-turkey') of Old World species of Anhingidae (Pelecaniformes, sub-order Pelecani); in the plural, general term for the family. The substantive name of the New World species is anhinga; in the plural, alternative general term for the family, which includes 4 allopatric forms that are treated as 1–4 species in 1 or 2 genera, subgenera or superspecies. Several other forms that have been described as subspecies are of doubtful taxonomic validity. Some authors place the darters in a subfamily Anhinginae of the cormorants Phalacrocoracidae.

Characteristics. Darters are medium to large in size (0.8–1.0 m long). The bill is of moderate length, spike-shaped with the distal halves of the cutting edges finely serrated. The head is slender with about the same circumference as the long G-shaped neck, with its peculiar articulation of the vertebrae and single carotid artery (2 in the cormorants). The short legs are set far back and the feet are totipalmate. The wings are long and the tail very long. Although they take off from water with difficulty, darters are excellent flyers, gliding and soaring like flying crosses. Outer webs of the central tail feathers have prominent transverse corrugations. There are age, sex and species differences in the amount and pattern of black, white, grey, brown and silver in the plumage. New World adult males have a black erectile crest on the nape, while Old World adults have instead a prominent white stripe on the side of the head and upper neck. In Old and New World adults the scapular coverts are extremely elongated and lanceolate with white or silver stripes. Bare part colours of the head, legs and feet vary individually and include black, brown, pink, red, orange, yellow, green and blue.

Habitat and distribution. Darters frequent tropical, sub-tropical and temperate regions where there are sheltered inland and marine waters with no waves, and wooded shores where they can perch in the trees. *Anhinga anhinga* occurs in the New World and there are several morphological differences that suggest that it is at least specifically and possibly generically distinct from the 3 Old World darters. All 4 forms differ from each other in their adult breeding plumage patterns. *A. rufa* occurs in Africa south of the Sahara, Madagascar and Asia Minor; *A. melanogaster* is found in southern Asia including Indonesia and the Philippines; and *A. novaehollandiae* occurs in Australia and New Guinea. A skin found in 1874 nailed to a shed wall on the west coast is the only New Zealand record. There have been errors in the specific name even in recent publications, when the Old World forms are lumped together as a single species. The order of priority is *melanogaster* 1769, *rufa* 1802 and *novaehollandiae* 1847.

Movements and feeding. Movements are mainly in response to weather-induced shortages in the availability of food. Darters feed mainly on fish and insects. Often they swim with the body under and the head and neck above water and thus appear like a swimming snake. From this posture they slowly submerge to stalk fish which they spear in the flank, with the bill slightly open. The rapid heron-like forward movement of the head under water is facilitated by highly modified hinges between the 7th, 8th and 9th cervical vertebrae. The fish is commonly brought to the surface, tossed in the air, caught in the bill and swallowed head-foremost. Plumage modifications for the reduction of buoyancy are similar to those of cormorants (see CORMORANT; SWIMMING AND DIVING). The bill is also used as a pair of forceps to pick insects off the water surface.

Communications. Clicking and rattling sounds are made away from the nesting area, where, when breeding, darters make several cawing and hissing calls with individual, sexual, age and species differences. They have no alarm call, but react to those of other birds. Visual signals are complex and are similar to those of gannets, cormorants, pelicans and herons.

Breeding. Darters nest in colonies often with other kinds of water-birds. The male selects the nest site, and the female builds the nest often overhanging water in the fork of a tree, initially with green and later with dry twigs gathered mainly by the male. The pair take turns guarding the nest and its contents, with nest relief occurring at least 3 times a day. The average clutch size is 4. The parents use their webbed feet to warm the eggs, and their body shade to keep them cool. Chicks are naked when hatched after about 4 weeks' incubation. Within 2 days they are covered with white or pale buff down, soon to turn darker brown above. Chicks squeal for food with a closed bill and beg silently for water with an open bill. Very small chicks take fluid from their parents' upper bill as in pelicans and not from the lower bill as in cormorants and gannets. When larger, they take solid bits of food from their parents' throats. They leave the nest after about 5 weeks and fledge when about 7 weeks old. Parents feed their chicks for some time after fledging. G.F. van T.

DARWINISM: see EVOLUTION.

DARWIN'S FINCHES: (alternative Galapagos Finches) general term for the Geospizinae, usually classified as a subfamily of the Fringillidae (Passeriformes, suborder Oscines). Opinions differ on the exact number of species and genera. 14 species are generally placed in 6 genera; *Geospiza* (ground finches), *Camarhynchus* (tree finches), *Cactospiza* (woodpecker and mangrove finches), *Platyspiza* (vegetarian finch), *Certhidea* (warbler finch) and *Pinaroloxias* (Cocos Island finch).

All the finches are found on the Galapagos archipelago which straddles the Equator 1,000 km west of Ecuador, except *Pinaroloxias inornata* which is on Cocos Island about 700 km north-east of Galapagos. These islands have been formed by volcanic activity in the last 5 million years and have never been connected to the mainland. Since all Darwin's finches are more similar to each other in anatomical and behavioural

Medium Ground Finch *Geospiza fortis* landing on land iguana in Galapagos. (*Photo: F. Pölking*).

characteristics than to any living species on the central or South American mainland, they are believed to be the product of a single over-water colonization followed by repeated evolutionary divergence and speciation on the different islands. They are of general importance for two reasons. First, they contributed to the development of Darwin's theory of evolution by natural selection. Second, they provide an unusually clear example of allopatric speciation and adaptive radiation.

Characteristics and song. The finches are 10–15 cm in length and weigh 8–40 g. There are plumage differences between genera, most noticeably among males. Females vary from streaked brown to olive. Immature males resemble females, but older males may develop a fully black plumage (*Geospiza* and *Pinaroloxias*), a black head and upper breast only (*Camarhynchus* and *Platyspiza*) or no black feathers at all (*Cactospiza* and *Certhidea*). Song is more differentiated. No two species have the same song. Populations of the same species on different islands sing different songs. There are frequently two or three song types within a population, but it is rare for an individual (male) to sing more than one type. There is territorial advertising song; also a song described as a hiss or a whistle, that occurs often in courtship when the males are stimulated by the presence of females.

Habitat. Ground finches occur mainly at low altitudes in arid zone vegetation. Tree finches occur mainly at higher altitudes in more mesic vegetation.

Populations and movements. Up to 10 species occur together on the central islands of the Galapagos group. Populations appear to be limited by food in the dry season. In a drought year population sizes may fall to about 10–20% of initial numbers. Short-eared Owls *Asio flammeus*, hawks *Buteo galapagoensis*, herons *Butorides striatus*, *Nyctanassa violacea*, and egret *Casmerodius alba* prey on finches, mainly on nestlings and fledglings. Altitudinal movements of the seed-eating finches occur, and inter-island movement is a recurrent, occasional phenomenon. In recent times only one population is known to have gone extinct. Human activities on Isla Santa Cruz were probably responsible for the disappearance of *G. difficilis*. In the last century, after Darwin's visit in 1835, *G. magnirostris* became extinct on Islas San Cristóbal and Floreana.

Food and beaks. Darwin's finches have adaptively differentiated in beak form. Beak size and shape is clearly related to diet, most conspicuously to that in the cool–dry season (June to December) when food is generally scarce. *Certhidea* (warbler finch) has a fine beak with which it feeds on small insects and spiders. The beaks of some of the ground finches (*Geospiza*) have a steep profile which makes them suitable for cracking seeds, and the largest species in the genus (*magnirostris*) cracks much harder and larger seeds than does the smallest (*fuliginosa*). *Camarhynchus psittacula* has a powerful blunt beak, used for extracting insects and termites from wood by bark-ripping and twig-breaking, while the tit-like *C. parvulus* has a smaller beak of similar shape which it uses to take smaller insects from the surfaces of twigs and leaves. The bullfinch-like beak of *Platyspiza* is used to feed, as in the European Bullfinch *Pyrrhula pyrrhula*, on buds, as well as on leaves. The long and slightly decurved bills of *G. scandens* and *G. conirostris* (on Isla Genovesa) are used to probe into *Opuntia* flowers for nectar.

Two feeding habits are unusual. The 2 species in the genus *Cactospiza* break off a twig or leaf petiole, grip it in the beak and use it by probing to excavate insect larvae and termites beneath bark and in cavities in branches. *Cactospiza pallidus* also uses *Opuntia* cactus spines to this end. On Isla Wolf and Darwin only, *G. difficilis* individuals draw blood from moulting boobies *Sula* by pecking at the developing feathers at the base of the tail; then they drink it.

Some populations are unusually variable in beak dimensions. The significance of this variation is not fully understood, but it is known that the smallest and largest members of some populations have somewhat different diets.

Behaviour. All species are territorial, and monogamy is the rule. They exhibit similar courtship postures and movements. Males build several nests and display at either their own or other nests, even those of other species, to attract a female. The female chooses a nest and lines it.

Breeding. All species build nests with domed roofs and side entrances, in cactus bushes and trees in the branches and twigs. They lay up to 6 (average 4) white eggs with orange or brown spots or streaks, and have similar incubation (*c.* 12 days) and nestling periods (13–15 days). Hybridization occurs, even intergenerically, but is apparently very rare.

DAW: popular abbreviation of JACKDAW (see CROW (1)).

DAWN CHORUS: name given to burst of spring song from many species in a more or less fixed order, beginning before and continuing after local dawn, then dying almost abruptly away; for its function, see under ROOSTING. There is a lesser peak of song at dusk.

DAYAL-BIRD: alternative name (variously spelt), in India, of the Magpie Robin *Copsychus saularis* (see THRUSH).

DEATH-RATE: see AGE; ECOLOGY.

DECOMPOSED: apart from its ordinary meaning, a rather ambiguous term sometimes applied to feathers, e.g. ornamental plumes, of which the vanes are incoherent because the barbules on adjacent barbs do not engage.

DECOY: derived from Dutch words 'eende' meaning ducks and 'kooi' meaning cage or trap, a duck decoy being a device constructed on the edge of a lake, or round a pond specially dug for the purpose, in which wild ducks *Anas* spp. etc. are caught. Typically the device is set in a woodland and consists of a pond of 0.5–1.5 ha, from which radiate 4 to 8 'pipes'—curved tapering ditches, each covered by a tapering tunnel of netting stretched over semicircular hoops. The pipes may be 50–70 m long, 5–8 m wide at the mouth and the hoops at the mouth 2–5 m above the water. The success of the system depends on the mobbing behaviour of ducks when confronted with a predator. By using a trained dog which the ducks will follow, the decoyman entices them into the pipe. Along the outside of the curve is a range of 2 m high screens in an overlapping pattern; these work on the principle of a sunblind, hiding the decoyman from the birds on the pond but allowing him to be seen by those in the pipe. In between these high screens, and making in plan a zig-zag pattern, are screens about 50 cm high known as 'dog-leaps'.

On many quite small decoy ponds a thousand, sometimes several thousand, ducks may be resting during the day. Selecting the best pipe for the wind direction, the decoyman peeps through a tiny slit in one of the screens near the mouth of the pipe. If the ducks are suitably placed he signals to the dog, which then jumps over the dog-leap, runs round the screen *away* from the ducks and returns to its master over the next dog-leap. Immediately, the ducks start to swim towards the pipe, apparently drawn partly by bravado and partly by curiosity. The process is repeated round the next screen, and the next; watching through each successive 'peep hole' the decoyman gradually works the dog up the pipe, the ducks following often only a few metres behind. When as many as possible have been drawn in (it may be only one or two, or it may be 70) the decoyman or a colleague runs silently by a screened path to the mouth of the pipe and appears suddenly to the ducks in the pipe. He is in the outermost gap in the screens, known as the 'show place'. The retreat of the ducks to the open pond appears to be cut off and they try to escape by flying farther up the ever narrowing pipe. The decoyman follows, constantly in their sight through the gaps in the screens, until he drives the birds into the detachable 'tunnel net' at the end. Meanwhile the remaining birds on the pond have seen nothing but the dog and are therefore undisturbed. Such catches may be made several times in a day.

The device was perfected in Holland in the late 16th century. More than 200 decoys were built in England, although only a handful now remain and are used for ringing and research. Some of those in Holland still send thousands of ducks to market each year; in 1956 it was estimated that some 300,000 ducks were caught in the 100 remaining Dutch decoys. The first and only decoy in the New World was built at the Delta Waterfowl Research Station in Manitoba, Canada, in 1949.

There are many variants on the method described above. Cats and ferrets have been successfully used instead of dogs, and also stuffed foxes and stuffed stoats. In certain decoys tame ducks are trained to come for food, offered either in conjunction with the appearance of the dog or by itself to the accompaniment of a soft whistle. These decoy ducks lead their wild fellows but do not react to the appearance of the decoyman and so are not caught. Tame ducks used in a similar way to entice their fellows to destruction in wildfowling (or 'duck hunting' as it is called in North America) are frequently described as 'decoy ducks' or 'decoys', and the word also includes dummy birds used to attract wild ones within gunshot. From this usage the word 'decoy' has been further extended to human deceptions. P.S.

DEFAECATION: see DROPPINGS.

DEFINITION: in taxonomy, see under DESCRIPTION.

DEFINITIVE PLUMAGE: the adult plumage finally assumed by species which show differing plumages previously (see PLUMAGE).

DELTOID: see MUSCULATURE.

DEME: term (used more by botanists than by zoologists) for a local population that can in some way be considered separately from other populations of the same species. The deme has no status in nomenclature, and the term may thus be useful in the discussion of what is often an essentially fluid situation, wherein adherence to rigid concepts of taxonomy would obscure the reality (see SUBSPECIES; SYSTEMATICS).

DEMOISELLE: see CRANE.

DENDROCOLAPTIDAE: see under PASSERIFORMES, suborder Deutero-Oscines; WOODCREEPER.

DENDROCYGNINI: see DUCK.

DENSITY: see AGGRESSION; COLONIALITY; FLOCKING; TERRITORY.

DENSITY COMPENSATION: compensatory increase in abundance of a species in the absence of competing species with which, elsewhere, it coexists (or compensatory decrease in the reverse situation, though the term is less often used in this sense).

Density compensation has been reported most commonly from islands colonized by one species but not by its competitors. It presumably happens because food or other important limiting resources are more abundant when not being used by the competitors. Density compensation has been reported for several bird populations on islands supporting reduced numbers of potential competitors, but it is by no means a universal phenomenon.

DENSITY DEPENDENCE: see ECOLOGY (Population dynamics).

DENTARY: a paired bone of the lower jaw (see SKULL).

DERMIS: the inner layer of the SKIN.

DERTRUM: term sometimes applied to the tip or hook (if any) of the upper mandible (see BILL).

DESCENDENT MOULT: term applied to moult of primary feathers, in which sequential loss of adjacent feathers proceeds from the innermost to the outermost feather (see MOULT).

DESCRIPTION: term used in taxonomy for a statement of the observed taxonomic characters of a specimen or a taxon. A 'definition' or 'diagnosis' is a statement only of the distinguishing characters of a taxon.

DESERT BIRDS: see ADAPTATIONS, ENVIRONMENTAL.

DESIGNATION: term used in taxonomy for the express act of an author in fixing the type specimen or type species of a taxon, or in stating a type locality (see NOMENCLATURE; TYPE LOCALITY; TYPE SPECIES; TYPE SPECIMEN).

DESMOGNATHOUS: see PALATE.

DETERMINATE LAYERS: species in which the number of eggs laid in a clutch cannot be altered by the addition or removal of eggs during laying (see LAYING).

DEUTERO-OSCINES: one of the two suborders of PASSERIFORMES, a name introduced by Voous 1977 (Ibis 119: 224).

DEVELOPMENT, EMBRYONIC: from fertilization of the egg-cell (ovum) to emergence of the young bird from the shell (see EGG; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; GROWTH; HATCHING).

Embryonic processes in birds are most often studied using the domestic hen *Gallus gallus* since the eggs are easy to obtain, but it is likely that all birds develop in essentially the same manner. However, the time of incubation may vary from as little as 11 days to as much as 2 months, and the level of maturity at hatching may also vary (see YOUNG BIRD).

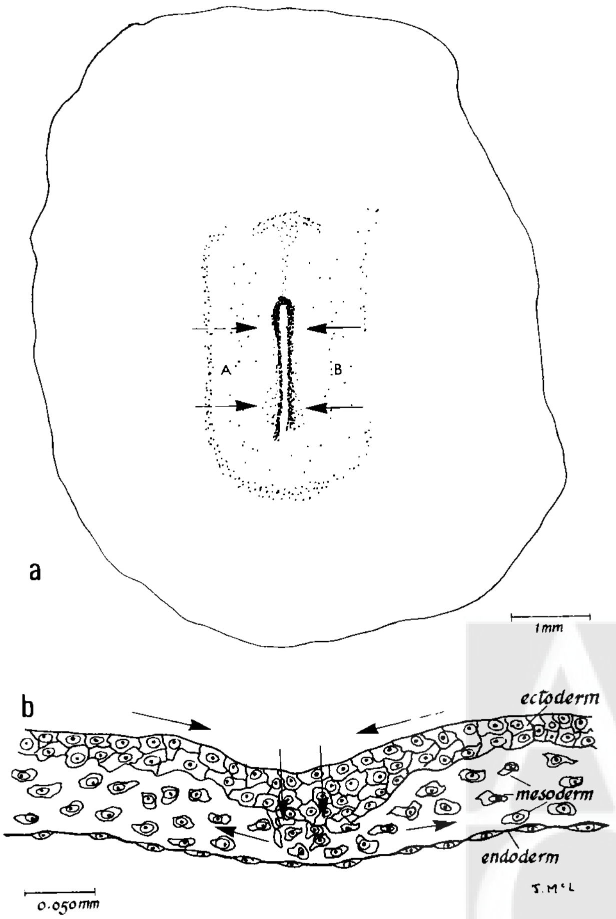

Fig. 1(a). The embryo lies at the surface of the yolk, and the yolk always rotates so that the embryo comes to lie uppermost. After a few hours of incubation, the chick embryo lies in the centre of an expanding disc of cells. The surface cells are flowing in the direction of the arrows towards the midline, where they sink down through the ectoderm. This midline marks where the backbone will form.

(b). A slice through the embryo between the points (A) and (B) shows how the cells migrate out towards the sides again, forming the mesoderm which lies between the ectoderm and the endoderm.

Development up to fertilization. Cells normally contain 2 complete copies of the genetic information used in making the adult. In the ovary, however, a 'meiotic' cell division occurs so that each germ cell contains only one copy of the genetic information. This genetic information, carried on molecules of DNA, is localized in the 'pronucleus'. The germ cells, now known as 'oocytes', then grow very slowly inside follicles in the ovary (reaching about 6 mm in diameter in the domestic hen), then they pause. When external and internal conditions are appropriate, a few of the oocytes will suddenly begin to increase enormously in size, reaching 40 mm in diameter in the domestic hen within about 9 days. This increase in size is caused by the cells of the follicle wall secreting particles of yellow yolk into the oocyte through the transparent membrane (known as the vitelline membrane) which surrounds it. The pronucleus remains at the periphery of the germ cell. Release of the oocyte occurs when the follicle ruptures along a predetermined band, and the oocyte then enters the upper part of the oviduct.

Fertilization. Sperm from the male, which like the oocytes contains only one copy of the genetic information, may be stored in the oviduct after mating and used to fertilize a number of eggs. Several sperm may enter the female oocyte, but only one will fuse with the pronucleus, restoring the number of complete sets of genetic information to 2 and enabling further development to proceed. It is, however, sometimes possible for development to begin without fertilization, and in some birds, notably turkeys *Meleagris*, full development can occur, giving rise to a chick carrying genetic information only from the mother—a parthenogenetic or virgin birth (see PARTHENOGENESIS).

Development up to laying. The fertilized egg continues to move down the oviduct, propelled by contractions of the oviduct wall. The upper part of the oviduct is lined with various glands which secrete the albumen or egg white, and the membranes which wrap round the egg, while the shell itself is secreted in the lower part of the oviduct, which is known as the uterus. The egg spends about 24 hours in the oviduct, and is normally laid as soon as it is completed. All this time cell division is taking place, so that when the egg is laid the embryo is composed of several thousand cells. The volume of the yolk is so enormous that the whole egg cannot be partitioned by the early cell divisions; instead the embryo lies as a small circular patch of cells at the periphery. Development can now pause for a short period without harm to the embryo until the parent begins incubation, which may be some days later if there are several eggs in the clutch.

The first days of incubation. The yolk is surrounded by the transparent vitelline membrane. The disc of cells which will give rise to the embryo lies inside this membrane, and the periphery of the disc adheres to it. Even by the time the egg is laid, the embryonic disc has separated into two layers with a space between them and, in the hours after laying, the cells of the upper layer begin to flow towards the mid-line of the disc (see Fig. 1a and b). There they pour through into the underlying space and begin to spread out again towards the edges. The embryo now consists of three layers: the uppermost is called the ectoderm, and will give rise to the skin, the nervous system, and the brain: the middle layer is called the mesoderm, and gives rise to muscles, bones, cartilage, tendons, as well as to some internal organs such as the heart and kidneys: and the lower layer, which lies next to the yolk and is known as the endoderm, gives rise to the lining of the gut, the stomach, the liver, and the lungs. The line through which the cells migrated to the inside marks out the main body axis and, beginning at the end which corresponds to the head, the ectoderm begins to form itself into a tube (see Fig. 2a and b). This, called the neural tube in the embryo, will become the spinal cord in the adult, and the main nerves will grow out from it. The first part to form also begins to bulge in various places to give a complex secondary structure; and this fore-part of the neural tube will form the brain.

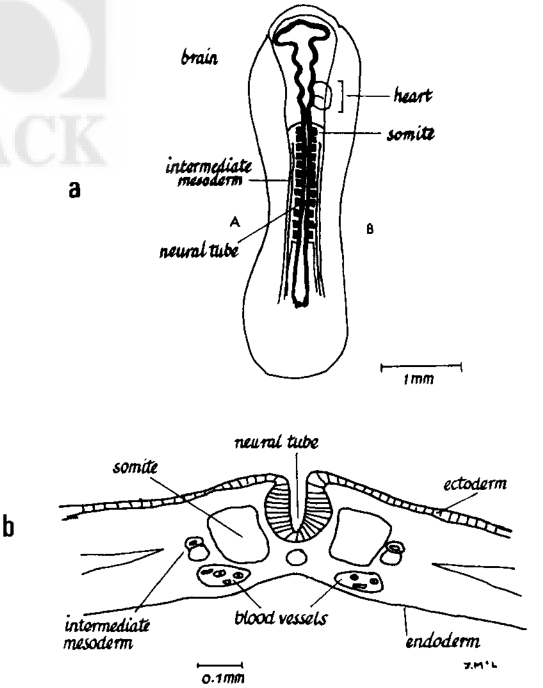

Fig. 2(a). After 48 hours of incubation, the ectoderm has rolled up to form the neural tube at the midline, and at the head end this has begun to form the complex structure of the brain. The mesoderm has formed the somites, the heart, and the intermediate mesoderm.

(b). A slice through points (A) and (B), in (a), reveals how the neural tube is sinking into the mesoderm.

While this is happening in the ectoderm, complex things are also happening in the mesoderm. On either side of the neural tube, which has sunk down from the ectoderm, pairs of small square condensations appear, beginning at the head end. These are called the somites (Fig. 2a and b). Part of each somite will grow round the neural tube to meet its neighbour on the other side, turning into cartilage as it does so. This cartilage is later replaced by bone in the same pattern, and becomes the vertebrae surrounding the neural tube. Other parts of the somite turn into muscle, and cells move out from these into the rest of the mesoderm to give rise to the skeletal muscles of the body. On either side of the somite rows the intermediate mesoderm is beginning to form tiny tubules which carry out the functions of primitive kidneys, filtering out waste materials.

Near the head end, where no somites form, a thickening appears in the mesoderm on each side of the embryo, and gradually these cells arrange themselves into a pair of tubes. These move towards the mid-line, under the neural tube, and fuse to form a single tube, which soon begins to twitch, and then to beat, revealing itself as the heart (Fig. 2a and b).

The endodermal tissues such as gut and lungs are not formed till later in development than the mesodermal tissues, since their functions in the adult are carried out by other structures in the embryo.

Extra-embryonic membranes. The developing embryo has 4 major concerns: air, food, waste disposal and something to sit on. It meets these problems by a set of remarkable structures which operate only in the embryo, and are discarded or resorbed at hatching. After hatching, of course, quite separate ways of meeting these needs are employed. It is convenient to deal with the problems facing the embryo in reverse order. Figure 3 is a guide through the rather complicated relationships of the various membranes.

Mechanical support. The membranes on either side of the embryo rise up, come together, and fuse, so that the embryo is trapped in a small space which subsequently becomes filled with fluid. This corresponds in function to the amniotic fluid of mammals, and is known by the same name (Fig. 3b).

Waste disposal. The waste products of metabolism (mainly uric acid in the chick embryo) are poisonous. The embryonic kidney tubules therefore pour them into an impermeable bag, called the allantois, emerging from the tail end of the gut. The allantois grows out into a space formed by a split in the mesoderm outside the embryo proper. It gets bigger and bigger with time as the yolk is used up, and eventually is left behind in the shell when the chick hatches.

Nutrient supply. The embryo is surrounded by a rich nutrient supply in the yolk. At first the embryo is so small and flat that enough nutrient material for its needs can diffuse into it, but this will only work over short distances, and the embryo soon becomes too large. At this point the *extra-embryonic circulation* takes over. As described above, the margin of the embryonic disc adheres to the underside of the vitelline membrane surrounding the yolk. The edge cells begin to migrate outwards, and the cells behind them divide to keep pace, so that the embryonic disc begins to expand. The mesoderm splits into two layers with a gap between them: the upper layer, together with the ectoderm, is called the chorion, and the lower, together with the endoderm, is called the yolk sac (Fig. 3). Little red spots begin to appear in the yolk sac; these are composed of differentiating red blood cells. Short lengths of tubule begin to appear in the yolk sac also, and link up to form a network of vessels which finally connect to the heart, which is already beating. Blood is carried in a set pattern out from the embryo proper through the thin-walled extra-embryonic yolk sac, where it can pick up nutrients from the yolk over which it passes. To aid in nutrient collection, the yolk sac is also thrown into folds, which increase its surface area. Then the blood is gathered in a blood vessel which runs in a circle just behind the advancing edge of cells, and flows back through veins to the heart, whence it is pumped through the embryo. The extra-embryonic vascular circulation is resorbed back into the gut round about the time of hatching.

Embryonic respiration. At about 5 days of incubation, the allantois fuses with the overlying chorion, and the combination 'chorio-allantoic' membrane rapidly grows round the inside of the shell. The allantois starts off as a bag-shaped structure which contains the poisonous waste products, so the inside surface of the bag must be impermeable. The outside of the bag, however, is covered with thin-walled blood vessels, and these are now pressed against the inside of the shell. The chorio-allantoic membrane now acts as a 'lung': oxygen diffuses through the shell into the blood vessels, and carbon dioxide diffuses out of the blood vessels and out through the shell. When the embryo begins to breathe the air in the air-space just before hatching, the chorio-allantoic membrane detaches and gets left behind in the shell.

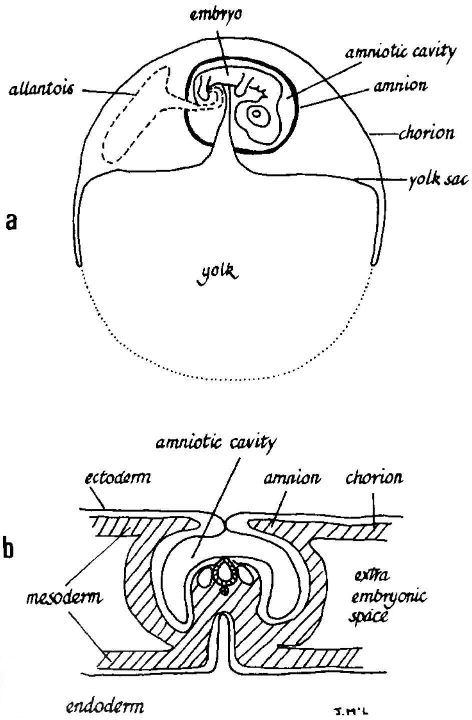

Fig. 3(a). A diagram of the relationships of the extra-embryonic membranes, looking at the embryo from the side.
(b). A stage a few days after that shown in Fig. 3(a).

Formation of the limbs. Once the plan of the body axis is established by 2 days of incubation, the *Gallus* embryo begins to roll over on to one side and rise up off the yolk. It is at first largely tubular but, after between 60 and 72 hours of incubation, 2 pairs of bulges begin to grow out from the flanks. By 3 days of incubation, these are distinct buds (see Fig. 4); and their growth continues as they give rise to the limbs. Cartilage begins to condense visibly in the centre of the limb buds at 5 days of incubation, and forms recognizable elements almost immediately: by 10 days of incubation, a tiny model of the limb can be seen, perfect

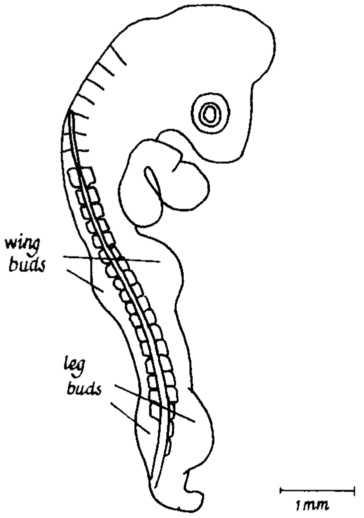

Fig. 4. Outline of the embryo at 3.5 days of incubation, showing the limb buds growing out from the flanks.

in all its details except size (see Fig. 6a). The cartilage elements are easiest to see; but muscles, blood vessels, tendons, and nerves are also present in the same pattern as the adult. At about this time, the cartilage begins to be replaced by bone, and this will continue throughout the growth up to and after hatching. It is not known why the embryo has to form a cartilage model of each bony element in advance of bone formation.

Formation of the internal organs. The splitting of the mesoderm described above takes place inside the body of the embryo as well as outside. It is the uppermost of these two layers which contributes mesoderm to the limbs. The lower gives rise to some of the internal organs. The development of the sexual organs is particularly curious. Twin ridges arise from the mesoderm on either side of the main axis but down towards the tail. These are invaded by cells from the extra-embryonic mesoderm from beyond the head. These primordial germ cells will eventually turn into the eggs or sperm. Depending on the sex of the animal, the mesodermal ridges, up to now identical in both sexes, will develop either into testes or ovaries. If the animal is female, only the left ovary will continue to develop, and it will move over towards the mid-line. This may be an adaptation for flight: two ovaries both full of maturing oocytes are probably just too heavy to carry.

Formation of gut and lungs. As the yolk sac becomes smaller and smaller, the endoderm begins to grow round it and take on the appearance and position of the normal gut. Up towards the head, a small hollow bud appears as an outgrowth from each side of the gut, and these continue to grow and branch until they are clearly recognizable as the rudiments of the lungs. These become functional before hatching, when the chick sticks its beak into the air-space, and this means that the chorio-allantoic membrane becomes redundant, and can be left behind on hatching.

Formation of feathers. At about 8 days of incubation in the domestic hen, dense condensations begin to form in the mesoderm of the back just under the ectoderm. One line forms first above the spine, and then others form on either side of this, covering the gaps in the preceding line so that eventually a hexagonal pattern develops. The mesodermal condensation begins to expand, raising a little lump covered by ectoderm, which will eventually grow into a long thin finger shape. Inside the ectodermal covering the mesoderm differentiates into a central barb with pairs of strands growing out round the inside of the finger, but not meeting on the opposite surface. Finally the ectoderm splits, and the fully formed feather uncurls. See also FEATHER.

Mechanisms of development. Development is still one of the great unsolved mysteries of biology, but some clues are frequently gained by experiments carried out directly on the developing avian embryo. Since the embryo cannot feel pain until the sensory nervous system has developed, operations can be carried out without causing distress to the embryo or to the experimenter. Some examples are given below.

Development of the heart. The heart develops from the fusion of paired structures arising from the mesoderm. If this fusion is prevented by the insertion of a small barrier, then each of the structures will form a functioning heart by itself. This may be a fail-safe mechanism which corrects for defects arising on one side of the embryo. If the heart is removed from an early embryo, and dissociated to single cells which are then cultured separately in glass or plastic dishes filled with nutrient fluid, then each individual cell can be seen to contract and expand rhythmically on its own. If two such cells come in contact, the rhythm of the slower changes to that of the faster almost immediately, and this will continue as more and more cells come in contact with the original group so that the whole clump is expanding and contracting synchronously. This indicates that the beating of the heart is due to a basic property of its cells.

Development of the limb. Limbs develop from buds which grow out from the flank. These are composed of mesoderm covered with a layer of ectoderm which is mostly one cell thick, but at the tip of the limb is pushed up into a ridge which is several cells thick—the Apical Ectodermal Ridge (AER) (see Fig. 5a). If this is cut off, the limb which develops from the bud is truncated at a level which depends on the time at which the AER was removed: if it is removed early in bud development, then nothing beyond the elbow may develop; if it is removed slightly later, then the limb may be truncated at the wrist; and later still, it may be truncated in the middle of the digits. This indicates that the parts of the limb are laid down in sequence, rather than being formed at once, then gradually expanding. If an AER is grafted on to the flank of a young embryo just at the time when the limb buds are beginning to grow out, then it will induce an extra limb to grow out. Together these experiments show that the AER is necessary for limb outgrowth. However, it is believed that a small piece of tissue on the edge of the wing bud nearest the tail (see Fig. 5b) acts with the AER to give the actual form of the limb, for if it is removed and grafted to the opposite edge of another limb bud, then the limb which forms is reduplicated in the head to tail axis (Fig. 6b). This phenomenon probably underlies the development of all vertebrate limbs, because if the corresponding region is removed from the developing embryos of a whole variety of animals, including the mouse *Mus* and the tortoise *Testudo*, and grafted to the chick limb bud in the same way, they are all capable of bringing about such a reduplication. The extra parts are always characteristic of the chick, not the donor. Such experiments on limb formation are of vital importance in understanding how limb defects, such as those brought about by Thalidomide, are caused.

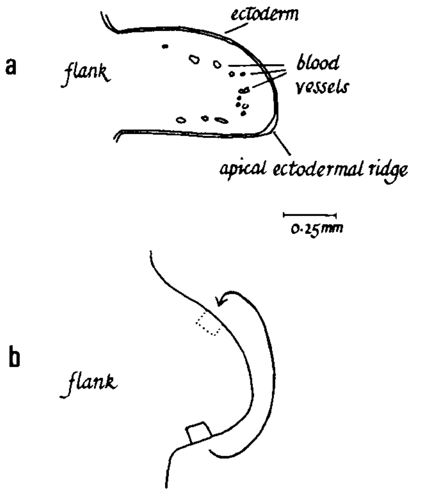

Fig. 5(a). A section through a wing bud after 4 days of incubation, showing the apical ectodermal ridge at the distal tip. Note that there are no blood vessels in the core of the limb where the cartilage is going to form.

(b). A small piece of tissue may be removed from the posterior edge and grafted to the anterior edge of a wing after 4 days of incubation. The result of this operation is shown in Fig. 6(b). The converse experiment (anterior tissue to posterior) has no effect.

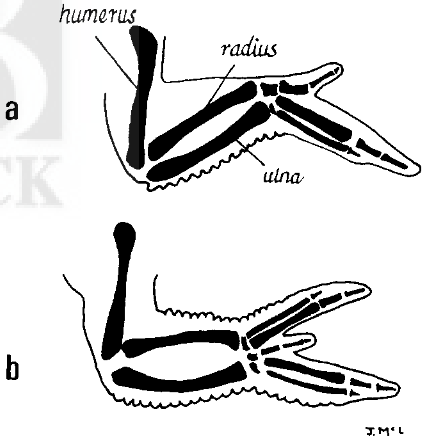

Fig. 6(a). A normal wing bud after 10 days of incubation. The cartilage elements have been stained dark and the remaining tissue made transparent. The form of the wing is very much that of the adult—apart from scale.

(b). 10-day limb after the operation shown in Fig. 5(b). The limb has reduplicated in the anterior-posterior axis from the elbow onwards.

Development of the feather germs. The feather germs develop as mesodermal outgrowths covered with ectoderm, not unlike limb buds, though smaller. However, here it can be shown that the ectoderm does not bring about the outgrowth. A small square of skin containing both ectoderm and mesoderm can be removed from the embryo, just before the feather germs form, and grown in a dish. The ectoderm can be removed, rotated through 90° and replaced. When the feather germs appear, they do so in the pattern characteristic of the mesoderm rather than the ectoderm. On the leg, scales form rather than feathers, and again, the mesoderm controls where they form. If a piece of back ectoderm is rotated and replaced on leg mesoderm, feathers form, but they do so with a distribution characteristic of scales. Curiously, however, if Vitamin A is applied to the developing embryo, feathers rather than scales form on the legs, and this is reminiscent of the owls, which naturally have feathers rather than scales in this position.

The colour of feathers depends in part on pigment cells which move out through the body from the neural tube. They seem capable of recognizing where they are and of going to the right place—even if they are placed in the wrong animal. So pigment cells from the 'Barred' variety of chicken if placed in the embryo of the 'White Leghorn' will migrate to the appropriate places and give a barred pattern. Similarly, if a piece of skin from a Robin *Erithacus rubecula* embryo is placed in an embryonic chicken wing, then the pigment cells will migrate out and take up their normal distribution, so that the resulting animal has a wing coloured grey and buff like that of a robin. Embryonic thermoregulation. The first distinctive step towards independent regulation of body temperature appears in the domestic fowl on day 7, when thyroid iodine is first produced, and by day 10 chicken embryos are able to produce thyroxine and TSH, two thyroid hormones implicated in temperature regulation. Thyroid activity increases sharply on day 15 and by the following day the chick is able to breathe. The developing embryo initially meets its oxygen requirements by simple diffusion but a circulatory system is already detectable in the domestic fowl after 48 hours. Haemoglobin synthesis can be detected midway through the second day of incubation and the concentration of erythrocytes increases linearly thereafter until hatching. These cells tend to form earlier in precocial species than in altricial species. Heart rate increases between day 4 and day 10 but then decreases slightly as the growing heart is able to cope with a larger volume of blood on each stroke. The oxygen affinity of the blood increases between days 14 and 17, thus contributing further to the embryo's ability to metabolize oxygen.

In altricial species oxygen consumption increases exponentially throughout the incubation period but in precocial species this increase ceases about two-thirds of the way through, thereafter remaining relatively constant.

Oxygen consumption in embryos of different species measured shortly before hatching, i.e. in full-term embryos, is a power function of egg weight according to the equation

$$m = 18.5\,W^{0.730}$$

where m is heat reduction (Kcal/day) and W is fresh egg weight (g). This equation thus describes a double logarithmic regression line, which is parallel to but below the Aschoff–Pohl regressions for adult metabolism on body weight (see METABOLISM). This means that full-term eggs have metabolic intensities about one-third of those prevailing in adults of the same body weight.

The initial energy requirements of the embryo are met by carbohydrate metabolism and once the liver has differentiated by about day 6–7 it can synthesize and store glycogen. Most carbohydrate is however drawn from the yolk sac membrane. Embryonic metabolism in domestic fowl embryos increases steeply after day 14 and this is fuelled largely by lipids; about 80% of the lipids in the egg are consumed during this period.

In a number of species eggs are neglected by the parents when the adults have difficulty finding food. Thus Fork-tailed Storm Petrels *Oceanodroma furcata* may absent themselves from their eggs for as long as 28 days and European Swifts *Apus apus* similarly allow their eggs to chill during wet and rainy weather. Their embryos show a number of special physiological adaptations to enforced neglect. Metabolism decreases, with metabolic rates in the Fork-tailed Storm Petrel, for example, increasing daily at only one-third the rate of increase of Japanese Quail *Coturnix japonica* eggs of similar size and taking 50 days for normal incubation (instead of the 21 days expected for a typical egg of that size). The embryos have particularly large stores of embryonic fat to fuel this slow development. Such adaptation is more costly than the normal development patterns but does accommodate to the need to 'switch off' metabolism at times when parental duties are not possible. In such conditions the embryo can continue to develop at temperatures as low as 30°C; if cooled further, e.g. to 10°C, the incubation period is simply prolonged by the corresponding amount. R.J.O'C.

DEVELOPMENT OF BEHAVIOUR: see BEHAVIOUR, DEVELOPMENT OF.

DEVELOPMENT, POST-EMBRYONIC: see GROWTH.

DEVIL BIRD: see SWIFT.

DIABLOTIN: name used in the West Indies for the Black-capped Petrel *Pterodroma hasitata* (see PETREL), and also (Trinidad) for *Steatornis caripensis* (see OILBIRD).

DIACROMYODIAN: see SYRINX.

DIAGNOSIS: in taxonomy, see under DESCRIPTION.

DIAL-BIRD: see DAYAL-BIRD; THRUSH.

DIAMOND-BIRD: alternative substantive name of *Pardalotus* spp. (see PARDALOTE; FLOWERPECKER).

DIAPHRAGM: a system of membranes partially dividing the thoraco-abdominal cavity, so that the lungs and cervical air-sacs occupy one chamber and the majority of the air-sacs another, while the heart and abdominal viscera are in the remaining space (see RESPIRATORY SYSTEM). This arrangement in birds contrasts with the complete and more muscular transverse partition between the thoracic and abdominal cavities in mammals.

DIASTATAXIS: see PLUMAGE; WING.

DICAEIDAE: a family of the PASSERIFORMES, suborder Oscines (see FLOWERPECKER).

DICHROMATIC: having two distinct types of coloration; used with reference either to the two sexes or to two colour MORPHS of a species ('dimorphic' being a loose equivalent, more often used but strictly applying to differences of form).

DICKCISSEL: *Spiza americana* (see CARDINAL-GROSBEAK).

DICRURIDAE: a family of the PASSERIFORMES, suborder Oscines (see DRONGO).

DIDUNCULINAE: see PIGEON.

DIENCEPHALON: part of the forebrain (see NERVOUS SYSTEM).

DIGESTION: see ALIMENTARY SYSTEM; GRIT; NUTRITION; PELLET.

DIGIT: a 'finger' or toe (see LEG; SKELETON, POST-CRANIAL; WING). Primary feathers borne on the wing digits are sometimes called 'digitals'.

DIKKOP: see THICKKNEE.

DIMORPHISM: see POLYMORPHISM; SEXUAL DIMORPHISM.

DINORNITHIDAE: extinct family of STRUTHIONIFORMES; MOA.

DIOCH: substantive name of *Quelea* spp. (see WEAVER).

DIOMEDEIDAE: see under PROCELLARIIFORMES; PETREL.

DIPPER: substantive name of the 4 members of the family Cinclidae (Passeriformes, suborder Oscines); is used without qualification in Britain for *Cinclus cinclus*.

Characteristics. The dippers as a group provide an excellent example of the adaptability of a typical passerine bird to an unusual environment without any very obvious modifications. It would hardly be suspected from a cursory examination of a dipper, even in the hand, that it is a water bird. Its size (*c.* 17–20 cm) and shape are approximately those of the Starling *Sturnus vulgaris*, although the plumage differs in colour and also in being soft and very dense in texture. The flight, too, resembles that of a starling. Whereas most water birds have feet modified in some way for swimming, dippers have feet of the kind normal for a perching bird. When swimming on the surface, the feet of a dipper have to be moved very rapidly indeed because they present only slight resistance to the water. Under water a dipper can walk on the bottom, but it uses its wings for swimming.

Like many other birds, dippers have a third eyelid or nictitating membrane. The dipper's membrane is unusual in being conspicuously white and this shows clearly when the dipper does its characteristic bobbing motion, and at the same time draws the white membranes across the eyes so that the bird appears to blink. When underwater, the third eyelid can be used to clean the eyes and keep them free from particles of matter in suspension.

Habitats. Typically swift-flowing streams or rivers which are cascading down from higher ground. This means that there are usually plenty of boulders and rocks on which dippers can perch beside the water. It also follows that dippers generally frequent hilly or mountainous terrain. But they may occupy stretches of slow-flowing rivers where man has created 'rapids' artificially, e.g. water mills.

Distribution. Mountainous regions of Eurasia, western North America, Central America, and western South America. Like the wrens, it is probable that the dippers originated in tropical America and then spread northwards, first to North America and then westwards to Asia and Europe. They do not occur on the eastern side of North America even where the country is mountainous.

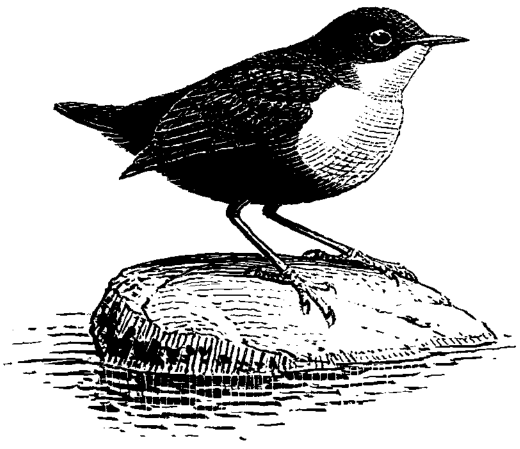
In the Andes there are several races of the White-capped Dipper *C. leucocephalus*. The North American species *C. mexicanus* is found only on the western side of that continent and the Dipper *C. cinclus* is discontinuously distributed in suitable habitats across Asia and Europe with a foothold in north-west Africa. The Brown Dipper *C. pallasii*, a sombre bird, chocolate-brown all over, inhabits mountainous parts of Asia eastwards to Japan. In the Himalayas, where the distribution of *C. cinclus* overlaps *C. pallasii*, the latter tends to frequent the lower levels from the foothills upwards, the former mostly from 2,000 m, and both species may reach heights of over 4,000 m.

Populations. Dippers are stricly limited by their habitat requirements. An average of 4–6 territories per 10 km of river is typical of British rivers (Marchant and Hyde 1980).

Movements. Dippers' movements are largely dictated by the severity of the weather. In montane populations there is some altitudinal shift with the seasons to escape the rigours of the higher regions in winter. In the colder northernmost part of the range, there is a movement south in winter. Apart from these movements, dippers are non-migratory.

Food. The diet consists of many kinds of small water creatures living in fast-flowing streams and rivers. The list of prey includes caddis-fly and dragon-fly larvae, small aquatic molluscs and crustaceans, worms, tadpoles and very small fish. When feeding, a Dipper will often wade into shallow water and snap up underwater creatures within reach. For feeding in deeper water a Dipper will wade further out and dive to the bottom, propelled downwards with powerful beats of its wings. Sometimes a Dipper will plunge off a stone or even from flight into the water and dive below. It can rise straight out of the water after a dive and fly off. In a remarkable film by J.W. Jones of a wild Dipper taken through the glass side of a fish-hatchery tank, the bird is seen swimming with a sustained effort of the wings to keep down; it only took ova which were exposed and made no attempt to uncover those which were buried in the usual way. Like many other birds, dippers eject pellets of indigestible material through the mouth.

Behaviour. Dippers cannot be described as sociable birds. They typically are well spaced out along the watercourses they inhabit. Pairs hold territories of several hundred metres. In one respect Dippers might seem to be sociable: they may roost communally. Up to a couple of dozen may use a roost under a bridge, but the main advantage appears to be that of shelter, especially from the wind (Shaw 1979).



Dipper *Cinclus cinclus*. (*D.W.*).

The Dipper has a display which resembles that of the Robin *Erithacus rubecula*. In both species two birds may face each other with beaks pointing straight upwards so that in the case of the Dipper the white bib is made as conspicuous as possible, just as in the Robin the red breast is prominently displayed. When a pair meet after being separated for a while they often face each other and posture in this way. The sexes are similar in both Dipper and Robin, and there are times when the females sing.

Voice. The call-note of the Dipper is a strident *zit*, *zit*, which may be given from a boulder or in flight. The song resembles that of a Wren *Troglodytes troglodytes* in being loud and penetrating, and like the call-note it can be heard above the roar of a cascading torrent.

Breeding. Nesting dippers require sites close to water. Usually there is water immediately below the nest. A typical natural nest site is in a steep bank overhanging the river, but man-made sites are often provided by recesses in bridges, or in walls that face a river. Sometimes a nest is close to or even under a waterfall, so that it is constantly wetted by spray. The domed nest is composed mainly of moss with a lining of dead grass and a few dead leaves. The clutch of 4 or 5 white eggs is laid early compared with most birds; in Britain it is usually in April, but sometimes earlier. Incubation is 16 days, fledging 20–24 days. The young disperse soon after leaving the nest. A second brood is sometimes reared. H.G.H.

DISEASE: may be defined as a departure from the normal state of health. Many injurious agents enter the body or may be produced in the body and bring about disease. Such agents include micro-organisms, parasites and poisonous substances. Deficiencies of food substances such as vitamins and minerals also cause disease, as do metabolic disorders and degenerative processes. All these conditions may cause biochemical changes in cells, leading to structural alterations which may be microscopic or macroscopic in nature. Such alterations in cells and tissues are called lesions.

Lesions are sometimes specific for the cause, e.g. inclusion bodies in certain viral diseases, but usually several different causes may produce very similar changes and effects. The primary cause of disease may act locally or be widespread through the body. Frequently primary lesions have a secondary action elsewhere in the body.

Disease occurs in domestic, free-living and captive birds. Some types of disease are more often associated with particular environmental conditions or with particular groups of birds. Much is known of the diseases of domestic poultry and of birds kept in captivity in zoological gardens, but relatively little collected information is available on the diseases of free-living wild birds.

The part played by disease in regulating populations of wild birds is not yet clear but in general it appears that numbers are controlled primarily by food supply and that disease is one of several factors of secondary importance (see ECOLOGY).

In some cases food shortage and disease may act together, since dense populations help the spread of disease and also reduce the available food. Climatic factors are also often linked to food supply and disease. The bird's resistance to disease may be lowered by poor nutrition or by sudden changes in temperature; thus abnormal heat or abnormal cold may cause heavy losses either directly or by predisposing to infectious disease or to the production of toxic substances (see later). Sustained wet and cold weather is liable to bring on pulmonary disease, a common source of trouble in young birds, especially of the nidifugous species, the main change being one of acute congestion and oedema of the lungs. It is probable that the poor heat-regulating mechanism of the young chick is also a factor in the development of this syndrome of 'chilling' (see HEAT REGULATION).

Wet weather, on the other hand, may increase food supply by allowing birds to catch more worms and molluscs. This, however, may be a disadvantage in that such animals act as intermediate hosts for many parasites and thus a well-fed nestling may receive a pathogenic burden of parasites such as the massive infection with trematodes sometimes seen in waders (Charadriidae) and gulls (Laridae). Periods of drought, conversely, increase the concentration of birds at drinking and bathing places and thus facilitate the spread of infectious diseases such as salmonellosis. A similar situation sometimes arises when birds are attracted in large numbers to confined supplies of food and water in times of severe winter weather, for example at garden feeding centres.

Diseases caused by pathogenic micro-organisms, fungi, bacteria, rickettsiae and viruses are known as the infectious diseases; when diseases are spread by contact, either direct or indirect, they are termed contagious diseases. Illnesses and death may also be caused by toxic substances, which may be produced by micro-organisms or by man in the wide range of chemicals which are used in industry, agriculture and horticulture, in particular the various pesticides and herbicides (see TOXIC CHEMICALS).

Emphasis will be placed here on some of the more important diseases of free-living wild birds; detailed reference to diseases in domestic birds should be sought in the standard textbooks of poultry disease.

Bacterial and fungal diseases:

Aspergillosis. This disease is due to infection with a mould, usually *Aspergillus fumigatus*, which is commonly present in decaying vegetable matter. Infection occurs when the bird inhales or ingests the spores of the fungus, producing lesions chiefly in the lungs and the air sacs. The pulmonary lesions vary in size from 1 or 2 mm to nodules several centimetres across: the air sacs may be converted into thick-walled sacs with caseous, necrotic (pus) centres; in some instances the air sac lining is covered by a greenish-blue mould. Sometimes the disease is widespread in the body, and many organs, including the brain, may be affected. Aspergillosis has been recorded in many species of birds, and occasionally occurs in large outbreaks with heavy mortality. Waterfowl and game-birds are particularly susceptible, especially when kept in a semi-wild state. The disease is also frequently seen in penguins kept in captivity. It is sometimes associated with other conditions such as salmonellosis and in cases occurring in captive exotic species stress and malnutrition play important parts in initiating infection.

Thrush, also called Candidiasis, Moniliasis and 'sour crop', is a mycotic infection of the digestive tract of birds. Thrush is most often seen in chickens, pigeons, geese, turkeys, pheasants, quail, grouse, and psittacine birds. The cause is a fungus, *Candida albicans*, and in young birds serious losses may occur in aviaries and bird gardens.

Ringworm or favus is caused by a fungus *Trichophyton gallinae*. It occurs chiefly in chickens and turkeys, but is also seen in pigeons and small passerines. Infection occurs chiefly about the head. There is partial or complete feather loss and the head may be covered with scales and sometimes scabs.

Avian cholera. This acute septicaemic disease is caused by a bacterium *Pasteurella multocida*. Most, if not all, species of birds are susceptible. The disease may occur in enzootic form with a high death rate, but more often sporadic cases occur. Exceptionally, very large outbreaks with large-scale mortality occur in waterfowl on migration or at their wintering grounds. As with many other diseases stress factors are important in initiating outbreaks. The chief lesions are multiple small haemorrhages on the body surfaces and, usually, small foci of necrosis in the liver.

Erysipelas. This disease, an acute septicaemia, caused by *Erysipelothrix rhusiopathiae* a Gram-positive bacillus, affects many species of animals both domestic and free-living. The organism can live for long periods in the soil. A wide range of avian species is susceptible and disease due to this organism is of economic consequence in bird parks, zoological gardens and especially domestic animals.

Listeriosis. Several forms of this disease, caused by the bacterium *Listeria monocytogenes*, occur in birds and mammals throughout the world. The avian disease is sometimes septicaemic in nature but its principal importance is that infected birds constitute reservoirs of infection for other animals.

Salmonellosis. Infections of birds with *Salmonella* bacteria are common and create important problems in the poultry industry. Wild birds sometimes harbour the organisms and may show lesions at post mortem examination. Both acute septicaemic and chronic forms of the disease are encountered. Usually the liver and spleen show lesions in the form of grey or white nodules scattered through the substance of the organ; there may be translucent nodules in the lungs. *Sal. typhi-murium* is the species most often isolated from wild birds. The organisms are excreted in the droppings, which thus serve as further sources of infection. It is not unusual for a build-up of infection to occur around drinking places and artificial feeding areas such as bird tables in gardens. Outbreaks have been recorded in Greenfinches *Carduelis chloris* and House Sparrows *Passer domesticus* under such circumstances. Salmonellosis sometimes occurs in epidemic form in gulls, probably as a result of their scavenging propensities.

Tuberculosis. The avian type of *Mycobacterium tuberculosis* is a common cause of the disease in birds, which become infected by ingestion of the organism. Affected birds frequently excrete the bacilli in vast quantities and so spread the infection. The incidence of the disease is variable and is higher in some species than in others, but all birds are susceptible. One survey of gulls revealed a 10.3% infection amongst 97 examined and in another survey approximately 4% of Woodpigeons *Columba palumbus* were affected. Avian predators become infected from their prey. The disease affects many organs and most commonly produces lesions in the liver, spleen and gut. The tuberculous lesions are nodular, white and cheesy in consistence, varying a good deal in size. Parrots are susceptible to the human type of tubercle bacillus as well as to the avian one.

Yersiniosis. This disease, also known as pseudo-tuberculosis, is frequently encountered in birds and mammals. It is due to the bacterium *Yersinia* (*Pasteurella*) *pseudo-tuberculosis* and occurs both as a sporadic and as an epizootic disease. Major outbreaks occur in Canaries *Serinus canaria* and other caged songbirds, and the disease has been reported in at least 12 orders of birds in many areas of the world. Stress factors are important in the development of outbreaks. Characteristic lesions, yellowish-white in colour and approximately 1–2 mm in diameter, occur in the liver and spleen, although in many acute cases only septicaemic lesions may be present.

Mycoplasmosis. Many serotypes of mycoplasmas have been isolated from birds; in particular raptors and psittacines may be infected. Some of the mycoplasmas cause disease of economic importance in domestic poultry. *Mycoplasma gallisepticum* occurs in chickens *Gallus gallus*, turkeys *Meleagris gallopavo*, pheasants, Chukar Partridge *Alectoris chukar* and Bobwhite Quail *Colinus virginianus*, as well as in other species, in all of which it produces a chronic respiratory disease, one form of which is coryza. *Mycoplasma synoviae* is responsible for infectious conditions of the joints and tendon sheaths of birds.

Coryza. This term is applied to infections of the upper respiratory tract of birds. It is a condition with many similarities to the human common cold. Some forms are infectious and occur most frequently in domestic poultry and game birds. The usual causes are the bacterium *Haemophilus gallinarum* and *Mycoplasma* spp., but several agents produce identical clinical signs and mixed infections are common. It is also associated with specific diseases such as Ornithosis and Newcastle Disease. Affected birds have discharges from the eyes and nostrils and the infraorbital sinus is frequently over-filled with mucus and purulent exudates. This disease may become chronic and extend to the air sacs.

Botulism. An anaerobic bacterial organism *Clostridium botulinum* produces a powerful exotoxin that is responsible for a serious and fatal form of food poisoning in man and animals. Various types of the organism occur; type C most often affects birds. The importance of botulism in birds is illustrated by the fact that millions of waterfowl die from it each year throughout the world. The toxin is formed when the anaerobic organism multiplies in water containing decaying vegetation, dead fish and, in particular, large quantities of dead insect matter on which birds feed. Outbreaks occur most often during the summer months when prolonged spells of fine weather with resulting high temperatures, low water levels, oxygen depletion and alkalinity of the water lead to rapid bacterial multiplication and hence the production of large quantities of toxin. Ducks are so often affected that the condition is termed 'duck sickness'. The disease is not, however, confined to waterfowl and birds of at least 21 families are known to have been affected. Extensive and severe outbreaks of botulism have been recorded in many parts of the world on game bird farms, especially pheasant rearing units. Intoxication and death follow the ingestion of blowfly larvae, *Calliphora* spp., which contain the toxin. Botulinum toxin may be carried through the larval and pupal stages to the adult insect. Major outbreaks sometimes occur in gulls which have fed on contaminated refuse dumps and many shore birds may be killed feeding in toxin-contaminated tidal estuaries.

It seems probable that spores of *Cl. botulinum* can be transferred on the plumage, the feet and via the excreta of birds. Mud samples from lakes, rivers, mud flats, etc. sometimes show a high incidence of several types of the organism and thus when environmental conditions become suitable, explosive outbreaks of the disease may occur.

Botulin toxin produces its effects on the nervous system, the chief clinical feature being a flaccid paralysis preventing the birds from flying; often the neck is held to one side, hence the term 'limber neck' used in this disease. Leg paralysis is also a common sign. Birds die from respiratory failure or from drowning.

Psittacosis or Ornithosis. Sometimes called Chlamydiosis, since it is caused by *Chlamydia psittaci*, this disease is a systemic, contagious, serious disease of birds and mammals. In the parrot family it is usually referred to as Psittacosis and the same condition in non-psittacines is termed Ornithosis. The disease has a world-wide distribution and has been identified in at least 17 orders of birds. Numerous strains of the organism have been found in many species, varying greatly in their pathogenicity and virulence. The disease is often endemic in wild populations and susceptibility is a function chiefly of age and species. Psittacines, ducks, geese, gulls, petrels and pigeons are perhaps most frequently affected, but over 140 species have been found to be infected. Infection often occurs at the nestling stage and severe disease may be precipitated by stress factors.

In birds there are no characteristic clinical signs and at autopsy an enlarged spleen may be the only lesion. Some avian cases may have necrotic foci in the liver and spleen and there may be fibrinous deposits on the pericardium and liver.

Viral diseases:

Arboviruses. These have recently been designated togaviruses. In general this group of viruses produce little clinical disease in birds but they are of importance in that they may cause encephalitis in man and other mammals, birds acting as reservoirs of infection. Mosquitoes, mites and ticks are the biological vectors and birds are infected usually at the nestling stage.

Avian leucosis complex. A complex group of diseases characterized by abnormal production of white blood cells and consequent changes in the organs and tissues. As a result of multiplication of the stem cells of the blood, tumour-like swellings are produced. These diseases are of great importance in domestic fowls and similar conditions have been recorded from game birds and owls.

Avian pox. This viral disease has been reported in at least 60 species of birds from 20 families. Several strains of the virus occur with different degrees of specificity. The strains affecting small passerines appear to be more host-specific than others. The disease usually presents in one of two forms. The common type is a cutaneous infection involving chiefly the head region but also the feet and legs; less frequently there is infection of the mucous membranes of the upper respiratory and digestive tracts. The other, internal, form was at one time called 'avian diphtheria'. The disease is usually mild in character, but young birds may suffer severe mortality and large numbers of roosting birds are often involved at one time, e.g. outbreaks have been seen in roosts of House Sparrows and Tree Sparrows *Passer montanus*. The disease is common in domestic gallinaceous birds and wild populations. In Canaries kept in bird rooms and aviaries there may be extensive, severe outbreaks with high mortality.

Herpesvirus infections. Several herpesviruses infect birds. One affecting homing pigeons *Columba livia* and other members of the Columbidae causes a serious disease which is characterized by, amongst other things, intranuclear inclusion bodies in the cells of the liver. Similar viruses occur in other species and the disease they produce is sometimes called '*inclusion body disease of raptors*' since it has been recorded in several species of falcons and owls. Affected birds have focal necrosis of liver cells and also parts of the reticulo-endothelial system. Herpesviruses have been recovered from psittacine birds with Pacheco's parrot disease.

In the domestic fowl a herpesvirus is responsible for an important respiratory disease known as *infectious laryngotracheitis*.

Marek's disease. This is one of the most common lympho-proliferative diseases of the domestic fowl and it is also recorded in several other species of bird. The cause is a herpesvirus which produces an infiltration of nerves, viscera, gonads and other tissues by mononuclear cells. It is of major importance in the poultry industry.

Duck plague. Also known as *duck virus enteritis* this is a serious, acute, contagious and often fatal herpesvirus infection of domestic ducks, geese and swans. Present also in free-living waterfowl, it probably has a world-wide distribution. The disease is apparently density-dependent and is more liable to occur under stress conditions. The disease is principally one affecting ducks and is characterized by high mortality. There are multiple haemorrhages throughout the body and diphtheritic membranes on the oesophagus and elsewhere. Many types of cells are attacked by the virus and undergo necrosis.

Myxoviruses and Para-myxoviruses. Members of this large group of viruses are responsible for serious epidemics amongst birds and mammals. In addition they are important in that some of these viruses which occur in wildlife populations may be progenitors of some human pandemic strains. Examples include:

Influenza A viruses, isolated from feral and domestic ducks, terns, gulls, shearwaters (Procellariidae), guillemots (Alcidae) and from a variety of cage birds from India and S.E. Asia. Also viral antibodies, indicating previous infections, have been found in the blood of many species of migratory birds. These influenza viruses in free-ranging birds have been suggested as the source of viruses responsible for outbreaks of disease in domestic livestock. It is apparent that diverse influenza A viruses circulate in waterfowl outside their breeding areas and along their migratory routes.

Fowl plague is a good example of a highly pathogenic member of the myxoviruses. The disease spreads rapidly in poultry and results in a high mortality. 'Fowl Pest' is the term used to embrace both this condition and Newcastle disease.

Newcastle disease, caused by a world-wide multistrain paramyxovirus, is one of the most serious diseases of the domestic fowl. The disease also occurs in representatives of most orders of birds. The various strains affect the central nervous system, the respiratory tract and the digestive system. Acute, chronic and symptomless forms of the disease occur. One major outbreak in the USA, which resulted in the deaths of millions of birds, was traced back to the importation of psittacine birds.

Quail disease. Several enzootic diseases occur in quail and there is sometimes confusion over what is meant by quail disease. *Quail bronchitis*, a fatal disease due to an adenovirus, occurs in the Bobwhite on game farms. The main lesions are confined to the respiratory tract. A more widespread and serious disease is *Ulcerative enteritis of quail*, also called quail disease, a bacterial disease caused by *Clostridium colinum*, which attacks many species of quail as well as, amongst other species, Ruffed Grouse *Bonasa umbellus*, Grey Partridge *Perdix perdix*, Pheasant *Phasianus colchicus*, and young domestic chicken and turkey poults. There may be 100% mortality in some outbreaks. At autopsy there is usually a severe haemorrhagic enteritis, sometimes with extensive ulceration of the gut lining.

Puffinosis. This is a viral disease affecting seabirds. First described in Manx Shearwaters *Puffinus puffinus*, it produces lesions on the webs and sometimes the eyes in these birds as well as in several species of gulls and in the Oystercatcher *Haematopus ostralegus* and Fulmar *Fulmarus glacialis.* There is evidence that the virus persists in Trombiculid mites.

Protozoal infections. Many protozoa parasitize birds, but few of them are pathogenic. They are to be found in many tissues of the body. Genera of the suborder Haemosporina are important pathogens, e.g. *Plasmodium* spp. which cause avian as well as human malaria, the parasites being transmitted by mosquitoes and undergoing complicated life cycles, the details of which differ in man and birds. The parasitized erythrocytes (red cells) break down at intervals, causing the symptoms and producing anaemia. *Plasmodium gallinaceum* produces a high mortality in domestic fowls. It is believed that the junglefowl is its natural host.

Blood parasites of the genus *Haemoproteus*, transmitted by louse-flies (Hippoboscidae) and midges (Ceratopogonidae), are common in many species of birds and occasionally cause disease. *Leucocytozoon* spp. occur in the white blood cells of birds as well as in the red cells. They are common in wild birds and also cause disease in many species of domestic birds. Leucocytozoon species are transmitted by blackflies *Simulium*. *Besnoitia* spp., sporozoan parasites, cause outbreaks of disease in Knots *Calidris canutus*, and probably other birds, with death following injury to blood vessels of the intestines.

Lankesterellosis is caused by *Lankesterella* spp. which parasitize lymphocytes and monocytes of birds. They are transmitted chiefly by mites.

Parasites of the order Eucoccidiorida, which includes the coccidia, are of importance in domestic poultry. They are responsible for the disease *Coccidiosis*. The infective oocyst is ingested by a bird and a multiplication cycle then occurs in the parasitized tissue, which is usually the intestine. Serious damage to the gut cells results in disease and death. See also ENDOPARASITE and ECTOPARASITE.

Non-infectious conditions: examples include:

Amyloidosis. A disease with multiple causes seen in a wide variety of birds principally in zoological gardens. Most susceptible of all are some species of waterfowl, but many wading birds, which do not adapt well to an artificial environment, such as Common Snipe *Gallinago gallinago*, sandpiper spp. (Scolopacidae) and Oystercatcher, may also have a high incidence. Amyloidosis is often associated also with chronic diseases like tuberculosis and aspergillosis. It is recognized by the deposition of amyloid material in tissues such as the liver and spleen and consequent malfunctioning of these organs.

Deficiency diseases. Lack or imbalance of amino-acids, proteins, carbohydrates, fats, minerals, water, and vitamins may lead to disease and death. Common signs of a deficiency disease include retarded or stunted growth, poor feathering, certain bone conditions and poor reproduction. Much is known of this group of diseases in domestic birds but little of the nutritional requirements of wild birds in nature. Young Mallard *Anas platyrhynchos* are sometimes affected with a disease characterized by lack of head feathers, and this appears to be due to a deficiency of vitamins of the B complex. Deficiencies of thiamine (Vitamin B_1) have been recognized in several species of captive raptors and lack of Vitamin A together with mineral insufficiency may also occur in these birds if they are fed an all-meat diet. Vitamin D_3 deficiency resulting in rickets occurs in captive birds deprived of adequate sunlight and on diets supplemented by Vitamin D only. Bone abnormalities occur in the Cape Vulture *Gyps coprotheres* due to lack of calcium in the diet when there is a shortage of carrion; this may be a factor in the decline of the species in South Africa.

Gout. A metabolic disorder characterized by the deposition of uric acid and urates in the tissues of the body. The disease is caused by an impaired blood clearance of uric acid due to kidney disease or metabolic dysfunction. It probably occurs in all birds but is most often seen in domestic poultry and aviary-kept falcons, eagles, hawks and owls. It appears to be uncommon in free-living wild birds.

Disorders of the female reproductive system. These are not uncommon, and cause considerable economic loss in the domestic poultry industry. One survey indicated an incidence of 8.9% in 88 species of 6 orders of birds. The most frequent abnormality is obstruction of the oviduct and ectopic ovulation.

Disorders of the cardiovascular system. Spontaneous arterial disease is seen in aviary kept birds and also occurs in free-living wild birds, but its real incidence is unknown. The frequency of occurrence of vascular degenerative disease varies amongst the different avian orders; arteriosclerosis, atherosclerosis, arteritis, arteriopathy, aneurysms and amyloidosis have all been described.

Tumours. Neoplasms (malignant new growths) are common in birds, and may arise from any organ or tissue. Some of them are of viral origin, and in domestic poultry an intensive study has been made of their properties and characters. One viral-induced tumour is a squamous cell papilloma which appears to be specific for Chaffinches *Fringilla coelebs*. It results in warty growths on the legs and claws. The Budgerigar *Melopsittacus undulatus* is particularly susceptible to neoplasia and incidences as high as 24.2% have been recorded.

Poisons. Many poisonous substances cause disease in birds. Some are biological toxins such as *Clos. botulinum* toxin (see above). Another is saxitoxin, produced by dinoflagellates. Saxitoxin causes paralytic 'shellfish poisoning', the outbreaks being associated with 'water-bloom' or a RED TIDE. Under certain suitable conditions there may be an over-production of flagellates and ciliates in the sea, some of which produce a potent neurotoxin which is picked up by filter-feeding molluscs and by sand eels *Ammodytes* spp. Saxitoxin is thus accumulated during the development of food chains and when cockles *Cardium*, mussels *Mytilus*, sand eels, scallops *Pecten* or queens *Chlamys* are eaten by man or birds, poisoning ensues. Terns, Shag *Phalacrocorax aristotelis* and Eider *Somateria mollissima* are the most commonly affected birds. There are differences in susceptibility to saxitoxin between the various avian species.

Chemical poisons affecting birds include the metals lead and mercury, many insecticides, herbicides and pesticides. *Lead poisoning* is a common and serious disease chiefly seen in waterfowl, usually resulting from the ingestion of lead pellets or lead fishing weights. Lead is a cumulative poison and is slowly absorbed from the tissues. Mortality due to lead on some migration routes and in areas which have been shot over for many years may be high; in some localities it is estimated to be from 5–10% of wildfowl using the area. The chief signs are loss of weight, lethargy and, in the later stages, muscle paralysis. *Mercury poisoning* usually results from the ingestion of seeds dressed with fungicides and from contamination of rivers and estuaries with effluents containing the metal. Mercury is another cumulative poison and may be present in many organisms. High levels may develop in seed- and fish-eating birds and in their predators with fatal results.

Pesticides may have serious and long-lasting effects on birds, species at the end of food chains being the most susceptible. The pesticides of greatest significance appear to be the organochlorine compounds, DDT and its analogues aldrin, dieldrin, heptachlor and heptachlor epoxide. The reported effects of these compounds include paralysis, delayed breeding, infertile eggs, reduced eggshell thickness and adult and embryonic mortality. A.R.J.

DISPERSAL: term used in general sense to describe non-breeding movements of birds away from areas of high density. So, for example, departure on a daily or seasonal basis from a roost or breeding colony to visit feeding sites may be referred to as dispersal.

More particularly, the term describes the movement of an individual from its birthplace to a breeding locality or between a series of breeding localities, and may be divided into two categories. Natal dispersal is the movement an animal makes from its site or group of birth to the site or group where it reproduces or would have reproduced if it had survived and found a mate. This can be distinguished from breeding dispersal, which is the movement of an animal, which has reproduced, between successive breeding groups or sites. When successful reproduction follows dispersal the movement can be described as effective. To facilitate comparisons between species, dispersal should be measured in terms of the spatial dispersion of individuals within a species and not in terms of distance.

Species differences. Some species show high levels of dispersal within all age groups. They are usually referred to as nomadic (see MIGRATION; NOMADISM). Examples include seed-eaters (e.g. Crossbill *Loxia curvirostra*, Nutcracker *Nucifraga caryocatactes*) and rodent predators (e.g. Snowy Owl *Nyctea scandiaca*, Rough-legged Buzzard *Buteo lagopus*) of Arctic regions which are subject to periodic fluctuations in their food supply. Species which inhabit arid areas with unpredictable rainfall (e.g. honeyeaters in Australia) may also have periods of nomadism, settling to breed where the food supply becomes locally abundant. Birds of this type frequently undergo periodic irruptions to areas outside their normal breeding range (see IRRUPTION).

Many species of birds exhibit relatively low levels of natal and breeding dispersal and the distributions are heavily skewed towards the point of origin. Examples range from the colonially breeding albatrosses (Diomedeidae), gulls and terns to numerous passerines such as the Great Tit *Parus major*, Pied Flycatcher *Ficedula hypoleuca* and Song Sparrow *Zonotrichia melodia*. Such species can be described as philopatric.

Age differences. Although many species are philopatric, only a proportion of individuals of any species is faithful to one locality. Almost invariably natal dispersal is much more widespread than breeding dispersal. Thus juvenile Great Tits, on average, move 4–7 territory widths from birth to breeding site whereas adults return to within one territory's width of their previous breeding site (Greenwood *et al* 1979). This age difference in dispersal is shown by many other species. There may also be a tendency for breeding birds to become more philopatric with age. Such site tenacity is usually assumed to have arisen from the advantages which individuals may gain from increasing familiarity with an area (e.g. locations of feeding sites and predators).

Sex differences. Sex differences in dispersal occur in a taxonomically wide range of philopatric species. Female-biased dispersal has been reported in the majority for both natal and breeding dispersal (see Table). Thus, amongst adult Pied Flycatchers in a Scandinavian population, 93% of males but only 37% of females returned each year to their first nesting locality: 61% of females nested in a different place each year (von Haartman 1949). Striking examples of sex differences in natal dispersal occur in certain species of communal breeders (e.g. babblers *Turdoides* spp., Florida Scrub Jay *Aphelocoma coerulescens*). Male jays normally remain within their territory of birth throughout life whereas the majority of females breed elsewhere. Female-biased dispersal occurs in species where males defend resources (e.g. territory) in order to attract females. Exceptions to this prevalent pattern of female-biased dispersal occur in one family, the Anatidae. For example, in the Lesser Snow Goose *Anser caerulescens* males return to the females' natal colony to breed. Male-biased dispersal occurs in species where males are primarily concerned with guarding and defending their mates and not resources (Greenwood 1980) (see MATING SYSTEM).

PREDOMINANT DISPERSING SEX

	NATAL			BREEDING		
	Male	Female	Both	Male	Female	Both
Species	3	21	6	3	25	1
Families	1	11	5	1	14	1

Table of sex differences in natal and breeding dispersal of birds. The number of species and families of birds with female biased and male biased dispersal and those in which males and females disperse equally. The data are from a wide range of passerine and non-passerine groups (from Greenwood 1980).

Causes. There are a number of factors which cause dispersal. Marked changes in the distribution of food resources accentuate dispersal. In more stable habitats, population density is a major influence on dispersal. Some individuals may be prevented from breeding in their natal area and forced to disperse. They are often the socially subordinate, younger and weaker members of the population. In the Song Sparrow the dispersal of juveniles is probably a consequence of many of the adults re-establishing their old territories. Subordinate birds are excluded from optimal breeding habitats in the Red Grouse *Lagopus lagopus*, whilst in several species of passerines offspring from second broods may disperse further than those from first broods.

Density and aggressive interactions mediated through density are not the only factors to influence dispersal. In many cases birds, particularly adult females, will change to a new nesting site following an unsuccessful breeding attempt. Amongst juveniles of species which are highly philopatric, those which select a breeding locality too near to their birthplace may increase the chance of mating with a close relative. It is known from a number of laboratory studies that the reproductive success of individuals which inbreed is lower than that of animals which mate with a non-relative. In natural populations, close inbreeding has been reported in the Great Tit, Yellow-eyed Penguin *Megadyptes antipodes*, Song Sparrow and Acorn Woodpecker *Melanerpes formicivorus*. In the one study where it was possible to measure the reproductive costs of inbreeding, nestling mortality of Great Tits was nearly twice as high among inbreeding pairs as among outbreeding pairs. The sex difference in natal dispersal close to the birth site in sedentary species may have evolved as a means of minimizing the chances of mating with a close relative and thereby avoiding the detrimental effects of inbreeding.

Consequences. Dispersal can have substantial effects on the genetic structure of populations. Since dispersal is a prerequisite for gene flow, widespread movement may disrupt local adaptations. Limited dispersal or philopatry may lead to the genetic differentiation of neighbouring groups. Genetic differences between neighbouring populations of the White-crowned Sparrow *Zonotrichia leucophrys* are associated with differences in song. The dialects may act as a barrier to movement between the two groups (Baker and Mewaldt 1978) (see VOCALIZATION). Philopatry of individuals to their natal group or area also provides conditions which facilitate the evolution of cooperation between close relatives. For example, in some communal breeders, e.g. Florida Scrub Jay, young males help their parents to rear offspring in the territory of their birth. Eventually they may secure a territory adjacent to the parental one or inherit the natal site on the death of their father. Male philopatry is clearly correlated with the evolution of this type of patrilineal social organization (Greenwood 1980). P.J.G.

DISPERSION: the state of spatial separation between individuals of a flock, colony, or population. Dispersion changes in time due to the processes of DISPERSAL from which term it should be distinguished (see AGGRESSION; ECOLOGY; FLOCKING; TERRITORY).

DISPLACEMENT ACTIVITY: term describing movements which appear to the observer to be out of context or to occur in a situation in which they seem irrelevant. Thus a gull in a dispute with a territorial neighbour may suddenly start to pull at grass, a component of nest building behaviour. In a similar situation, fighting Red Burmese Junglefowl *Gallus gallus* frequently peck at food on the ground without ingesting it, while a Chaffinch *Fringilla coelebs* mobbing an owl will often wipe its beak on a perch in an apparently irrelevant grooming movement. Much has been written about why behaviour patterns occur out of context but it is important to realize that labelling such an occurrence as a displacement activity is in no way an explanation: it simply indicates a phenomenon that has to be explained (Tinbergen 1952). It is because it explains nothing that the term has tended to fall from use in recent years.

The most commonly proposed theory for the causation of displacement activities is that they occur when the animal is thwarted or in a state of motivational conflict. Unable to perform the behaviour pattern or patterns of highest priority, the animal carries out an alternative, less relevant, behaviour. Conflict was originally seen as between drives or instincts, the dammed up energy from which was thought to 'spark-over' and activate another system (Tinbergen). Thus a fighting bird in a conflict between aggression and escape might suddenly show grooming behaviour without any stimuli appropriate to grooming being present. This view has been modified by subsequent research. Because behaviour (see BEHAVIOUR, HISTORY OF) cannot be thought of as caused by discrete and easily separated drives, it has become more usual to refer to conflict as being between tendencies or between motor patterns which are incompatible. Displacement activities have also been found to be affected by stimuli relevant to themselves: for example, a bird in a conflict situation will show more grooming if its plumage is wet (C.H.F. Rowell). Rather than being motivated by one of the conflicting systems, it has been proposed that displacement activities occur because of a phenomenon known as disinhibition: when the conflicting tendencies suppress one another this removes their inhibition on other activities so that the behaviour next in priority is able to appear (McFarland 1966).

Although still influential and attractive (Baerends 1975), the conflict theory for the causation of displacement activities is open to the objection that it could too easily explain anything. It is easy to postulate conflicting tendencies, but not easy to measure or observe them; furthermore, in cases where displacement activities have become ritualized as displays (see below) it can be argued that the original conflict may no longer exist, making the idea even more difficult to disprove. In any case, given the heterogeneous nature of displacement activities, it is essential that alternative possibilities are borne in mind. One of these is that the preceding behaviour pattern may cause the displacement activity directly: for example, an energetic display may lead to dishevelment of the plumage and thus to grooming. Alternatively, the posture of the bird may be such as to bring it into contact with the appropriate external stimulus for the activity so that it is elicited in the normal manner even though apparently out of context. Beak-wiping as a bird turns round on a perch may be an example of this, in which case it is not necessary to propose that it occurs because approach and avoidance are in equilibrium.

Words such as 'brief', 'incomplete', 'hurried' or 'frantic' are often applied to displacement activities. These suggest that, even though stimuli for that behaviour pattern may be present, the performance is not having its usual function. Where conflict is involved, this may be because the conflict is resolved rapidly and inhibition on the displacement activity is re-established before its usual goal is achieved. It has, however, been suggested that displacement activities may have important functions additional to those normally served by the same behaviour patterns performed in context. Lowering of arousal, the achievement of a shift in motivation and the reduction in alarm of a fighting bird are three possible effects for which there is some evidence. Thus displacement activities may, in some circumstances, have motivational effects which are beneficial to the animal showing them.

Whatever their original causation and function, there is no doubt that displacement activities have been a rich source of movements which have subsequently evolved into social signals (see DISPLAY; RITUALIZATION). In courtship behaviour striking examples are the preening of an enlarged wing feather by male Mandarin Ducks *Aix galericulata* and the beak wiping of male estrildine finches which is, in some species, reduced to little more than a nod as they approach the female. Ritualization has led such behaviour patterns to become highly stereotyped and clearly recognizable as signals. In the process, they have lost their original functions: signals derived from preening movements have, for example, no further use in feather maintenance. Analysis of the contexts in which these displays occur suggests that the messages they signal often indicate ambivalence: this may be taken as evidence for an underlying conflict or, more simply and descriptively, as indicating that the animal may do one of two things (e.g. escape or attack) depending on the response shown by its partner. DISPLAY: term denoting movements that have become specialized in the course of evolution to serve as 'signals' in social communication. Although it is usually restricted to visual signals, many primarily visual signals are associated with characteristic calls; and visual and auditory signals may both have a display function. The discussion here is primarily concerned with visual signals.

Functional aspects. Display movements can be roughly classified according to the context in which they appear.

Fulmars *Fulmarus glacialis* displaying. Note distension of neck of left-hand bird. (*Photo: B. Zonfrillo*).

Threat. These movements are used in encounters with rivals, and indicate the potential aggressiveness of the displaying individual. They can be seen as signals used in negotiation between rivals. Two common types are the 'head forward', in which the body is horizontal and directed towards the rival, and the 'head up', where the bill is pointed upwards and the breast directed towards the opponent. Some species have a repertoire of several different threat postures.

Submissive. These are used between rivals or mates and serve to reduce the aggressiveness of the bird to which the display is directed. Amongst passerines a common submissive posture consists of perching slightly crouched, with the head withdrawn and the body feathers raised. Thus a subordinate bird in a dominance hierarchy will display in this way to a superior, and a receptive female may adopt such a posture at pair formation (see DOMINANCE (2); PAIR FORMATION).

Begging. These are used primarily by juveniles begging for food from their parents, and also in COURTSHIP FEEDING.

Sexual. These are used between mates or potential mates; they serve a variety of functions such as pair formation, maintenance of the pair-bond, reduction of mutual aggressiveness, synchronization of reproductive rhythms, and facilitation of COPULATION.

Greeting and nest-relief. This category overlaps the two previous ones. It

Grey-headed Albatrosses *Diomedea chrysostoma* courtship display. (*Photo: British Antarctic Survey*).

consists of displays given when two individuals meet after a temporary separation, and thus occurs in the contexts of parent/young and male/female relations. These displays probably function in reducing aggression.

Social. These are without obvious sexual or aggressive significance, and are important, for instance, in flock integration (see FLOCKING).

Anti-predator. This includes a number of displays given to predators—for instance, the 'mobbing' displays given by passerines and others to predators, and distraction displays (see DISTRACTION BEHAVIOUR).

Such a classification according to content is useful for many purposes. However, it is important to note that many displays occur in more than one context. In such cases it is useful to distinguish between the 'message', or features of the sender common to all the situations in which the display is given, and the 'meaning', which includes contextual factors that also contribute to the response of the recipient. Thus tyrannid flycatchers have a 'locomotory hesitance vocalization' given in a number of situations in which locomotion is inhibited, but the response of the recipient varies with the nature of the caller (e.g. juvenile, intruding male, etc.) and the context (e.g. position in territory) (Smith 1977).

Although displays function as social signals, this does not necessarily imply an immediate response by the partner. Thus the importance of submissive and greeting displays lies not so much in evoking a response as in inhibiting the aggressiveness of the partner. Further, many courtship displays occur at intervals during periods of maintenance activities, and although they may have long-term stimulatory or pacificatory effects they often seem to produce no immediate changes in the situation.

Smew *Mergus albellus* male and female (on left) courtship display. (*Photo: Y. Shibnev*).

Causation. In nearly all cases that have been analyzed, display movements are associated with tendencies to behave in incompatible ways and are then spoken of as involving an internal 'conflict' between the two or more types of behaviour. In some cases it is profitable to regard the conflict as concerned with incompatible patterns of behaviour: for instance the tail-flicks of many passerine birds occur in situations in which causal factors for flight and for staying put are both present. In other cases there is evidence that the conflict involves higher level 'tendencies'. With aggressive displays, tendencies to attack and flee from the rival are involved. In courtship display, a sexual tendency is involved in addition—although the meaning of 'sexual' here is to be interpreted rather broadly, as many courtship displays are only distantly related to copulation—and sometimes also tendencies to nest-build, preen, etc. In mobbing, the tendencies are to investigate, to attack, and to flee; and in distraction display, conflicting tendencies to show parental behaviour, to attack, and to flee may be involved.

When any one of these tendencies is present alone, the behaviour is simple—e.g. pure attack, escape, or sexual behaviour may be shown. When two or more incompatible tendencies are present, various types of ambivalent behaviour may occur (see AMBIVALENCE), and some instances of this have been specialized in evolution for a communicatory function and thus may be designated as displays. Most species have a large repertoire of display movements, and each is associated with a particular range of strengths and relative strengths of the conflicting tendencies. Thus, where there are several threat postures, each is associated with different values of attacking and fleeing tendencies. Similarly, as the absolute and relative values of the male's tendencies to attack, to flee from, and to behave sexually towards the female change throughout the reproductive season, there are correlated changes in the courtship displays. Often particular components of a display (e.g. crouching, wing raising) are associated primarily with one of the conflicting tendencies; the nature of the display then indicates the motivation. Thus, although the displays of any one species usually fall into a number of fairly distinct types, each type shows considerable variability and there may be intermediates between them.

There are some exceptions to this general rule that display movements are associated with conflicting tendencies. Thus the various components of the soliciting posture of most female passerines all fluctuate together; although the female may change over suddenly from soliciting to aggressive or fleeing behaviour, it may be that the posture itself is purely sexual. Similarly, although the begging displays of young birds may contain aggressive or fleeing components, these may not be essential to the display.

Ontogeny. Display movements characteristic of the species normally appear in individuals on the first occasion that the relevant circumstances arise. Furthermore, the response to display movements made by other individuals is also usually appropriate on the first occasion it arises (see BEHAVIOUR, DEVELOPMENT OF).

Evolution. Display movements are usually characteristic of the species, and are more similar in closely related species than in distantly related ones. The comparative study of display can thus provide evidence about phylogenetic relationships between species. Alternatively, by comparing the displays of species of known phylogenetic relationship, it is possible to form hypotheses about the evolution of the displays.

So far, three evolutionary sources of display movements have been recognized—intention movements (e.g. intention movements of attack, escape, nest building, etc.); displacement activities (used here in the sense of a heterogeneous category of activities appearing in contexts in which they appear to be functionally irrelevant); and redirection activities (see DISPLACEMENT ACTIVITY; REDIRECTION). In addition, displays of one type may be evolved from displays originally used in another context—e.g. courtship feeding from parent/juvenile behaviour, or sexual from aggressive behaviour. In evolution the display movements have been ritualized—i.e. they have become more adapted for a signal function. The changes involved in RITUALIZATION have resulted in the movement becoming more conspicuous and more different from other signal movements of the same species and from signal movements of other species. They consist in:

(*a*) Changes in the form of the movement itself (e.g. changes in the intensity or co-ordination of the components).

(*b*) Changes in the relations between the associated internal and external causal factors and the movement; important here is the development of 'typical intensity', whereby a movement of constant form is given over a wider range of causal factors than that

Little Egret *Egretta garzetta* defensive display. (*Photo: E.J. Hosking*).

which evoked it initially. In this way variability of the movement is reduced and it becomes more efficient as a signal.

(*c*) The development of conspicuous structures that are shown off by the display movement. Since homologous movements in related species often show off different structures, it would seem that the movements must be evolved first and the structures later; but there has undoubtedly been much interaction.

(*d*) Recombination of single displays into various rigid sequences.

In general, the threat and anti-predator displays of related species are more similar than are the courtship displays; and the early courtship displays, functioning in pair formation, diverge more than those used in copulation. This is to be expected on the view that the early pair-forming displays are important in promoting reproductive isolation. There may even be some selective advantage in similarity of the aggressive and anti-predator displays to those of related species. The degree of differentiation between the courtship displays of closely related species renders these displays useful as taxonomic characters, and they have been so used with effect in a number of groups (e.g. Anatidae).

It is not possible here to attempt any description of the variety of display types to be found amongst birds. Often the displays are extremely elaborate—as in the manakins, bowerbirds, or birds-of-paradise, or in those sexually monomorphic species that have intricate reciprocal ceremonies between the mates (e.g. Great Crested Grebe *Podiceps cristatus*)—see articles on the groups named. To what extent the principles discussed in the preceding paragraphs, which have been derived from the study of relatively simple cases, can be applied to these highly ritualized and elaborate cases remains to be seen. R.A.H.

DISTAL: furthest from the centre of the body or from the point of attachment (e.g. of a limb); opposite of PROXIMAL.

DISTRACTION BEHAVIOUR: general term for those active parental anti-predator strategies which aim to deflect a predator or to divert its attention from eggs or young. The terminology of the behaviour is still confused, but attempts to establish elaborate classifications and to substitute synonyms for long-accepted names have not been generally welcomed.

Distraction behaviour includes: (1) stratagems in the form of distraction–lure displays etc; (2) distraction-threats; (3) demonstration; and (4) diverting attacks. They reach their most developed form in ground-nesting birds such as waders (Charadrii). In distraction displays a parent bird presents stimuli to the predator that elicit and direct its prey-seizing responses (distraction-lure display) or alarm it (distraction-threat display). Though the two have been confused, and do intergrade in some species, the functional distinction is clear, the one aiming to induce approach, the other withdrawal. Such displays are species-characteristic in form and type, and are often highly ritualized.

1. Distraction-lure displays and other stratagems are often accompanied by calls serving to attract attention and function as 'tricks' or 'ruses' for deceiving the predator, especially ground predators hunting opportunistically by sight. In addition to a crouching run away from the predator, distraction-lure displays comprise (a) the small-mammal type ('rodent-run', 'rat-trick') in which the resemblance to a scurrying beast may be most realistic, including squealing cries, and (b) the disablement or incapacity type ('injury-feigning', 'broken-wing trick', 'exhausted-bird posture') in which the bird appears to be vulnerable in some way, even acting as if mortally wounded or like a helpless chick; the small-mammal type and the mobile forms of the disablement type are typically performed as the bird retreats from the predator, the stationary forms of the disablement type often with the back to it, though some species may turn and face it at a safe distance. In waders, distraction-lure displays are most likely to occur when the young are most vulnerable: at hatching or when seized by a predator (especially if the young call). Other stratagems of waders include the 'fly-away trick'; ground-pecking (mock or real feeding or the picking up of nest material); mock or real side-throwing of small stones and other 'busy-bird ruses'; pseudo-sleeping; mock-brooding; decoy-brooding; and distraction flights. Special flights round or away from the predator—often in the form of 'impeded-flight' with slow or flicking wing-beats—may serve to draw attention to the bird and its subsequent behaviour on the ground.

New Zealand Dotterel *Charadrius obscurus* distracting predator from nest. (*Photo: G. Moon*).

2. **Distraction-threat displays** involve the spreading of the wings, tail or both in a bold, alarming fashion, sometimes suddenly in a 'flash-' or 'shock-display'. In waders and some other ground-nesting birds, distraction-threat displays may be performed while advancing towards the predator as closely as the bird dares, or from a stationary defensive position over eggs or young, and may lead to attack or to distraction-lure display.

3. **Demonstration** consists of loud and persistent calling from a perch, on the ground, or in the air. The bird often makes itself conspicuous, especially in flight as it 'scolds' the predator while circling; it may also approach aggressively on the ground or more usually in the case of large birds, e.g. Oystercatcher *Haematopus ostralegus*, Avocet *Recurvirostra avosetta*, in mock attack-flight, the bird typically swerving off without striking. Demonstration is akin to MOBBING, especially when performed by 2 or more birds together (see also DISPLAY).

4. **Diverting attacks** tend to follow demonstration, e.g. at the climax of attack-flights, the bird striking the predator with wings, legs or bill. Such an attack may develop in other situations, e.g. from nest-protecting display, the bird fluttering into the face of the predator or pecking it.

DISTRACTION DISPLAY: see DISTRACTION BEHAVIOUR; PARENTAL CARE.

DISTRESS CALLS: loud vocalizations emitted by birds when caught by a predator, a mist-net, or held in the hand. The calls have a harsh, tonal quality and contain a wide range of frequencies. They thus differ from alarm calls given when a predator is merely sighted. Their function may be to startle the predator into releasing his prey. Some distress calls attract conspecifics who mob the predator, but others have the opposite effect and have been broadcast in an attempt to disperse unwanted flocks of birds.

DISTRIBUTION, FREQUENCY: see BIOSTATISTICS.

DISTRIBUTION, GEOGRAPHICAL: the distribution of species or other categories considered in broad terms of range. Since local abundance and local distribution within the limits of the range depend on ecological factors (see ECOLOGY), the range may be limited by the same factors, such as climate or its effect on habitats, habitat availability, or presence of competitors, predators, or prey. Ecology and ZOOGEOGRAPHY thus have broadly overlapping interests. The range boundaries may, however, also be set by evolutionary history, plate tectonics (continental drift), effective dispersal barriers, or the different dispersal abilities of species.

Zoogeographical studies address themselves to various aspects of geographical distribution. The time scale examined may vary from a static 'snap-shot' view of the present distribution to millions of years, and the geographical focus of interest may range from global distribution to distribution on islands or to dynamics of a portion of the range boundary. In addition, the emphasis may be qualitative or quantitative.

In terms of scientific research and the philosophy of science, a distinction can be made between descriptive, analytic, and predictive zoogeography. The descriptive view records facts of distribution, past or present. Analytic zoogeography attempts to relate results of descriptive studies to various causes, ecological or historical. Predictive zoogeography uses theoretical, often mathematically formulated, models in order to derive predictions on patterns of geographical distribution. In recent years, analytic and predictive aspects of zoogeography have developed rapidly, and, at the same time, quantitative approaches and population biology have been increasingly used in order to understand distribution patterns.

Breeding and non-breeding ranges. The breeding range often differs from the non-breeding range because of seasonal migrations or other movements (see MIGRATION). Distribution maps normally take seasonal movements into account. Mapping breeding distributions has progressed far, and detailed range maps are now available for the breeding bird faunas of many countries. For example, the ranges of all bird species breeding in the British Isles have been mapped using a grid of 10 km squares, with several symbols indicating various degrees of certainty of breeding (see ATLAS). The non-breeding range of many temperate-zone species is in the Tropics, where bird distributions are often inadequately known.

The range of a species is usually presented in a qualitative map showing whether the species is present in an area or not. Exact breeding localities of rare species or species breeding in readily found colonies (e.g. seabirds) have also been mapped. Quantitative distribution maps are difficult to obtain because of methodological problems involved in censusing large regions. Since density may vary by several orders of magnitude within the limits of the range, quantitative maps (published, e.g., for many North American and Finnish birds) nevertheless tend to show gradients in average density correctly. Ranges are dynamic (see RANGE CHANGES). Spectacular expansions in the European avifauna include that of the Collared Dove *Streptopelia decaocto* and of the Serin *Serinus serinus*. In Northern Europe, faunistic information shows that Denmark, Norway, Sweden and Finland were colonized by an average of 2.8 species per decade and country in 1850–1970; several species, such as the Lapwing *Vanellus vanellus*, the Black-headed Gull *Larus ridibundus*, or the Scarlet Rosefinch *Carpodacus erythrinus* have expanded there dramatically. On the other hand, many ranges shrink rapidly. Examples include the abrupt decrease and finally the extinction of the once widespread and abundant Passenger Pigeon *Ectopistes migratorius* in North America in the 19th century, or the increased patchiness and contraction of the Western European ranges of the Great Bustard *Otis tarda* or the White Stork *Ciconia ciconia* in recent decades.

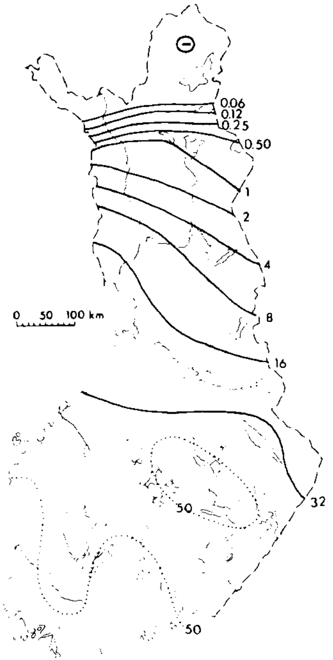
Quantitative data are helpful in understanding dynamic aspects of geographical distribution. The expansion of the Scarlet Rosefinch in Finland was rapid from the 1940s to the 1970s, and it was observed in population ecological studies that increased numbers of Scarlet Rosefinches started breeding in open bushy habitats created by man. The breeding success in this new habitat was observed to be unusually high, and quantitative estimates on the concomitant population increase—the Finnish population increased approximately 30-fold in 30 years—fitted extremely well with observations on the increased breeding success. Thus habitat changes in the Finnish breeding range of the species are a sufficient explanation for the expansion, and no changes in the poorly studied non-breeding range of the species need to be invoked. But in many species changes occurring in the non-breeding range are probably responsible for the changes that can be observed in the expansion or contraction of the breeding range, and vice versa.

Dynamic aspects are relevant also in historical zoogeography. For example, the Old World vultures (see VULTURE (1)) are presently confined to Europe, Africa and Asia, but Tertiary and Quaternary fossils are known from North America, and the place of origin of this taxon may be either the New World or the Old World. No decision can be made on the place of origin of the New World vultures (Cathartidae), either, for Eocene and Oligocene fossils have been found also in Europe, even though the family is presently strictly American.

Kinds of species boundaries. Populations on the periphery of the species range define the species boundary. Regulation of these populations may differ greatly from the regulation of central populations; for example, some peripheral populations may perish without a constant influx of immigrants, but there must also exist populations producing a surplus of emigrants. The boundary may thus fluctuate in response to events in other than peripheral populations. Abundant data show that many range expansions first involve disproportionately numerous young males, and thus the reproductive output of the population at the expanding fringe may be very low.

Species boundaries of insular endemics are well-defined. Equally obvious are many species boundaries determined by the configuration of continental land-masses, for the world oceans are major dispersal barriers for most birds. Even moderate expanses of open sea seem to act as psychological barriers to many species. For example, more than 100 of the bird species breeding on New Guinea have never been recorded on any of the islands surrounding it. European examples of species whose range boundary is partially set by avoidance of moderate sea-crossings include the Green Woodpecker *Picus viridis*, the Marsh Tit *Parus palustris*, and the Nuthatch *Sitta europaea*. Effective dispersal barriers divide continental land-masses and create species boundaries. The Saharan desert, lowland rain-forest or lowland savanna between mountainous areas in the Andes or in Africa, or the Himalayas, provide good examples.

The HABITAT requirements of species may be inflexible and give rise to clear range boundaries. For example, species of rain-forests, deserts, coniferous taiga forests, or oceans, often have their boundaries at least partially set by the availability of their habitats. But many species boundaries run through apparently suitable habitats where there are no obvious dispersal barriers. Birds of the Eastern Siberian taiga differ considerably from the avifauna of Scandinavian coniferous forests, and the distribution of many species in the seemingly uniform Amazonian rain-forest is quite restricted, to take only two examples.



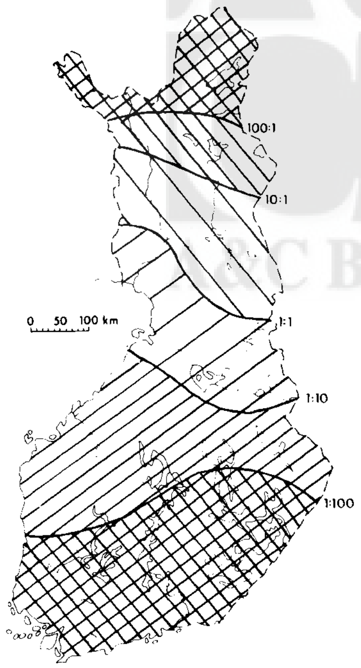


Fig. 1. (*left*) Breeding season densities of the Chaffinch *Fringilla coelebs* (pairs/km^2) in Finland, according to line transect censuses made in 1973–77. True densities are somewhat higher owing to the fact that all birds are not observed in a line transect. Since the proportion of densities at 2 successive lines is 1:2, the northward decline in densities is sharp. (After Järvinen & Väisänen 1981 Studies in Avian Biology).

Fig. 2. (*right*) Ratio of the density of the Brambling *Fringilla montifringilla* to that of the Chaffinch *F. coelebs* in Finland, according to line transect censuses made in 1973–77. The species are ecologically similar and replace each other on a south-to-north gradient. As shown in the figure, there is a 10,000-fold change in the ratio of the densities of the 2 species within about 600 km in Finland. (Redrawn from Järvinen & Väisänen 1979, Oikos).

It is sometimes stated that, in the Northern Hemisphere, northern range boundaries tend to be determined by climate, while southern boundaries are often caused by interspecific competition. But many other factors than climate or competition may be decisive. It is nevertheless true that the climate becomes harsher northwards, in the sense that the percentage of migrants tends to increase northwards, and that the effect of competition may be intensified southwards owing to the general trend that species numbers (often called diversity or preferably, species richness) become progressively higher towards the Equator.

Climatic explanations for enigmatic boundaries are usually supported by a correlation between a particular climatological variable and the range boundary. Such correlations prove nothing, unless independent data are available about the effects of that particular climatological variable on the species. For example, the northern boundary of the Goldcrest *Regulus regulus* has been correlated with a particular isotherm in the breeding season, and this is likely to be biologically meaningful, since the corresponding ambient temperature has been shown to be critical for the survival of the nestlings. Similarly, the ranges of several European species of ducks correlate well with the cold-hardiness of one-day-old ducklings. Annual fluctuations in the weather during the spring migration have a clear effect on the fluctuating species boundaries, as shown by many studies in northern Europe. Warm weather often results in an extension ('prolongation') of migration, while cold spells during migration periods result in 'abbreviation'; and the species boundary may consequently fluctuate several hundreds of kilometres from year to year. It has been suggested that climatic amelioration has, by the same mechanism, caused the northward range expansion of a number of southern species, but the expansions have often been more dramatic than expected from climatic changes. Many authors now believe that habitat changes due to man and his livestock are the major cause behind these shifts in species boundaries.

Interspecific competition is inferred to be the cause of a species boundary when two ecologically and morphologically similar species replace each other geographically. For example, the Carolina Chickadee *Parus carolinensis* and the Black-capped Chickadee *P. atricapillus* show almost completely mutually exclusive ranges in North America. A broader overlap zone is observed in other species pairs, such as the Chaffinch *Fringilla coelebs* and the Brambling *F. montifringilla* in Europe. Direct evidence on the effect of competition on such species boundaries is nevertheless meagre. Mutually exclusive ranges are not always due to competition. For example, the Corsican Nuthatch *Sitta whiteheadi* is restricted to Corsica, while the Nuthatch *S. europaea* is common on the adjacent mainland. However, the Corsican Nuthatch is confined to pine forests on mountains, and thus there are no species of *Sitta* in deciduous forest, the favoured habitat of the Nuthatch, on Corsica. Even though very little supportive evidence is available, other interspecific interactions, such as predator–prey relations or host–parasite relations, may be important in determining range boundaries.

As regards migrant birds, remarkably few studies have been devoted to the role of the non-breeding range in the determination of the range boundaries. For example, Kirtland's Warbler *Dendroica kirtlandii* only breeds in north–central Michigan, USA. This may be a consequence of the low carrying capacity of the wintering range in the Bahamas.

Historical causes have also been offered for certain distributions. Many restricted ranges in the Amazonian rainforest avifauna correspond well to Pleistocene refugia, and the present species boundaries may thus reflect events that took place thousands of years ago. Since *ad hoc* explanations based on past geological history can be used to explain practically everything, historical explanations should not be invoked lightly. This is particularly pertinent as many birds have demonstrably expanded or contracted their ranges very rapidly in response to changing geological conditions.

Major zoogeographical regions. Beginning from P.L. Sclater (1858) and A.R. Wallace (1876), bird distributions have been studied in order to divide the continental land-masses into broadly homogeneous regions.

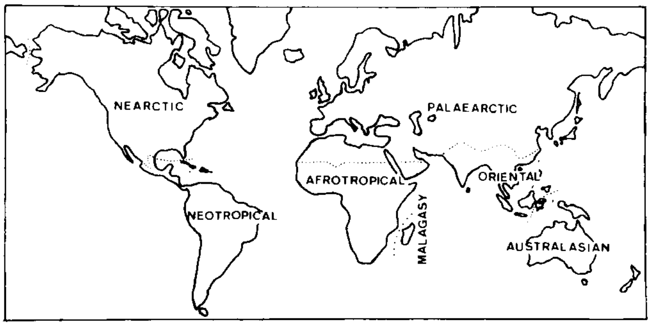

Fig. 3. The six major and one minor zoogeographical regions. Antarctica and the oceanic islands are not included in any region. Boundaries are only approximate, and in reality tend to be represented by transitional zones. Therefore, other classifications often differ in details, and some large islands (such as New Zealand and Madagascar) are classified differently. A distribution in both Nearctic and Palearctic regions is often called Holarctic, and species distributed in several tropical regions are often characterized as pantropical.

Many species have a wide range and inhabit several faunal regions, but the major zoogeographical regions remain a useful descriptive aid. It is an open question whether the avifaunas of each biogeographical region represent coadapted, ecologically more or less compactly 'packed' wholes or not. The success of many introductions and spontaneous invasions in historical time suggests that each avifauna is not a fully packed entity, though this conclusion is debatable—most species from other zoogeographical regions seem to be best established in habitats disturbed by the activities of man. The idea of the coherence of regional avifaunas can be supported by the similarity of the trophic composition of, say, various tropical avifaunas, despite great differences in their taxonomic affinities.

The continents of conventional geography do not provide a satisfactory framework in zoogeography. The avifaunas of the Old World and the New World are fundamentally different. In the Old World, Europe, North Africa north of the Sahara, and northern Asia north of the Himalayas are a fairly coherent region, called the Palearctic. Most of Africa belongs to the Afrotropical region. Tropical Asia and western Indonesia belong to the Oriental region, while the Australasian region comprises eastern Indonesia, New Guinea, Australia, Polynesia, and New Zealand. The Oriental and Australasian faunas are in balance along Weber's Line running through the Indonesian archipelago. Two large islands, Madagascar and New Zealand, are sometimes distinguished as minor regions separate from the Afrotropical and Australasian regions, respectively. As Madagascar supports a reasonably distinct avifauna, it is treated here as a minor region (see MALAGASY REGION). In the New World, North America above the tropics comprises the Nearctic region, and the rest belongs to the species-rich Neotropical region. Despite considerable differences between the avifaunas of the Nearctic and Palearctic regions, it is sometimes convenient to lump them together into the Holarctic region. This classification of the world avifaunas is useful from a pragmatic standpoint, but there are transitional areas, e.g. in Arabia, China, Indonesia, and Mexico, where the boundaries must be drawn arbitrarily. It is also necessary to take some separate account of the Antarctic continent and its neighbouring islands (see ANTARCTIC) as well as of pelagic birds (see OCEANIC BIRDS). See separate articles on the AFROTROPICAL, AUSTRALASIAN, NEARCTIC, NEOTROPICAL, ORIENTAL, and PALEARCTIC REGIONS.

The zoogeographical regions are often grouped into three realms. They are Megagea (previously Arctogea), consisting of the 'paleotropical regions' (Afrotropical, Oriental) and the 'holarctic regions' (Palearctic, Nearctic), Neogea (comprises the Neotropical region), and Notogea (comprises the Australasian region). In early literature, Notogea included both Neogea and Notogea. Other authors combine the Nearctic and Neotropical as Neogaea.

Most of the recent orders of birds are cosmopolitan, i.e. represented in all the main continental regions. Exceptions include the small orders of ratites, the Neotropical Tinamiformes, the Sphenisciformes of the southern hemisphere, the Holarctic Gaviiformes, and certain 'pantropical' orders that are absent from higher latitudes (Trogoniformes, Psittaciformes). Cosmopolitanism is less true of families, for many families are restricted either to the Old World or the New World, or in extreme cases to the minor Malagasy region or to small island groups. The insular families are the Rhynochetidae (New Caledonia), Todidae (West Indies), Drepanididae (Hawaii), and the New Zealand endemics: Apterygidae, Acanthisittidae, Callaeidae and Turnagridae.

The Oriental region shares nearly all its characteristic families with other southern parts of the Old World, but other regions have major families not found elsewhere, though the Palearctic example (Prunellidae) has a slight extension to the Oriental region. The Australasian and, in particular, Neotropical avifaunas are characterized by a great number of unique families.

At the level of genera and species, cosmopolitan distribution is rare. Cosmopolitan, or nearly so, are *Podiceps*, *Phalacrocorax*, *Ardea*, *Circus*, *Falco*, *Rallus*, *Columba*, *Caprimulgus*, *Anthus*, *Turdus*, *Corvus* and several seabird or shorebird genera. A few nonpasserine species are (nearly) cosmopolitan, such as the Osprey *Pandion haliaetus*, the Peregrine *Falco peregrinus*, the Kentish (or Snowy) Plover *Charadrius alexandrinus*, and the Barn Owl *Tyto alba*. The most widespread passerine, in terms of zoogeographical regions, is the Swallow *Hirundo rustica*.

Historical zoogeography. Present geographical distribution is the result of a most complicated process involving the evolution of a taxon and its subsequent dispersal to different regions, where further evolution may have taken place. Two different approaches may lead to quite different conclusions. First, interpretations can be based on a careful examination of the fossil record, though this is incomplete (see FOSSIL BIRDS). Second, the evidence available on continental drift may be examined in order to construct hypotheses on the origin of various taxa.

The evolution and recent distribution of the ratites may serve as an example. The ratites include the Struthioniformes of Africa, the Rheiformes of South America, the Apterygiformes of New Zealand, the Casuariiformes of New Guinea and Australia, and, in addition, the presumably related extinct orders of elephant-birds (Aepyornithiformes, Madagascar) and moas (Dinornithiformes, New Zealand). Before the continental drift separated the present southern continents, there was a huge southern supercontinent called Gondwanaland. It has been suggested that flightlessness evolved once in the ancestors of recent ratites, and the various ratite orders were derivatives from a common stock. This hypothesis, supported by, e.g., ethological data, predicts that late Cretaceous fossils of ratites exist, for South America and Africa separated from each other in that geological period. Such fossils have not been found, however. We are thus confronted with a hypothesis which is parsimonious but not supported by 'critical' fossil finds, and a hypothesis that ratites are in fact polyphyletic, the different orders having evolved long after the splitting of Gondwanaland into several continents. Flightlessness would then have evolved several times. Studies of molecular and chromosomal similarity, however, now seem to rule out the polyphyletic hypothesis. Other taxa suggested to have evolved in Gondwanaland (in predrift configurations of the continents) include the Sphenisciformes, the Galliformes, and the suboscine Passerines.

The differing dispersal abilities of various taxa give rise to special difficulties. The extremely rapid expansion of the Cattle Egret *Bubulcus ibis* (see RANGE CHANGES) shows that a nearly world-wide distribution may be attained within the ecological, in contrast to evolutionary, time scale. On the other hand, many genera or families or even orders may be confined to a particular region.

Faunal analysis has been a major approach in historical zoogeography. The fauna of a geographical region has been studied to examine its probable geographical origins; usually different faunal elements are represented. For example, the avifauna of North America can be divided into three groups: primarily South American families (such as Furnariidae or Formicariidae), Old World and primarily North American families (such as Troglodytidae, Mimidae, or Parulidae), and families with readily colonizing genera (such as Trochilidae, Tyrannidae, or Icteridae). Since most families of suboscine passerines have their distribution centres in South America, this evidence has been given as support for the Gondwanaland origin of the Suboscines. The prevalence of Suboscines in South America has been explained, on one hand, by the relative isolation of the continent, which has sheltered Suboscines from extensive Oscine competition, or, on the other hand, by arguing that Suboscines are competitively adept in their Neotropical environment, which is supported by their extreme taxonomic and morphological diversity there. Smaller regions than continents have also been analyzed to elucidate the probable origins of the fauna. Different habitats usually contain differing proportions of faunal elements, e.g. birds on European mountains frequently belong to northern elements in the fauna.

Faunal analysis may also be based on a certain ecologically defined zone or area, rather than a geographically defined one. Eurasian steppe birds, and the avifaunas of the lowland forests of Africa or of the non-forest habitats of the Andes, have been subjected to such analysis. For example, the high Andean bird fauna, rather than being closely related to forest avifaunas of South America, shows great faunistic similarity to the steppe (and other non-forest) fauna of Patagonia. In several cases, there has probably been extensive radiation after the colonization of the Andean non-forest habitats, while there has been little Andean radiation in other taxa.

Island biogeography. Since the publication of *The Theory of Island Biogeography* by MacArthur and Wilson in 1967, zoogeography has been transformed considerably. They pointed out that species numbers on many islands follow a well-defined relationship with area. In many cases, but not always, there is an approximately linear relation between the logarithms of area and numbers of species (A and S, respectively). This leads to a power-function description $S = CA^z$, where C and z are fitted constants. Of these constants, z often assumes a value between 0.2 and 0.35, implying that species numbers increase much less rapidly than area—a 10-fold increase in area gives rise to a 2-fold increase in the number of species, according to a useful rule of thumb. In many instances the power function is not the best-fitting relationship between species numbers and area.

The species–area relation has three explanations, which are not mutually exclusive. First, large samples are expected to include more species than small samples, for purely statistical reasons. This is a reasonable explanation to the extent that island bird communities can be expected to be random samples from communities on the adjacent mainland—this may be partially realistic as regards, for example, coastal islands or 'habitat islands' in regions where most birds are migrants and thus probably have little difficulty in overwater dispersal. Second, habitat diversity probably increases with island area: certain rare habitats are missing from small islands. This ought to lead to higher numbers of species on larger islands. Third, communities on islands may represent immigration–extinction equilibria.

The immigration–extinction model by MacArthur and Wilson predicts that species numbers on an island tend to be fairly constant, although species composition changes with time owing to immigrations and local extinctions. It is argued that species new to the island colonize at a rate that decreases with increasing numbers of species, because fewer potentially colonizing species are available after many species have already colonized, and the best colonists tend to arrive first. On the other hand, the rate of local extinctions, in terms of the number of species per year that disappear from the island, would increase with increasing species numbers. When there are few species on an island, they may not be competitively so harassed as species on a similar island with more species would be. Also, even if the probability of extinction were independent of species numbers, the number of actual extinctions taking place is expected to increase with the number of species. With a certain number of species on the island, the increasing extinction curve and the decreasing immigration curve intersect, and immigrations and extinctions thus balance each other.

Applying the immigration–extinction model to problems of insular bird distribution has given rise to many new insights. The major contribution has been to focus attention on ecologically meaningful and measurable problems of dispersal and extinction; the theory of island biogeography thus gives rise to predictions that are testable, and there is a major emphasis in this theory on processes leading to various distributions. Further, the view emerging on natural populations stresses dynamic patterns where chance plays a role—immigration (colonization) is certainly partially a random process, and it has also been shown conclusively that small populations have an appreciable probability of chance extinction, i.e. extinction just because deaths happen to occur before births. Accordingly, there is no reason to expect that a species will occur on all islands having suitable habitats, but some islands, depending on the colonization and extinction probabilities of the populations, can be expected to lack the species in question. It can also be expected that small islands have fewer species than large ones (the species–area relation), because the extinction rate on small islands is probably higher than on large islands, owing to the smaller average population size. Also, distant islands are expected to have an impoverished fauna because of lower immigration rates to isolated islands.

Despite its logical simplicity, the theory of island biogeography has been criticized for its lack of realism. The species–area relation has often been interpreted in terms of immigration–extinction equilibria, even if other alternatives have not been excluded. Estimates of immigration and extinction on islands have also been questioned. In our modern world, many estimates are affected by the activities of man on islands, and there are also problems in defining what constitutes an immigration or an extinction—despite their diurnal habits, many birds are elusive, and it is quite difficult to establish definitively whether a breeding population exists on an island or not. Immigration and extinction rates also fluctuate with time—e.g., climatically exceptional 'key years' may account for most of the immigrations to and/or extinctions on an island.

The role of competition in shaping insular communities is controversial. According to one view, low species numbers on islands result in 'competitive release', i.e. the absence of close competitors makes it possible for a species to have higher densities and utilize a broader range of habitats. There are many examples of this phenomenon: insular populations do tend to have higher average densities than on the adjacent mainland, and habitat use is often but by no means always broader than on the mainland. Another view emphasizes alternative explanations, such as habitat differences between islands and the mainland. Further, competitive release is not an easily understood phenomenon anyway, as theoretical models show that, under various conditions, the absence of competitors may give rise to lower, equal, or higher average densities on islands. Therefore, more direct evidence of competition is necessary.

Two other problems of insular distribution are also controversial. First, the absence of a species from a small island may or may not be a result of certain minimum-area requirements. A species may indeed need large tracts of uniform habitat, but, according to another view, a small mainland area would also lack many species merely by chance. Second, it is debatable whether interspecific competition 'forbids' certain species combinations or not. It would be expected by chance that certain species combinations do not occur on real islands in a certain archipelago just because one or several of the species are rare. On the other hand, if a combination of two or three ecologically closely related species never coexist, it is attractive to attribute this to interspecific competition. This is especially so because of the difficulty of conducting experiments with natural populations of birds. But difficulties in making experiments ought not to imply lack of understanding.

Minimum area requirements of a species have been analyzed with so-called 'incidence functions'. They show the percentage of islands in a certain size class that are inhabited by the species; incidence on small islands is frequently low compared with large islands. This approach omits reference to species densities, partially because densities of tropical species are difficult to census. If censuses are possible, an alternative is to construct 'prevalence functions'. They show the average density of the species on islands in a certain size class, as compared with average density on the mainland. Prevalence functions thus include more information than incidence functions, but both are directed towards understanding the colonization 'strategies' of birds. This problem has deep implications for nature conservation, for human activities tend to make natural habitats more patchy and therefore less suitable for species requiring wide expanses of homogeneous habitat.

Various processes operating in insular communities cause profound differences between islands and the adjacent mainland as regards their avifaunas. Coastal islands tend to be similar to mainland communities, though there may be habitat differences that give rise to differences in the species lists. More isolated islands often support endemic taxa not found elsewhere (e.g. Geospizinae on Galápagos), and oceanic islands are therefore not typical representatives of their geographical regions. Particularly good examples of islands supporting fairly unique avifaunas are Sulawesi, New Caledonia, the Hawaiian Islands, the Galápagos Islands, and some Atlantic islands, such as Tristan da Cunha, where there are five independently descended species of land birds. DISTRIBUTORS: see SEED DISPERSAL.

DIUCON: substantive name of *Pyrope pyrope*, a tyrant-flycatcher of southern South America (see FLYCATCHER (2)).

DIVER: substantive name of all species of the Gaviidae (Gaviiformes); alternatively 'loon' (generally used in North America), and in the plural general term for the family. (For the question of scientific nomenclature see under COLYMBIDAE.) The family consists of a single genus, *Gavia*. The relation to other genera is uncertain, the relation to the Podicipediformes being more distant than formerly suggested, and the assumed relation to the Laridae and Alcidae still being tentative.

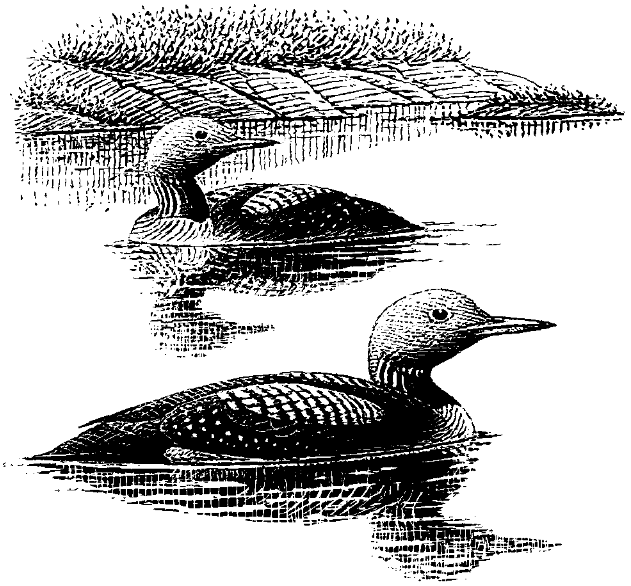
Characteristics. The divers form a well-marked Holarctic group of large (53–100 cm long) aquatic birds, with straight, sharply pointed bills and front toes fully webbed; they are long-bodied and thick-necked, with relatively small, pointed wings and a well-developed but short tail. The tarsi are laterally compressed and the legs are set so far back on the body that progress on land is extremely difficult and awkward. Adult divers are coloured in strikingly contrasting patterns, mostly black and white, and at all times the sexes present the same general appearance. The body plumage is hard and compact, while feathers of head and neck are soft and velvety. Divers moult their flight feathers simultaneously and thus become flightless for a time. The young have two coats of nestling down, the first coat in which they hatch, and a second set of down that pushes out the first and carries it on its tips, later to be pushed out by the feathers of the first winter plumage. The downy young of all divers are somewhat alike; they are uniform blackish brown or greyish brown above, changing to white or dull grey on the under parts.

The Red-throated Diver *G. stellata* is clearly differentiated from the other divers, lacking the chequered pattern, habitually feeding outside the nesting lake, and showing colonial nesting and a more complex social behaviour. The 2 largest species, the Great Northern Diver (or Common Loon) *G. immer* and the White-billed Diver (or Yellow-billed Loon) *G. adamsii* are similar, differing only in bill shape and colour, in the coarseness of the patterning and in size, and may be regarded as allopatric members of a superspecies. Two species, *G. adamsii* and *G. stellata*, have upturned lower mandibles and a field of binary vision below the bill, suggesting different feeding habits.

The divers spend their whole life on the water, only coming ashore for breeding. The normal diving time of 30–60 s can be extended to several minutes, and the body's buoyancy can be changed so that the bird may float with only the bill and eyes above water. The larger species in particular need a long run to become airborne, but once in the air the flight is rapid and powerful, often at higher altitudes than other waterfowl. *G. stellata* has a larger wing beat amplitude than the other divers, and often gives a flight cackle.

Habitat. For the 3 larger species, *G. immer*, *G. adamsii* and *G. arctica*, the normal habitat is large, clear-water lakes in the forest or tundra region. *G. stellata*, in contrast, habitually nests by a small pond or tarn, flying to the sea or to larger lakes to feed, a type of nesting occasionally seen also in *G. arctica*, especially in the high Arctic. Small islands or even tussocks are preferred for nesting.

Distribution. *G. immer* is essentially Nearctic, with a range from south Alaska and northern USA, to Greenland and Iceland. It is replaced by *G. adamsii* in north Alaska and north-west Canada, across the Palearctic region to Murmansk. This species is more confined to the arctic coast, however, and is replaced in the forested region by the large *G.a. arctica*. Both *G. arctica* and *G. stellata* are birds of the arctic coasts, *G. stellata* being circumpolar whereas *G. arctica* is absent from Iceland, Greenland and adjacent parts of Canada. Both these species extend more to the south in the western Palearctic than elsewhere. This extension of *G.a. arctica* into the habitats typical of *G. immer* in North America may be due to the lack of competition with this species, and also explains why *G.a. arctica* is considerably bigger in this range. *G.a. arctica* is replaced by the smaller *G.a. viridigularis* in the eastern parts of the Palearctic, and by the considerably smaller *G.a. pacifica* in the Nearctic range of the species. A similar difference in size is also seen in *G. immer*, the west Nearctic population being smaller. In all species, the choice of winter quarters may be expected to act as a population separation factor, since in the middle of both the Palearctic and the Nearctic the populations switch from wintering in the Atlantic to wintering in the Pacific Ocean.



Black-throated Diver *Gavia arctica*. (*D.W.*).

Movements. All species winter at sea, in inshore waters in the north Pacific and the North Atlantic–Mediterranean–Black Sea regions.

Food. The chief food is fish, with the addition of water insects and larvae (especially to feed the young), crayfish, frogs and also plant matter. In marine waters, molluscs and other invertebrates are included.

Behaviour. All species are extremely territorial and form pairs for life, generally returning to the same lake and even nest from year to year. The 3 larger species normally do not tolerate other pairs within sight, but *G. stellata* may nest colonially where only a few tarns are available close to the fishing grounds. Even so, territories around the nest are vigorously defended, by both parents. In all species, defence consists of threatening intruders with raised neck, alarm or territorial calls, splash-dives and long chases on the water. Vicious fights, even with fatal results, are not uncommon. *G. stellata*, probably as an adaptation to colonial breeding, has some added territorial behaviour (previously interpreted as courtship) involving ritualized zigzag runs and slow races in upright position, often performed simultaneously by the pair.

All species will congregate for cooperative fishing in small flocks, especially in winter and during migration, but also on a neutral area during the breeding period.

Voice. The vocalizations are among the loudest of any birds, especially the yodelling calls used to declare the territory. In the 3 larger species, the male calls with clear notes, sounding like low-pitched whistles, whereas in *G. stellata* the call is performed by the pair as a duet. All species have low-intensity wailing territorial calls. The alarm call is a tremulous laugh in *G. immer* and *G. adamsii*, a ravenlike croaking in *G. arctica* and *G. stellata*. A goose-like cackle is often heard from *G. stellata* in flight.

Breeding. Courtship is scanty, a mutual bill-dipping and dive, and copulation takes place on the shore. The nest, chosen by the male, lies directly by the water and may be quite void of any nest material. The 2 (rarely 3) olive-brown/green eggs are elliptical, with dark spots. Both sexes incubate, for 27–29 days. The young immediately take to the water. They are brooded ashore at night for the first few days but otherwise taken on the back or warmed under the wing. Both parents feed the young, at least for some time after fledging, which is 50 days for *G. stellata* and 60–65 days for the other species. Food is mostly or wholly collected in the breeding territory, except in *G. stellata* where it is flown in (one fish at a time, crosswise in the bill). The young can move well on land, and compete aggressively for food. The death of one young through such competition is a common occurrence. Renesting after the loss of the eggs only occurs early in the cycle, in the same territory but at a new nest site. (F.G.) S.S.

DIVING: see SWIMMING AND DIVING.

DIVING PETREL: see PETREL.

DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA: because the genetic material (DNA) of different species can be compared, and because the structure of protein molecules is genetically determined, these 'informational macromolecules' are valuable sources of taxonomic data.

DNA hybridization. The genetic material is composed of deoxyribonucleic acid (DNA), a linear double-stranded molecule composed of four subunits called nucleotides which differ in the structure of their 'bases'. The four bases, Adenine (A), Thymine (T), Guanine (G), and Cytosine (C), occur in the two strands as complementary pairs; A pairs only with T, G only with C. Chemical bonds between base pairs hold the two strands together. Genetic information is encoded in the sequence of the bases. The two strands of conspecific DNA will separate if heated to *c.* 100°C which ruptures ('melts') the bonds between base pairs. Upon cooling, the double-stranded configuration reforms as the A-T and G-C base pairs reassociate. In the DNA–DNA hybridization technique, the DNAs of two species are mixed, melted into single strands, and allowed to form 'hybrid' double-stranded molecules between homologous sequences. The hybrid molecules are then heated again, under controlled conditions, and their melting temperature is measured. The melting temperature depends upon the complementary matching of A-T and G-C pairs, thus the hybrids melt at a temperature lower than that required to melt conspecific DNA strands. The difference in melting temperature is an index to the degree of base sequence similarity between the two species, thus it is a measurement of the amount of genetic difference that has evolved since the two species diverged from their most recent common ancestor. Details of the technique are described by Sibley and Ahlquist (1981a; 1983).

A DNA hybridization study of the 5 genera of living RATITE birds indicated that the ancestral ratite species was separated into 3 populations when the fragments of the southern protocontinent of Gondwanaland drifted apart in the Cretaceous. One gave rise to the modern ostriches of Africa, a second to the rheas of South America, and the third to the Australasian ratites. The latter subdivided in the Eocene when the ancestors of the moas and kiwis of New Zealand, and the emu–cassowary group of Australia and New Guinea, branched from one another (Sibley and Ahlquist 1981a).

In other studies Sibley and Ahlquist have demonstrated the relationship between the Hawaiian honeycreepers (see HAWAIIAN HONEYCREEPER) and the cardueline finches (1982a); the close relationship between the genus *Sylvia* and the timaliine babblers (1982b); the relationships of the accentors (*Prunella*) (1981b) and the wagtails and pipits (1981c) to the weaver finches (Ploceidae), and the relationship of the Australian sittellas (*Daphoenositta*) to the Australian thickheads or whistlers (*Pachycephala*), not to the nuthatches (*Sitta*) (1982c). The New Zealand wrens (Acanthisittidae) were found to be the descendants of the oldest branch in the suboscine suborder Oligomyodi, a divergence that occurred in the Cretaceous (Sibley *et al* 1982). DNA–DNA comparisons were the basis for the new classification of the Passeriformes (Sibley and Ahlquist in press a, b) which follows this article.

Proteins. Protein molecules are composed of specific sequences of 20 kinds of amino acids and are synthesized on a nucleic acid template, thus they reflect genetic information. A foreign protein injected into an animal will induce the formation of antibodies in the blood serum. This 'immune reaction' may be used to compare the degrees of similarity between species by using various serological methods. Studies using 'microcomplement fixation' have dealt with several avian taxonomic problems (Wilson *et al* 1977). The technique of radio-immuno-assay also promises to be informative in comparing the proteins of living taxa with fossil proteins, up to several million years old (Lowenstein 1981).

Proteins may also be compared by using electrophoresis which characterizes the different proteins in a mixture by their net charge, size, shape, or isoelectric properties. The higher avian categories have been studied using several different protein systems (e.g., Sibley 1970; Sibley and Ahlquist 1972) but the limitations of the technique prevented definitive answers in most cases. Electrophoresis has been more successful in solving problems at the level of genera and species (e.g., Gutiérrez *et al* 1983) and populations (e.g., Corbin *et al* 1979). Sibley *et al* (1974) reviewed the immunological and biochemical taxonomy of birds up to 1972. C.G.S.

PROPOSED CLASSIFICATION OF THE AVIAN ORDER PASSERIFORMES

- Order Passeriformes
  - Suborder Oligomyodi
    - Infraorder Acanthisittides
      - Family Acanthisittidae, New Zealand Wrens
    - Infraorder Eurylaimides
      - Superfamily Pittoidea
        - Family Pittidae, Pittas
        - Family Eurylaimidae, Broadbills
        - (Family *inc. sedis* Philepittidae, Asities)
    - Infraorder Tyrannides
      - Parvorder Tyranni
        - Superfamily Tyrannoidea
          - Family Tyrannidae
            - Subfamily Tyranninae, Tyrant Flycatchers
            - Subfamily Tityrinae
              - Tribe Schiffornithini, *Schiffornis*
              - Tribe Tityrini, Tityras, Becards
            - Subfamily Cotinginae, Cotingas, Plantcutters, Sharpbills
            - Subfamily Piprinae, Manakins
          - Family Mionectidae, Mionectid Flycatchers
      - Parvorder Furnarii
        - Superfamily Furnarioidea
          - Family Furnariidae
            - Subfamily Furnariinae, Ovenbirds
            - Subfamily Dendrocolaptinae, Woodcreepers
        - Superfamily Formicarioidea
          - Family Formicariidae, Ground Antbirds
          - Family Rhinocryptidae, Tapaculos
          - Family Conopophagidae, Gnateaters
      - Parvorder Thamnophili
          - Family Thamnophilidae, Typical Antbirds
  - Suborder Passeres
      - Parvorder Corvi
        - Superfamily Menuroidea
          - Family Climacteridae, Treecreepers
          - Family Menuridae
            - Subfamily Menurinae, Lyrebirds
            - Subfamily Atrichornithinae, Scrub-birds
          - Family Ptilonorhynchidae, Bowerbirds
        - Superfamily Meliphagoidea
          - Family Maluridae
            - Subfamily Malurinae
              - Tribe Malurini, Fairy-wrens
              - Tribe Stipiturini, Emu-wrens
            - Subfamily Amytornithinae, Grass-wrens
          - Family Meliphagidae, Honeyeaters, incl. *Ephthianura*
          - Family Acanthizidae
            - Subfamily Pardalotinae, Pardalotes
            - Subfamily Dasyornithinae, Bristlebirds
            - Subfamily Acanthizinae
              - Tribe Sericornithini, Scrub-wrens
              - Tribe Acanthizini, Thornbills, Whitefaces, etc.
        - Superfamily Corvoidea
          - Family Eopsaltriidae, Australo–Papuan Robins, incl. *Drymodes*
          - Family Orthonychidae, Log-runners or Chowchillas
          - Family Pomatostomidae, Australo–Papuan Pseudo-babblers
          - Family Corvidae
            - Subfamily Cinclosomatinae, Quail-thrushes, Whipbirds, etc.
            - Subfamily Corcoracinae, Australian Chough, Apostlebird
            - Subfamily Pachycephalinae
              - Tribe Neosittini, Sittellas
              - Tribe Falcunculini, Shrike-tits
              - Tribe Oreoicini, Crested Bellbird
              - Tribe Pachycephalini, Whistlers, Shrike-thrushes, etc.
            - Subfamily Corvinae
              - Tribe Corvini, Crows, Magpies, Jays, Nutcrackers, etc.
              - Tribe Paradisaeini, Birds of Paradise
              - Tribe Cracticini, Currawongs, Wood-swallows, *Pityriasis*, *Peltops*
              - Tribe Oriolini, Orioles, Cuckoo-shrikes
            - Subfamily Monarchinae
              - Tribe Rhipidurini, Fantails
              - Tribe Dicrurini, Drongos
              - Tribe Monarchini, Monarchs, Magpie-larks
            - Subfamily Malaconotinae
              - Tribe Malaconotini, Bush-shrikes
              - Tribe Prionopini, Helmet-shrikes, Vangas
          - Family Laniidae, True Shrikes = *Lanius*, *Corvinella*, *Eurocephalus*
          - (Corvoidea *incertae sedis*)
            - (?Subfamily Vireoninae, Vireos, Pepper-shrikes)
          - Family Callaeidae
            - (?Category *Irena*, *Aegithina*, *Chloropsis*)
      - Parvorder Muscicapae
        - Superfamily Turdoidea
          - Family Bombycillidae
              - Tribe Dulini, Palm Chat
              - Tribe Ptilogonatini, Silky Flycatchers
              - Tribe Bombycillini, Waxwings
          - Family Cinclidae, Dippers
          - Family Turdidae
            - Subfamily Turdinae, Typical thrushes, incl. *Chlamydochaera*
            - Subfamily Muscicapinae
              - Tribe Muscicapini, Old World Flycatchers
              - Tribe Erithacini, Chats
          - Family Sturnidae
              - Tribe Sturnini, Starlings
              - Tribe Mimini, Mockingbirds, Thrashers, Catbirds
        - Superfamily Sylvioidea
          - Family Sittidae
            - Subfamily Sittinae, Nuthatches
            - Subfamily Tichodrominae, Wallcreepers
          - Family Troglodytidae
            - Subfamily Certhiinae, Northern Creepers
            - Subfamily Troglodytinae, Wrens
            - Subfamily Polioptilinae, Verdin, Gnatwrens, Gnatcatchers
          - Family Paridae
            - Subfamily Remizinae, Penduline Tits
            - Subfamily Parinae, Titmice, Chickadees
          - Family Aegithalidae, Long-tailed Tits, Bushtits
          - Family Hirundinidae, Swallows
          - Family Regulidae, Kinglets
          - Family Pycnonotidae, Bulbuls
          - Family Cisticolidae, African Warblers
          - Family Zosteropidae, White-eyes
          - Family Sylviidae
            - Subfamily Phylloscopinae, Leaf Warblers
            - Subfamily Megalurinae, Grass Warblers
            - Subfamily Sylviinae
              - Tribe Sylviini, Old World Warblers
              - Tribe Timaliini, Babblers and Wrentits
        - Superfamily Fringilloidea
          - Family Alaudidae, Larks
          - Family Nectariniidae
            - Subfamily Melanocharinae, Papuan Berrypeckers, etc.
            - Subfamily Promeropinae, Sugarbirds
            - Subfamily Nectariniinae
              - Tribe Dicaeini, Flowerpeckers
              - Tribe Nectariniini, Sunbirds, Spider-hunters
          - Family Ploceidae
            - Subfamily Passerinae, Sparrows, Rock Sparrows, etc.
            - Subfamily Estrildinae, Waxbills
            - Subfamily Motacillinae, Wagtails and Pipits
            - Subfamily Prunellinae, Accentors
            - Subfamily Ploceinae, Weaverbirds
          - Family Fringillidae
            - Subfamily Fringillinae
              - Tribe Fringillini, Chaffinches, Bramblings
              - Tribe Carduelini, Goldfinches, Crossbills, etc.
              - Tribe Drepanidini, Hawaiian Honeycreepers
            - Subfamily Emberizinae
              - Tribe Emberizini, Buntings, Longspurs, etc.
              - Tribe Parulini, Wood Warblers, incl. *Zeledonia*
              - Tribe Cardinalini, Cardinals
              - Tribe Icterini, Troupials, Meadowlarks, Oropendolas, etc.
              - Tribe Thraupini, Tanagers, Neotropical Honeycreepers, Swallow-Tanager, Plush-capped Finch, Tanager-finches.

DNA–DNA HYBRIDIZATION: a technique for determining degrees of genetic similarity, by splitting the double helix of the genetic material into single strands, and mixing preparations from different species. Single strands of DNA pair to re-form double helices, but only where they possess complementary sequences of the nucleotides which carry the genetic code. This means that the percentage of 'hybridization' is a measure of the similarity in nucleotide sequences between the species being compared.

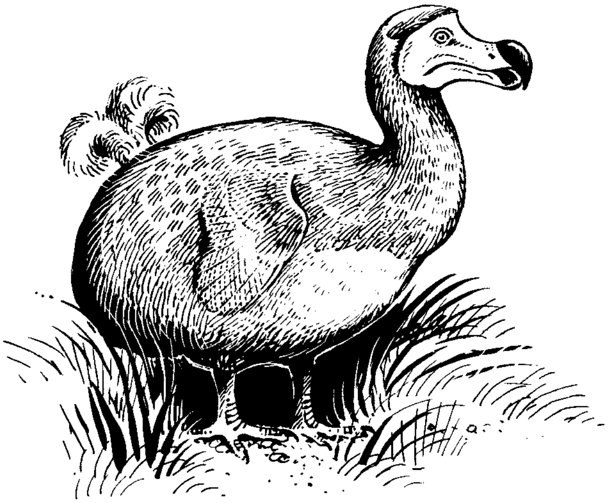
Sibley, C.G. & Ahlquist, J.E. 1981. The phylogeny and relationships of the ratite birds as indicated by DNA–DNA hybridization. Evolution Today, Pittsburgh. Proc. II Int. Congr. Systematic & Evolutionary Biology: 301–335.

DODO: *Raphus cucullatus* (=*Didus ineptus*); type species and best known member of the family Raphidae, usually considered to have been derived from pigeons and placed in the order Columbiformes. This family was only found on the Mascarene Islands, in the Indian Ocean east of Madagascar; all its members have become extinct in historical times (see EXTINCT BIRDS). Remains are only known for 2 of the species, and Storer (1970) has proposed that the second of these, the Rodriguez Solitaire (genus *Pezophaps*), be raised to familial status ('Pezophapidae') on the grounds that it must have evolved flightlessness independently from the Dodo. This approach seems to over-stress the differences rather than the affinities of the forms and has not found wide acceptance; neither has Lüttschwager's (1959) suggestion that an affinity with rails (Rallidae) rather than columbids is to be considered.

The flightless Dodo from Mauritius and the Rodriguez Solitaire *P. solitaria* are well known both from 17th century eye-witness accounts and a mass of skeletal material excavated from swamps and caves on the islands in the 19th century. Réunion also harboured a 'Solitaire', but travellers' accounts are somewhat contradictory, leading Hachisuka (1953) to postulate the presence on the island of 2 large white-plumaged flightless 'didine' birds, '*Ornithaptera solitaria*' and '*Victoriornis imperialis*'. Cheke has recently argued that paintings of 'White Dodos' usually considered to come from Réunion are in fact of albino Mauritian birds, and that no illustrations exist of the species on Réunion. He further considers, using previously unknown accounts, that only one 'Solitaire' occurred there; as Storer points out, it cannot, without evidence of remains, be legitimately assigned to either of the other 2 genera, so must be known by Selys's name *Ornithaptera solitaria*.

The turkey-sized Dodo was regarded as a curiosity by early 17th century visitors to Mauritius, and a number were shipped alive to Europe, India, Java and even Japan. Numerous paintings and sketches by Roelandt Savery survive of birds drawn from life in Holland, an excellent Moghul miniature depicts a bird in India, and rough sketches done by a Dutch sailor in Mauritius also survive. Despite the attention the birds received, virtually nothing was recorded of their habits. The only description of the egg is from a rather dubious source, and nothing is known about their feeding, although they always had, as did the Rodriguez Solitaire, a large stone in the gizzard. A marked annual fat cycle has been postulated (see Hachisuka) on the basis of 'fat' and 'gaunt' individuals in old pictures; this cycle was common to many Mascarene species (Cheke). Temple has suggested that the seeds of a Mauritian tree needed to pass through a Dodo's gut to germinate, and that the present near-extinction of the tree is due to a 300-year absence of Dodos. The evidence for this intriguing theory is, however, very tenuous (Owadally 1979); introduced seed predators account for most of the seeds on the remaining trees, and seeds planted in the forest nursery germinate adequately by themselves. Dodos were reported to be clumsy and stupid, and were slaughtered in large numbers by sailors visiting Mauritius. They became very rare on the mainland by 1640, though some survived to 1662 at least on offshore islets (Cheke). There is an unconfirmed report *c.* 1665–70, but that is the last. The 'dodos' reported in 1681, the generally accepted date of the last record, were Red Rails *Aphanapteryx bonasia* (Cheke). The cause of extinction is likely to have been egg predation from introduced pigs, monkeys and cats.

By contrast the habits of the Rodriguez Solitaire are quite well documented, as the Huguenot castaway Leguat has left us a detailed description of their behaviour, recorded in 1692, supported in 1726 by another good, if brief, account. These large birds were strongly sexually-dimorphic in size (males larger), lived in pairs, were territorial, and laid a single egg. The hatched young apparently joined crèches after a period with their parents. The birds fed on seeds, *Latania* palm fruit, and foliage. They, like the Dodo, appear to have had a marked annual fat cycle. A few were reported in 1755 and 1761, but these seem to have been the last. The last witness blamed feral cats for their demise, but later authors have argued that dry season fires sweeping the island may have been a very significant factor.



Dodo *Raphus cucullatus*. (*D.A.T.*).

The Réunion bird, also known to early French settlers as the 'Solitaire', is described in 17th and 18th century accounts. It was a solitary bird living, latterly at least, in remote mountain forests and rarely seen. It fed on worms and soil insects. Nothing is known of its breeding. It was considered quite frequent around 1705, but seems to have disappeared rather suddenly thereafter. It was last reported in 1708, but perhaps survived in remote places to about 1715–20 (Cheke). The bird commonly reported as having been shipped to France around 1735 was a Rodrigues Solitaire (Cheke).

These birds were all about the size of a turkey *Meleagris gallopavo*, heavily built, with strong feet and bills. The wings were rudimentary, though used in fighting by the Rodriguez birds. As the islands never had any land connections, the birds must have arisen from flying ancestors; flightlessness and gigantism were able to evolve in the absence of native ground predators. The Dodo was remarkable for its clumsy shape, very large head, heavy hooked bill and little tail of curly feathers. The plumage was bluish or brownish grey. The Rodriguez Solitaire was taller and slenderer, with a smaller head and slighter bill, largely brown in plumage. The Réunion bird was whitish with black wing-tips, and was described as turkey-like in size and in its feet.

The only complete stuffed Dodo, in Oxford, was destroyed by burning in 1755, but the head and a foot were saved and are still displayed in the University Museum. One or two other skulls and feet from live birds brought to Europe exist, but most of our knowledge of the bird's anatomy comes from bones dug up in Mauritius in the 19th century—complete skeletons reconstructed from these can be seen in many museums. The Rodriguez Solitaire is known anatomically from huge numbers of bones found in limestone caves on the island in the 19th century, and reconstructed skeletons are numerous. Remains of Réunion Solitaires have yet to be found. A.S.C.

DOMESTICATION: a term that may be defined as the state of animals the breeding and maintenance of which are continuously controlled by man. Further criteria of domestication which stress the economic value of the animal, the morphological and behavioural differences between the domestic animal and its wild type progenitor, or its degree of tameness, cannot be applied *in toto* to all domestic species. Some of our domestic species were first domesticated for religious rather than economic reasons; others are little altered morphologically from the original wild type, while others can scarcely be called tame and indeed are less tame than some wild birds in rarely frequented places. While most domesticated species usually fulfil one or more of these secondary criteria, the important implication in the definition is that, with control over the breeding and maintenance, man can change the animal as far as its genetic potentialities will allow. The number of species that have been domesticated at some time or other is probably very large; in many cases domestication has been on only a very small scale and of very short duration. Most of the avian examples considered here fulfil one or more of the secondary criteria of domestication listed above and have been domesticated in relatively large numbers and for considerable periods of time. Cage and aviary birds, together with ornamental waterfowl, have been excluded (see AVICULTURE; CAGE BIRD). The differences seen in our domestic birds, including the degree of change from the wild progenitor and the amount of intra-specific variation, have developed from the interaction between man's breeding and selection practices and the genetic variability available within a species. Assuming that mutation rates are approximately equal in our domestic birds, any differences between species in the initial amount of genetic variability available for selection would have depended on the population structure of the ancestral species, on the number of the breeding birds first brought into captivity, and on the introduction of further wild birds from other places and at other times. In general, however, the breeding practices and the amount of conscious or unconscious selection exercised by man have been responsible for the state of our domestic birds today.

Domestication could be facilitated in birds by their possession of a catholic diet, plasticity in reproductive behaviour, and ability to become accustomed to man and the environment supplied by him. Although all these traits are not found in every ancestral species of our domestic birds, domestication of one species might have aided the process with another species; e.g. the hatching of wild ducks' eggs by domestic hens. It appears that food production was not always the primary object of domesticating what are now important agricultural species; as will be seen from the histories of many individual species, a species may have had varying functions in societies in different times and places.

Domestic fowl. This species, usually regarded as a domesticated form of *Gallus gallus gallus*, may in fact be descended from any one or more of all 4 species of jungle fowl *Gallus* spp. inhabiting south-eastern Asia. The exact date of its domestication is unknown; it was recorded in India as early as 3200 BC and in China it was known as a domesticated bird by 1400 BC. It reached Persia at a very early date, and appeared in Egypt and Crete in 1500 BC. However, it may not have become a common domestic animal in Egypt until after the Persian conquest of the country in 525–524 BC.

The different attitudes of early European societies to the domestic fowl suggest that it entered Europe by two routes: one through Scythia to the Teutons and Celts and from Gaul to Italy; the other through the Dardanelles to the Aegean. In Greece the cock is first found on coins from the Temple of Artemis at Ephesus of at least 700 BC. Its arrival in the New World was formerly considered to have been shortly after the voyage of Columbus, but now it seems more likely that it was brought from Asia to the coasts of Peru and Ecuador.

The fowl was popular in many societies as a sacrificial or religious animal, so that this usage and cock-fighting were probably more responsible for its distribution than were its food-producing potentialities. In Persia, for example, it had an exalted position in the Zoroastrian religion. In Greece and Rome it also had religious significance, but whereas the Greeks valued it primarily as a fighter, the Romans also developed its agricultural potentialities; a complex poultry industry was formed, together with specialized breeds, but with the decline of the Roman Empire the industry collapsed and it was not until the 19th century that poultry keeping on a large scale was resumed.

The modern breeds are divided into Mediterranean and Asian; within these two groups numerous breeds and varieties have been developed. In Western countries today 37 breeds (including 5 Asian breeds) are kept for food production, while there are at least 24 ornamental breeds. The variation produced during domestication includes differences in plumage, body size, shape and size of comb, number of toes, egg-shell colour, skin colour and osteology. Physiological differences are found in many traits including egg production, fertility, hatching quality, broodiness, efficiency in food conversion, resistance to certain diseases, and responsiveness to certain hormones. Behavioural dissimilarities are also present. The large-scale breeding methods employed today entail the use of inbred lines derived from one or more breeds, and many of these lines may differ from one another to an extent comparable to that found between breeds.

Domestic duck. All breeds of this species are descended from the Mallard *Anas platyrhynchos*, which is thought to have first been domesticated in China or south-eastern Asia at a very early date. Birds were doubtless domesticated elsewhere at later dates, as there are records from Roman times of eggs being collected from the wild and being hatched by domestic hens. Although the wild Mallard does not breed in captivity, its young if hatched artificially will do so.

The amount of variability in the domestic duck is very small compared with that found in the domestic fowl. There are approximately 12 breeds in the United Kingdom used for meat or egg production or as dual purpose breeds. Morphologically the most striking ones are the Indian Runner, with its upright carriage and cylindrical conformation, and the Crested Duck, which possesses a large globular crest of feathers on the head. Modern breeding methods are similar to those used with chickens.

Domestic goose. The European goose was domesticated probably in south-east Europe and the Chinese goose in Asia, either in China or south-eastern Asia. It is generally agreed that the European goose is descended from the Greylag Goose *Anser anser* and the Chinese goose from the Swan Goose *Anser cygnoides*. They cross easily and the progeny are fully fertile. (For the Egyptian Goose *Alopochen aegyptiacus*, a not closely related bird, see below.) The domestic goose was already known in Europe by the time of Homer. There are about 9 breeds, some of which are very distinctive. The Chinese and African geese both possess large tubercles at the base of the bill; the Toulouse and the African have 'dewlaps'. The Crested Roman goose, which is of great antiquity and has a large globular crest, reputedly saved the Capitol in Rome from the Gauls in 390 BC by cackling and giving the alarm; geese are used as 'watch dogs' today. The Sebastopol has curled breast feathers and long-plumed feathers on the back. Little known in the West is the Russian fighting goose, which is a very old breed (with several sub-breeds) that was used for gaming in Russia for a long time.

Turkey. The Mexican subspecies of the wild Turkey *Meleagris gallopavo gallopavo* is considered to be the ancestor of this bird, and domestication probably took place near Oaxaco in Mexico. The date, however, is uncertain although it may have occurred at a time equivalent to the Neolithic age in Europe. Its importation into Britain between 1525–1532 may have been effected by William Strickland of Boynton-on-the-Wold, Yorkshire, for he was allowed to incorporate a turkey cock in his family crest. 'A Dietarie' published in 1541 by Archbishop Cranmer mentions the turkey, but during the 16th and 17th centuries much confusion existed between the Turkey and the Guineafowl, which had been called *Meleagris* by the Romans.

Several studies have sought to compare the wild Turkey with domestic birds in the United States of America. In a comparison of the Missouri sub-species *M.g. silvestris* and the domestic Bronze turkey, differences in body conformation, thickness and colour of tarsus, head appendages, plumage colour and tranquillity were apparent. Also the weights of brain, adrenal and pituitary glands expressed as a percentage of body weight were greater in wild birds. Three varieties have been widely bred in Britain today, *viz.* the Brown, the White and the Black, and now large-scale methods as in the fowl are used. Turkey first appeared on the Christmas menus in England in 1585.

Muscovy Duck. This bird was also domesticated in pre-Columbian times in the New World, where the wild Muscovy Duck *Cairina moschata* is a tropical tree-nesting bird that apparently avoids human habitation. Its name may have come from the Muisca Indians of central Colombia. Apart from the establishment of 3 varieties differing in colour, there has been no selection for more divergent breeds. The domesticated Mucovy Duck has been introduced into other parts of the world; it is familiar, for instance, in West African villages. It is sometimes crossed with domestic ducks of Mallard stock, but the progeny are infertile.

Guineafowl. Subspecies of the wild Guineafowl *Numida meleagris* are widespread in Africa. The isolated north-west African subspecies *N.m. sabyi* was present as a sacred bird on an Aegean island in the 4th century BC. The Romans called this subspecies the Numidian fowl, and they kept it as well as the north-east African subspecies which they called *Meleagris*; both were used for food, but the latter was the more popular. With the decline of the Roman Empire both forms appear to have been lost to Europe. One reference, however, shows that birds were kept in Athens in the 10th century AD. After the voyages of the Portuguese navigators in the 15th and 16th centuries, the West African subspecies *N.*

m. galeata was brought to Europe. No breeds have been developed.

Domestic pigeon. Descended from the Rock Dove *Columbia livia*, this may well be one of our oldest domestic animals, for it was a sacred bird in the early cultures of the Near East. It was associated with Astarte, the Goddess of Love and Fertility, and images of pigeons dating from 3100 BC have been found. In Egypt it was used not only as a source of food but also as a carrier and was domesticated before 2600 BC. There are records of it in Crete in the 2nd millennium BC. In classical Greece it became sacred to Aphrodite, and later in Rome it was associated with Venus but was also used for food and as a messenger. After the rise of Islam it was protected on religious grounds in most Mohammedan countries. It arrived in India and China at a very early date, but its role differed from place to place.

Nearly a century ago Darwin estimated that there were 150 breeds of pigeons, many of which he noted 'differ fully as much from each other in external characters as do the most distinct genera'. He divided the breeds or races into 4 groups. Group I contains the Pouter pigeons in which the oesophagus is of great size, barely separated from the crop and often inflated; the body and legs are elongated and the bill is of moderate dimensions. In Group II the breeds are characterized by bills with the cere swollen and often carunculated or wattled, and by large feet. Group III contains very divergent breeds, but the type of the group is characterized by the bill being shorter than that of the Rock Dove and the bare patch of skin round the eyes not being much developed. The breeds of Group IV resemble the Rock Dove in all important points of structure.

Peafowl. Our domesticated birds are descended from the Peafowl *Pavo cristatus* inhabiting parts of India, Assam and Ceylon. Although the bird was known in ancient Egypt, it was probably not widely known in Europe until the time of Alexander the Great. It is thought to have been introduced into Britain by the Romans and in mediaeval times was a popular bird for banquets. No varieties have been developed under domestication. Another species, the Green Peafowl *P. muticus*, has also been domesticated.

Ostrich. The subspecies of the Ostrich *Struthio camelus camelus*, *S.c. molybdophanes*, *S.c. massaicus* and *S.c. australis* appear to have been at least partially domesticated at some time during the recorded history of man. The greatest incidence of domestication occurred in the latter half of the 19th century, when the feathers became fashionable. The main area of ostrich farming was in the Cape Province of South Africa, which is within rage of *S.c. australis*. The first records of birds hatching eggs in captivity at the Cape date from the 1860s. In 1865 there were 80 birds in captivity there and by 1913 there were 776,313 domesticated birds, the vast majority of which had been hatched by artificial incubation. Ostrich farming was also carried out in North Africa, the United States of America, France, Spain, Italy and Australia. In 1914–18 the industry collapsed, but in 1960 about 30,000 birds were farmed in South Africa for the production of high-quality leather as well as the feathers.

Little Egret. When the ostrich feather trade was at a maximum the Little Egret *Egretta garzetta* was domesticated and farmed on a small scale for its plumes in what is now Pakistan and in Tunisia.

Cormorant. The custom of using Cormorants *Phalacrocorax carbo sinensis* for fishing dates back to the Sung dynasty (960–1298 AD) in China and to the 6th century AD in Japan. In China the birds are bred by special breeders while in Japan birds are obtained from the wild. The truly domesticated birds are sometimes variable in colour (see COUNTING).

Egyptian Goose. In ancient Egypt the Egyptian (or Nile) Goose *Alopochen aegyptiacus* was the main domestic bird. Its domestication took place very early and in the Old Kingdom, which ended in 2300 BC, it was very common. Its flesh was widely eaten, although the bird was the sacred bird of the God Geb, but its eggs also had symbolic value and were not eaten. There are very few records of the domesticated bird outside Egypt; and after the Persian conquest of Egypt in 525–524 BC the species ceased to be a domestic animal.

Game birds. Between the 13th and 16th centuries pheasants are reported to have been bred domestically for the London markets. Today many enterprises breed game birds on a very large scale for restocking wild populations and marketing. The most usual birds include the Pheasant *Phasianus colchicus*, the Partridge *Perdix perdix*, the rock partridges *Alectoris*, the Bobwhite Quail *Colinus virginianus* and several species of true quails *Coturnix* spp. In China and Japan the Quail *Coturnix coturnix japonica* is also kept for egg production. A number of aquatic species have also been bred on a large scale for re-stocking. Although no conscious selection has been practised on these birds, and they may not be considered domesticated in the generally used sense of the word, difficulty is often encountered in maintaining wildness in these stocks; this point again emphasizes the difficulty in defining domestication.

(For the wild birds concerned see chiefly under DUCK (goose and swan); GUINEAFOWL; OSTRICH; PHEASANT; PIGEON; TURKEY.)

DOMINANCE (1): see GENETICS.

DOMINANCE (2): term used to describe relationships between birds in aggressive encounters which have predictable outcomes. The dominant individual regularly defeats or displaces its rival, which is described as being subordinate or 'subdominant' (an incorrect usage best avoided).

Males tend to dominate their partners during the early stages of pair-formation in many species, although a subsequent reversal of roles, with the female assuming dominance, has been described in various gulls, buntings and finches. The context in which aggression occurs between members of a pair may, nevertheless, affect its outcome; male Chaffinches *Fringilla coelebs* dominate their partners in most social situations early in the breeding season but are often attacked by them during courtship. Dominance relationships are also important in non-breeding groups of birds. So-called 'peck orders' or 'dominance hierarchies' have been described in, among others, groups of domestic fowl, cage birds, such as Canaries *Serinus canaria*, Bengalese Finches *Lonchura striata* and Zebra Finches *Poephila guttata*, and broods of young Magpie Geese *Anseranas semipalmata* and Oystercatchers *Haematopus ostralegus*. Classically such orders are linear; the birds can be ranked so that each of them is dominant to all of those below it in the order but subordinate to those above it. Stable orders of this kind have been described in small groups of domestic fowl, but the order is frequently more complex. Those in large groups of fowl, for example, tend to be unstable, presumably because individuals cannot learn to recognize all members of the group. Hierarchies may also be complicated by cases of incomplete dominance between individuals, and by triangular relationships, i.e. Bird A is dominant to B, and B is dominant to C, but C dominates A.

Assessment of dominance is important to individual members of social groups because it enables subordinates to recognize birds of higher rank and to avoid them without fighting. Dominants also benefit because they may suffer injury in fights, even against birds which they are capable of defeating. It is not surprising therefore that social status is signalled in a variety of different ways. Behavioural postures are important in domestic fowl but plumage characteristics are used in some other birds. It is possible to increase the ranking of female Chaffinches by dyeing their breasts red so that they are more like those of males. Similarly, Rohwer (1977) has shown that the amount of black plumage on the throat, crown and breast is an indication of dominance in Harris Sparrows *Zonotrichia querula*. Subordinate individuals which are made to 'cheat' by dyeing their feathers black are persecuted by other birds, whereas dominants with bleached feathers have to fight more often than usual in order to maintain their rank. Dominance relationships can also be manipulated experimentally by injections of hormones. Doses of testosterone propionate increase the social status of recipients in groups of canaries and domestic fowl, as do doses of testosterone and the luteinizing hormone in male Red-billed Queleas *Quelea quelea*.

There is surprisingly little information on the advantages that are gained by high status in social groups, although there is some evidence that dominant Slate-coloured Juncos *Junco hyemalis* and Harris Sparrows survive better than birds of low rank. One probable advantage is that dominant birds forage more efficiently than subordinates because they can occupy the more rewarding feeding patches. Caraco (1979) has shown that dominants in groups of Volcano Juncos *Junco vulcani* maintain access to sites of high seed density and use foraging time more efficiently than subordinates. Furthermore, individuals in captive groups of crossbills *Loxia* are said to feed in order of dominance when there is competition for food. Another advantage may be over competition for mates. Dominant males in groups of domestic fowl achieve more matings, and father more offspring, than subordinates. S.M.E.

Caraco, T. 1979. Time budgeting and group size: a test of a theory. Ecology, 60: 618–627.
Rohwer, S. 1977. Status signalling in Harris sparrows; some experiments in deception. Behaviour, 59: 107–129.
Wood-Gush, D.G.M. 1971. The Behaviour of the Domestic Fowl. London.

DONACOBIUS, BLACK-CAPPED: *Donacobius atricapillus.* Formerly in Mimidae (see MOCKING-THRUSH). For family now see WREN (1).

DORADITO: substantive name of the 4 species of *Pseudocolopteryx*, small tyrant-flycatchers inhabiting open country, so named because of their yellow underparts (see FLYCATCHER (2)).

DORSAL: pertaining to the back, or generally to the upper surface of the body (in a more or less horizontal position); opposite of VENTRAL.

DOTTEREL: properly *Eudromias morinellus* (see PLOVER (1)); also used, particularly in Australia and New Zealand, as substantive name of various *Charadrius* spp., and even of *Peltohyas australis* (Glareolidae—see COURSER).

DOUBLE BROODED: species which normally lay a second clutch after fledging of the first brood (see CLUTCH-SIZE).

DOVE: substantive name of some species of Columbidae (see PIGEON). The names 'dove' and 'pigeon' are to some extent interchangeable (see also AVICULTURE).

DOVEKIE: alternative name of the Little Auk *Plautus alle* (see AUK).

DOWITCHER: substantive name of *Limnodromus* spp. (see SANDPIPER).

DOWN: feathers characterized by their fluffy vanes (see FEATHER; PLUMAGE). The use of down, plucked by the female from her own body, is characteristic of ducks and lyrebirds (see EIDER; UTILIZATION BY MAN).

DRAKE: special term for a male DUCK.

DREAD: see PANIC.

DREPANIDIDAE: a family of the PASSERIFORMES suborder Oscines; HAWAIIAN HONEYCREEPER.

DRIFT: (a) lateral displacement of a migrant from its heading by the wind, resulting in an achieved flight TRACK. Many migrants probably attempt to maintain a chosen track by altering their heading to allow for drift. (b) displacement of a migrant downwind at the speed of the wind, resulting from disorientation of the bird and consequent flight in random directions. (c) actively flying downwind under certain circumstances which do not permit a migrant to maintain its chosen course (see also MIGRATION).

DRINKING: birds drink so as to balance the loss of water by excretion and pulmocutaneous evaporation (loss of water through the lungs and skin). Even though birds do not sweat, a small amount of water may be lost through the skin quite incidentally. Birds need to drink only if their food does not provide enough water to effect a balance. It is therefore not surprising that birds with dry diets (especially seeds) need to drink more often than those with succulent diets (insects, meat, fruit, nectar, etc.).

Sources of water. Drinking water may be obtained from free open water such as rivers, streams, lakes and the sea, as well as from rainwater puddles on the ground or in the bases of leaves of large plants, falling rain, condensed fog, and dew.

Drinking methods. The methods by which birds actually take up water vary somewhat, but fall into five basic types which may intergrade.

Black-headed Gull *Larus ridibundus*, in winter plumage, drinking. (*Photo: H.E. Grenfell*).

(a) Sipping—this is the 'dip-and-tilt' method of drinking, in which the bill is dipped into the water and the head then raised with the bill tilted slightly upward to allow the water to run down the throat and be swallowed with the aid of rapid tongue movements. This is probably the commonest method in birds and is exemplified by the domestic fowl and most passerines.

(b) Suck-and-tilt—instead of merely dipping the bill and allowing water to be taken up between the jaws by capillary or surface tension, some birds (notably sandgrouse (Pteroclididae)) actively suck up water into the buccal cavity before raising the head to swallow the mouthful in a single gulp; this movement is repeated until the crop is full. The appearance of suck-and-tilt drinking is similar to that of sipping but is quicker and more vigorous.

(c) Sucking—the bill is immersed in the water which is taken in by a series of sucking movements of the gular region, without raising the head until the bird has drunk its fill. This is the common method of drinking seen in doves, but is found also among some waxbills (Estrildidae), the mousebirds and some other groups, including the waders (Charadrii). The waxbills appear to use a tongue-pumping mechanism rather than a gular mechanism, although it is often difficult to decide if the two mechanisms are mutually exclusive. A few birds may change their drinking pattern with age; thus, young sandgrouse are said to drink by sucking, but the adults use the suck-and-tilt method.

(d) Tongue drinking—two types of specialized tongue structures are involved here. One is a grooved or tubular tongue adapted for sucking up nectar or fruit juice as found in sunbirds and hummingbirds and which can be used for sucking up water in the same way. The second is a brush-like tongue found in some honey-eaters and parrots, also adapted for feeding on nectar, but which can be used for lapping up water.

(e) Drinking in flight—good flyers like swifts and swallows drink on the wing by swooping over the surface of a body of water with the bill open; water is scooped up in the lower jaw as it touches the water. Presumably the mouthful thus obtained is swallowed as the bird circles for the next swoop and scoop. A great advantage of this drinking method is that the birds avoid landing on the ground where they are vulnerable to predators.

Frequency of drinking. The frequency with which birds drink depends largely on their ecology and body size. In most environments birds have water available all the time and may drink several times a day, although one or two drinking times seem to be the rule for most birds—either morning or evening, or both. Birds of arid zones have to time their drinking more critically to avoid flying to and from water in the heat of the day and to avoid the main pressure by predators. For example Gambel's Quail *Callipepla gambelii*, a gamebird of the Sonoran Desert in Arizona, drinks between 0700 h and 0900 h and again between 1700 h and 1800 h; avian predators around the waterholes are active mainly between 0900 h and 1500 h.

Birds with a crop need to drink only once a day as a rule (parrots, doves, sandgrouse) unless, like finches, they are very small, in which case they may need to drink several times a day, especially in hot weather. Indeed, most small granivorous passerines drink frequently throughout the day, including the midday hours.

Birds that are fully water-dependent, even if they limit their drinking to certain times of the day, will be restricted in their distribution to the vicinity of water. The degree of restriction will depend in part on their powers of flight; larger birds with good flying ability (like doves and sandgrouse) can exploit food sources further from water than can small birds like buntings (Emberizinae), waxbills, finches and sparrows (Ploceidae).

Water requirements. The minimum drinking-water requirement for small granivorous birds in arid environments is about 10% of the body weight per day, but this amount will increase in hot weather. Most birds can reduce evaporative water loss when deprived of water, while at the same time increasing the rate of water resorption in the cloaca so that their excreta may contain as little as 50% of water by weight. At moderate ambient temperatures (20–30°C) many small birds such as larks, waxbills and the Budgerigar *Melopsittacus undulatus* can survive on dry seed without drinking and without losing body weight, but in hot dry weather they do need to drink to offset water lost by evaporative cooling. Presumably these birds augment the small amount of water in their food (as little as 12–15% in air-dried seeds) with metabolic water produced during cellular respiration.

Most birds prefer fresh water for drinking, but saline or brackish waters can be drunk by birds possessing a salt gland (see EXCRETION, EXTRARENAL) which removes excess salts from the body fluids. Seabirds can drink seawater for this reason and the salt gland, kept as a legacy from a marine ancestor, has enabled several desert-dwelling waders (coursers, pratincoles and plovers in particular) to process the body fluids of their insect food and to become quite independent of drinking water. Few land birds, however, can drink water with a salt content higher than about a third to a half that of seawater.

Opportunistic drinking has been seen in the Australian Pelican *Pelecanus conspicillatus* in which the birds open their bills and expand the pouch of the lower jaw to catch falling rain. The pouch forms a catchment area of about $0.039\,m^2$. This further illustrates birds' preferences for fresh water, since lake water was available nearby. G.L.M.

DROMAIIDAE: see under STRUTHIONIFORMES; EMU.

DRONGO substantive name of most of the species of Dicruridae (Passeriformes, suborder Oscines), and in the plural (drongos) as a general term for the family. 'Drongo' is the indigenous vernacular name for *Dicrurus forficatus* used by the Betsimasaraka and Sakalava tribes of northern Madagascar, and has passed into universal use for the family.

Characteristics. The drongos are a natural and well-defined family of 20 species of the Old World tropics, characterized by their long forked tails, a variety of modifications of the head and tail feathers and, in all but 2 species, glossy black plumage. Their relationships have been the subject of much speculation, and they have certain features in common with such groups as bulbuls, shrikes, crows, orioles (Oriolidae), flycatchers (Muscicapidae), and birds-of-paradise. In behaviour, drongos seem most similar to, and are to some extent the ecological counterpart of, the tyrant-flycatchers of the New World, although no relationship is implied in this observation.

African Drongo *Dicrurus adsimilis*. (*C.E.T.K.*).

Drongos are birds of medium size, varying from about 18 cm to 38 cm, though the elongated tail feathers of some species can extend total length to around 72 cm. The shape and structure of the tail varies enormously, but typically it is long and deeply forked, with the tips of the outer feathers curving outwards or sometimes upwards, or with the outer feathers extremely long or curled. In some species there is a marked prolongation of the shaft of the outer feathers, which ends in a second barbed section of the feather known as a racket (or racquet) or spatula. In all but one species, the tail is composed of 10 feathers. There are 10 primaries in the wings, which are long and pointed, and together with the tail confer great aerial manoeuvreability, seen to advantage as the bird twists and turns in pursuit of an insect or when harrying a foe. The Papuan Mountain Drongo *Chaetorhynchus papuensis* of New Guinea is the only member of the family to have 12 tail feathers, and also differs in some details of structure and colour pattern.

The bill is stout, arched and slightly hooked, with a small notch in the upper mandible, the nostrils often being partly concealed by dense feathering over the base of the bill. The rictal bristles are well developed, being long and stiff. The legs are short, with strong toes and sharp claws. The iris is red in most species.

The sexes are alike in plumage, which is black in all except 2 species which are grey to whitish. Juveniles are less glossy than adults, with shorter wings and tails, and in most species apparently acquire adult plumage in their first complete, post-juvenile, moult in their second year. Full development of crests and tails in the Greater Racket-tailed Drongo *Dicrurus paradiseus* and the Lesser Racket-tailed Drongo *D. remifer* is attained in succeeding moults. In adults, all but the 2 greyish species have the black velvety, or glossed with greenish, bluish or purplish. The intensity of the gloss, which can be brilliant and metallic, and its distribution to certain areas of the plumage or to certain parts of individual feathers, vary from species to species but are constant in each, and provide the best systematic character. In some species the gloss forms brilliant spangles on the throat and chest, and some have glossy hackles at the side of the neck. Many species are crested, and the structure and shape of the crest varies as much as the tail feathers. It may consist of only a little brush at the base of the bill, or may extend over the culmen, or may be very full, consisting of webbed feathers which curl over the crown and nape. In some species the crest feathers are partly or completely denuded of barbs and vary from a little erect tuft about 2 cm long, to filaments which may reach a length of 12 cm. The ornamental modification of some body feathers, the crest and the tail vary geographically in the same species and are of much interest. A few forms (species or subspecies) are white on the abdomen, upper wing coverts or face, or have a white spot at the corner of the mouth. In one found in the Comoro Islands the wings and tail are reddish brown.

Habitat. Drongos are largely arboreal birds, and are found in a wide range of woodland habitat from open country with scattered trees to dense secondary jungle or primary forest, at altitudes ranging from sea-level to around 3,300 m in the Himalayas. The most widely distributed species, the African Drongo *D. adsimilis* of Africa and the King-crow *D. macrocercus* of Asia (often regarded as conspecific), are characteristically more tolerant of open country, and perch readily on large mammals, vantage points such as ant-heaps or posts, or even on level ground.

Distribution, populations and movements. With a total of 10 species, the drongos are most numerous (and also have more highly evolved ornamental characters) in southern Asia, from Iran to China. The most noteworthy of all is the Spangled Drongo *D. hottentottus*, which occurs almost throughout this area from the west coast of India, and also in Indonesia, the Philippines, New Guinea, the Solomon Islands and north and east Australia. Over 30 subspecies of this bird have been described, and it has freely colonized oceanic islands, some of them by repeated invasions. A further 3 species are endemic in the Australo–Papuan region. In the Afro–tropical region there are 3 endemic species, while a further 4 are endemic to Madagascar, the Comoro Islands and Aldabra. Three of the Oriental species have penetrated deeply into the Palearctic region, to south-east Iran in the west and to Manchuria and the Amur river valley in the north-east. These northerly populations are migratory, but otherwise drongos are largely resident, though there is some seasonal wandering, often altitudinal in the Himalayas, or in the case of the Spangled Drongo, in search of flower nectar.

Food. Drongos are mainly insectivorous, the prey ranging in size from the smallest Diptera to large moths, termites, beetles and mantids. When opportunity arises they will also take other animal food such as lizards and small birds, and even bats have been reliably recorded. At least some species are piratical, robbing other birds of food in flight. Flower nectar is also an important element in the diet of many species.

Behaviour. Drongos are well known for their pugnacity and fearlessness in attacking and chasing larger birds such as crows and hawks. Other species of birds often nest in the same tree as a pair of drongos and this is assumed to be an association in which they benefit from the drongos' pugnacity. Other behavioural traits worthy of note are that drongos associate with cattle or man, are inquisitive, and follow grass or forest fires to prey on the disturbed animal life. They are also regular members of the mixed parties of birds which hunt through the forest, and which are a characteristic feature of the woodland bird-life in southern Asia. Although often described as solitary, drongos commonly gather in small or large groups either when feeding at forest fires, or in flowering or fruiting trees, or when flying into communal roosts which are used outside the breeding season.

Voice. The normal vocabulary is a mixture of harsh, scolding notes and pleasant musical whistles, but some species are good mimics, and can produce a wide variety of different calls with great skill. The Greater Racket-tailed Drongo is particularly noted in this respect, while the Spangled Drongo is often noisy on its own account, with its fluty rather oriole-like calls interspersed with metallic or grating noises.

Breeding. The nest is normally a rather shallow cradle or saucer, made of rootlets, fibres, fine grass or leaves, often bound together or decorated and camouflaged with lichens and cobwebs. Although inconspicuous, it is often placed in an exposed position on the outside of a bush or tree, from 3 m to 20 m, and is partially suspended from a horizontal or vertical fork in a slender branch. The normal clutch is 3–4 eggs, less in some species. The eggs are sometimes immaculate, but typically are speckled and blotched with dark or reddish brown on a creamy or pinkish background. Nests are sometimes brood-parasitized in India by the Drongo-Cuckoo *Surniculus lugubris* and the Koel *Eudynamys scolopacea*. Both sexes share in nest-building, incubation and care of the young. The incubation period remains unrecorded for many species, but is given as 16 days for the African species *D. adsimilis*, which may raise two or three broods. M.W.

DROP NET OR **DROP TRAP**: see TRAPPING; MARKING.

DROPPINGS: consist of a combination of materials from the EXCRETORY SYSTEM (urine) and the ALIMENTARY SYSTEM (faeces). The mixture of renal and alimentary products occurs because the ureters empty into the cloaca at the posterior end of the alimentary tract where the faeces collect before defaecation. The faeces, which generally contain indigestible residues, water, microbes and microbial products, are formed in the posterior small intestine and in the large intestine, where some water is absorbed during their formation. The water content varies according to the environment of the bird; the droppings of birds from arid regions usually contain less water than those of birds from humid places. In birds which possess substantial caeca, some of the contents of the posterior part of the tract enter the caeca where changes occur to produce the very distinctive caecal faeces. These are usually discharged separately from the intestinal faeces, but not without urinary contamination. About 7 to 11 times as much material may be discharged from the intestine proper as from the caeca of a healthy domestic fowl during a given period. Caecal faeces are rarely discharged from the bird during darkness. The pattern or rhythm of defaecation is often disturbed during the course of an infection of the alimentary tract. Predatory birds and several other widely differing species eject some of the indigestible parts of their diet in the form of pellets in addition to droppings (see PELLET).

The droppings of the nestlings of many species of passerine bird and of some others are often produced in a form which facilitates easy disposal for nest sanitation (see PARENTAL CARE). The droppings are sometimes fairly characteristic of a species; those of adult geese and grouse are easily recognized. The droppings of sea and cave birds, which breed in enormous colonies, accumulate to form deep deposits (see GUANO; GUANO, CAVE). Examination and analysis of droppings can give much qualitative information about the diet of the species involved. Some indigestible plant and animal remains are relatively easy to identify and sometimes the colour of the droppings provides a clue to the diet of the birds under observation. When experimental methods are used, analysis of the droppings can aid in studies of the digestion, growth and diseases of birds. The dispersal of various seeds, spores and parasites may take place through the defaecatory habits and droppings of birds. D.W.T.C.

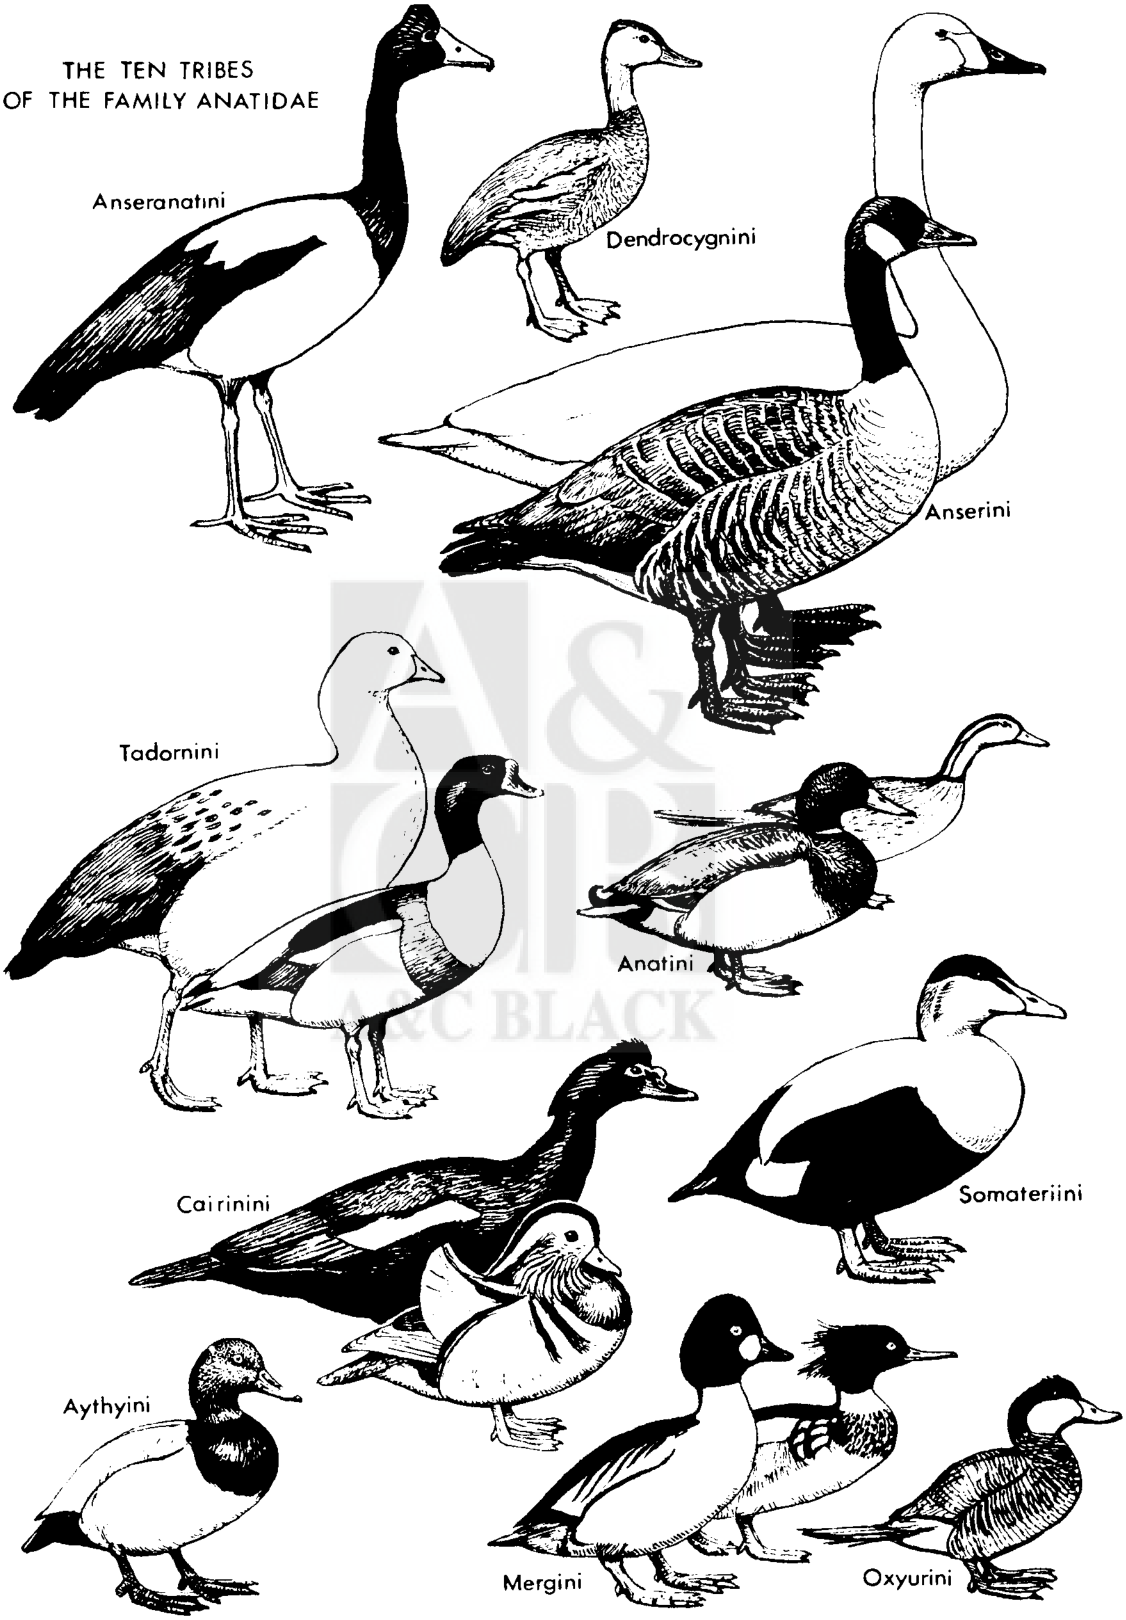
DRYING: see COMFORT BEHAVIOUR and photo.

DUCK: substantive name of most of the smaller species of Anatidae (Anseriformes, suborder Anseres); in the plural, usually in the combination 'ducks, geese, and swans', general term for the family. Apart from a number of ducks that have special names, the other species have the substantive names 'goose' and 'swan'. As the application of 'duck' and 'goose' does not correspond with the taxonomic subdivisions, the whole family is dealt with in this article; but see also GOOSE; SWAN; COUNT; DOMESTICATION; HYBRID.

Ornithologically 'duck' is applied irrespective of sex, but one usage restricts this to the female (even in species with special substantive names, e.g. 'duck Shoveler'), the corresponding term for the male being 'drake'; in North America 'hen' is often used for the female. The diminutive 'duckling' is used for the young. 'Duck' is often used unchanged in the plural as a collective term—for individuals rather than species.

The members of the family are essentially aquatic, many species obtaining their food principally by diving; three of the toes are linked by webs (see SWIMMING AND DIVING). All have relatively long necks and blunt, rather spatulate bills. All lay unspotted eggs, mostly nearly white or pale coloured, in nests on the ground, in thick vegetation, or in holes in trees, rocks, or earth, usually lined with down plucked by the female from her breast; and all have nidifugous down-covered young. All ducks, swans, and most geese moult the flight feathers of the wings simultaneously and pass through a flightless period, lasting from 3 to 4 weeks, after the breeding season; in all the Anatidae the only exceptions to this are the Magpie Goose *Anseranas semipalmata*, and at least some individuals of at least one of the species of sheldgeese of the genus *Chloephaga* (see below).

The classification of the Anatidae now generally accepted is based, with minor modifications, on that proposed by Delacour and Mayr. They used the following special characters in arriving at the new system: the



THE TEN TRIBES
OF THE FAMILY ANATIDAE

pattern of the scales on the tarsus, the plumage pattern in adults and downy young, the presence or absence of a double moult, the posture and general body proportions, the structure of the trachea and syrinx, and the behaviour, particularly courtship display.

In all, 247 forms, belonging to 147 generally accepted species, have been described. These are placed in 43 genera, grouped in 10 tribes and more broadly divided into 3 subfamilies, thus:

Family:	Anatidae	
Subfamily:	Anseranatinae	
Tribe:	Anseranatini	Magpie Goose
Subfamily:	Anserinae	
Tribes:	Dendrocygnini	Whistling ducks or tree ducks
	Anserini	Swans and true geese
Subfamily:	Anatinae	
Tribes:	Tadornini	Shelducks and sheldgeese
	Anatini	Dabbling ducks
	Aythyini	Pochards
	Cairinini	Perching ducks and geese
	Somateriini	Eiders
	Mergini	Scoters, goldeneyes, and mergansers
	Oxyurini	Stifftails

Of the 10 tribes, 8 contain species to which the substantive name 'duck' is applied, and the degree to which some ducks may differ in their relationships from other ducks is illustrated by the fact that the single tribe Anserini includes such apparently different birds as swans and geese, while much greater taxonomic differences exist between, say, pochards and stifftails, in spite of their similarities of appearance and habit. Similarly, 'goose' is the substantive name of some species of 4 of the 10 tribes and all 3 of the subfamilies. 'Swan' is applied only in 1 tribe, but not to all its members.

Magpie Goose. The subfamily Anseranatinae (and sole tribe Anseranatini) consists of a single species, the aberrant and apparently primitive Magpie Goose *Anseranas semipalmata* of Australia, an untidy black-and-white bird in which the elongated toes are only slightly webbed and in which, unlike almost all other Anatidae, the flight feathers are moulted progressively instead of simultaneously, so that there is no flightless period. The Magpie Goose seems to form some kind of link with the family Anhimidae, placed in the same order (see SCREAMER and NEST FUNCTION).

Whistling ducks (tree ducks). The Dendrocygnini are confined to the tropics. They show no sexual dimorphism, and, as in the Magpie Goose and some swans, both sexes incubate the eggs. They dive freely for food, and they indulge in mutual preening. One species, the Fulvous Whistling Duck *Dendrocygna bicolor*, has a remarkably wide range, occurring (apparently without geographical subspeciation) in North America, South America, Africa, and India.

Swans and 'true geese'. The Anserini comprise the swans, in the genera *Coscoroba* and *Cygnus*, and the geese of the genera *Anser* and *Branta*. There are 9 forms of swan—all large, herbivorous, aquatic birds with notably long necks and powerful, spatulate bills. They show no sexual dimorphism in plumage, and all the species lay pale-coloured eggs in a bulky nest on the ground; the nidifugous down-covered young ('cygnets') hatch after an incubation period of from 34–40 days. The immature plumage is brownish or greyish.

Fig. 1. (opposite). Examples of the 10 tribes of the Family Anatidae.
Anseranatini: Magpie Goose *Anseranas semipalmata* (Australo-Papuan area).
Dendrocygnini: Fulvous Whistling Duck *Dendrocygna bicolor* (pantropical).
Anserini: Bewick's Swan *Cygnus columbianus bewickii* (northern Palearctic), and (in front) Canada Goose *Branta canadensis* (northern Nearctic).
Tadornini: Andean Goose *Chloephaga melanoptera* (western Neotropical), and (on right) Shelduck *Tadorna tadorna* ♂ (Palearctic).
Anatini: Mallard *Anas platyrhynchos* ♂ (Northern Hemisphere), and (behind) Peruvian Torrent Duck *Merganetta armata leucogenis* ♂ (Peru and Ecuador).
Cairinini: wild Muscovy Duck *Cairina moschata* ♂ (Neotropical), and (in front) Mandarin Duck *Aix galericulata* ♂ (eastern Asia).
Somateriini: Eider *Somateria mollissima* ♂ (northern Holarctic).
Aythyini: Pochard *Aythya ferina* ♂ (Palearctic).
Mergini: Goldeneye *Bucephala clangula* ♂ (northern Holarctic), and (behind) Red-breasted Merganser *Mergus serrator* ♂ (northern Holarctic).
Oxyurini: North American Ruddy Duck *Oxyura jamaicensis jamaicensis* ♂ (North America and West Indies). (*Peter Scott*)

The Coscoroba Swan *Coscoroba coscoroba*, a South American species, is the smallest of the world's swans, and has been held to show some affinities with the whistling ducks (Dendrocygnini). The remaining swan species are now generally placed in a single genus, *Cygnus*, and include 2 Southern Hemisphere forms, the Black-necked Swan *C. melanocoryphus* of South America and the Black Swan *C. atratus* of Australia, and in the Northern Hemisphere 5 distinct forms in which the adult plumage is white (and a sixth poorly differentiated local race).

The Mute Swan *C. olor*, which has some affinities with *C. atratus*, is an Old World species semi-domesticated in western Europe for about 900 years, originally as a source of food. In England these swans were subject to special legislation and the Crown granted 'royalties' enabling certain noblemen and corporate bodies, such as livery companies of the City of London, to own swans and to mark their bills with registered symbols or 'swan marks'. Any Mute Swans on the River Thames not so marked were the property of the Crown. Annually on the Thames the young swans were, and still are, captured for marking in a traditional colourful ceremony known as 'swan upping'. The only royalties in swans still remaining are those granted to the Dyers and Vintners Companies and to the Earl of Ilchester, owner of a famous 'swannery' or colonial nesting site for Mute Swans at Abbotsbury in Dorset, where in some years more than 50 pairs nest in close company. An albinistic phase of the Mute Swan known as the Polish Swan, in which the legs and feet are pinkish grey instead of black and the first plumage of the cygnets is white instead of the normal brownish grey, is rare in Britain but common in parts of Europe and among introduced Mute Swans in North America.

In the Palearctic Region are 2 rather similar migratory wild swans with yellow patches on their bills—the larger Whooper Swan *C. cygnus cygnus* and the smaller Bewick's Swan *C. columbianus bewickii*, from which an eastern race, Jankowski's Swan *C. columbianus jankowskii*, has been separated. In North America, the largest of the world's swans, the Trumpeter Swan *C. cygnus buccinator* and the smaller Whistling Swan *C. columbianus columbianus* are held to be analogous to the Whooper and Bewick's Swans, although by some not to be respectively conspecific. The Whistling Swan breeds in the Arctic and is migratory, while the much less numerous Trumpeter Swan does not apparently migrate far from its breeding grounds in the Rocky Mountains and Alaska.

There are 14 species of 'true geese'—grey geese *Anser* spp. and 'black geese' *Branta* spp. They are wary birds which graze in flocks or 'gaggles', fly in 'skeins', and are confined to the Northern Hemisphere. Most of them breed in Arctic or subarctic latitudes, and many are divided into numerous and well-marked geographical races in spite of a strongly migratory habit. In such cases, populations from a particular breeding area preserve a high degree of reproductive isolation because of strong social bonds uniting the families (and probably larger groupings) during the winter migrations. They show no sexual dimorphism in plumage; and they lay unspotted, almost white eggs, which require from 24–33 days of incubation before hatching into nidifugous down-covered young. For the most part geese are less aquatic in habit than swans or ducks. Geese have been recorded as living in captivity to an age of at least 42 years.

The typical 'grey goose' is the Greylag Goose *Anser anser*, a widespread Palearctic species from which, by selective breeding, man has evolved various domestic forms of farmyard geese; the domestic Chinese Goose was derived (probably more than 2,000 years ago) from the Swan Goose *A. cygnoides* breeding in Siberia and wintering in China (see DOMESTICATION). The White-fronted Goose *A. albifrons* has the widest range of all the grey geese, 4 races spanning the Palearctic and Nearctic Regions. The Bean Goose *A. fabalis* has a number of distinguishable races, all confined to the Old World. The most westerly form, the Pink-footed Goose *A. fabalis brachyrhynchus*—the commonest wild goose in Britain in winter—is sometimes regarded as a distinct species. In Europe and Asia these grey geese have been extolled in poetry, prose, and painting as the most romantic of wildfowl, the traditional quarry of particular wariness, the mysterious wanderers whose wild musical cries on migration mark the changing seasons. In many parts of Europe their great assemblies are the finest wild-life spectacle that remains to be seen.

The Bar-headed Goose *A. indicus* is probably the species of which a skein of 17 was recorded on a photograph of the sun taken at Dehra Dun, India, at a height variously estimated at between 7,500 and 8,500 m; it has a slightly larger wing area for its weight than the other grey geese, perhaps because of the high altitudes required for its migration from breeding grounds in Tibet to the plains of India.

In North America the Snow Goose *A. caerulescens* is dimorphic. In adult plumage one phase is pure white with black primaries, while in the other—the 'Blue Goose'—there is a variable amount of slate grey on the body, most characteristically only the head and part of the neck being white. This dark plumage, perhaps a recent mutation, appears to be dominant (although the genetics are complex), increasing in its incidence and spreading westwards in the most widespread race of the species, the Lesser Snow Goose *A. c. caerulescens*. No blue phase is known in the larger eastern race, the Greater Snow Goose *A. c. atlanticus* (although some blue Lesser Snow Geese are found in flocks of Greater Snow Geese), or in the much smaller Ross's Goose *A. rossii*, which is specifically distinct and confined to a narrow western range in very much smaller numbers. The handsome Emperor Goose *A. canagicus*, with small heavily loaded wings, has a short migration route from the Alaskan coast along the Aleutian chain; the white head of this species in the wild state is usually stained to a deep orange yellow by iron deposits in the water, a condition also seen in Snow Geese and in swans.

The name *Branta*, like the English 'brent' and the American 'brant', is taken from the rolling call of the bird. Three or possibly 4 distinguishable races of the Brent Goose (or Brant) *Branta bernicla* breed in the high Arctic in a circumpolar distribution and winter in the intertidal zones of temperate coasts. The failure (probably through disease) of its principal food supply, the sea-grass *Zostera*, caused catastrophic reductions in the numbers all over the world between 1930 and 1940. Unlike other species of geese, wild-caught Brent Geese rarely nest in captivity. The Barnacle Goose *B. leucopsis* is also a high Arctic breeding species but has a very restricted winter range in western Europe. In the Middle Ages it was believed that these geese were hatched from ship barnacles (*Cirripedia*) and were therefore 'fish' rather than 'fowl'; they were thus permitted as food on Fridays. This belief also extended to the Brent Goose, which was known—particularly in Roman Catholic Ireland—as the 'Barnacle' (or 'Bernicle'); *B. leucopsis* was called the 'Land Barnacle'.

The most elaborate and striking plumage pattern among the Anserini is that of the Red-breasted Goose *B. ruficollis*, breeding in northern Siberia and wintering now mainly near the Black Sea. It is handsomely marked in black and white and chestnut brown and is the smallest of the true geese (although Ross's Goose is scarcely larger).

The Canada Goose *B. canadensis* has been divided into at least 12 distinguishable geographical races. Some authorities hold that many more discrete populations can be recognized. All have the same black head and neck with white cheek patches, but they vary greatly in size and in the shades of brown of the body plumage. The larger races, known as 'honkers', provide one of the principal quarry species of the American 'duck-hunter'. The Ne-ne or Hawaiian Goose *B. sandvicensis* is an island species, probably of common stock with *B. canadensis*, which now has reduced webs to its feet and shorter wings because of its less aquatic and non-migratory habit. In 1950 the total population was believed to be under 50, but intensive captive breeding projects in Hawaii and England had increased the figure to more than 2,000 by 1979. The Ne-ne is the 'state-bird' of Hawaii.

Shelducks and sheldgeese. Somewhat gooselike are the shelducks in the tribe Tadornini. The Crested Shelduck *Tadorna cristata* is believed to have become extinct; it is known only from 3 specimens, 2 from Korea and 1 from near Vladivostok, although it is illustrated in several ancient Japanese prints. The New Zealand Shelduck *T. variegata*, and to a lesser extent the South African Shelduck *T. cana*, exhibit a bright plumage in the female that is evidently analogous to the bright plumage in the males of other duck species; for example, in *T. variegata* the immature plumage resembles that of the male, in which the head is black, while the adult female assumes a white head and moults annually into a slightly duller post-nuptial 'eclipse' plumage. This sexual inversion is incomplete and, in contrast to the phalaropes (Phalaropodinae) and certain Accipitriformes, the male shelduck is larger than the female and dominates the pair.

In Australia the Cape Barren Goose *Cereopsis novaehollandiae*, a large grey bird mainly confined to islands in the Bass Strait and now apparently increasing in numbers, has been held to link the 'true geese' with the Tadornini although it may more properly belong to the Anserini. The South American genus *Chloephaga* consists of 5 species of goose-like grazing birds all with a sharply defined mirror or 'speculum' of iridescent colours on the secondary coverts (in contrast to the iridescent secondaries in the 'true ducks' of the tribe Anatini). At least some individuals of one species, the Ruddy-headed Goose *C. rubidiceps*, now considered an endangered species, moult their flight feathers progressively and have no flightless period; this may be true of other *Chloephaga* species. Two of the species, the maritime Kelp Goose *C. hybrida* and the Upland (or Magellan) Goose *C. picta*, display very marked sexual dimorphism, the males being white or predominantly white, the female predominantly dark brown or reddish brown. In the other 3 the sexes are scarcely to be distinguished by plumage differences, although in the Andean Goose *C. melanoptera* both are largely white ('male' colour), while in the Ashy-headed goose *C. poliocephala* and the Ruddy-headed Goose both are dark ('female' colour). In the Abyssinian Blue-winged Goose *Cyanochen cyanoptera* (which is closely related to *Chloephaga*), there is no sexual dimorphism, and the same applies to the Egyptian Goose *Alopochen aegyptiacus* and the Orinoco Goose *Neochen jubatus*, which seem to link the sheldgeese with the shelducks of the genus *Tadorna*.

Certain further South American species have been included in this tribe—the Crested Duck *Lophonetta specularioides*, and the 3 steamer ducks *Tachyeres* spp.—but doubt has been cast on this relationship. The latter are marine diving ducks of heavy build and plain plumage, and 2 of them are unable to fly (see FLIGHTLESSNESS).

Dabbling ducks. The great majority of the Anatini or dabbling ducks have been placed in the large and very various genus *Anas*, which includes the mallards, pintails, wigeons, shovelers, and many different species of teal. In some, especially those frequenting the Northern Hemisphere, there is a sharp sexual dimorphism, the males having a bright nuptial plumage (linked with a more or less elaborate courtship display), which is replaced by a cryptic 'eclipse' plumage (resembling the plumage of the female) during the annual flightless period. The males of most Southern Hemisphere species, however, remain similarly coloured throughout the year; the bright plumage of the males of northern species seems to have been lost (rather than never developed) in sedentary and island races, and the brightness is most marked in the most migratory forms.

Of the dabbling ducks only the Mallard *A. platyrhynchos* has been domesticated, giving rise to various familiar forms (see DOMESTICATION). Aberrant species that have been included in the dabbling duck tribe are the Torrent Duck *Merganetta armata* subspp. of the Andes, the now probably extinct Pink-headed Duck *Rhodonessa caryophyllacea* of India (which may have formed a link with the pochards), the Marbled Teal *Marmaronetta angustirostris* of the Mediterranean and Near East (which almost certainly forms such a link), and 2 strange species from Australia—the little Pink-eared Duck *Malacorhynchus membranaceus* specially adapted for feeding on blue-green algae, and the Freckled Duck *Stictonetta naevosa* which shows some affinities with the geese and may finally prove to belong to the subfamily Anserinae, perhaps in a tribe of its own. The taxonomic position of the Blue (or Mountain) Duck *Hymenolaimus malacorhynchos* of New Zealand, of which the bill is adapted as a sucker and the principal food is probably green algae sucked from the stones of fast running streams, is still obscure; but the Ringed Teal *Callonetta leucophrys* is now believed to belong to the tribe Cairinini, perhaps forming a link with the Anatini.

The Pintail *Anas acuta*, which has a wide circumpolar range, is probably the most numerous duck species in the world, and the dabbling ducks of the genus *Anas* provide three-quarters of the quarry for the wildfowler or duck-hunter (see WILDFOWL); most of the other quarter is provided by the next tribe.

Pochards. The Aythyini include the famous North American sporting bird the Canvasback *Aythya valisineria*, which is closely related on the one hand to the Pochard *A. ferina* of Europe and on the other to the sympatric American Redhead *A. americana*. The Tufted Duck *A. fuligula* is the most familiar representative in Britain. The Greater Scaup *A. marila*, called in North America 'Bluebill' or 'Broadbill', has a circumpolar breeding range and is found in huge 'rafts', principally on salt water, in many parts of the world. Several of the species share the substantive name 'white-eye'. With the exception of the genus *Netta*, the pochards are all accomplished divers.

Perching ducks and geese. The tribe Cairinini shows the widest range in size in the Anatidae. Male Spurwinged Geese weigh up to 10 kg, while the smallest of the Pygmy Geese (or Cotton Teal) *Nettapus* spp. weigh only 230 kg. The tribe also includes the most brilliantly coloured and fantastically marked of the Anatidae. The drakes of the Mandarin Duck

Aix galericulata of China, and of the related Wood (or Carolina) Duck *Aix sponsa*, of North America, have patterns of astonishing complexity and beauty. Pairs of caged Mandarin Ducks were formerly given as presents at Chinese weddings as symbols of marital fidelity. The influence of the drake's pattern and colour on Chinese art and culture is demonstrated by the inescapably 'Chinese' appearance of the bird.

The large polygamous Muscovy Duck *Cairina moschata* of Central and South America is one of the 4 species of Anatidae to be domesticated (the others being the Greylag Goose *Anser anser*, the Swan Goose *A. cygnoides*, and the Mallard *Anas platyrhynchos*). The wild form of the Muscovy Duck is black, glossed with green, with extensive white patches on the wings. Domestic birds are of increased size (although relatively less so than in some domesticated varieties of the Mallard) and have white, grey, and speckled plumage patterns; the enlarged caruncle on the bill becomes conspicuously scarlet.

The largest of the Cairinini is the Spurwinged Goose *Plectropterus gambensis* of Africa, an untidy bird of dark glossy green with variable amounts of white. Related is the polygamous Comb Duck *Sarkidiornis melanotus* subspp., often called Knob-billed or Knob-nosed Goose, in which the metallic colours of the mantle are very brilliant; one form is common in Africa and India, while the other is found in South America. The Australian Wood Duck (or Maned Goose) *Chenonetta jubata* is rather closely related to the ducks of the genus *Aix* (above) in spite of its gooselike bill and gait. The 3 species of Pygmy Geese of the tropical genus *Nettapus* (the smallest of the Anatidae) must have been called 'geese' because of the triangular gooselike bill, apparently adapted for eating the seeds of water lilies, but they are in fact tiny perching ducks.

Eiders. The Somateriini are a tribe consisting of 4 species of marine ducks all living in the north. The Eider *Somateria mollissima* is divided into 5 races and commonly nests in colonies, which have been exploited by man for the manufacture of eiderdowns. As in most other species of Anatidae, the female plucks down from her breast in order to line the nest. The best quality down is taken from the Eider's nest, without harmful effect, a few days before hatching, and the second best quality after the eggs are hatched and the young have left the nest. No artificial substitute for this down has been found, and that from a single nest may be worth about £3.00. Some Eider colonies in Iceland have up to 10,000 nests and are intensively encouraged by their owners by methods that include the spreading of coloured ribbons, musical instruments which play in the wind, and rows of 'semi-detached' artificial nesting sites. The species is common in northern parts of Britain.

Scoters, Goldeneyes, and Mergansers. The tribe Mergini includes a number of ducks which, like those in the Cairinini, do not at first sight appear to be closely related. All are good divers. With the exception of the rare Brazilian Merganser *Mergus octosetaceus* and the now extinct Auckland Island Merganser *M. australis*, the tribe is confined to the Northern Hemisphere. The small extinct Labrador Duck *Camptorhynchus labradorius*, of which the last was shot in 1875, was related to the scoters and may have linked them to the eiders (by way of the small Steller's Eider *Polysticta stelleri*). The 3 scoters *Melanitta* spp. are largely marine except in the breeding season; the males are predominantly glossy black.

The affinities of the goldeneyes *Bucephala* spp., Harlequin Duck *Histrionicus histrionicus*, and the Long-tailed Duck (or Oldsquaw) *Clangula hyemalis*, are evident; but the last exhibits an unusual moulting sequence, with contrasting dark summer and light winter plumages in the male, which may or may not be strictly analogous to the 'eclipse' in other species. The Long-tailed Duck is one of the fastest fliers among the Anatidae; a speed of 115 kph has been reliably recorded in level flight. The little Bufflehead *B. albeola* links the goldeneyes with the scoters, and perhaps also (by way of the Smew *M. albellus*) with the sawbills of the genus *Mergus*, which is held to be rather closely related to the goldeneyes in spite of the long narrow serrated bill adapted for catching fish.

Stifftails. The last and rather isolated tribe of the Anatinae is the Oxyurini, a group of extremely aquatic and largely nocturnal freshwater ducks, in most of which the rectrices are long and stiff and evidently have an important underwater control function. The genus *Oxyura* is represented in all 6 continents by small round diving ducks in which the male in breeding plumage is chestnut red with a brilliant blue bill. The display is elaborate and differs widely in the various species. The male of the very large Musk Duck *Biziura lobata* of Australia carries a large fleshy lobe under the bill. The Black-headed Duck *Heteronetta atricapilla* of South America lacks the long tail of the tribe and is interesting specially for its apparently parasitic egg-laying habit; the eggs have been found in nests of coots and rails (Rallidae), herons, and even of a carrion-eating hawk, one of the caracaras *Polyborus* spp. (see BROOD-PARASITISM). The African White-backed Duck *Thalassornis leuconotus* appears to be an aberrant stifftail, although its voice, anatomy, and behaviour, and the pattern of the downy young suggest that the relationship may not be very close.

DUCKLING: special term for a young (not full grown) DUCK.

DUCTLESS GLANDS: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

DUETTING: male and female of a pair singing or calling together, or almost together and responsively (see VOCALIZATION).

DUIKER, REED: name, in South Africa, for the Long-tailed Shag *Phalacrocorax africanus* (see CORMORANT).

DULIDAE: a family of the PASSERIFORMES, suborder Oscines; see PALMCHAT and under BOMBYCILLIDAE.

DUMP NESTING: laying of eggs by more than one female of usually the same species in one nest.

DUNLIN: *Calidris alpina* (see SANDPIPER). See photo COMFORT BEHAVIOUR.

DUNNOCK: alternative and often preferred name of the Hedge-sparrow (misnomer) *Prunella modularis* (see ACCENTOR).

DUODENUM: the anterior part of the small intestine (see ALIMENTARY SYSTEM).

DUSTING: highly specialized, stereotyped behaviour of birds whereby 'dust' (fine earth, sand, etc.) is deliberately introduced into the plumage and later expelled. The synonyms 'dust-bathing' and 'sand-bathing' are also used but it seems preferable to restrict the term 'bathing' to true bathing in water; see COMFORT BEHAVIOUR. The habit is most characteristic of species living in or originating from bare open habitats, particularly desert, steppe, and savanna, where water for bathing—especially of the 'stand-in' type—is scarce or absent, seasonally at least. Among non-passerines, dusting occurs regularly in the Ostrich *Struthio*, rheas, gamebirds, buttonquails, seriemas, bustards, seed-snipes, sandgrouse, nightjars, mousebirds, motmots, bee-eaters, rollers, hoopoes, and hornbills; it has also been reported among some hawks, falcons, doves, and owls. Fewer passerines are known to dust but the habit is well-documented for the larks, wrens, and sparrows of the genera *Passer*, *Petronia*, and *Montifringilla*, and has also been reported in the Wren-tit *Chamaea*, White-winged Chough *Corcorax melanoramphus*, some American sparrows of the genera *Spizella* and *Pooecetes* (Emberizinae), and the Common Grackle *Quiscalus quiscula* (Icteridae). Many birds that dust do not bathe at all and others only in the rain (e.g. larks) or from flight (e.g. bee-eaters); some, however, both dust and stand-in bathe (e.g. Ostrich, Common Rhea *Rhea americana*, falcons, grouse *Lagopus*, seed-snipes, owls, mousebirds, rollers, wrens, and sparrows *Passer*).

Dusting bouts are typically organized in three main phases, often repeated: (1) loosening the substrate if necessary and the formation of dusting hollows or wallows by scraping and digging; (2) tossing the dust up into and on the plumage and rubbing the head in the dust; and (3) ruffling the dust through the plumage and shaking it out. Though the dusting bird may stand initially, it squats or lies down for most of the bout with feathers ruffled and wings drooped, often rotating its body, rising from time to time and at the end to shake. Details vary between groups and the behaviour has evidently evolved independently a number of times, even among birds of the same order in some cases (e.g. passerines). No species, however, really 'bathe' in dust, i.e. confine their activity to the movements and co-ordinations of true stand-in bathing in water, though some use odd water-bathing elements; neither is there any good reason to believe that dusting is the exact functional replacement for bathing. Among passerines, the House Sparrow *Passer domesticus* gets dust into the plumage mainly by wing-flicking (a bathing movement) but loosens the earth and forms its dusting hollow by leg-scraping (scratching) and bill-flicking; the Wren *Troglodytes troglodytes* dusts similarly but uses a wing-flipping action (also a bathing movement); the White-winged Chough dusts in an aberrant manner while standing, applying billfuls of dust to various parts of its plumage and dealing with the wings by movements like those used in oiling (see COMFORT BEHAVIOUR) and active anting behaviour (see ANTING). Among near-passerines, the Hoopoe *Upupa epops* digs up earth round its breast with a hoe-like raking movement of the bill, mandibles opening and closing as it pecks up detritus and flicks it inwards; it then tosses up the dust into the plumage mainly with the feet, moving forward repeatedly into freshly prepared earth. Among galliform birds, dusting has been studied best in the Phasianidae, especially the Bob-white *Colinus virginianus*, Red-legged Partridge *Alectoris rufa*, and Japanese Quail *Coturnix japonica*, their behaviour being closely similar to that of fowls *Gallus* and pheasants *Chrysolophus* and *Phasianus*; all loosen earth by pecking with the bill, scratch up dust into the plumage with the feet, and throw it up on the back with the wings.

Recent evidence strongly suggests that dusting helps in feather maintenance (see COMFORT BEHAVIOUR), either on its own or in combination with the head-scratching and preening that intersperse or follow bouts (but see ANTING and SUNNING). Experiments on quails (both *Colinus* and *Coturnix*) indicate that regular dusting maintains the optimum amount of oil on the plumage by removing excess preen-oil and other feather lipids, these being absorbed by the dust and then removed with it plus any dry skin, feather débris, etc.; the plumage of birds deprived of the opportunity to dust becomes oily and matted within a few days. (Similar results have been obtained in studies of small mammals, including gerbils *Meriones*, chinchillas *Chincilla*, and kangaroo-rats *Dipodomys*.) The House Sparrow and the Wren often dust and preen, etc. after bathing. Other functions in feather maintenance are also likely, including the treatment of ectoparasites (if present) and their discouragement; as with anting and sunning, the absence of such parasites at times when the behaviour occurs does not disprove the theory. Speculation that dusting soothes the skin during the moult by applying heat to the feather tracts seems ill-founded; there seems to be no seasonal correlation, incidental or otherwise, between dusting and moulting and, indeed, moulting *Coturnix* quail have been shown to dust significantly less during the moult than at other times. E

EAGLE: substantive name of large members of the Accipitridae, e.g. *Aquila*, *Haliaeetus* and *Circaetus* (see HAWK).

EAR: see HEARING AND BALANCE.

EAR COVERTS: modified contour feathers which cover the outer openings of the ears (see PLUMAGE; TOPOGRAPHY).

EAR TUFT: a bunch of long feathers towards the top of the head found particularly in owls. They can be erected when the bird is excited or afraid but have nothing to do with the ears or with hearing. An ear tuft may also be called a 'horn'.

EARLY EVOLUTION OF BIRDS: the debate over the origin of birds has been renewed in recent years after many decades of relative quiescence. There never has been any question that the late Jurassic fossil *Archaeopteryx lithographica* is the closest relative of all modern birds, (see ARCHAEOPTERYX), but opinions differ as to which group of archosaurs, the crocodiles, thecodonts or theropod dinosaurs, is most closely related to the avian lineage. The classic work of Heilmann in the 1920s suggested a thecodont ancestry, quite independent of those lineages which led to the crocodiles or to the sauropod and theropod dinosaurs. This traditional view has been challenged by Ostrom, who has argued that the avian lineage (including *Archaeotperyx*) is most closely related to theropods. He cites an impressive list of shared similarities in the postcranial skeleton in support of his claim. A third view is that *Archaeopteryx* and modern birds are more closely related to crocodiles than to theropods. At present the theropod hypothesis is to be preferred, if only because of the greater volume of evidence marshalled by Ostrom (1974, 1976).

With respect to our attempts to understand the biological transformations that took place between 'reptiles' and modern birds, it may not matter which of the above hypotheses we accept, because the most relevant source of evidence for inferring these transformations would seem to be *Archaeopteryx*. But the problem remains: how are hypotheses about the origin of birds to be tested? The structure of *Archaeopteryx* can be reconstructed and inferences can be made about its functional-mechanical characteristics. From this, 'scenarios' about the transformation to the modern avian condition can be created, but must be subject to critical evaluation, i.e. it must be possible to reject them, even if only by challenging the consistency of the arguments, since the chances of testing them empirically are small. Ostrom's hypothesis about the origin of flight is a case in point. He postulates that *Archaeopteryx* and its close relatives were primarily terrestrial predators and in pursuit used their feather-covered forelimbs as 'insect nets'. Such behaviour and morphology, he theorizes, 'pre-adapted' this lineage for powered flight. The traditional hypothesis is that an arboreal *Archaeopteryx* developed the ability to fly by parachuting and gliding between trees or to the ground. *Archaeopteryx* itself does not provide compelling evidence against either hypothesis. The latest interpretations suggest that *Archaeopteryx* possessed moderate aerodynamic capabilities, if not powered flight, but this is consistent with either a terrestrial or arboreal origin of flight. If *Archaeopteryx* is interpreted as arboreal, one could argue that its ancestors were terrestrial and already had the power of flight (Ostrom's hypothesis); if *Archaeopteryx* is interpreted as being primarily terrestrial, acquisition of arboreal habits could still be necessary for the evolution of an aerodynamic capability. Actually, the structure of *Archaeopteryx* does not seem designed exclusively either for a terrestrial or an arboreal existence, further complicating the issue. Any preferred hypothesis could be saved from falsification by shifting the postulated events backward or forward in time. Thus, such narrative-type scenarios on evolution of FLIGHT, homeothermy, origin of FEATHERS or other characteristics can scarcely be scientifically tested. Phylogenetic hypotheses, on the other hand, are rigorously testable in that they can be supported or not by analysis of new characters or new taxa. Some of these hypotheses, and their implications for the early history of birds, are considered below. It must be stressed that opinions on almost any hypothesis differ widely, that few critical evaluations have been published and that space does not permit extensive description of the evidence for or against.

One major lineage, comprising the divers, grebes, penguins, petrels, shearwaters and allies, may be one of the basal groups of birds. The divers, grebes and several Cretaceous diving birds, including *Hesperornis*, share many unique characteristics of pelvis, hindlimb and skull. Relationship of those groups to the penguins is supported by similarities of skull, sternum and pelvis. Pelecaniforms and procellariiforms seem to be good monophyletic taxa and similarities in their skull morphology suggest that they may be sister groups and related to the diving birds and penguin lineage, thus forming a single large aquatic assemblage.

Further, A.C. Wilson and his colleagues have argued that these aquatic groups share a general similarity in their proteins that sets them somewhat apart from other avian lineages. Also it has long been accepted, though without compelling evidence, that penguins and procellariiforms might be closely related.

This hypothesis involves interesting implications. First, this lineage must extend back to the beginnings of avian history. The extinct diving group, the enaliornithids, is related to divers, grebes and hesperornithids. *Enaliornis* is found in lower Cretaceous deposits, which implies that the common ancestors of the lineages leading to the diving birds and penguins on the one hand, and to pelecaniforms and procellariiforms on the other, are older, extending virtually back to the time of *Archaeopteryx*, much further than previously suspected. (This does not mean that the recent families of these orders are as old.)

Secondly, the hypothesis indicates that an early evolutionary line produced an entirely aquatic radiation, thus implying that each did not occupy that environment independently.

Thirdly, the hypothesis implies the loss of reptilian features such as teeth independently in at least two lineages. *Hesperornis* possessed teeth and, if this genus is related to divers and grebes, it can be inferred that teeth were lost in the latter lineage. Likewise *Ichthyornis*, the other late Cretaceous genus known to have teeth, may be more closely related to the charadriiforms than to any other group; this implies a second independent loss of teeth in charadriiforms.

A second group, the 6 orders of ratite birds and the tinamiforms (tinamous) were considered to be very primitive unrelated taxa, with separate ancestral stocks flying to the far-flung southern continents, evolving there in isolation to produce distinct lineages of large flightless birds. But much recent morphological, behavioural and biochemical data indicate that these birds comprise a monophyletic group. One hypothesis unites the South American rheas and African ostriches, on the one hand, with the Australian cassowaries and emus on the other. These 4 groups are related to the elephant birds of Madagascar, and all 5 in turn to the moas and kiwis. Finally, the ratite assemblage is most closely related to the Neotropical tinamous, capable of flight.

Much can be inferred from this hypothesis. First, because of their relationship to the tinamous, and because they possess features (e.g. pygostyle, alula) associated with flight, the palaeognaths were not primitively flightless; this contrasts with the old view that ratites were intermediate between reptiles and 'true' birds. Secondly, the ratites became flightless once, rather than many times independently. Thirdly, large body size evolved only once, soon after the ratite lineage separated from that of the tinamous, the kiwis apparently representing a secondary reduction. Not only are the closest relatives of the kiwis, the moas, of medium to very large size, but kiwis also lay an egg that is the largest relative to body size of any bird.

The hypothesis of ratite monophyly correlates well with what is known about continental drift and the timing of the break-up of the continents. It is thus possible to erect a fairly simple hypothesis regarding the biogeographic history of the ratites, involving continental fragmentation, isolation of once widespread ancestral populations, and subsequent evolution of the various taxa.

To what extent were the ratites and tinamous a part of the basal radiation of birds? A satisfactory answer will come only when an hypothesis has been presented and corroborated regarding their closest relatives among the remaining non-passerine birds. At present there is little or no evidence supporting the earlier view that ratites represent the sister-group of all other birds (although some biochemical data are said to point to this position). Ratites and tinamous seem just as advanced morphologically as other non-passerine groups, and thus it may be they are related to some non-passerine taxon fairly far removed from the basal radiation of birds.

Recently a small number of phylogenetic hypotheses, interrelating avian orders, have been proposed which, if corroborated by further evidence, may give increasing knowledge about the early evolution of birds. Most of these hypotheses are highly controversial and all the evidence has not yet been published. Nevertheless, it is useful to summarize their findings because they provide the best picture we have of avian evolution.

The Charadriiformes (shorebirds, gulls, and allies) are undoubtedly a very old group, extending well into the Cretaceous. Interrelationships within the order are a matter of some dispute and await a well-corroborated hypothesis. The Gruiformes (cranes, rails, and allies) have been considered as related to charadriiforms, possibly on the basis of a general similarity seen between the gruiform bustard-quails and plains-wanderers (Turnicidae) and some charadriiform groups, such as the seed-snipe (Thinocoridae) or the pratincoles and coursers (Glareolidae); and the similarity of the latter family to the sandgrouse and pigeons has suggested a close relationship between columbiforms and charadriiforms. If eventually these 3 groups are seen to have close ties with one another, the relationship very possibly would define one of the major early radiations within birds.

Recently, Feduccia (1976) and Olson (1978) have suggested that flamingos (Phoenicopteridae) are not related to ciconiiforms but to avocets and stilts (Recurvirostridae) within the charadriiforms. This hypothesis is based on some osteological similarities between the 2 groups and on a general similarity in breeding habits between flamingos and the Australian Banded Stilt *Cladorhynchus*. But there are data from osteology, myology, and biochemistry in conflict with their scheme of relationships and consistent with the view that recurvirostrids are advanced charadriiforms and that ciconiiforms comprise a monophyletic assemblage.

Another phylogenetic hypothesis links the ducks, geese, and swans (Anseriformes) and the pheasants, grouse, and their allies (Galliformes). That these are sister-groups is suggested by shared similarities, interpretable as derived, in their skull morphology and behaviour, as well as a general similarity in their biochemical make-up. On the basis of an electrophoretic analysis of egg-white proteins, Sibley and his colleagues (1972) postulated that the Hoatzin (Opisthocomidae) is not related to galliforms but to cuckoos (Cuculiformes). Conflicting evidence, both from morphology and the immunological examination of their proteins, suggests that the Hoatzin may not be related to cuckoos but is instead the sister-group of the other galliforms. Whichever hypothesis about *Opisthocomus* is correct, the relationship between anseriforms and galliforms involves two orders in which the history of the primitive families seems closely tied to the break-up of the southern continents by continental drift. This implies that their ancestry extends back into the Cretaceous. For example, within the galliforms the Hoatzin is South American in distribution; the next most primitive group, the megapodes, is found in Australasia; and the next most primitive group after the megapodes, the cracids, is primarily South American. Within the anseriforms, the primitive sister-group of the ducks, geese, and swans is the screamers (Anhimidae) of South America, whereas the most primitive member of the Anatidae, the Magpie Goose *Anseranas*, is Australian. These relationships imply trans-Antarctic relationships between South America and Australia, a common biogeographic pattern in plants and animals.

There is as yet no compelling evidence to suggest a relationship between the anseriform-galliform lineage and any other order. Several candidates have been suggested, including the ratites and tinamous and also the ciconiiforms. Once a corroborated hypothesis is put forth, it will almost certainly define a major lineage in avian history extending well back into the Cretaceous.

Most of the more 'advanced' non-passerine groups cannot be viewed amongst the earliest of avian lineages, but a consideration of alternative phylogenetic hypotheses and our present knowledge of avian paleontology strongly suggest that most of these orders had their origins in the Cretaceous.

The interrelationships of the diurnal birds of prey (hawks, falcons, and their allies) and the owls (Strigiformes) have been controversial and debated for more than a century. Some well-known 19th century avian systematists, such as T.H. Huxley and F.E. Beddard, believed in a relationship whereas others, such as M. Fürbringer and H. Gadow, thought owls to be closer to the nightjars and their allies (Caprimulgiformes). Some recent workers, most notably M. Jollie, hypothesize that the diurnal birds of prey are an unnatural group, composed of perhaps 4 separate taxa.

There are a number of unique osteological and myological characteristics uniting owls with at least some of the falconiform birds, and there are few similarities between owls and caprimulgiforms. To complicate matters further, some birds of prey, such as the secretary-birds (Sagittariidae) and New World vultures (Cathartidae), show no clear-cut relationships.

The origins of these orders must go back to a time in the Cretaceous. Virtually all of them have fossil representatives in the early Cenozoic, and thus the interordinal common ancestors were older still. Of considerable interest would be the discovery of the groups of non-passerine birds to which diurnal birds of prey and strigiforms, on the one hand, and caprimulgiforms on the other, are related. Such knowledge would help define several very old lineages within birds and provide much information about the evolution of the predatory life-style.

Two orders, the cuckoos (Cuculiformes) and the parrots (Psittaciformes), require brief mention. Both have been perennial enigmas as far as their relationships are concerned. Given the array of their possible relationships to other non-passeriform groups, both must be rather old, very likely Cretaceous.

All workers have recognized the orders Coraciiformes and Piciformes to be the most 'advanced' of the non-passerine birds and have considered the song-birds (Passeriformes) to be related either to one or the other, or to both. There is general agreement that the piciforms and passeriforms each constitute a monophyletic group, and equally that the coraciiforms may be an assemblage of unrelated taxa. Passeriforms have traditionally been related to piciforms but recent work suggests that passeriforms might be related to at least some coraciiform taxa. Moreover, the trogons (Trogoniformes) and mousebirds (Coliiformes) are also possibly related to some coraciiforms. The interrelationships of these groups are being studied by several systematists. In any case, fossil evidence already suggests that the common ancestors of these lineages must have been Cretaceous in age, although many of the recent families, particularly those in the Passeriformes, are almost certainly the results of Cenozoic radiations.

It can be seen from the preceding account that the interrelationships of the avian higher taxa are in a state of flux. Yet, it is equally obvious that this is a period of great excitement within avian systematics and that each year more and more is being revealed about the evolutionary history of birds. Once we have tested and corroborated hypotheses about the phylogenetic relationships of avian taxa, we can begin to answer a number of fascinating and important questions. For example, how many times did foot-propelled and wing-propelled diving evolve? How many different lineages of birds entered an aquatic environment? How many times did raptorial behaviour and morphology evolve?

In addition to these and other questions, phylogenetic hypotheses will also allow us to reconstruct the biogeographic history of avian taxa and relate that history to the paleogeographic and paleoclimatologic changes that took place in the Mesozoic and Cenozoic. One thing is almost certain to emerge from such analysis; avian phylogeny and biogeography are more intimately related to large-scale continental movements and climatic changes than previously realized. J.C.

EARTHCREEPER: substantive name of *Upucerthia* spp. (see OVENBIRD (1)).

ECDYSIS: see MOULT.

ECHOLOCATION: the ability to detect the presence of nearby objects by emitting sounds and analyzing echoes that return to the ears. This is found in 2 groups of birds: the Oilbird or Guacharo *Steatornis caripensis* (Caprimulgiformes, Steatornithidae) of northern South America and Trinidad, and in cave swiftlets of the genus *Aerodramus* (formerly included in *Collocalia*; Apodiformes, Apodidae) of the Indo-Pacific region (see SWIFTLET).

Uses. All these birds are cavernicolous in habit, using echolocation to find their way into the safety of caves where many of them nest and roost in complete darkness. Echolocation does not appear to be used in finding food. Oilbirds feed nocturnally on fruits and nuts which they appear to find visually, for they fly silently outside the caves. Swiftlets feed on insects, probably by sight, for they fly mainly by day although echolocation allows them to leave or return to the roost during darkness and so to forage much farther afield than would otherwise be possible. Swiftlets have also been observed feeding at night near artificial lights. Measurements of the sensitivity of their echolocation (described below) suggest that they are quite unable to detect targets as small as flying insects by this means.

Sounds. Unlike the very high-frequency (ultrasonic), vocal pulses emitted by most bats, the echolocation sounds of birds are clearly audible to man as a continuous train, or 'rattle', of sharp clicks. Sound frequencies range from 1 kHz to about 12 kHz (peak 2–4 kHz) in *Steatornis* and from 1–2 kHz to 7–16 kHz (main energy 2–7 kHz) in various *Aerodramus* species (Fig. 1). During flight in complete darkness, clicks are emitted continuously at rates of 3–20 per second, the higher rates being used when landing or negotiating an obstacle. The structure of the clicks varies in different species. The clicks of several *Aerodramus* species have been studied in detail and consist of 2 quite distinct sound impulses (Fig. 2a), each lasting for about 1 ms (millisecond) and 15–16 ms apart; the first impulse is of lower intensity than the second. These double clicks somewhat resemble those of the echolocating fruit-bats *Rousettus* (2 impulses of similar intensity, 20–30 ms apart but with sound frequencies of 10–65 kHz). Occasional triple clicks have been reported in *A. vanikorensis granti*. In *Steatornis* and in *Aerodramus maximus*, however, each click consists of a rapid burst of about 5–8 impulses within an interval of 20 ms (Fig. 2b, c). The significance of these different patterns is not yet clear but probably each provides more detailed information about the target than could be obtained from a single impulse.

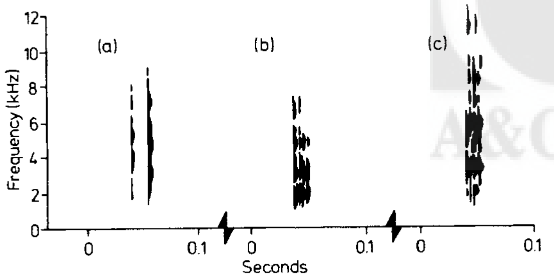

Fig. 1. Sound spectrograms of the echolocation clicks of: (a) the Edible-nest Swiftlet, *Aerodramus fuciphagus*; (b) the Black-nest Swiftlet, *Aerodramus maximus*; (c) the Oilbird, *Steatornis caripensis*.

The mechanism by which the clicks are generated is not known. In the fruit-bat *Rousettus* the double impulse is produced by clicking the tongue and this may also occur in the birds. Other suggestions are that the sounds originate in some part of the respiratory tract, such as the syrinx. However they are produced, the sounds seem to be emitted via the open bill since the echolocating *Aerodramus vanikorensis* swiftlets that incorporate vegetable material in their nests carry it in their feet; the non-echolocating species of swiftlets, *Collocalia esculenta* and *Hydrochous gigas*, carry nest materials in the bill.

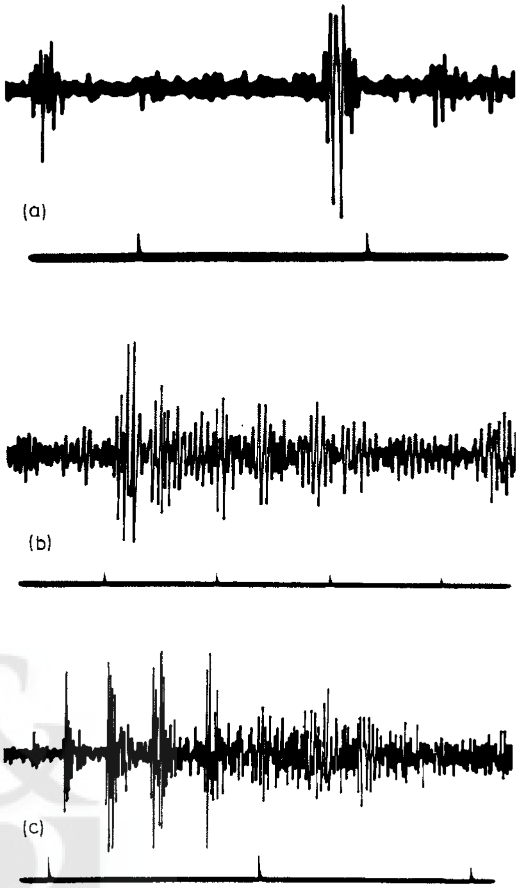

Fig. 2. Oscilloscope waveforms of the echolocation clicks of: (a) *Aerodramus fuciphagus*; (b) *Aerodramus maximus*; (c) *Steatornis caripensis*. All time markers equal 1/100 sec.

Hearing. The ears of echolocating animals form the receiver of the system so the sense of hearing in these species is of special interest. In general birds do not hear high frequencies (unlike most mammals) and recent observations suggest that *Steatornis* is no exception. Both the inner

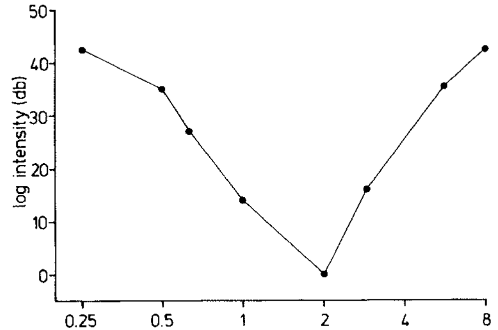

Fig. 3. Characteristic hearing curve of *Steatornis caripensis*. (Derived from Konishi & Knudsen 1979).

ear and the auditory region of the brain show sensitivity extending from 250 Hz to 8 kHz with a pronounced peak at 2 kHz (Fig. 3). This is at the lower end of their click spectrum but coincides with the most intense components. The effective wavelengths used for echolocation are therefore about 17 cm. Nothing is known of the range of hearing in *Aerodramus* although tests of its echolocation acuity (described below) suggest that shorter wavelengths and therefore higher frequencies are used.

It has been suggested that the auditory nerve in birds is able to follow much more rapid changes of sound intensity than is possible in mammals. If this is the case, birds would seem to be pre-adapted for the detection of echoes from emitted clicks. More recent work, however, suggests that the original comparison was not entirely valid and that birds in general are not especially outstanding in this respect. It remains to be seen whether echolocating birds show any special adaptations, as *Rousettus* does when compared with other, non-echolocating fruit-bats.

Acuity. One test of the accuracy and sensitivity of an echolocating system is the ability to detect and avoid fine wires or rods suspended in the flight path. Early work on different species of *Aerodramus* produced rather conflicting results. *A. fuciphagus* was apparently unable to detect wooden rods of 1 cm diameter although *A. vanikorensis* could avoid 6 mm rods. More recent tests on *A. hirundinaceus* with rods of 1 cm or 4 mm and wires of 1.5 mm diameter support the earlier results for *A. vanikorensis* and suggest that even the finer wires were often detected.

Results of tests on *Steatornis* in outdoor aviaries indicate that vision is used in preference to echolocation even on moonless but starlit nights. When blindfolded, the birds clicked continuously but hovered instead of negotiating obstacles. Arrays of plastic discs, with diameters from 5 cm to 40 cm, were then hung in turn in a passageway of the roosting cave. Only discs of 20–40 cm were avoided, suggesting that the acuity of echolocation is very low in this species. Direct comparisons are difficult because flat discs reflect sound in a different way from cylindrical rods or wires. Nevertheless, it seems likely that acuity and sensitivity are higher in *Aerodramus* than in *Steatornis*. The strength and directionality of echoes depend on the sound wavelength in relation to the size of the reflecting object, so it is possible that *Aerodramus* actually 'use' shorter wavelengths from the higher frequencies present in their clicks.

Both groups of birds are far inferior in their echolocation performance to the ultrasonic bats that use centimetre or even millimetre wavelengths and can detect wires as fine as 0.1 mm diameter. This is not surprising for their systems have very different purposes. Whereas many bats have to detect and intercept small flying insects that may be actively evading pursuit, the birds apparently have only to negotiate their presumably familiar caves, find their nests and avoid collision with their neighbours. How they (and bats) manage to do this when enormous numbers are flying in a confined space is still a complete mystery. J.D.P.

ECLECTUS: former generic name used as English name (otherwise 'Eclectus Parrot') of *Lorius roratus* (see PARROT).

ECLIPSE: a post-nuptial plumage stage occurring in some species. It is characterized by being of much shorter duration than the winter (or non-breeding) plumage in most species that show marked seasonal change, as well as by being dull in comparison with a conspicuous breeding dress. Notably, the males of many of the Anatidae are in full breeding plumage for the greater part of the year but have a dull plumage during the latter part of the summer (while a simultaneous moult of the remiges may render them temporarily flightless)—see DUCK; MOULT; PLUMAGE.

ECOGEOGRAPHICAL RULES: term proposed by Mayr (1956) as a replacement for the less satisfactory term 'ecological' or 'climatic rules', for the 'rules'—used in the sense of generalizations that are widely valid but not without exceptions—relating geographical variation in size, proportions, colour, and other characters of animals to climate and other environmental factors. The best known of such rules in birds are BERGMANN'S, ALLEN'S and GLOGER'S, and the tendency for clutch-size to increase with latitude. (See also ENERGETICS, Climatic adaptation).

Mayr, E. 1956. Geographical character gradients and climatic adaptation. Evolution 10: 105–108).

ECOLOGICAL ISOLATION: a term used in at least two quite separate ways.

Oceanic islands, or mountain tops surrounded by forest are ecologically isolated, in a purely physical sense from other, similar areas of habitat. Extreme isolation favours the evolution of endemic species.

In an entirely different context, a set of species may be said to be ecologically isolated from one another by virtue of their distributions, feeding or nesting ecologies. The term may be applied either to a set of closely related species from one geographical area, or to a set of species, only some of which are closely related, sharing a habitat.

In both cases, ecological isolation refers to the manner in which each of the species in question differs in its ecology from congeners and/or cohabitants. Species may be isolated geographically, locally between habitats, or have different feeding or nesting ecologies within habitats. The European titmice (Paridae) provide excellent examples of all these methods of ecological isolation.

Lack, D. 1971. Ecological Isolation in Birds, Oxford and Edinburgh.

ECOLOGICAL RELEASE: an increase in the abundance of a species and/or a broadening of its feeding ecology in the absence of a competing species: most often used to describe what happens to the ecology of a species if it occurs on a faunally impoverished island with few competitors.

ECOLOGICAL SUCCESSION: the changes that occur in a habitat over time, due to habitat modification by former colonists (the build-up of humus, for example) and the arrival of new species. Thus bare ground undergoes succession through scrub to woodland, and lakes gradually fill in and become marshes. Many bird species are associated with ecological communities in a particular stage of succession; scrub woodland, second growth forest, or reed-swamps for example, all of which are stages in ecological successions to different habitats.

ECOLOGY: variously defined as the study of plants and animals in relation to their environment; the study of the distribution and abundance of organisms; and the study of the structure and function of nature.

It is well known that each species of bird breeds and spends the non-breeding season, respectively, in characteristic areas of the earth; these areas, which in many instances are the same, form the geographical range or distribution of the species (see also DISTRIBUTION, GEOGRAPHICAL; MIGRATION). Within these areas, the species will occupy only certain habitats, and within the habitat, each species has a characteristic behaviour and abundance. It interacts with other birds, with its food organisms, with its own predators, and less directly with numerous other living things that share its habitat. The search for patterns within these phenomena, and for the principles which underlie them, constitute the main objectives of avian ecology.

Ranges and niches. Evidence for direct climatic limitation of species' ranges is generally poor, but there are some well-documented examples. The further dispersal of the House Sparrow *Passer domesticus* into desert regions of North America may now be limited by daily maximum temperatures surpassing its upper limit of tolerance. The same species is limited northwards by low winter temperatures, except where it makes use of man-made shelters and food. The remarkable northward spread of the Fan-tailed Warbler *Cisticola juncidis* in Europe after 1971 is apparently due to a long succession of mild winters: the limit to this expansion of range may be set by the 5°C January isotherm. Whereas it seems obvious that climate must impose similar limits on the distributions of many other species of birds, most ecological data are anecdotal, and confounded by the effects of climate on vegetation and hence on food supplies. Many species avoid seasonal climatic extremes by migrating, and to this extent climate has profoundly influenced their ecology.

The total geographical distribution of many species is most easily described in terms of a vegetation type: here the effects of climate appear to be indirect, via the plants. Thus, boreal forests that have survived on southern mountains since the last retreat of the glaciers are occupied by outlying populations of typical northern birds. The Redpoll *Carduelis flammea* in Europe and the Blackpoll Warbler *Dendroica striata* in North America are examples. Many species have also extended their ranges over wide extremes of climate by taking advantage of the agricultural habitats created by man (see RANGE CHANGES). In these cases at least it is reasonably clear that the nature of the vegetation rather than the climate governs the distribution of the species.

Ranges can be mapped (see ATLAS; CENSUS) and habitats described by the vegetation, topography and local climatic conditions. A species's 'niche' is a more abstract concept, not helped by the word being used in two different ways. Sometimes it refers loosely to the role or job of the species: Old World vultures (Aegypiinae) and New World vultures (Cathartidae) both fill the 'scavenging niche' in their respective continents. More rigorously, niche refers to the full range of key environmental conditions within which the species can survive: vegetation of particular heights, food of particular types and sizes, temperatures within defined limits, etc. If one species is prevented from occupying or using some particular combination of environmental variables by the presence of a second competitively superior species, it is convenient to refer to the range of environmental conditions which the first species could occupy as its 'Fundamental Niche'; and to the range which it actually does occupy as its 'Realized Niche'.

Local diversity. Four factors, at least, are important in determining the number of species of birds breeding in an area. They are the size of the area, its distance from similar areas, habitat complexity, and latitude. Differences in the richness of local bird communities reflect differences in these four major variables, which also influence broader, geographical patterns in bird diversity.

Size and distance effects. Large areas support more species than small areas. This is true both of real islands surrounded by water, and 'pseudo-islands' isolated by other environments, e.g. the southern isolates of boreal forest, lakes, woods in agricultural land, or urban parks and cemeteries. In virtually all cases, if the logarithm of the number of breeding species (S) is plotted against the logarithm of the size of the area (A), the resulting graph is a straight line with an average slope very close to 0.3 (i.e. $S \propto A^b$ with $b \simeq 0.3$). Slopes in individual studies range from 0.052 for the total bird species found on 'pseudo-islands' in the Southern Venezuelan Highlands, to 0.78 for breeding seabirds on Hawaiian atolls. The steeper the slope, the bigger the difference will be between the species diversity of large and small islands of comparable type.

The conservation implications of these findings are important. As a good approximation, if an island is reduced to one tenth its former size, (e.g. by felling, reclamation, or natural disaster), approximately one half the breeding species will disappear. Which species will be lost is more difficult to predict. As an example, in English broad-leaved woodland, Moore and Hooper (1975) found Nightjars *Caprimulgus europaeus* and Lesser Spotted Woodpeckers *Dendrocopos minor* breeding only in the largest areas (> 100 ha): many species, including Tawny Owls *Strix aluco* and Treecreepers *Certhia familiaris*, were apparently absent from the smallest woods which they censused (less than 0.01 ha). In urban cemeteries in Chicago, only American Crows *Corvus brachyrhynchos* and Chipping Sparrows *Spizella passerina* nested in the smallest plots: large cemeteries (> 100 ha) supported 18 breeding species (J. Lussenhope).

Why should large islands support more species than small islands? *The Theory of Island Biogeography* (MacArthur and Wilson 1967) views the number of species as being set by a rapidly achieved dynamic balance between immigration and extinction (and see DISTRIBUTION, GEOGRAPHICAL). Small populations on small islands have a higher probability of becoming extinct because natural disasters more often wipe out rare species than common ones: and high extinction rates lead to fewer species. Alternatively, and no less likely, the 'Theory of Habitat Heterogeneity' proposes that larger islands contain a greater variety of habitats, and hence more species. Both explanations undoubtedly contribute to the species-area relationship. Differences in slope in species-area relationships presumably reflect, in part, the different rates at which new habitats are added as islands increase in size.

The distance of the island from suitable source areas is also important. Area for area, isolated islands support fewer species than otherwise similar islands nearer to large pools of potential colonists. It is generally agreed that isolation reduces the rate of immigration, and hence lowers the equilibrium species number.

Habitat complexity. Areas of comparable size and isolation may still differ markedly in the diversity of their breeding birds. In a few hectares of habitat, the number of species of breeding land birds is strongly influenced by the amount of foliage at different heights, and to a lesser extent by the variability in these layers from place to place (habitat patchiness). The variety of plant species has little effect: a habitat composed of all sizes of a single tree species will support more birds than a uniformly mature stand of many different trees. Intriguingly, the same foliage profiles generate similar numbers of breeding species in North America and in Australia even though the birds and plants are totally different (H.F. Recher). Less attention has been paid to other types of habitat but, for example, the breeding bird diversity of Swedish lakes is influenced by productivity (S.G. and I.N. Nilsson): area for area, naturally more productive (eutrophic) lakes have more species than oligotrophic water bodies.

When a plot of land is abandoned by man, or is denuded by natural causes, its vegetation undergoes a regular succession usually leading to vegetation resembling that of undisturbed areas nearby. The birdlife undergoes a succession paralleling that of its habitat, some species being present only in early stages of the plant succession and others in later stages. Species abundances also change gradually. Vegetation has a profound effect on which species of birds occur and how many of each there will be. The number of species found at any one point on the successional gradient, however, is determined mainly by the foliage height profile at that point, as already outlined.

Latitude. There are astonishing variations in the number of species breeding in single habitats at different latitudes. The general trend is for species diversity to increase towards the Equator. Thus a few ha of rain-forest in Mexico may have over 100 species of breeding birds, while a comparable forest, with similar foliage profile, in temperate regions seldom has more than 30 species, and in high latitudes far fewer species breed in any single habitat. Two species of heron breed on the coast of Newfoundland, 8 in the vicinity of Long Island, and 12 in southern Florida. What is the cause of the much greater diversity of species in the tropics? One possibility is that evolution (speciation) has proceeded faster or for longer in the tropics and, given enough time, temperate regions will eventually acquire as many species as the tropics have at present. Alternatively, all habitats are saturated or very nearly saturated with species, and the limit is for some reason higher in the tropics. The data available at present are more consistent with the second explanation than the first. Tropical rain forests support numerous birds with very specialized or 'narrow' niches—resident fruit, flower or large-insect feeding species relying on a predictable supply of such resources the whole year round; most of these species could not possibly survive at higher latitudes.

Not all geographical regions or groups of birds show a cline in diversity towards the tropics. In mature eastern deciduous forests of North America, breeding passerine species diversity increases steadily northwards, almost doubling over 16° of latitude (K.N. Rabenold). Long distance migrants (e.g. Parulidae) are the main contributors to this reverse gradient. There are several possible explanations, but no concensus, as to why. In Fenno-Scandinavia, the number of species of breeding waders (Charadrii) (and the proportion of wader species in the total land-bird fauna) increases northwards from a minimum of 7 species in each '100 km' square in the south to 23 in the far north. O. Järvinen and R.A. Vaisanen suggest that this cline is a function of habitat heterogeneity: for example, the presence of more 'seashore' and 'mountain' habitats further north increases the number of wader species by 5–6 and 2–3 respectively.

Two final points about species diversity are worth making. First, a great deal of work has been done on the factors controlling species diversity during, and much less outside, the breeding season. In general the same broad patterns appear to hold throughout the year, although the numbers and kinds of species in particular habitats often change dramatically as migrants come and go (see MIGRATION). Second, diversity can either be described simply by the number of species, S (sometimes called 'Species Density'), or in more sophisticated ways using mathematical 'Indices of Species Diversity'. The latter have two principle advantages. They take into account not only the numbers of species, but also their relative abundances; and most are insensitive to the omission or inclusion of occasional, rare, species. The commonest Index of Diversity in the bird literature is the Shannon-Wiener Index (H′), described in detail by Krebs (1978). In practice, for bird communities, H′ and S are usually highly correlated and can be used interchangeably.

Population dynamics. Within a habitat, different species of birds differ noticeably in their abundances: woodpeckers, for example, are usually much rarer than titmice (see TIT) in woodland. Moreover, providing the habitat does not change, each species-population remains relatively stable from year to year, fluctuating within narrow limts. The long-term sustainable abundance of a species is referred to as its 'Carrying Capacity', denoted symbolically by the letter *K*. Unusually severe winters inflict heavy mortality upon small resident passerines (e.g. Wrens *Troglodytes troglodytes*) pushing their populations well below *K*; recovery follows quickly over the next 2 or 3 breeding seasons. The interesting question is why such populations eventually stop growing and what regulates them.

Some species do, from time to time, show remarkable and sustained population growth, increasing exponentially (that is, by a constant percentage each year) over several years. The colonization of Britain by the Collared Dove *Streptopelia decaocto* and its subsequent dramatic increase is a good example. The population of Shags *Phalacrocorax aristotelis* on the Farne Islands in North-east England grew continuously at a little over 15% a year for over 30 years from 1930 onwards. Indeed all species have the potential to increase exponentially in this way; technically, it is referred to as their 'Intrinsic Rate of Increase', *r* (see also NATURALIZED BIRDS).

Processes of two kinds prevent most populations from growing exponentially for very long. The first are 'density independent' and include natural disasters such as hard winters which kill large numbers, irrespective of initial density. The growth of the Shag *Phalacrocorax aristotelis* population on the Farne Islands was terminated abruptly by an outbreak of 'Paralytic Shellfish Poisoning': 82% of the breeding population died during a few days in May 1968 (see RED TIDE). Limits to population growth are also imposed by processes of a second kind, called 'density-dependent'. The term refers to changes in one or more of the rates of immigration, reproduction, emigration or death in response to changes in population density. Density-dependent processes regulate populations, for example through an increase in the death rate (i.e. the proportion dying) as population density increases; or a decrease in the birth rate (i.e. the number of eggs laid by each female) as density increases; or some combination of the two. Competition for a limited food supply, disease, and predators are all potentially capable of imposing density-dependent restrictions upon population growth. Populations eventually stabilize when births and immigration are balanced by deaths and emigration.

By comparison with many other groups of animals, the number of species of birds for which the key density-dependent processes have been identified is very small (see Krebs 1978: Lack 1966). Female Great Tits *Parus major* in Wytham Woods, near Oxford, lay progressively smaller clutches as the density of the breeding population increases; Weasels *Mustela nivalis* also prey more heavily upon Great Tit nests in those years, and those parts of the wood, where the birds are most dense. Together, these two density-dependent processes control the abundance of this particular population of Great Tits.

Territorial behaviour may provide density-dependent control of some bird populations, by limiting the number of breeding pairs. Experimental removal of territory holders often shows there to be a surplus of birds waiting to occupy vacant sites. It would be a mistake, however, to assume that territorial behaviour evolved in order to regulate population density. Ownership confers considerable advantages on individual territory holders, and natural selection operates on individuals, not on populations. Hence, whilst one consequence of territorial behaviour may be to regulate population density, it is not the reason territorial behaviour evolved (see Krebs and Davies 1978). It is now generally agreed that many other behaviours, such as periodic abstinence from breeding and deferred maturity, have similarly evolved to maximize individual fitness. Whilst they may again have consequences for population dynamics (by reducing recruitment) the hypothesis that they evolved specifically to adjust population recruitment to available resources is not tenable.

Diversity and population stability. A popular belief is that more diverse ecological communities are more stable: a second that they are more stable because they are more complex. Data to support the first contention for birds (or any other organisms) are almost non-existent. The second is certainly wrong.

Unfortunately ecologists use the word 'stability' to mean several different things. Here it refers to the amplitude of the fluctuations in population numbers measured at comparable time-intervals; from one breeding season to the next for example. By comparison with many animals, birds have remarkably stable populations. Occasional spectacular irruptions (see RANGE CHANGES), or precipitous declines to extinction (see EXTINCT BIRDS), are exceptions which prove the rule. Whereas it is quite common for an insect population to change in density from one year to the next by a factor of 100 times or more, a 10-fold change in density for most birds is a very large fluctuation indeed. But within these rather narrow limits, certain patterns are still discernible. It seems likely that tropical rain-forest birds are not only members of extremely diverse communities, but also that their populations are very stable by comparison with temperate forest species; unfortunately really good data are hard to come by. A detailed study using 15 long-term censuses of breeding land birds by O. Järvinen showed that central European and southern Scandinavian communities are made up of fairly stable populations, but, as expected, more northerly populations from species-poor communities fluctuated markedly.

The argument that populations fluctuate more in simple communities because diversity is low appears on theoretical grounds to be misguided. Mathematical models (May 1974; see also Krebs 1978) of simple as opposed to complex communities show quite the reverse; as a general rule, complex systems (with many species, and numerous interactions between species) are less, not more stable than simple ones. Hence, if species-rich systems in nature are more stable than simple ones, it is despite, not because of, their complexity. Present evidence suggests that cause and effect work the opposite way round to popular intuition and belief. Harsh, unpredictable and fluctuating environments are a primary cause both of the lower diversity of northern bird communities, and the greater instability of their component populations. The much more benign and stable environment of a tropical rain-forest supports numerous species with very specialized or 'narrow' niches that could not possibly survive at higher latitudes. Stability begets diversity and not the other way round.

Species interactions and the competitive exclusion principle. In 1934, G.F. Gause wrote: 'As a result of competition two similar species scarcely ever occupy similar niches, but displace each other in such a manner that each takes possession of certain peculiar kinds of foods and modes of life in which it has an advantage over its competitor'. The ideas embodied in this quotation are often referred to as the 'Competitive Exclusion Principle.' In the terms outlined previously, Gause's principle asserts that two species cannot coexist indefinitely if they are limited in their population sizes by the same density-dependent factor. *Inter alia*, the members of a local bird community, it is argued, must be sufficiently different in their ecological niches to reduce, if not eliminate, interspecific competition and hence avoid competitive exclusion. Since there are likely to be only a limited number of ways of exploiting an environment (a limited number of niches), there must be limits to the number of species which coexist in different communities.

Innumerable studies document such differences in the ecological niches of coexisting species. For example, species may differ in body-size and hence food-size as in the fruit pigeons *Ptilinopus* and *Ducula* of New Guinea lowland rain forest (J.M. Diamond); or in feeding stations, like the antbirds in the genus *Myrmotherula* which differ in their foraging heights in South American rain-forest (J. Terborgh). Less esoteric examples include differences in body-size and hence prey-size and feeding station in tits *Parus* spp. coexisting in European broad-leaved woodland; differences in bill length (and hence maximum probing depth) and leg length (and therefore in the maximum depth of water exploited) in waders sharing a muddy shore; and in the use of feeding grounds at different distances offshore by seabirds from mixed colonies. Lack (1971) provides an outstanding review of numerous examples.

There are two main caveats attached to the admittedly plausible view that such ecological differences necessarily have anything to do with minimizing competition. First, species cannot compete unless something, for example food or nest sites, is in short supply. It is therefore crucial to know when the main periods of resource limitation operate on individual species. If, for the sake of argument, individual populations are mainly controlled by food shortages outside the breeding season, then resources may not be limiting for breeding birds, and differences in their ecology during the breeding season have nothing to do with minimizing competition for food (Fretwell 1972). Second, it is obviously absurd to regard each difference in the ecology and morphology of species sharing a habitat, or indeed any particular difference, as necessarily having anything to do with 'minimizing competition' or 'permitting their coexistence'. It is a difficult matter to decide which, if any, of the observed differences are important. Wiens (1977) argues strongly that competition and 'niche-differentiation' play an extremely small part in structuring most bird communities; others (e.g. Cody and Diamond 1975, and Lack 1971) would certainly disagree.

None of this is to say that the competitive exclusion principle does not operate sometimes: only that in most cases much more rigorous evidence is badly needed. Sometimes, 'natural' experiments are provided. The mainland flycatcher *Elaenia flavogaster* appears to be driving the West Indian species *E. martinica* from the Grenadines, and the Topknot Pigeon *Lopholaimus antarcticus* apparently almost exterminated the White-headed Pigeon *Columba leucomela* in Australia when, due to palm-fruit shortage, both were forced to feed on the same camphor laurels.

Such examples are reasonably convincing. Much more equivocal are distribution patterns which are consistent with the effects of interspecific competition, but which certainly do not prove it. Some species are much commoner on islands than in similar mainland habitats (Northern Cardinals *Cardinalis cardinalis*, Gray Catbirds *Dumetella carolinensis* and White-eyed Vireos *Vireo griseus* on Bermuda for example), possibly due to an absence of competitors on the island (K.L. Crowell). But it is also possible that cases of apparent 'Competitive Release' on islands are due to an absence of predators or disease, a more abundant food supply, or subtle differences in the vegetation. The only way to be really sure is to do experiments, and with birds this is often technically very difficult or ethically unacceptable. But some experiments on competition have been carried out.

Removal of Red-headed Woodpeckers *Melanerpes erythrocephalus* from Illinois woodlands in the winter allowed two previously excluded species to invade, (the Red-bellied Woodpecker *Melanerpes carolinus* and White-breasted Nuthatch *Sitta carolinensis*) and a third (the Downy Woodpecker *Picoides pubescens*) to broaden its feeding niche by foraging higher up the trees (J.B. Williams and G.O. Batzli). And by experimentally inducing Jackdaws *Corvus monedula* to nest in Magpie *Pica pica* territories in Sweden, competition between these two species for food during the nesting season was elegantly demonstrated by G. Hogstedt.

Finally, we should note that if predation or disease play an important part in controlling some bird populations, then competition for limiting resources will again be markedly reduced. The link between population dynamics and the interpretation of community structure is therefore a very close one.

Food chains, food webs and energy flow. Each species of bird in any community is part of a network of feeding relationships encompassing many sorts of organisms. In the simplest case they are members of a 'food chain', with green plants at the base, and one or more bird species as higher members. A typical food chain is:

Sparrowhawk (*Accipiter nisus*)
↑
Great Tit (*Parus major*)
↑
Winter Moth caterpillars (*Operophtera brumata*)
↑
Oak leaves (*Quercus*)

The concept of a food chain is a convenient abstraction; a way of focusing on parts of much more complicated 'Food Webs'. Thus, Great Tits not only take Winter Moth caterpillars, they also feed on a broad spectrum of woodland invertebrates and seeds, each of which in turn is exploited by other organisms. Great Tits also suffer predation from Weasels. Weasels and Sparrowhawks take many other sorts of prey. The resulting web of interactions can be very complex.

One of the interesting generalizations to emerge from food-web studies is this. If we follow individual pathways through a web, the number of steps from bottom to top is typically short, involving not more than 3, 4 or at most 5 levels, from plants (level one) through herbivores (level 2), carnivores (level 3) and carnivores on carnivores (level 4). ('Carnivore' is used here to denote a species which eats other animals: it includes insectivorous and predatory birds). The assignment of individual species to such 'trophic levels' is useful but necessarily simplistic, because most select food from more than one level. Great Tits take caterpillars from trophic level 2, and spiders from trophic level 3, and hence straddle the third and fourth trophic levels. But few would deny that Great Tits feed, on average, lower in the food chain than Sparrowhawks.

A second useful generalization is that species higher in the chain tend to be rarer than species lower down. Dense swards of vegetation support between 10 and 100 voles per hectare; we do not expect to find more than one pair of Tawny Owls on 10 hectares feeding on the voles. At certain times of the year there may be more than 100,000 Winter Moth caterpillars per hectare, but only between 1 and 10 pairs of Great Tits, and one pair of Sparrowhawks per square kilometer.

All organisms require energy to survive. Food chains represent the transfer of energy from the 'primary producers' (plants) which make food energy available by photosynthesis to higher trophic levels (see ENERGETICS). Of the energy consumed by an individual, population or entire trophic level, only a fraction appears as useful production (food) for the next step in the chain. The rest is dissipated in respiration, or lost as faeces. Birds, being warm blooded (endothermic), dissipate a very large amount of energy in respiration. On an annual basis, a typical bird population makes available as production only 1% or less of the energy it consumed. It is not surprising, with such a rapid dissipation of energy at each step in the food chain, that hawks are rarer than their passerine prey and food chains are short. But there may be more to it than this. Food chains are not noticeably longer in more productive communities; nor are chains dominated by cold-blooded animals (which use up much less energy in respiration and hence make more available as production) noticeably longer than those in which birds (or mammals) are important components (S. Pimm and J.H. Lawton). These paradoxes are not fully understood but, as far as birds are concerned, body-size must also constrain the lengths of food chains. Most predators must be bigger than their prey, so that even if enough energy reached the ends of some food chains to support a population of predatory birds at trophic level 6, such 'super-predators' would probably be too large and heavy to fly.

In the total energy economy of terrestrial communities, birds are trivially important. In a Northern Hardwood Forest in New Hampshire, R.T. Holmes and F.W. Sturgess showed that the plants made available over 40 million kilocalories per hectare per year as 'primary production' (1 kilocalorie = 1,000 calories; an alternative way of measuring energy is in joules. There are 4.18 joules in a calorie). Of the 40 million kc, 56 species of birds between them consumed only 0.17% as primary consumers (trophic level 2) and 0.14% as secondary consumers (trophic level 3). In marine communities, the impact of vast seabird colonies may well be more substantial. Fourteen species of seabirds, including Fulmars *Fulmarus glacialis*, Guillemots *Uria aalge* and Puffins *Fratercula arctica* consumed an estimated 29% of the mean annual fish production within a 70 km radius of their colony on Foula, Shetland (R.W. Furness).

As energy flows down food chains, so do a wide range of compounds pass from victim to exploiter and back to the environment. The role of birds in the cycling of key elements, like nitrogen and phosphorus, has received comparatively little attention, except in the case of the accumulation of the vast GUANO deposits from the faeces of the Guanay Cormorant *Phalacrocorax bougainvillei* along the coast of Peru. In one study, the faeces of Rooks *Corvus frugilegus* brought more calcium and potassium into an English woodland in 8 weeks than entered the community in a whole year of normal rainfall (J.S. Weir). How crucial this input was to other members of the community is not clear.

Harmful compounds also pass through food chains and may accumulate in vulnerable top carnivores both of terrestrial and aquatic environments. The havoc wrought by chlorinated hydrocarbons (DDT, Dieldrin and their relatives) on the Peregrine Falcon *Falco peregrinus* and other raptor populations is well known; see e.g. EGGSHELL THINNING; TOXIC CHEMICALS.

Evolutionary ecology. Not all interactions in ecology involve aggression, competition and being killed. A small but important component involve co-operation: the technically correct term is 'Symbiosis', where two species gain mutually in fitness from the interaction. The removal of ectoparasites from the bodies of large African mammals by Oxpeckers *Buphagus africanus* and *B. erythrorhynchus* is one example. Of much more general importance are the roles of birds as plant POLLINATORS, and as agents of SEED DISPERSAL.

Compared with insects, birds are minor pollinators of flowers, but for certain specialized plant species in some communities they are vital. The birds gain by feeding on nectar and the plants by setting fertile seeds. Classical flower-feeders are the hummingbirds of the New World, and the sunbirds and honeyeaters of the Old. Birds and flowers often show a high degree of mutual adaptation or COEVOLUTION; for example typical hummingbird pollinated flowers in North America (e.g. *Penstemon*, and *Ipomopsis*) are red (bees cannot see red, hummingbirds can), with long corolla tubes and copious nectar. In the south-western deserts the Ocotillo or Candlestick Plant *Fouquieria splendens* times its flowering to coincide with the northward spring migration of Rufous Hummingbirds *Selasphorus rufus*.

Reliance on birds as pollinators becomes progressively rarer outside the tropics. The role of birds as dispersers of fruits and seeds, however, is of widespread importance. The sizes, colours, time of ripening and composition (i.e. protein, fat and sugar levels) of many fruits appear highly evolved for the needs of particular species or groups of birds. The marked changes in colour which accompany ripening in numerous fruits serve as conspicuous signals to their avian consumers. Many seeds will not germinate until they have passed through a bird's intestine. A particularly remarkable example may be the Mauritian tree *Calvaria major*. Formerly widespread and abundant on the island, by 1973 only 13 old and dying specimens remained, prompting the suggestion that seeds must have passed through the gut of the Dodo *Raphus cucullatus* before germinating: unfortunately the evidence is at best equivocal (see DODO). The message, however, remains: too close a mutual dependence on other species carries a price as well as evolutionary advantages.

Evolutionary ecologists are concerned not only with coevolution, but also with understanding the whole range of adaptations shown by species to their environments: that is, with questions of how niches are moulded. The habitats chosen by a species are likely to be those in which the individuals have the greatest production of surviving offspring, as the genes of these individuals will be preserved by natural selection. The survival of the offspring will depend upon the adaptations of the bird to life in that area, and upon the number and habits of other species already utilizing the area. From a bewildering variety of specific adaptations several broad generalizations are now emerging.

Average CLUTCH-SIZE, for example, increases with latitude in single species, and within a group of close relatives (like *Emberiza* buntings or stiff-tailed ducks *Oxyura*). The longer hours of daylight further north and seasonal flush of insect food presumably allow birds to produce and rear more offspring, and select for individuals laying larger clutches.

A convenient but necessarily crude distinction, encompassing a whole range of adaptations, is between 'r-selected' and 'K-selected' species. r-selected species (from the technical notation for the Intrinsic Rate of Increase of a population) have high reproductive rates; live in unpredictable environments; suffer high density-independent mortalities; are generally small and short-lived, with good powers of dispersal; and are opportunistic with markedly fluctuating populations. K-selected species (from the technical notation for the carrying capacity of a population) are usually large, but have low reproductive rates; live in predictable environments; suffer low density-independent mortalities; are long-lived and colonize new habitats slowly; they are ecologically restricted and normally have very stable populations maintained close to their carrying capacities by density-dependent controls. Budgerigars *Melopsittacus undulatus* and California Condors *Gymnogyps californianus* lie at opposite poles of the r-K continuum. J.H.L.

ECONOMIC IMPORTANCE: see PESTS, BIRDS AS; UTILIZATION BY MAN.

ECOSYSTEM: the totality of factors of all kinds that make up a particular environment.

ECOTONE: an area of transition (or the actual boundary) between adjacent plant associations, and hence between the animal communities associated with them.

ECOTYPE: a locally adapted population or race, having characters resulting from the selective pressures exerted by its particular environment.

ECTOPARASITE: a parasite inhabiting the exterior of the host's body, as distinct from an ENDOPARASITE. Apart from the nest parasites discussed below, birds are parasitized by the following groups of ectoparasites: chewing lice (Phthiraptera, 'Mallophaga'), louse-flies (Diptera, Hippoboscidae), fleas (Siphonaptera) and bugs (Hemiptera, Cimicidae) belonging to the Insecta, and ticks and mites belonging to the Arachnida. Not included here are the free-living biting flies (e.g. Ceratopogonidae, Culicidae, Simuliidae, Tabanidae) and leeches, although these can be important vectors of endoparasites such as protozoa and arboviruses.

Chewing lice (Mallophaga). These belong to the insect order Phthiraptera that also includes the sucking lice, and spend the whole of their life-cycle on the body of the host. They live amongst the feathers, with the exception of species of one genus that live in the throat pouches of pelicans and cormorants. They feed on feathers and blood or other tissue fluids; blood may be taken by some species from developing feathers and species of at least one genus feed exclusively on fluids; lice living inside the calamus of the quill feed on the central pith. The eggs are attached to feathers or in a few cases are laid inside the quills. Mallophaga are closely adapted to the environment formed by the feathers of the bird; their pigmentation, size and shape and certain morphological characters of the head are apparently dependent on feather colour and structure. In size and shape they are adapted to the different ecological niches found on the body of the bird; thus, for example, on the head and neck is found a short round-bodied type, and on the wings and back a more flattened, elongate type. A bird is usually parasitized by a number of different species of Mallophaga, some adapted to the different ecological niches on the body of the host; the Rook *Corvus frugilegus*, for example, has 6 species belonging to 5 genera, and some of the tinamous have as many as 12 species of Mallophaga.

The present distribution of Mallophaga suggests that they became parasitic on the class Aves at an early stage and that they evolved with their hosts. Different species of birds do not normally come into contact with one another, so that there is little opportunity for interchange of lice populations; these have, therefore, become strongly isolated, so that in many cases a species of Mallophaga is found on only one host species or a group of related host species. Thus, in general, Mallophaga of related hosts are themselves related; within the order Charadriiformes, for example, there are a number of mallophagan genera common to the 3 suborders, and the species of these genera parasitizing the suborder Alcae are more closely related to each other than to those on the other suborders, Charadrii and Lari.

Thus each order of birds is parasitized by species belonging to one or more genera that are frequently peculiar to it, and the relationship between the species of these genera generally reflects the relationship between the hosts within the order. It is, therefore, usually possible to place a bird correctly in its order, and often in a lower category, if the mallophagan genera parasitizing it are known, and for this reason Mallophaga may be useful evidence in deciding the relationships of birds of doubtful affinities. The affinities of the Mallophaga suggest, for example, relationships between the Struthionidae and the Rheidae, between the Phoenicopteridae and the Anseriformes, and between the Musophagidae and the Galliformes. However, many factors, such as discontinuous distribution of genera and species, parallel and convergent evolution, secondary infestations, and human error in interpretation of the evidence, may obscure the initial relationship between host and

House Martin *Delichon urbica*, with Hippoboscid fly on back, collecting mud for nest. (*Photo: E.J. Hosking*).

parasite, so that evidence from Mallophaga cannot be used as an infallible guide to relationships between the hosts.

Louse-flies (Diptera, Hippoboscidae). The Louse-flies are true flies. They are blood-suckers specialized for living on birds and mammals by being tough, leathery, flattened dorso-ventrally and with strong curved claws. The wings are usually fully developed, but may be reduced and useless for flight. The larvae develop, singly, inside the abdomen of the female; the fully developed larva (prepupa) pupates immediately after its release from the female. In the case of Swifts *Apus apus* and House Martins *Delichon urbica*, which return to the same nest site each year and whose flies are flightless, the next generation of flies is produced from pupae deposited in the nests. In many other species the pupae are deposited away from the nest and the emerging adult must fly in search of a suitable host. There are *c.* 200 species, of which *c.* 150 are recorded from 24 orders of birds. Some species, e.g. *Pseudolynchia canariensis*, are widespread and polyphagous, while others have a much more restricted distribution and host preference, such as *Crataerina pallida* confined to certain *Apus* spp. in the western Palearctic. Some show a distribution more dependent on habitat, such as the *Ornithomya* spp. in Britain: *O. chloropus* occurs on all birds in open, particularly moorland, areas; *O. avicularia* and *O. fringillina* in other areas, the former on thrushes and larger birds, the latter on smaller birds. The Ostrich louse-fly *Struthiobosca struthionis* is much more closely related to the hippoboscids of larger mammals than to the rest of the bird flies.

These relatively large parasites can occur in large numbers—over 30 of the flightless *C. pallida* have been found on one swift and over 40 of the related *C. hirundinis* on one House Martin. They are often accused of weakening birds, but there is little evidence for this and the birds only suffer their attentions for relatively short periods since the flies die before the birds migrate. Very few flies are carried on migrations to or from the breeding site.

Mallophaga and pregnant females of certain mites attach to hippoboscids to aid their dispersal from host to host. These flies are the principal vectors of some trypanosomes and *Haemoproteus* (Protozoa).

Fleas (Siphonaptera). The fleas are blood-suckers; the body is flattened laterally to allow them to move easily through fur or feathers, and their power of jumping enables them to reach a new host or escape capture. Of the more than 2,000 species and subspecies of fleas only *c.* 125 are bird fleas. The entire pre-adult life is passed away from the host, usually in the host's nest, where the larva feeds on organic debris. Bird fleas are found on the body of the bird, but are more numerous and most species are largely resident in their nests. As the flea may spend so much of its life-cycle off the host, it is influenced as much by climatic and other environmental factors as by the host itself. This, together with the fact that in each generation the flea, on emerging from the pupa, may have to find a new host, has generally limited host restriction. There are, nevertheless, a number of host-specific bird fleas, of which *Ceratophyllus rossittensis* on the Crow *Corvus corone* is an example. On the other hand some bird fleas have a restricted geographical distribution; thus *C. borealis* is found in the British Isles almost exclusively on the outlying islands. In others environmental factors clearly influence distribution; for example, there is considerable overlap in the hosts used by *C. garei* and *C. gallinae*, but the former occurs mainly in damp nests on or close to the ground, while *gallinae* occurs mainly in looser built dry aerial nests. Similarly, the House Martin in Britain is host to 5 species of fleas, but 2 species (*Callopsylla waterstoni* and *Frontopsylla laeta*) occur only on nests on cliffs, while one species (*Ceratophyllus hirundinis*) is found only in nests on buildings.

Large numbers of fleas may be found in one nest—up to 2,000 have been recorded.

Bugs (Hemiptera, Cimicidae). Less than a third of the 80 species of the bed-bug family Cimicidae occur on birds, mainly on Hirundinidae and Apodiformes. Most of the others feed on bats. In Britain the Martin Bug *Oeciacus hirundinis* of House Martins and the Pigeon Bug *Cimex columbarius* of domestic pigeons are common. The eggs are fixed on or close to the nests of their host, and the emergent nymphs and subsequent stages feed on blood. They can occur in large numbers in the nests, but they are not well adapted to travelling on their hosts and so are not often found on birds away from the nest.

Mites and ticks (Acari). Some mites ectoparasitic on birds are blood-feeders, for example the Red Mite of poultry *Dermanyssus gallinae* (Dermanyssidae) occurs frequently on both wild and domestic birds. This species feeds at night, passing the day in dark retreats in the nest or roost, except in heavy infestations, when it is found on the host at all times. The widespread macronyssid species *Ornithonyssus sylviarum* (the European Fowl Mite) and *O. bursa* (the Tropical Fowl Mite) complete their life-cycle on the host, feeding by both day and night. *Bakericheyla chanayi* (Cheyletiellidae) has been recorded feeding on the blood of passerines. The chelicerae of blood-sucking mites are generally stylet-like for piercing, and, in some, the shafts are grooved to form a blood canal. The Knemidokoptidae and Epidermoptidae are skin parasites of birds; the former usually attack specific tissues and cause characteristic conditions such as 'scaly-leg' and depluming scabies. Females of some epidermoptid genera are also found on the host's hippoboscid and mallophagan ectoparasites.

Certain larval Trombiculidae ('chiggers') are ectoparasitic lymph-feeders, while representatives of the Rhinonyssidae, Dermanyssidae, Ereynetidae and Cytoditidae inhabit the nasal cavities of numerous birds.

'Feather-mite' species of the Analgoidea, Pterolichoidea and Freyanoidea have adapted to fill the various microhabitats provided by feathers. Modifications chiefly affect body shape and terminal leg setae and are most marked in those mites inhabiting exposed sites, such as the primary flight feathers. Feather-mites remain on their host throughout their life cycle; those living on the feather surface feed on desquamated skin cells and oily secretions from dermal glands, while those found within the calamus utilize quill substances. Species are generally restricted to a particular avian family, host specificity being most marked in sea-birds and least in passerines.

Other mites associated with feathers include members of the Syringophilidae (Cheyletoidea); these are elongate species which live inside the quills. Some 18 genera are reported from 10 bird orders.

Ticks (Metastigmata) comprise a specialized order of large blood-sucking Acari which are all ectoparasites of terrestrial vertebrates. They are an economically important group, being vectors of many disease organisms including rickettsias and spirochaetes.

Ticks are usually confined to the head region of birds, probably due to the efficiency of the beak as a 'de-ticking' instrument. The tick's mouthparts are adapted both to secure it to the host during feeding and to facilitate blood-sucking.

Of the soft ticks (Argasidae), a number are primarily associated with birds. *Argas persicus* and *A. reflexus*, for example, infest domestic fowl and pigeons respectively, although both have also been reported from wild birds. *Ornithodoros capensis* parasitizes sea-birds, while other species of this genus have been found on both avian and mammalian hosts.

Argasids spend most time in the dwelling place of the host. The larvae may remain attached to the host for several days, but the nymphal stages (of which there may be up to 8) and adults only feed during the host's visits to its roost or nest. Due to the rather irregular and limited opportunity for meals, argasids engorge rapidly and can survive for long periods without feeding.

Birds are also primary hosts for a number of hard ticks (Ixodidae), for example *Ixodes rothschildi*, *I. unicavatus* and *I. uriae* are parasites of sea-birds, while *I. passericola* infests passerines. Ixodids associated with birds are often 3-host species; each stage (larva, the single nymphal stage, adult) feeds on a different host before dropping to the ground to moult or lay eggs. In contrast to argasids, hard ticks may take some days (some males even take months) to engorge.

The immature stages of several genera of ticks which normally infest mammals are also found attached to avian hosts, and it has been suggested that bird migration contributes to the spread of mammalian tick-borne organisms.

Nest fauna. Birds' nests may contain a great many animals apart from the rightful occupants (see NESTING ASSOCIATION): 529 different kinds, chiefly arthropods, have been taken from 56 nests in Finland. The groups discussed above are all obligate parasites, that is, they are obliged to spend at least part of their life on or in very close association with their hosts, and receive nourishment directly from the host. Apart from any of these that may be in the nest, probably 20–25% of nest dwellers are actually dependent on the occupied nest, the rest being casual visitors or those that are also found elsewhere in similar microhabitats. Included among those dependent on the nest are certain beetles, moths and flies. It is the blood and tissue-feeding larvae of some flies, e.g. the genera *Protocalliphora* (Calliphoridae), *Philornis* and *Passeromyia* (Muscidae) or *Neottiophilum* (Neottiophilidae), that can be the most dangerous parasites of the young birds, sometimes being responsible for their deaths. *Carnus* species are tiny flies (Diptera, Carnidae) that emerge from the previous season's nests and then fly, if necessary, to an occupied nest, where the wings are shed and the abdomen becomes greatly distended (physogastric). Even then they are only *c.* 2 mm long. They probably feed on secretions of wounds etc and, although often found on unfeathered nestlings, are unlikely to do them much harm. On the other hand, many of the inhabitants of the nest act as useful scavengers and some feed on the parasites, such as beetles and their larvae that feed on flea larvae. The nest fauna is dependent on the type of nest; those in burrows and holes, especially when occupied from year to year, have a richer fauna than open, scantily lined nests, such as that of the Woodpigeon *Columba palumbus*.

Harmful effects. Apart from being vectors of certain diseases (see DISEASE), ectoparasites when present in large numbers may have a debilitating effect on their hosts and may even cause death; heavy infestations of feather mites may practically denude a bird of feathers, and some Mallophaga cause damage to wing feathers by chewing holes in these when in pin. The presence of large numbers of ectoparasites has been accused of causing the host to injure itself by scratching and to interfere with egg production and fattening of poultry. Secondary infections may occur at sites of attachment in particular of ticks. Scaly-leg caused by knemidokoptid mites can deform or cripple the bird. Predation by the host is the main control of ectoparasites and a debilitated or injured bird may accumulate excessive populations; dust bathing may also help in ectoparasite elimination (see COMFORT BEHAVIOUR; DUSTING).

ECTROPODACTYL: term applied to an unusual arrangement of the toes, found in some Picidae (see LEG).

EDAPHIC: term applied to environmental factors dependent on conditions of the soil or substratum.

EDIBILITY: see PALATABILITY OF BIRDS AND EGGS.

EDIBLE NESTS: the nests of certain species of SWIFTLET (Apodidae), composed largely of saliva or nest-cement, being the mucilaginous secretion of the paired sublingual glands (Bernstein 1859, Marshall and Folley 1956). The salivary glands have no digestive function, but are periodically increased in size in both sexes and solely in relation to nest building. Once dry, the secreted gelatinous nest-material is very difficult to dissolve in water, buffer solutions, or even dilute acid or alkali. This is an ecological adaptation, enabling the bracket-shaped nests to stick to the rock surface even under permanently humid cave conditions. Little is known about the chemical nature and nutritive value of the nest material. The secreted product is a mucoprotein yielding on hydrolysis proteinous compounds and reducing sugars (17%). Because of its rather high carbohydrate content, the product contains polymers of amino sugars, i.e. glycopeptides. Hydrolysis of the proteins yields a high content of amide-N, arginine, cystine and histidine, the last two being S-containing amino acids. An overall analysis showed that the commercial product contained 11% water, 9% nitrogen, 1% sulphur and very small amounts of phosphate. Its mineral (ash) content was rather high, being 2.5% (Wang 1921). Isoelectric focusing of the proteins showed a protein pattern to some extent similar to the blood protein pattern of the same species.

Edible, i.e. sufficiently 'saliva-rich' nests to make commercial harvesting worth while are produced by 3 species of *Aerodramus*:

(1) *Aerodramus fuciphagus*, the Edible-nest Swiftlet, building a white, bracket-shaped self-supporting nest. Its nest-cement is nearly unadulterated as it is only very sparsely mixed with a few downy feathers of the bird's own plumage. It breeds in sea caves in the Malayan and Indonesian Archipelago, also in caves of limestone outcrops far inland and in old buildings, often in Chinese quarters. Usually the caves or colonies are protected and subjected to careful harvesting.

(2) *Aerodramus unicolor*, the Indian Edible-nest Swiftlet, which builds a nest of moderately copious nest-cement intermingled with large feathers (sometimes rectrices and primaries) of the bird's own plumage and vegetable materials. The nest is also self-supporting. This swiftlet breeds in sea-caves on rocky islets off the southern coast of the Indian sub-continent and Sri Lanka.

(3) *Aerodramus maximus*, the Black-nest Swiftlet, makes a self-supporting relatively small, more saucer-shaped nest with saliva hinges of firm nest-cement. In contrast to the foregoing species, the nest-cement is copiously mixed with small feathers of the bird's own plumage. Moreover, in contrast to the first two species which invariably lay 2-egg clutches, the full clutch of this species is one egg. This species is the main occupant of the Great Cave of Niah, Sarawak, N. Borneo (probably the largest single site, with 2 million nests) and other caves in this region. It breeds together with the Edible-nest Swiftlet in inland caves in Indonesia and only sporadically in buildings (Malaysia).

Unfortunately, the species named *Collocalia esculenta*, the Glossy Swiftlet, makes nests of mainly extraneous materials that render them inedible even by Chinese standards.

Edible nests are highly valued by the Chinese as a culinary delicacy, being made into the most expensive food in Asia, 'caviar of the East', namely bird's nest soup. The nutritional value will be that of protein-sugar solution, although its complete amino acid composition has not yet been determined. Eaten alone, it is a practically tasteless gelatinous substance to an untrained palate. Chinese and other Asians esteem it, however, as a tasty, nourishing and even aphrodisiac food. It is also used for convalescents and the aged. Because of their relative tastelessness, bird's nests are often served by the Chinese in soup or jelly mixed with chicken, spices, sauces or sweets. Nests of the Edible-nest Swiftlet are of the highest grade as they are white in colour and contain few feathers. They are generally sold tied up in rows or strings as intact nests. The lowest grade is that of the Black-nest Swiftlet, whose nests require cleaning in order to remove the feathers, as they are sold as powder.

The collecting of edible nests reaches far back into antiquity, probably to pre-historic times, as indicated by remains found in the Niah cave

Edible-nest Swiftlet *Aerodramus fuciphagus* at nest. (*Photo: J.H. Becking*).

(Harrisson 1959). The trade in nests was established in China as long ago as the T'ang Dynasty (AD 618–907), as is evident from figures on pottery. The first written records are from Arabic sources (Idrisi, AD 1154). The trade is mentioned by the Dutch naturalist-surgeon J. Bontius in 1625, referring to edible nest sales in the newly founded Jacatra (now Jakarta), and in records in the Daghregister of Batavia for 1637. Records of harvests from the caves on the southern coast of Central Java (Rongkop) date back to 1743 (Voltz 1905). In 1840 the rights were purchased from the feudal authorities by the Government of the Dutch East Indies for the large sum of Hfl. 130,000, and leased by the government in 1886 for Hfl. 725 and in 1893 for Hfl. 1,495 monthly (Van der Meer 1927). Junghuhn (1853) mentioned that the Chinese paid in 1847 Hfl. 4–5,000 per picul (= 62 kg) of nests and that the total annual revenue of the cave of Karangbolong (Central Java) was *c.* Hfl. 200–250,000. In Malaysia (Penang) in 1978 the yield of a house colony for a 7-month period was 1,200 nests (12 kg), worth £560 (Langham 1980).

Collecting the edible nests in high, dark caves is a hazardous occupation and only done by special collectors, whose skill is often passed on from father to son. The crevasses, chimneys and galleries where the swiftlets breed in dense clusters are normally reached by long sets of single bamboo poles, pinned or socketed together, and (at Niah) reaching up to 130 m in height. One man climbs and balances, wielding a long bamboo to which is attached a beeswax candle above a hoe-like blade with which he scrapes the nests off; on the floor far below an assistant gathers them as they fall. The sea-cave at Rongkop can only be reached by rattan (or rope) ladders. When the sea is rough, its entrance is alternately opened and closed by the rolling waves and the climber (like the swiftlets) has to select the right moment to enter by launching himself into the cave on a swinging rope. Throughout south-east Asia this difficult and dangerous work is falling out of favour with the younger generation, so that the number of nests taken is slowly dwindling. In N. Borneo the bird's nest industry is falling into decay, at least temporarily; this process is assisted by the austerity of recent policy in China, for over a thousand years the prime consumer. However, in other parts of south-east Asia (Malaysia, Indonesia) the industry is still flourishing, as is evident from the high prices for the product and high rents paid by the leaseholders. (T.H.) EFFERENT: opposite of AFFERENT (see NERVOUS SYSTEM).

EGG: the development of the female reproductive cell or ovum with additional layers added in the oviduct and then laid by the female.

The avian egg is a complicated structure whose essential components are yolk, albumen, and shell, together with various membranes segregating the constituents (Fig. 1). The relative proportions of the three major components vary substantially between species in response to differing ecological pressures on each.

Yolk. The ripe ovum is richly endowed with yolk, the main nutritive component for the development of the embryo. Essentially a viscous liquid enclosed in a thin elastic vitelline membrane, the yolk nevertheless has a distinct structure of alternating thick layers of yellow fat-rich material and thin layers of white, poorer in fats and pigment. The central core of white yolk is called the latebra and extends outwards in a narrow column towards the vitelline membrane. This it meets in an expansion called the 'nucleus of Pander' enveloping the 'germinal spot' or blastodisc from which the embryo will develop after fertilization. This blastodisc is visible only in unfertilized eggs, as a small opaque white circle containing some vacuoles. Once fertilized, the ovum commences development at the blastodisc, turning it into a blastoderm visible on dissection of a new-laid egg as a wide oval region with a central transparent portion known as the area pellucida; from this the embryo develops.

The yolk of an egg provides the main reserves of food materials for the developing embryo and correspondingly varies between species. Nidifugous species have proportionally more yolk in their eggs than have nidicolous species and the yolk itself is also rich in lipids. Since such eggs are also unusually large for the species body size, the total yolk and lipid contents are substantially above those of nidicolous species. Part of this extra lipid fuels the greater developmental maturity of the nidifugous hatchlings and part provides the food reserve needed until they can find their own food.

Albumen. The albumen or egg-white comprises 4 more or less concentric layers about the yolk, with the innermost layer extending along the long axis of the egg from opposite ends of the yolk to meet the shell membranes and form a protective suspension system for the yolk called the chalaziferous membrane. On this the yolk hangs in a layer of liquid albumen, in turn encased in an albuminous sac, a structural framework of semi-solid mucin fibres whose interstices are filled with liquid albumen. The fibres extend at each end of the egg into the inner shell membrane, thus locking the entire sac in place to form a cushioning shell, isolating the yolk from deformation stresses. The sac is otherwise isolated from the shell membranes by the fourth zone, a thin layer of liquid albumen.

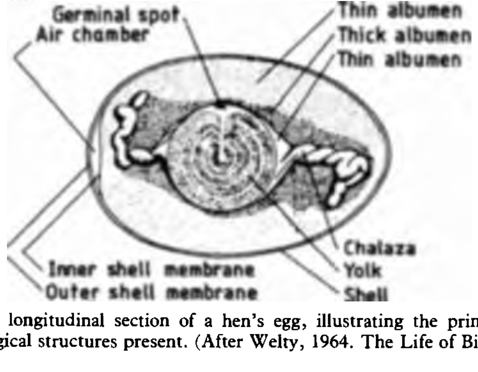

Fig. 1. A longitudinal section of a hen's egg, illustrating the principal morphological structures present. (After Welty, 1964. The Life of Birds).

The main components of the chalaziferous membrane supporting the yolk are the chalazae, a pair of dense spirally twisted cords of mucin fibre attached to the yolk as a fibrous capsule over its surface and interlacing with similar fibres in the albumen at the two free ends (Fig. 1). The arrangement allows the yolk to rotate freely as the position of the egg changes in the nest, resulting in a permanently 'up' position for the developing embryo. The chalazae acquire their twisted dense structure during the rotation of the egg as it descends the oviduct.

Albumin accounts for about 90% of the protein of the albumen, with mucin and globulin contributing about 5% each. It is the main component that provides the viscosity of the egg white. The albumen is secreted by the magnum of the oviduct in response to the passage of the ovum along it.

Membranes. The egg membranes consist of 2 layers of parchment-like texture, separated at the blunt end to form an air chamber (Fig. 1). The inner one is about one-third the thickness of the outer and consists of matted protein (keratin) fibres bound together with an albumin-based 'cement' and penetrated by numerous pores. The outer or true shell membrane contains fewer pores and consists in detail of 3 separate layers, the outermost of relatively coarse, unbranched and flattened fibres of keratin, the inner 2 of much finer and branched fibres of keratin and mucin. Both are laid down in the isthmus of the oviduct.

The air cell does not appear until the egg is laid and subsequently enlarges as the embryo develops. Its function is apparently to conserve the limited water supply of the embryo, by re-condensing respiratory water through a 'cold nose' effect.

Shell. The outer layer of the egg is heavily calcified, its inner surface closely attached to the outer of the shell membrane. In detail its inner structure is of an array of approximately hemispherical knobs, each containing a core of organic material in which shell membrane fibres are embedded. These knobs or mammillae fuse basally, before giving way to an outer 'spongy layer' (so called for its appearance in decalcified specimens) in turn encased in a cuticle of organic material. Numerous pores penetrate the shell, commencing in small surface depressions and terminating between the mammillary knobs, and provide for respiratory exchange of oxygen, carbon dioxide, and water (see also EGGSHELL, ULTRASTRUCTURE OF).

The shell is secreted in the uterus and consists of a basic protein framework heavily deposited with minerals, largely calcium carbonate in the form of calcite. The organic material—which resembles but is not identical with collagen—accounts for about 3% of the shell, calcium carbonate about 94%, and magnesium, sodium and potassium salts accounting for much of the rest.

The shell provides the mechanical strength of the egg and its thickness therefore varies between species. A thick shell provides considerable protection against accidental breakage but imposes a difficult task on an embryo attempting to cut its way out. The shell can, however, be weakened during incubation, for the embryo draws heavily on the calcium for its own skeletal growth and the shell is thus thinner when the embryo is ready to hatch. Shells can also be selectively thicker where they are subject to wear: Guillemot *Uria aalge* eggs are thicker at their narrow end, where they are in contact with the surface of the rocky nesting ledges and are thinner at their broad ends, where the chicks emerge. Conversely, the eggs of megapodes are buried in a mound of rotting vegetation or in sun-warmed soil which provides the heat necessary for incubation; the parents hardly touch them at all, and the shells are correspondingly unusually thin.

Shell thickness has proved particularly susceptible to the effect of certain widely used agricultural chemicals, notably DDT. Birds ingesting high levels of these compounds or their metabolic residues subsequently laid thinner shelled eggs than did uncontaminated birds and consequently suffered reduced breeding success through frequent breakage of these eggs during incubation (see EGGSHELL THINNING).

Shape. Eggs vary greatly in shape but within a species they are similar. Also, related groups of species tend to have similar egg forms. Some broad generalities are possible: owls and kingfishers and a few other groups lay almost spherical eggs and most aerial and fast-flying species—swifts, swallows, hummingbirds—lay long elliptical eggs. Most of the species laying pyriform (top-shaped) eggs lay 4 eggs per clutch, with little intraspecific variation. Such eggs can be closely packed together by arranging the narrow ends to point inwards, thus minimizing the area to be covered by the incubating adult; a compact group also dissipates heat rather slowly. A further correlation is that species breeding on bare ledges tend to have pointed eggs, the small rolling circle of the egg when knocked being adaptively advantageous.

Egg-shape is determined during its passage through the oviduct which exposes it to morphological, physiological and genetic influences. A wide variety of terminologies are in use by oologists describing the resulting variety of egg shape. Some of the major terms are illustrated in Fig. 2.

Colour. Eggs derive their colour from pigments secreted by cells in the wall of the oviduct, particularly of the uterus. The pigments are deposited at different depths in the shell according to the position of the eggs in the oviduct at the time of secretion. Much of the ground colour of an egg is provided by pigments in the spongy layer of the shell and must therefore be secreted at the upper end of the oviduct, whilst the markings, spots, and scrawls of the cuticle must be secreted only shortly before laying. There are major differences between species in this respect; in some raptors and plovers the pigment deposits are purely superficial whilst in the Cassowary *Casuarius casuarius* egg the outside is uncoloured but the inner layer is green.

The shell pigments are derived from two sources, blood haemoglobin and bile pigments, respectively giving red-brown colours based on porphyrin and blue-green colours based on cyanin. In certain regions, notably Australia and parts of southern India with red soil, erythrism (production of reddish eggs) is unusually common. The same phenomenon is also unusually frequent (for unknown reasons) in certain species, for example, in Herring Gulls *Larus argentatus*.

In many species the eggs are uniformly coloured or tinted, as in the blue or blue-green of many thrushes and the pale green of many ducks. But in many other species the ground colour is over-laid with dense patterns of blotches, spots or streaks of one or more colours. The density and intensity of these may vary along the egg, possibly reflecting the pressure applied to the egg in the oviduct. If the egg is still when pigment is applied, a pattern of spots will be generated but if the egg is in motion then lines or streaks will result.

Despite the great variety of markings, the eggs of individual females are often distinctive and therefore under hereditary control. This is also implied by the precision with which European Cuckoos *Cuculus canorus* and other brood-parasites mimic the eggs of their host species (see BROOD-PARASITISM).

Egg coloration shows a number of broad ecological correlates. Most ground-nesting species have cryptic brownish eggs if laying on dead vegetation, lighter, sandy-coloured eggs if nesting on beaches or in deserts, or even blackish eggs if nesting on burnt ground (as with *Cursorius temminckii*). Within the thrush family, ground nesters tend to have relatively cryptic eggs in brown, grey or olive, tree-fork species to have eggs with heavy blotches resembling shadow-marks, crevice nesters to have speckled white or blue or just plain blue eggs and hole-nesters to have pure white eggs. The gradient with nest situation suggests exposed eggs benefit from coloration by making them inconspicuous to predators whilst white eggs are needed in dark situations where the birds risk putting their feet through their own eggs. Both ideas have been confirmed experimentally.

White eggs are also found in those open-nesting species which cover their eggs when leaving the nest, as do various ducks and grebes, or which incubate or cover their eggs from the laying of the first one, as do herons, owls and doves. This also suggests that the ancestral egg was white, with colour an evolved characteristic against predation.

Individual variation in egg markings or colour is most pronounced in those species in which confusion of egg ownership is possible. For most birds, return to their nest is a guarantee of return to their own eggs but in crowded colonies and in species without nests this certainty is reduced. Guillemots have been shown to identify their own eggs on the basis of individual combinations of ground colour and profuse blotch patterns; each bird can thus be certain it has returned to its own egg on the crowded cliff ledges. Individually recognizable eggs have also been reported from Great-tailed Grackles *Quiscalus mexicanus* nesting colonially in crowded coconut palms.

Certain species are particularly prone to the attentions of brood-parasites and egg discrimination is generally higher among these species than among unparasitized species. In general, the former recognize only species-specific characteristics of their own egg, perhaps because the selective costs to the bird of erroneously rejecting its own eggs in attempting individual discrimination would be greater than the costs of occasionally failing to detect parasitization by another species.

Size. The size of eggs laid by birds ranges across 5 orders of magnitude

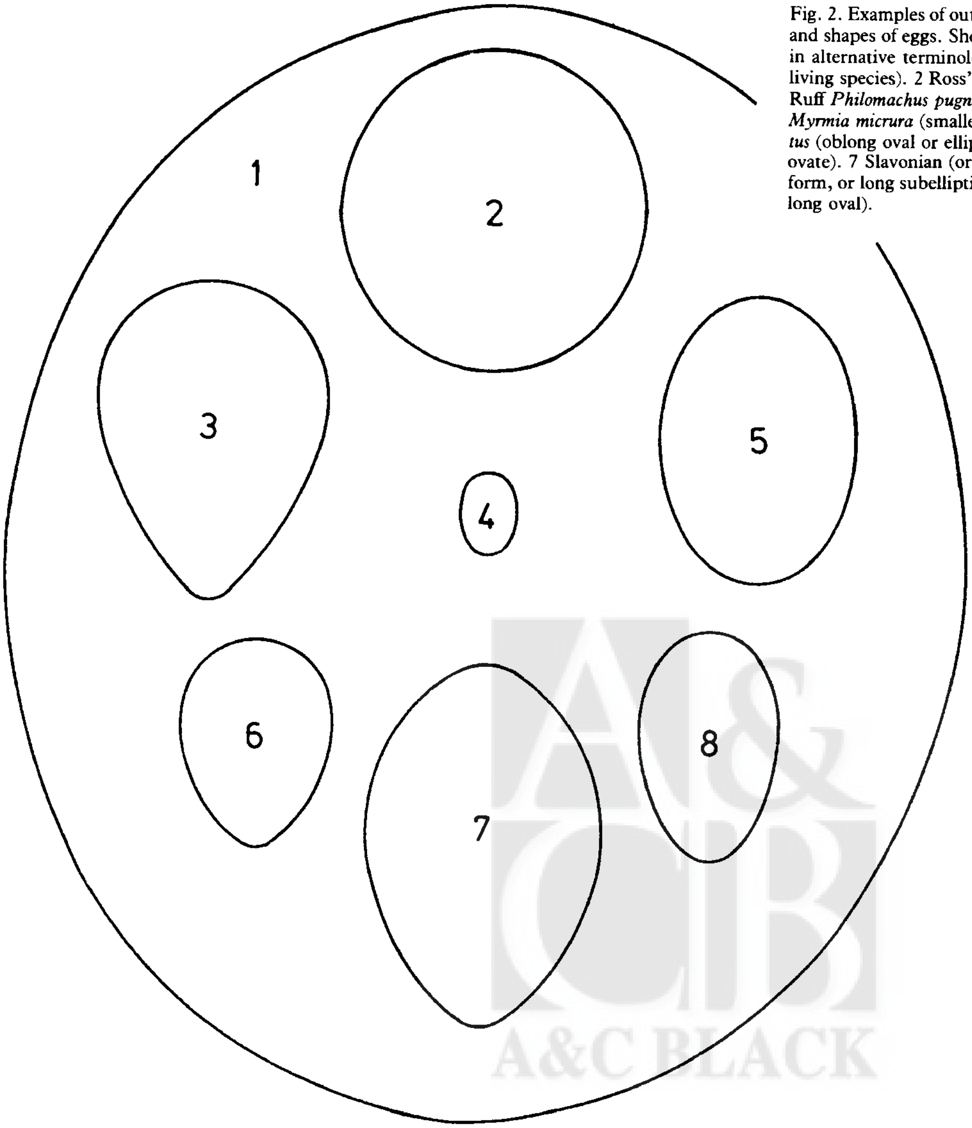

Fig. 2. Examples of outlines (or 'profiles') to illustrate some different sizes and shapes of eggs. Shown in natural size; the shapes here are designated in alternative terminologies. 1 Ostrich *Struthio camelus* (largest egg of a living species). 2 Ross's Turaco *Musophaga rossae* (round or spherical). 3 Ruff *Philomachus pugnax* (pyriform or conical). 4 Hummingbird species *Myrmia micrura* (smallest egg). 5 Coroneted Sandgrouse *Pterocles coronatus* (oblong oval or elliptical). 6 African Thrush *Turdus olivaceus* (oval or ovate). 7 Slavonian (or Horned) Grebe *Podiceps auritus* (bi-conical, fusiform, or long subelliptical). 8 Alpine Swift *Apus melba* (elliptical ovate or long oval).

from a hummingbird's 0.3 g through to the 1,600 g egg of the Ostrich *Struthio camelus*. Egg weight is closely correlated with the weight of the female, however, varying allometrically within each order or family to a 0.67 exponent. That is, if species A weighs twice species B its eggs will weigh $(2.0)^{0.67}$ or 1.59 times those of species B.

Substantial differences in egg-size exist between different orders once body size is allowed for: a 100 g falcon lays a 15 g egg whilst a 100 g dove lays only a 6 g egg. Such differences (which for a 100 g bird range from 4.5 g in the Cuculiformes to 21 g in the Procellariiformes) are associated in part with whether the chick is nidicolous or nidifugous. Precocial chicks must fend for themselves in whole or in part from shortly after hatching and therefore have to hatch from a relatively larger egg. Within a particular development class the extent to which the chick is covered with down at hatching is correlated with egg-size.

Some parasitic cuckoos have unusually small eggs for the size of the female, evidently adaptive for their habits of parasitizing species smaller than themselves.

Even within a single order of birds there may be considerable variation in the size of egg laid by individuals of common size but from different families. In the Passeriformes egg weights from 30 g birds vary from 6.0 g in the Fringillidae through 4.0 g in the Troglodytidae, 3.3 g in the Turdidae, 2.9 g in both Motacillidae and Alaudidae to 2.6 g in the Hirundinidae. The trend suggests that the more aerial species lay relatively lighter eggs for their body size.

Similar differences exist within even a single tribe. In the Anatidae, for example, each tribe has a very similar egg weight to female weight relationship but average egg weights differ between tribes. For a 100 g bird egg weights range from 53 g in the Cairinini through to 101 g in the Oxyurini. Interestingly, the ducks of the Anatini have eggs at the light end of the spectrum (59 g at 1,000 g body weight) whilst the geese of the Anserini are the second heaviest tribe (74 g at 1,000 g).

Within a species egg-weight varies considerably, both between females and between clutches by an individual female. Egg-size is correlated with female size, heavier individuals producing larger eggs. This effect is genetically controlled, so that egg-size is inherited. But egg-size is also phenotypically modified by other factors. Females breeding for the first time generally lay slightly smaller eggs than do more experienced individuals and the very oldest birds may revert to producing smaller eggs. Also, since females of many species have difficulty acquiring enough food for egg-formation even in normal conditions, a scarcity of food during the egg-laying period may result in rather smaller eggs than usual. Small eggs are less successful at producing viable fledglings, however, and the majority of birds with multi-egg clutches produce a smaller number of eggs of near normal size in such circumstances. Species with already low clutch-size (the extreme being single egg species) cannot readily adjust clutch-size in this way and instead take longer to produce each egg. The European Swift *Apus apus*, for example, normally lays 3 eggs at two-day intervals but in bad weather lays only 2

Snares Crested Penguin *Eudyptes robustus* male and clutch. Note larger second egg (29% heavier). (*Photo: J. Warham*).

eggs with a 3 (or even 4) day interval between them.

Differences in egg weight between the eggs of an individual clutch have also been recorded but the pattern varies between species. In the domestic fowl the first egg of a set is often slightly smaller than those following, perhaps because the oviduct stretches slightly with the first egg. Amongst wild birds, however, the most frequently observed divergence from a common egg-size for the clutch is for the last egg to be smaller than the others. This is regularly observed amongst gulls, raptors, herons, and other groups with unpredictable food sources. The small final egg produces a smaller and weaker chick than do the other eggs and it dies quite quickly if the food supplies are inadequate for the entire brood. Were all the young equally sized, all might get equal but inadequate shares of the available food and all might die. In good seasons the last chick survives despite its small size. In other species, including some owls and Coot *Fulica atra*, the later eggs of the clutch decrease in size with laying order so that the resulting young are a graded series with respect to competitive ability and 1, 2, or more of the weaker young die off in turn until brood size and food supply are matched. An extreme form of this type of within-clutch weight-difference occurs in Macaroni Penguins *Eudyptes chrysolophus* (and in other penguins of the genus) in which the first egg (which is smaller, by about 42% than the second egg), is neglected by the parent unless the second egg is lost; it never produces a fledgling if the second egg hatches.

In House Martins *Delichon urbica* unusually small eggs have been shown to result from the depression of aerial insect abundance brought about by bad weather while the females were laying. In other species of medium body size, 'runt' eggs appear in the nest on the final laying day, probably because the female concerned has exhausted her energy (or other) reserves before completion of a normal egg. In these cases, of course, small egg-size is maladaptive.

Since egg-weights are proportional to female body weight raised only to a 0.67 power rather than to a 1.0 power, large species lay relatively smaller eggs than do smaller species. At one end of the range small hummingbirds lay eggs about 25% of their own body weight. At the other Ostriches *Struthio camelus* lay eggs about 1% of their weight. The smallest species thus achieve a remarkable feat of metabolism in the production of each egg. However, many birds produce not one but several eggs as a set (see CLUTCH-SIZE) so that the total egg mass they produce is substantially larger. Clutch-size decreases slowly with body weight, however: for each 10-fold increase in body weight the average clutch-size decreases by 30% amongst the ducks and by 28% amongst the pheasants. Large birds thus do not make the same relative effort in egg production as do small species.

Very few birds produce more than their own body weight in eggs in a single clutch. Some finches reach a mximum of 95–110%, and clutch weights similarly only slightly exceed body weight in even the most productive ducks and pheasants. There may, therefore, be some physiological limit to egg production about this point. R.J.O'C.

EGG COVERING: eggs are sometimes covered by adult birds about to leave the nest-site. Grebes (Podicipedidae) provide the best known examples, disturbed birds pulling pieces of nest material over the eggs when mildly alarmed, completing the process and slipping away if further alarmed. If surprised from the nest the bird may return briefly to the eggs to cover them before staying away for a longer period. Many northern ducks and geese (Anatidae) also cover the clutch when leaving it unattended, using a thick layer of the feather or downy lining of the nest for the purpose. Tits *Parus* spp. regularly cover the eggs until the clutch is complete. Egg covering is also observed in warmer climes: at least two African sand-plovers *Charadrius* cover their eggs with sand when driven from the nest by human approach (see also SEEDSNIPE). These cases all probably constitute examples of anti-predator precaution but in other species thermal factors may be more important. Scandinavian Goldcrests *Regulus regulus* build a 'flap' of soft feathers across the entrance to the nest which lessens the circulation of near-freezing air across the clutch when the eggs are left unattended. This flap does not occur in nests in the more southern parts of the species' range.

EGG MIMICRY: see BROOD-PARASITISM.

EGG PROTEIN: see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA.

EGG RECOGNITION: the ability of individual birds to recognize their own eggs. The ability is well-developed in species nesting colonially without substantial nest structures e.g. Guillemots *Uria aalge*—and in species subject to BROOD-PARASITISM. Recognition may be achieved by responses to individually distinctive patterns of colour and markings or by recognizing a foreign egg as 'odd man out' within a clutch. See EGG; RECOGNITION, INDIVIDUAL.

EGG RETRIEVAL: several scrape-nesting species—terns, sandpipers, gulls and others—will retrieve eggs which are accidentally ejected from the nest, provided they are not too far away. Few species will retrieve eggs as much as a metre from the nest site. The retrieval process has been particularly studied in the Greylag Goose *Anser anser* and found to involve a rather stereotyped behaviour pattern. The goose retrieves a displaced egg by stretching the neck towards it, bringing the bill to the far side of the egg and rolling it back into the nest; any wobbling of the egg is compensated by lateral movements of the bill. If the egg is removed experimentally during this process, the backward motion with the bill may be completed even though no egg is present. The lateral bill movements do, however, disappear. The retrieval behaviour thus involves the release of a complex 'action pattern' which runs to completion once released, with only its orientation modified by stimuli from the egg wobble.

EGGS AS FOOD: see PALATABILITY OF BIRDS AND EGGS; UTILIZATION BY MAN.

EGGSHELL DISPOSAL: see PARENTAL CARE.

EGGSHELL THINNING: disease, nutritional deficiency, age, stress and certain drugs can cause birds to lay abnormally thin-shelled eggs. In wild birds, eggshell thickness typically shows a normal frequency distribution around a constant mean for each species, but occasional extra thin-shelled eggs can result from chance adversities to individual birds. In 1966, investigation of an unprecedented increase in frequency of broken eggs in nests of Peregrine *Falco peregrinus*, Sparrowhawk *Accipiter nisus* and Golden Eagle *Aquila chrysaetos* in Britain revealed that it coincided with pronounced and widespread eggshell thinning in those raptors. Large samples of eggshells in egg collections, going back to the 19th century, showed a sharp drop in shell thickness to new means which were, for the above species, 19%, 17% and 10% lower than the previous constants. In the Peregrine and Sparrowhawk the onset of decline was precisely dated to 1946–47. Other species showing post-1947 eggshell thinning in Britain included Heron *Ardea cinerea* 20%, Gannet *Sula bassana* 20%, Merlin *Falco columbarius* 13–22%, Shag *Phalacrocorax aristotelis* 12%, Hobby *Falco subbuteo* 5%, Kestrel *F. tinnunculus* 5%, Crow *Corvus corone* 5% and Rook *C. frugilegus* 5%. Species examined but showing no significant change were Buzzard *Buteo buteo*, Raven *Corvus corax*, Guillemot *Uria aalge*, Razorbill *Alca torda*, Kittiwake *Rissa tridactyla*, Black-headed Gull *Larus ridibundus*, Golden Plover *Pluvialis apricarius* and Greenshank *Tringa nebularia*.
Shell thickness was measured first as an index by the formula

$$\frac{\text{Weight of shell (mg)}}{\text{length (mm)} \times \text{breadth of shell (mm).}}$$

Precise and direct measurements confirmed that this decrease in relative weight of eggshells is the result of decrease in their thickness. Eggshell thinning has been shown to be widespread and pronounced in many North American bird species, mainly raptors and fish-eaters, including the Guillemot. In the Peregrine (10–26% less) the onset was again dated to 1946–47. Shell thinning in Peregrine eggs is reported also from mainland Europe, Siberia, North and South Africa, Arctic North America and Australia.

Correlative and experimental evidence have established repeatedly that the principal cause of the eggshell thinning phenomenon is contamination of the parent females by the environmental pollutant pp′ DDT and its metabolite pp′ DDE, which were sufficiently widespread in 1946–47 to account for the onset then. The subsequent success of DDT as an agricultural insecticide has caused almost global risks of eggshell thinning in vulnerable species. The population effects of DDT/DDE-induced eggshell thinning vary. There appear to be inter-specific differences in sensitivity, with flesh- and fish-eating birds showing the most marked shell thinning. The populations of some species are variably exposed to DDT/DDE contamination because of geographical and ecological factors. The virtual extinction of the Peregrine in the eastern United States and south-east Canada by 1964 is attributed largely to the effect of shell thinning in causing egg breaking and nesting failure, and hence an unfavourable recruitment/mortality balance. Any species' population showing an overall shell thinning of 20% or more is at serious risk of decline, and a general relationship between population status and degree of eggshell thinning for a range of North American birds has been found. As uses of DDT have been phased out in parts of the western world, monitoring has revealed recoveries in shell thickness in certain species.

The biochemical mechanism of DDT/DDE induced eggshell thinning is not precisely known despite much study. Cooke concludes that it may vary between different species, but that in the Peregrine a reduction in shell components in the shell gland during calcification is probably involved, perhaps in response to decreased enzyme activity in the shell gland tissue. Ratcliffe, D.A. 1970. Changes attributable to pesticides in egg breakage frequency and eggshell thickness in some British birds. J. Appl. Ecol. 7: 67–115.

EGGSHELL, ULTRASTRUCTURE OF: composed chiefly of calcite, one of the crystalline forms of calcium carbonate, and a small amount of organic matrix. The calcified layers may be covered by an organic cuticle, as in some Galliformes, and sometimes also by a crystalline layer of vaterite, a form of calcium carbonate, as observed in the 'chalky' cover of the eggshells of certain seabirds, such as gannets and cormorants (Tullett *et al* 1976). Small amounts (usually not over 0.1% by weight) of other inorganic constituents such as phosphorus, magnesium, sodium and potassium are also incorporated in the calcified shell. Phosphorus quantities may occasionally reach *c.* 2.5% by weight in some Galliformes.

The various calcified layers can be revealed by scanning electron microscopy. Usually the calcified eggshell can be subdivided into the following zones: caps, cone layer, palisade layer, surface crystalline layer, and a surface stratum, either organic (cuticle) or crystalline (vaterite). Below the basal caps there are two membranes, which adhere to each other except at the broad pole of the egg, where an intervening airspace is formed. The thickness of the fibres forming the eggshell membrane varies with the size of the egg. For instance in the Double-crested Cormorant *Phalacrocorax auritus* the fibres of the outer membrane are 5.0 µm in diameter, but the same fibres in the Long-tailed Tit *Aegithalos caudatus* measure 0.5 µm in diameter (Becking 1975). The palisade layer is distinguished by the presence of numerous pit-like cavities, which are in fact vesicular holes because they have an organic lining, as is evident by carefully dissolving the calcite with dilute acid. On the outer membrane there are centres of crystallization, called mamillary cores, which are small masses of organic matter adhering to the eggshell membrane. From these, crystals of calcite ('spherulite crystals') grow radially in all directions to enclose the membrane fibres, thus firmly binding the calcified part of the shell to the eggshell membrane. Calcite crystals which grow inward and sideways produce the basal caps, and those which grow outward to meet crystals from other centres of crystallization form the cones.

As is obvious from scanning electron micrographs, the eggshell near the outside is very compact. It shows a lamellate pattern approximately parallel to the surface of the eggshell and at an angle to the lamellae of the underlying palisade layer. The latter lamellar structure is produced by the rhombic cleavage pattern of the calcite crystals. The calcite lattice is, under natural cleavage conditions, a fundamental rhombohedron with an angle of 105° between adjacent faces and each face with plane angles of 102° and 78°. As indicated by measurements, the palisade layer of a radially fractured eggshell has a perfect calcite cleavage pattern. The lower part of the palisade layer shows many holes, the so-called vesicular holes, randomly distributed. These pit-like holes, which appear to be lined with organic matter, are larger and more abundant in the eggshells of tropical birds than in those of Palearctic birds. Nothing is known about their physiological significance, but it may be related to the facilitation of gas exchange, which is hampered by high humidity.

Large pores are sparsely but uniformly distributed over the eggshell surface. Most bird species have a characteristic number (with small variations) of pores per eggshell surface area. The pores provide direct connection between the outside environment and the spaces between the cones. Scanning electron microscopy reveals that the pore entrances at the surface are always situated at the borders of the polyangular fields of similarly orientated crystals forming the columns of the eggshell. Different bird groups show a different size and shape of pore channels. In ostrich and rhea they are branched, whereas in other species, in particular in passerines, they consist of a single more or less straight channel from eggshell membrane (or basal cap) to the surface. Pores regulate the gas pressure through the calcified shell, allow the access of oxygen to the blood vessels of the embryo (chorioallantois) in contact with the inner membrane of the shell, and serve for the discharge of carbon dioxide and water, the waste products of the oxidative metabolism of the embryo (Rahn *et al* 1979). Pore openings may be different in shape and size in different groups of birds. Eggs of Galliformes have large pores filled with plaques showing an irregular surface texture of hair-lines and cracks very reminiscent of mud cracked by drought. Many small passerines show straight pores without filling material at the entrance. Eggs of parasitic cuckoos show pores with a funnel-like entrance which is sealed with granular organic matter material. By this characteristic cuculid eggs can be immediately distinguished from similarly coloured host eggs (see BROOD-PARASITISM); moreover cuckoo eggs have a very compact outer texture with triangular or multiangular raised faces (Becking 1975). The surface texture of eggshells as observed by scanning electron microscopy is different in various bird groups and often characteristic of the group. Passerines (e.g. Sylviinae) have eggshells with many minute pits on the surface, whereas cuculids have rather compact pitless shells. Thus the ultrastructure of birds' eggs allows their classification to a certain group and sometimes even to generic or species level. It is a useful tool for determining the identity of putative cuckoo eggs (Becking 1981), and is also useful for studying the morphological aspects of egg breakage by EGGSHELL-THINNING as the result of dietary intake of DDT or other toxic chemicals. EGG TOOTH: a small sharp projection on the upper mandible of the full-term embryos of many species, used in chipping open the egg shell during hatching. It is usually lost from the bill within a few days from hatching. See photo PARENTAL CARE.

Whimbrel *Numenius phaeopus* 2 h after hatching, showing the egg tooth. (*Photo: E.J. Hosking*).

EGG WHITE: see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA; EGG.

EGRET: substantive name of several species of Ardeidae (see HERON). See photos CREST; DISPLAY.

EIDER: substantive name, sometimes 'eider-duck', of *Somateria* spp. and *Polysticta stelleri*; used without qualification for *S. mollissima*; in the plural, general term for the tribe Somateriini (see DUCK). 'Eider-down' is the breast down with which the female *S. mollissima* lines its nest and is in some countries collected commercially.

ELAENIA: generic name used as substantive name of *Elaenia* spp. and *Myiopagis* spp. (see FLYCATCHER (2)).

ELANINAE: see HAWK.

ELBOW: see under MUSCULATURE; SKELETON, POST-CRANIAL; WING.

ELECTROPHORESIS: see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA.

ELEPAIO: *Chasiempis sandwichensis* of Hawaii (for subfamily see FLYCATCHER (1)).

ELEPHANT-BIRD: in the plural, general term for the extinct Aepyornithidae (Struthioniformes). Three genera of these large, flightless, graviportal ratites have been recognized. Four generally accepted species of *Aepyornis* and 3 of *Mullerornis* have been described from extensive skeletal and egg remains from Pleistocene to Recent deposits in Madagascar, though not all of these forms may be valid. *Stromeria fajumensis* is known from an incomplete tarsometatarsus from the lower Oligocene of Egypt; its allocation to the Aepyornithidae is, however, controversial (see FOSSIL BIRDS). The Eocene *Eremopezus* is not now considered to be aepyornithid. Miocene and Pliocene eggshell fragments, tentatively identified as aepyornithid on the basis of microstructure, have been found in Lanzarote (Canary Islands), North Africa, Turkey, India and Inner Mongolia (Sauer 1972, 1976). Thus there is no certain evidence that the family ever existed outside Madagascar. The family appears to have been a primitive member of the ostrich-rhea-emu lineage (see EARLY EVOLUTION OF BIRDS).

The Malagasy forms were massive birds with strong, conical bills and vestigial wings. *Aepyornis maximus*, the largest species, stood 3 m tall and may have weighed 450 kg, rivalling the Moa *Dinornis giganteus* and the Australian *Dromornis* (Dromornithidae) as the largest known bird. The legs of *Aepyornis* spp. were very stout, with relatively short tarsometatarsi, suggesting that these birds were probably slow-moving forest-dwellers (Cracraft 1974). The Ostrich-sized *Mullerornis* spp. were more gracefully proportioned. The feet of elephant-birds were apparently three-toed, the hallux usually if not always missing.

Entire aepyornithid eggs measuring as much as 33 × 24 cm have been found in Madagascar, one containing bones of an embryo (Wetmore 1967). Their average capacity has been estimated at 9 litres. These eggs have been described as the largest known single cells in the Animal Kingdom.

Aepyornis apparently persisted until comparatively recent times. Eggshell fragments have been radiocarbon-dated at 1,000 ± 150 years B.P. (Burger *et al* 1975). Flacourt (1658) recorded Malagasy tales of the Vouron-Patra (or Vorompatra), a large Ostrich-like bird supposedly still extant. These may represent, however, a tradition of a bird by then extinct, reinforced by the eggs, of which well-preserved specimens were locally prized. The legendary Roc (see FABULOUS BIRDS), which, according to Marco Polo, lived on islands south of Madagascar, may possibly be linked with such a tradition. The Malagasy natives probably brought about the final extinction of the elephant-birds by a combination of habitat loss through deforestation, with ensuing drought, and hunting pressure. See also EXTINCT BIRDS; MALAGASY REGION. (A.L.T.) R.O.

EMARGINATION: see FEATHER.

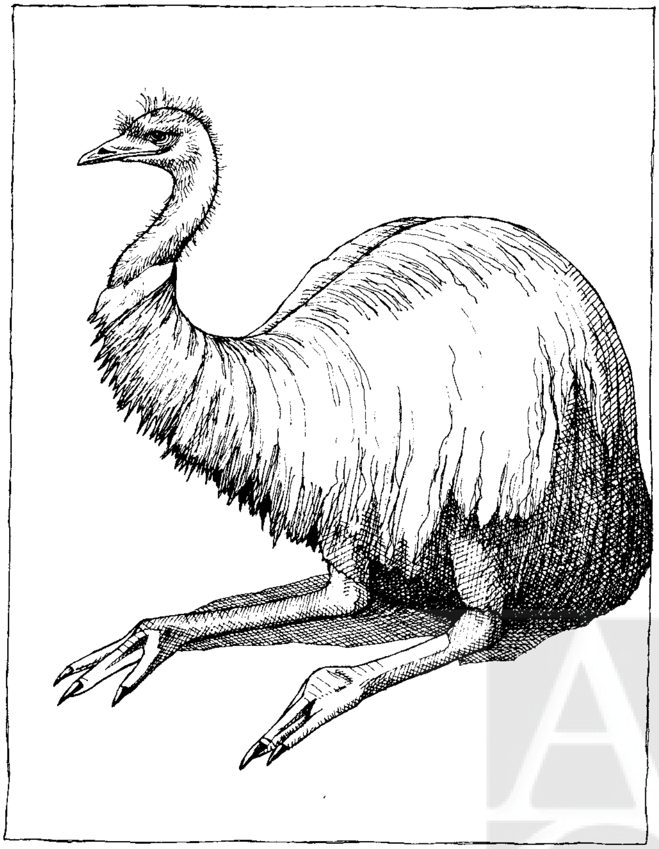
EMBERIZIDAE: a family of PASSERIFORMES, suborder Oscines; BUNTING; CARDINAL GROSBEAK.

EMBRYO: the young bird from the earliest stage of its development within the egg until the time of hatching (see DEVELOPMENT, EMBRYONIC).

EMERALD: substantive name of *Chlorostilbon* spp., *Elvira* spp., and some *Amazilia* spp. (for family see HUMMINGBIRD).

EMIGRATION: term used to describe migration from an area without postulating a return (see MIGRATION).

EMU: name of the sole surviving member of the Dromaiidae (Struthioniformes); in the plural (emus) also general name for the family. The Emu *Dromaius novaehollandiae* occurs over much of Australia, most commonly in sclerophyll forest and wooded savanna. It is rarely found in the centre of the deserts or in the environs of the major cities. In the dense tropical rain-forests of northern Queensland it is replaced by another large ratite species, the Australian Cassowary *C. casuarius* (see CASSOWARY). Smaller island forms of emus, which existed on Tasmania, King I and Kangaroo I (South Australia) were exterminated soon after white settlement. Their respective tarso-metatarsal lengths were (aver-



Emu *Dromaius novaehollandiae*. (*N.W.C.*).

ages) 21, 23 and 27 cm compared to 38 cm for the mainland form; their taxonomic positions are not clear. The mainland Emu is monotypic. Several extinct forms are known from Pleistocene fossils.

Characteristics. The second largest surviving ratite, an adult Emu standing erect is 1.6–1.9 m tall and generally 30–45 kg in weight. On average, females are larger and heavier. No reliable plumage features differentiate the sexes, though during pair formation in late summer females are more recently moulted and often show blacker neck plumes and darker facial skin. The wings are more vestigial than those of other large ratites, lack quills and have no muscular control or part in displays.

Many advanced and derived features of the skeleton are similar to those shown by *Casuarius*, emus and cassowaries being each others' closest living relatives. Other features in common are the double-shafted feathers, lack of an oil gland, inflatable neck sac and coloured facial skin. The types of diet are similar, as are the patterns of breeding biology.

Distribution, populations and movements. Emus remain common over much of Australia, despite persecution in the agricultural zones where birds have caused damage to fencing and growing crops. They drink frequently from sources of fresh water, especially in hot weather; on large rangeland holdings in semi-arid country they have exploited new sources of permanent water provided by dams and troughs. Their populations have probably increased as a direct result of white settlement and provision of water in these areas. The population as a whole is highly mobile and some birds move into marginal areas of the semi-arid and arid interior when rainfall stimulates the productivity of native vegetation. The capture and banding of adults has shown the Emus in Western Australia are truly nomadic and capable of changing their location by up to 500 km in 9 months. Emu-proof fencelines have been built to protect agricultural zones from winter movements of birds attempting to leave unfavourably dry areas. They have had the effect of deflecting seasonal movements of the increased numbers now existing in semi-arid regions. Large concentrations have built up along fences in Western Australia on several past occasions; control measures have been invoked but mostly to little effect.

Food. Emus feed on a great variety of plant material: green herbage; growing tips of shrubs and forbs; fruits; seeds; flowers. Insects and their larvae are also taken. A primitive form of coprophagy occurs, semi-digested particles frequently being consumed from fresh droppings. Coprophagy may have a role in the nutrition of young chicks, which sometimes hatch in a dry, depauperate environment. Geographic and seasonal variations in the availability of food stuffs require that Emus live mainly in low density populations which are seasonally nomadic. The anatomy of the digestive system differs from the general avian type in that there is no crop: the gizzard hangs in the living bird in such a way that the anterior entry and posterior exit are both dorsal, the gizzard extending ventrally as a suspended bag. The caeca are relatively small, bacterial action evidently having little importance in the digestion of a nutrient-rich diet.

Behaviour. Socially there is much aggressive behaviour and display by both sexes, the ontogeny of which is traceable from actions first shown within one week of hatching. During pair formation the larger female is dominant to the male; males accompanying young chicks become aggressive and will attack Emus or other large animals which approach them.

Voice. Both sexes make a variety of bubbling and booming noises, but only displaying females utter single loud, resonant bass notes (referred to as drumming) from an inflated pouch. Males are more inclined to grunt.

Breeding. Wild birds evidently breed in pairs; in captivity 'trios' sometimes occur but pairs are more usual. A clutch of 5–15 blue-green eggs, each weighing 450–650 g, is laid on the ground in autumn and winter at intervals which decline from 4 days or more to 2 days or less over a period of about one month. Females pay little attention to the nest and have no part either in incubation or rearing the young. The male alone incubates the eggs, rising to roll them over once to several times daily. During incubation he does not normally eat, drink, defaecate or leave the immediate vicinity of the nest, but spends his time in nest-building, preening and dozing. The eggs hatch in synchrony after 53–61 days (average 56). Nests of hatchlings are sometimes taken by foxes and dingoes (wild dogs); Wedge-tailed Eagles *Aquila audax* are reported to attack young and occasionally adult birds. Unattended eggs are eaten by Black-breasted Buzzards *Hamirostra melanosternon*, and crows *Corvus* spp.

The young feed themselves and leave the nest with the male when 2–7 days old. Male and chicks maintain close contact and call to each other frequently. The family is solitary and diurnally active, resting in the open at night. Parent-chick bonding loosens after 4 months and family life lasts for 6 months or more; the young grow to nearly adult size and appearance when 1 year old.

Day-old chicks weigh about 1% of adult body weight, can peck at food items on their second day, run and swim competently at one week. They hatch in a thick down patterned with black, white and tan stripes. In 3–4 months this is replaced by a blackish-brown immature plumage consisting of variegated double-shafted plumes. Adult-type plumes appear from 6 months, by which time the young average half adult weight and three-quarters adult height. Sexual maturity occurs from the second year.

Economic use. Attempts to farm Emus intensively in Western Australia have not yet met with success. The skins, from which valuable dress leather can be made, are easily damaged on the living bird. Carved eggs for decoration, subcutaneous fats and Emu meat also have commercial potential if successful husbandry procedures can be devised. See also EMU WAR. (D.L.S.) P.J.C. (2)

EMU-TAIL: substantive name of the 2 Madagascar warblers of the genus *Dromaeocercus* (see WARBLER (1)).

EMU WAR: name given to the 1932 'campaign' by an Australian Commonwealth machine gun unit, at the request of the State of Western Australia, to destroy invading Emus *Dromaius novaehollandiae*. It attracted bizarre notice, with front line press despatches. The offensive began on 2 November when an artillery detachment attempted to engage some 20,000 birds, which apparently adopted guerilla tactics and split into small units. This made use of the military equipment uneconomic. The crestfallen field force withdrew after about a month and the method was abandoned in favour of emu-proof fences to check seasonal incursions into the marginal wheat-growing country. D.L.S.

EMU-WREN: substantive name of *Stipiturus* spp. (see WREN (2)).

ENDANGERED BIRDS: any bird species whose numbers are declining can be said to be in some danger of extinction, but the term endangered is usually reserved for those species whose numbers have fallen to a critically low level. Some birds, such as the Mauritius Kestrel *Falco punctatus* and the California Condor *Gymnogyps californianus*, have been reduced to a mere handful of individuals and it is very possible that they will shortly join the list of EXTINCT BIRDS.

Extinction is a natural part of the evolutionary process, which involves the continual replacement of existing species by new ones. It is very difficult, if not impossible, to separate natural changes in the environment from those brought about by humans, but for some endangered species, such as the Kakapo *Strigops habroptilus* of New Zealand, it seems that a decline in numbers was already occurring before the arrival of Europeans accelerated the process. However, throughout the world the last 300 years have been a period of greatly accelerated decline and extinction which has been the result, not of a natural process, but of human activities. It is clear from a geographical and historical analysis of recent extinctions that they have closely followed the spread of industrialized European man as he has colonized various parts of the world. Sometimes the impact of man on birds has been direct, for example when birds are killed for food or clothing or because they are considered to be pests. Of greater importance are man's indirect effects on birds through the destruction or alteration of their habitats.

The history of man as a predator of birds is a mixed one. With some species, such as game birds and wildfowl, he has often avoided over-exploitation. Other species, such as the Eskimo Curlew *Numenius borealis* and the Society Islands Pigeon *Ducula aurorae*, have been driven to the verge of extinction as a result of their nutritive value to humans. The extinct Carolina Parakeet *Conuropsis carolinensis* owes its sad fate to its habit of raiding orchards which caused it to be ruthlessly hunted. Many birds of prey are still shot by gamekeepers on the pretext that they eat game birds, though the impact of birds of prey on gamebird populations is generally minimal.

Probably the most dramatic change in the environment wrought by modern man has been deforestation. This has destroyed or drastically reduced the habitat of many species. The Ivory-billed Woodpecker *Campephilus principalis* still survives in small numbers in Cuba and possibly in isolated pockets of swampland in south-eastern North America. Many species, notably wildfowl, have had their habitat destroyed or reduced by the draining of wetlands to create new agricultural and building land. Another very widespread factor in the decline of many species has been pollution, particularly by pesticides such as DDT (see TOXIC CHEMICALS). These have seriously affected a number of marine and freshwater birds and several birds of prey, such as the Peregrine *Falco peregrinus* and the Osprey *Pandion haliaetus*, which, through eating contaminated prey, absorb and accumulate large amounts of pesticide derivatives in their bodies. Pesticide poisoning causes birds of prey to lay eggs with such thin shells that they are crushed during incubation (see EGG-SHELL THINNING). Another major factor in the decline of many birds has been the introduction by humans of animals such as cats, dogs, rats, sheep and goats to parts of the world where they did not previously exist. These may prey upon indigenous birds or else destroy their habitat. Other indirect human influences on bird mortality are oil spillages at sea, the catching of sea birds such as auks in fishing nets, and collisions with overhead power cables.

Endangered birds may be grouped into 5 categories. These are:

1. Predatory species that occupy an ecological position at the top of a food chain. These are usually large birds that require an extensive area for hunting. Such areas are under constant threat from the expansion of human agricultural and industrial activities. Predators are also the species most prone to pesticide poisoning, and they are adversely affected by a reduction in numbers of any of the species in the food chain of which they represent the highest level.

2. Species with specialized habits. Birds that need a very specific diet or breeding site have difficulty finding alternatives if such resources become scarce. For example, the Everglade or Snail Kite *Rostrhamus sociabilis* of North America has become very rare following the decline in a species of snail which constitutes its sole source of food.

3. Species endemic to small islands. This is perhaps the largest category of endangered species and also includes the majority of those that have become extinct in the last 300 years. Mauritius and the Hawaiian islands have the unhappy distinction of having a greater number of extinct or endangered bird species than any other locality of comparable size. Island species are vulnerable to human influences for two reasons. First, as a result of being isolated from larger and more complex ecosystems for millions of years, many have lost adaptations against predators and competitors. Many island birds have reduced powers of flight, and some, like the Kagu *Rhynochetos jubatus* of New Caledonia cannot fly at all (see FLIGHTLESSNESS). Consequently, they are particularly vulnerable to animals such as rats and cats that have been introduced by man. Second, islands necessarily provide their endemic species with only a very limited range of movement. If islands are heavily exploited by humans, many birds have no alternative refuge.

4. Species that breed in dense colonies. These are particularly vulnerable to direct human exploitation simply because a dense aggregation of many birds in a limited space facilitates the killing of adults or the collection of their eggs and chicks. The Great Auk provides the classic example (see EXTINCT BIRDS). Abbott's Booby *Sula abbotti*, which breeds on Christmas Island in the Indian Ocean, is currently threatened because its one and only breeding colony is also the site of valuable deposits of phosphate fertilizer.

5. Migrants. Migratory species are vulnerable for two reasons. First, since they live in two, often widely separated localities, they may be subject to two quite different sets of hazards. Second, while on migration they often form flocks that fly along traditional flight paths and provide easy targets for hunters. The rarity of the North American Whooping Crane *Grus americana* is largely attributable to shooting along its migration routes.

The first step in the CONSERVATION of endangered birds is to identify those species whose populations are declining and to discover the causes of their decline. In this exercise the work of international agencies such as the International Union for the Conservation of Nature and Natural Resources (IUCN) makes a major contribution. The IUCN publishes the Red Data Book, which is a continually updated list of the world's rare and endangered species. In 1977 and 1979 the Red Data Book listed a total of 167 species and subspecies of birds as endangered. T.R.H.

ENDASPIDEAN: term applied to the tarsal sheath when it has an anterior scutellated segment extending across the inner side of the tarsus; if, on the other hand, this extends across the outer side, the condition is termed 'exaspidean'.

ENDEMIC: term applied to a species or other taxon in relation to a stated area, meaning that it is restricted thereto; also applied to a disease as the antonym of 'epidemic', meaning that it is always present.

ENDOCARDIUM: see HEART.

ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM: in birds, as in all other advanced animals, two complementary control systems exist to co-ordinate the activities of the various tissues within the body. The NERVOUS SYSTEM, based upon nerves running directly to the target organ, has the great advantage of speed and specificity and so is used to control such activities as movement and behaviour. For other functions though, such as growth, metabolism or reproduction, speed and a transient effect are not important and these activities are regulated by the endocrine system. Here, specialized chemical messenger molecules (hormones), produced in small discrete structures called endocrine glands, are poured directly into the blood system and have their effects some distance from where they are manufactured. Not surprisingly, the two systems of communication have great influence on each other. The brain, as the organ which processes information about the outside world, largely controls the endocrine system via the pituitary gland, a good example of this brain-endocrine pathway being found in the way environmental factors regulate seasonal reproduction. An influence in the other direction is seen in the mating and parental behaviour shown by birds during breeding. These activities are products of the nervous system but are not exhibited unless hormones (in this case sex steroids) have primed the necessary brain circuits.

Endocrinology may quite reasonably be said to have been discovered in birds. In 1849 Dr A.A. Berthold of Göttingen published a short article in which he reported that removing the testes from young cockerels prevented the growth of the comb, wattles and spurs but that these were normal in castrated cockerels with testes transplanted back into the body cavity. The effects of castration had been known since ancient times but Berthold had demonstrated that they were reversible and, even more importantly, concluded that something from the testis influenced the secondary sexual characters. Fifty years later his observations were confirmed, but another 30 years were to pass before testosterone was isolated chemically and shown to be the agent responsible for comb growth. The subsequent development of endocrinology means that the basic structure and function of the avian endocrine system is now well understood and probably few new hormones wait to be discovered. In fact, the vertebrate endocrine system is very conservative and a shark possesses virtually the same complement of glands and hormones as a Blackbird *Turdus merula* or a lion. Many of the functions are also similar (e.g. insulin on blood glucose) and where differences do exist it is often the target tissue, where the hormones act, that has changed rather than the actual messenger. For example, in the Salmon *Salmo salar* prolactin changes the permeability of the gills to salts so allowing the fish to migrate from the sea into the river. In ducks the same hormone acts on the brood patch to cause its growth and probably also on the brain to trigger INCUBATION behaviour, whilst in the female mammal prolactin controls milk production in the mammary gland.

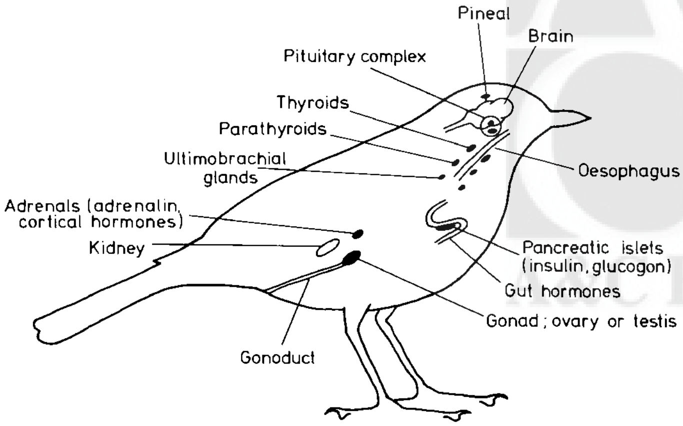

Fig. 1. The endocrine glands in a typical bird. A few other body structures are added as reference points.

Despite the wide range of functions controlled by them, most hormones have relatively similar chemical structures, being either peptides or proteins, or fat-soluble steroids. One implication of this is that the target tissue cells must possess specific receptors that can pick out and bind hormone molecules of only the correct configuration, e.g. the comb of a cockerel binds testosterone but is not interested in the closely related steroid oestradiol that is produced in the hen. If such specificity did not exist the system would obviously fail. Hormones are produced in minute amounts and are very potent molecules: in a laying hen the all-important oestrogens are present in the blood at 100 pg/ml (1 pg is one million millionth of a gram). Hormones also have the tendency to work together rather than individually to induce an effect and so in many cases (e.g. to control blood glucose levels, or growth of the oviduct) more than one is involved. This complicates the story somewhat.

The pituitary gland complex. The endocrine glands in a typical bird are shown in Fig. 1. At the centre of the system lies the pituitary, a glandular complex ($5\ mm^3$ in a chicken) located at the base of the brain. It is this location that gives to the pituitary such a dominant role over the other endocrine organs. The gland consists of two separate areas (Fig. 2). The neurohypophysis is actually part of the brain itself and contains the terminals of many thousands of neurosecretory neurons whose cell bodies lie scattered through the hypothalamus. Neurosecretory neurons play a key role in linking the brain to the endocrine system. In part they act like ordinary nerves, the cell bodies having extensive contact with the rest of the brain, but from their terminals they secrete hormones not neurotransmitters. This dual function allows them to act as bridges linking the brain to the endocrine system. The other part of the pituitary—the adenohypophysis—is entirely glandular and contains cells that produce 7 important hormones. The 2 gonadotrophins (Follicle stimulating hormone or FSH; Luteinizing hormone or LH) control gamete and sex steroid formation in the gonads, whilst thyroid stimulating hormone (TSH) controls the thyroid glands and adrenocorticotrophic hormone (ACTH) steroid production from the adrenal. Prolactin affects various aspects of reproduction. The other 2 hormones—growth hormone and Melanocyte stimulating hormone (MSH)—do not have discrete target tissues and act widely throughout the body. All 7 are protein or polypeptide hormones, LH, FSH and TSH are glycoproteins, containing sugar molecules attached to the protein backbone, and are closely related structurally. The 2 polypeptides (ACTH and MSH) probably derive from a common precursor called lipotrophin.

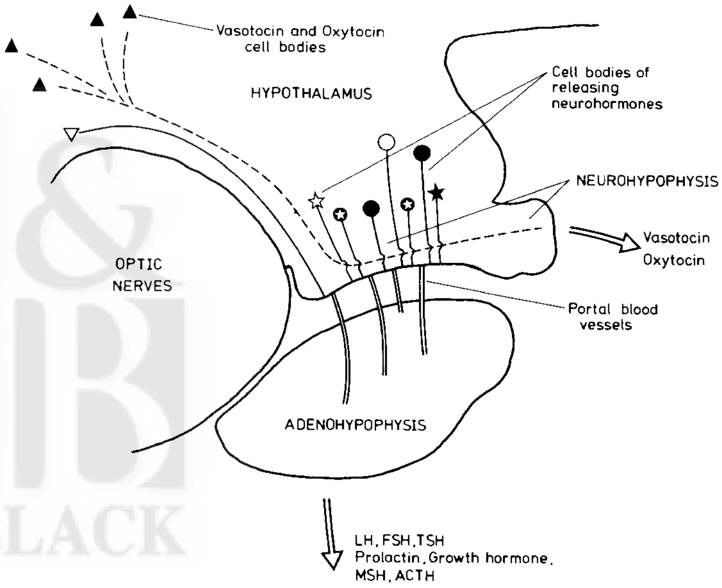

Fig. 2. Diagrammatic representation of the pituitary gland complex. Note that various types of neurosecretory neuron exist in the hypothalamus. The cell bodies are scattered through the hypothalamus but the nerve terminals all end on blood vessels in the neurohypophysis. The releasing hormones travel to the adenohypophysis via a number of special portal vessels. The trophic hormones of the adenohypophysis are secreted into the general circulation.

It appears that for each adenohypophysial hormone there is an equivalent releasing hormone present in the neurohypophysis. Thus, for TSH there is a TRH and for the 2 gonadotrophins (LH and FSH) a gonadotrophin-releasing hormone (Gn-RH). These neurohormones are synthesized within different neurosecretory neurons and released from the terminals into a special blood supply (Fig. 2) that carries them to the adenohypophysis where in turn they cause the release of the appropriate trophic hormone. In this way, the brain controls a wide range of peripheral endocrine functions including reproduction and growth. Some balance is restored to this control by the fact that in many cases the peripheral hormones can feed back on to the pituitary complex and influence its activity. For example, in response to cold there will be enhanced nervous activity in the brain and increased TRH release. The TSH secreted in response to this TRH will elevate thyroxine secretion and so stimulate more heat production. However, to ensure a balance, the thyroxine also acts back on the pituitary to dampen down further TRH/TSH release. Another example of this so-called negative feedback effect is that if the sex steroids are present in excess they depress LH and FSH secretion—a property made use of in the oral contraceptive pill.

Two of the neurosecretory hormones from the posterior part of the neurohypophysis—vasotocin and oxytocin—do not cause the release of other pituitary hormones but act directly on peripheral target tissues. Vasotocin is crucial for preventing dehydration and it achieves this by preventing water loss through the kidney, primarily by acting on the collecting ducts to increase water reabsorption back into the body but also by lowering the rate of filtration through the kidney. Both vasotocin and oxytocin are also involved in egg-laying, acting in concert with prostaglandins to cause waves of muscular contraction along the oviduct so expelling the egg (see LAYING).

The thyroid glands. The thyroids are paired ovoid structures (about 5 mm long in the chicken) lying low in the neck region close to the great veins and arteries. In response to TSH from the pituitary they release 2 hormones—thyroxine and tri-iodothyronine. As their names suggest, these hormones are unique in containing a number of iodine atoms. As in other vertebrates, the thyroid hormones are essential for normal growth and their absence in the young leads to dwarfism. In the adult, the main function is to maintain normal heat production. In addition, the thyroid is somehow involved in feather growth and in the MOULT. Thyroxine stimulates the development of young feathers and in its absence they become elongated and lose their rounded shape. The actual shedding of the feathers (moult) may result from a fall in sex steroids, e.g. at the end of the breeding season, at a time when thyroxine secretion is above normal.

The adrenal glands. The adrenals are small (3 mm^3) paired structures, often orange in colour, that lie just anterior to the kidneys in the body cavity. As in reptiles and mammals, the gland is a composite and contains 2 types of tissue (chromaffin or medullary; interrenal or cortical) which have quite different functions. The chromaffin cells produce adrenaline (and noradrenaline) in response to various stressful situations. This hormone acts rapidly to increase blood pressure and mobilize sugars and fats. As a result the bird is in a better position to take evasive action. Of greater importance, however, are the hormones from the interrenal cells (the corticosteroids, corticosterone and aldosterone) without which life would be impossible. Their secretion is under the control of pituitary ACTH. The corticosteroids have two important sets of functions. Firstly, they are metabolic hormones influencing the long term utilization and storage of carbohydrates, lipids and proteins. At first glance these actions may not appear important but this is deceptive and Cushing's syndrome in man emphasizes the point. In this illness too much corticosteroid is produced and as a result large deposits of fat are laid down. In birds living under natural conditions such intense lipid depositions may actually occur at the beginning of MIGRATION. The second function of the corticosteroids is on salt and electrolyte balance. In most terrestrial and freshwater birds this can be achieved by the actions of the hormones on the kidneys alone but in marine birds which drink seawater the situation is rather more complex. To lose the extra salt many marine birds have nasal salt glands which excrete an extremely concentrated solution of sodium chloride and potassium chloride. Control over this gland is complicated but secretion, having been initiated by nervous stimulation, requires corticosterone for the full activity to be maintained.

Growth hormone and prolactin. These closely related pituitary hormones have widespread effects on growth and tissue development. Growth hormone itself is usually thought to control general body development in young birds. Prolactin appears to have more specific actions. Acting with the sex steroids it is responsible for brood patch development and growth of the female reproductive tract. One of its other classic functions is to cause 'milk' formation in the crop glands of pigeons and doves (CROP MILK). In these birds the tissues in the walls of the crop sac proliferate during brooding and the protein and fat rich cells are sloughed off and regurgitated to feed the young. Prolactin is also involved behaviourally during incubation but its precise role is still unclear.

Hormones of the alimentary tract. Digestion in birds is regulated by both nervous and hormonal influences. It is a complicated process and only recently has it been studied in great detail. Gastrin and cholecystokinin are synthesized in the walls of the proventriculus and duodenum. Gastrin is thought to stimulate acid secretion while cholecystokinin causes gall bladder contraction and pancreatic enzyme secretion. This last function is also stimulated by another peptide hormone from the intestine called secretin (or its related VIP, vasoactive intestinal polypeptide).

The bird's pancreas produces both insulin and glucagon and these peptide hormones (together with adrenalin and corticosterone) are responsible for regulating sugar metabolism. Glucagon increases carbohydrate breakdown so elevating blood glucose and the availability of this sugar to the muscles, whilst insulin acts antagonistically to cause sugar uptake into cells and hence a decrease in blood glucose. In mammals insulin is the dominant hormone in this relationship and its absence leads to high blood glucose and to diabetes. However, in birds the position seems to be reversed and glucagon is the crucial hormone. When absent, blood glucose levels are unnaturally low and it acts to increase the circulating concentrations. Insulin may be primarily responsible for ensuring that levels do not become dangerously high.

Calcium metabolism. It is crucial for life that the various salts and ions are maintained at stable levels. In the case of potassium and sodium the corticosteroids play the key role but for calcium regulation 3 other hormones are involved. Calcium is, of course, particularly important in birds since the eggshell is largely composed of calcium carbonate. It is perhaps best to consider the situation first in the normal bird and then see how this is modified during egg-laying. Blood calcium levels are maintained primarily by 2 hormones acting antagonistically. Parathyroid hormone, a peptide produced in paired glands lying just behind the thyroids, increases blood calcium, whilst calcitonin from the nearby ultimobrachial glands depresses it. Both act in opposite fashions, on resorption of calcium from the bird's bones. A third hormone—1,25-dihydroxycholecalciferol—is also involved. This is produced in the kidney from Vitamin D_3 and acts on the intestine to enhance the absorption of calcium ions from the diet.

Once a bird begins laying its needs for calcium change dramatically. The shell 'gland' or uterus in the oviduct of a chicken has to secrete about 5 g of calcium carbonate in 20 hours to provide the eggshell and thus 2 g of calcium ions must be removed from the blood each day, at the rate of about 100 mg per hour. Since the total circulating quantity of calcium is 400 mg, it is clear that extensive bone resorption must take place each day. However, this cannot continue indefinitely since the bones themselves only contain enough calcium for 10 eggshells and so large quantities of calcium must be obtained from the diet. The end result is to place considerable pressure on the Vitamin D_3 metabolites such as 1,25-dihydroxycholecalciferol that stimulate the uptake of calcium from the gut, and on parathyroid hormone which is responsible for bone resorption. The turnover of bone calcium is so high that birds have evolved a special type of medullary bone which forms in the marrow of the long bones. At times of the day when requirements for eggshell calcium are low the excess is channelled into medullary bone. Later when the bird enters a calcium debt this can be mobilized by parathyroid hormone thus avoiding the need to withdraw calcium from the structural bones. The insoluble calcium carbonate shell is laid down by the cells lining the shell 'gland' in the lower oviduct. These cells contain an enzyme—carbonic anhydrase—which converts CO_2 into carbonate ions. These combine with the calcium ions and precipitate in an ever thickening layer of $CaCO_3$.

The pineal gland. Over the years many functions have been ascribed to the pineal organ, including that of being the seat of the soul! In lower vertebrates and in birds it contains photoreceptors but this function has been lost in mammals. In all it acts as an endocrine gland. The pineal is a small organ (1 mm^3 in chicken) located just behind the cerebral hemispheres on the top of the brain. It is attached by a stalk to the brain but is normally regulated by a nervous innervation from the base of the brain. In birds, as in mammals, it secretes a number of chemical compounds, of which melatonin is the best characterized. Most interestingly, melatonin is not secreted continuously but rhythmically with far more being released at night. In some birds this rhythmic secretion is used as a biological clock to regulate other physiological processes such as locomotor activity and feeding.

Reproduction—endocrinology and physiology. Most birds breed annually, and for three-quarters of the year the reproductive system remains undeveloped. The ecological reasons for this are discussed elsewhere (see BREEDING SEASON). This article concentrates on reproductive physiology, first considering how eggs and sperm are produced and then how these processes are moulded together to produce the offspring at the correct time of the year.

All male birds possess paired testes lying in the body cavity. These increase in size dramatically at the start of the breeding season, often becoming 200 times larger than during the non-breeding part of the year. This change is sometimes known as the progressive or acceleration phase.

The testes are filled with a mass of convoluted seminiferous tubules, each of which is lined by a layer of primary germinal cells. Between the tubules lie clumps of Interstitial (or Leydig) cells which are the source of the male sex steroids (androgens). Growth of the testes occurs as a direct result of increased pituitary LH and FSH secretion. FSH acts on the tubules causing cell division to begin. Within 3 weeks each primary germ cell has divided 5 or 6 times and the tubules are greatly expanded. The production of sperm involves not only ordinary mitotic divisions to increase the total number of germ cells but also a meiotic division to halve the chromosome complement and the transformation of these 'haploid' cells into spermatozoa. The spermatozoa have a characteristic structure with a head containing the nucleus, a middle piece filled with energy-producing mitochondria and a long tail with which to swim up the female tract. How FSH causes all these effects is still unknown but it probably acts not on the germ cells but on the Sertoli cells, which are non-germinal cells also lying within the tubule. In response to FSH, the Sertoli cells are believed to take up testosterone from the interstitium and it may be the sex steroid that actually influences mitosis. The sperm pass out of the testis into a duct (vas deferens) that leads to the cloaca. Near the cloaca this duct is expanded into a storage organ for the sperm. During copulation the cloaca is everted and semen is deposited in the female's cloaca. The volume of semen ejaculated in birds is relatively small (0.2–1.5 ml in the chicken) but it contains many million individual sperm. Artificial insemination is used in the poultry industry and is virtually mandatory in domestic turkeys where the males are now so large that they cannot mate properly. Penis-like organs exist in some birds (e.g. Anseriformes, Tinamidae, Cracidae, and the ratites).

Testosterone, the primary androgen, is secreted when LH acts on the Leydig cells. It has a wide range of functions, all associated in some way with the primary function of fertilizing the egg. Thus, it is responsible for growth of the sperm ducts and storage organs, often for the colourful plumage of the male, and also for much aggressive and sexual behaviour—including song. It also regulates the general level of reproductive activity, since testosterone feeds back negatively to the pituitary complex and suppresses excess LH and FSH secretion.

Most female birds have only a functional left ovary and oviduct, the right being rudimentary. Some of the more bizarre cases of farmyard hens turning into cockerels occur because very occasionally the rudimentary right gonad develops and often turns not into an ovary but into a testis (see OVOTESTIS). Hawks of all the major families (Cathartidae, Accipitridae, Falconidae) can be found that have two functional ovaries. Seasonal changes in the size of the reproductive organs are even greater than in the male. For example, in captive Japanese Quail *Coturnix c. japonica* in winter the ovary weighs 15 mg and the oviduct 20 mg, whereas in the breeding season the respective weights are 6,500 mg and 5,000 mg. In newly hatched birds the ovary contains a mass (a million or more) of minute oocytes. Only a miniscule fraction of these ever develop completely, the vast majority dying at some stage during growth. Each oocyte is surrounded by layers of follicular cells (zona granulosa and theca interna). These produce the sex steroids (oestrogens, progesterone and also some testosterone). During ovarian growth LH and FSH stimulate the follicular cells to secrete oestrogens. These act on the liver to cause the synthesis of yolk, a mixture of proteins and fats. The amounts of yolk produced are quite prodigious—about 15 g every day in a laying hen. In many small birds, e.g. Great Tits *Parus major*, the resources necessary to lay down yolk are so great that breeding cannot be started until there is a sufficient supply of food for the female to manufacture her eggs. In a poor season CLUTCH-SIZE may have to be reduced. The yolk proteins travel from the liver to the ovary in the circulation and are then absorbed by the growing oocyte. Eventually, at maturity, the average bird's ovary contains a hierarchy of about 10 yolky follicles, the largest being the most mature and ready to ovulate. During its final maturation phase this largest follicle appears to stop producing oestrogens (though the smaller ones do not) and instead starts to secrete progesterone. This steroid has a positive feedback effect on the pituitary and triggers a surge of LH secretion. Over the next few hours the LH causes a breakdown in the layers of follicular cells and ovulation of the naked yolk-filled oocyte from the ovary. This is picked up by the open end of the oviduct and fertilized by sperm lying in special crevasses at the top of the oviduct. During ovarian growth the oestrogens, together with progesterone, have also acted on the oviduct to cause its differentiation into an organ capable of investing the oocyte with various protective coats. In birds such as quail and chickens the fertilized oocyte spends about one day in the oviduct. It first stays for about 3 hours in the magnum and acquires layers of albumen (egg white protein). The cells begin to secrete albumen when stretched by the oocyte or by any foreign body in the magnum, even a table-tennis ball. After this the albumen-coated oocyte moves to the isthmus where the shell membranes are secreted. It then travels to the shell 'gland' or uterus and over the next 20 hours the calcareous shell is secreted around the egg (see section above on Calcium Metabolism). Water is also pumped into the albumen, causing it to swell considerably. In the final hour any shell markings are acquired and the egg is then laid as a result of increased oxytocin and prostaglandin secretion causing contractions of the shell 'gland'.

Birds vary widely in their clutch sizes and little is known of how this is controlled physiologically except that in some species ovulation can be stopped prematurely by adding eggs to a clutch. In the chicken, of course, man has learned that ovulation can be sustained for very long periods by regularly removing the laid eggs and well managed commercial strains lay about 270 eggs in 52 weeks. For most species, however, such a trick does not work indefinitely although it is proving valuable in breeding a number of endangered species. Chickens (and other Galliformes) lay to a consistent time pattern. In a few birds ovulation occurs every day at the same time, and the egg from that ovulation is duly laid 24 hours later. This can lead to prolonged sequences, which in one Japanese Quail was continued without a break for 140 days. Such patterns are not common though, and most birds normally lay in sequences containing 2 to 10 eggs, ovulation being restricted to an 8 hour period of each day. Thus, chickens lay their eggs only in the morning and early afternoon. In contrast, quail lay late in the day and early in the night. This periodicity is controlled by a biological clock (see RHYTHMS AND TIME MEASUREMENT).

As emphasized elsewhere (see BREEDING SEASON), environmental factors have to trigger reproductive growth well ahead of the time when the young have to be hatched simply because sexual maturity takes about 2 months to complete. Away from the tropics daylength is used as the main environmental cue heralding the arrival of the breeding season and the way in which photoperiod acts has been extensively studied. Other factors, of course, fine tune the precise time of breeding, but little is known about their physiological effects. One remarkable discovery has been that birds do not use their eyes for photoperiodic light detection. Light floods through the top of the skull and is detected by a photoreceptor lying in the hypothalamus (Fig. 2). Incidentally, the situation is different in seasonally breeding mammals which use their eyes to detect light for the photoperiodic response. Once the light has been detected, day length must then be measured and this requires a clock of some sort. Birds use their circadian clocks for this purpose. It is unclear exactly how this works but possibly there is a daily rhythm of sensitivity to light. For most of the day the bird is insensitive to light but for a period of a few hours, beginning about 12 hours after dawn, it becomes highly sensitive and if light is still present at this time, as occurs for the first time in early spring, then the day is read as 'long'. Experimentally, this means that reproduction can be triggered in birds by day lengths very much shorter than, say, 13 hours provided it can be arranged for some light to fall when the bird is photosensitive. In quail two 15 minute pulses of light set $12\frac{1}{2}$ hours apart mimic a long day and are nearly as effective as a full photoperiod of 13 hours.

If the daylength is interpreted as long by the clock/photoreceptor complex then this leads to Gn-RH release from the neurohypophysis and

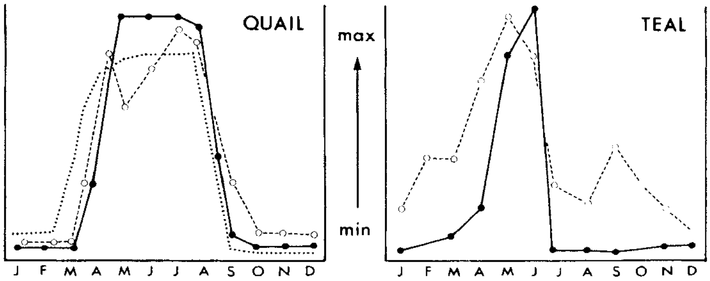

Fig. 3. Annual reproductive cycles (——, testicular size; - - - -, circulating LH and . . . ., FSH) in Japanese Quail *Coturnix coturnix japonica* and Green-winged Teal *Anas crecca* under natural daylengths.

thus LH and FSH secretion from the adenohypophysis, and eventually to the production of sexually mature birds. Each species differs slightly in the timing and duration of its breeding season and this is reflected in the photoneuroendocrine response. Figure 3 shows data for two birds, the Japanese Quail with a long multiple clutch breeding season and the Green-winged Teal *Anas crecca*, a single-clutch species. These graphs emphasize another important feature of bird reproduction: breeding invariably ceases when the days are still long, often even still increasing as in the Teal (and Rook *Corvus frugilegus*). This so-called photo-refractoriness (when the bird is refractory to the influence of long days) is an adaptation to ensure young are not produced too late in the season when food and weather conditions are about to deteriorate. Somehow, the refractory state develops in the brain and suddenly overrides the effects of daylength, cutting off LH and FSH secretion and leading to gonadal collapse. The refractory state is sometimes referred to as the post-nuptial regeneration phase.

Whilst the sex hormones have many actions on the reproductive organs they are also responsible for sexual behaviour. Under their influence, territories are firmly established and courtship begins (see DISPLAY; TERRITORY). The nest is then built and mating begins for by then the sex steroids have acted on the brain to allow copulatory behaviour. During the laying of the clutch the brood patch develops and finally INCUBATION begins. Prolactin and progesterone are involved in this behaviour. Once the young are hatched PARENTAL CARE develops. ENDOGAMY: mating within the group.

ENDOGENOUS: originating from within the body. The converse, 'originating from outside the body', is 'exogenous'.

ENDOPARASITE: a parasite inhabiting the interior of the host's body, as distinct from an ECTOPARASITE. Birds are hosts for a wide variety of endoparasites, but certain genera and families of endoparasites are particularly prevalent, and only these are dealt with here.

With the vast majority of endoparasites there is no direct immediate transmission of infection from bird to bird as occurs, for example, with bacterial and viral infections. A period of development outside the final bird host is usually necessary. Often this is in an invertebrate which is then referred to as an intermediate host, or development occurs directly without the intervention of an intermediate host. Various developmental stages are undergone to produce an infective stage for the final host and, following infection, a further series of developmental stages occurs; these constitute the life cycle of the parasite. Examples of intermediate hosts for bird endoparasites include snails, earthworms and flies.

Evolutionary pressures have led to synchronization of life cycles of parasites with the feeding habits of birds and also with major physiological events in the life cycle of birds. Thus the endoparasites of waterfowl and sea birds use fish and aquatic invertebrates as intermediate hosts, while with insectivorous birds the parasite fauna is largely restricted to those forms that develop in insects. Synchronization of the life cycle with the breeding season ensures transmission of infection to a susceptible chick population, as is exemplified by the increased availability of blood protozoa to expanded populations of blood-sucking flies during the egg laying and nestling season.

Pathogenic effects. When extremely heavy burdens of endoparasites occur, then ill health and death can confidently be attributed to such infection. Nevertheless, it is often difficult to assess the importance of any given parasitic burden as regards the health consequences.

Limited surveys have generally shown that minimal burdens of parasites exist in the natural state, but seemingly heavy burdens sometimes occur without causing any apparent ill health. However, such burdens may become important if the food supply is curtailed or if other diseases occur concomitantly. There are instances when even a very small number of parasites may result in ill health and death, particularly when a vital organ of the body is incapacitated.

Heavy burdens of endoparasites often occur when birds are reared under intensive conditions, without adequate attention to hygiene. Infections may be acquired from domestic poultry, but more usually wild birds introduce infection by faecal contamination into intensive rearing establishments for domestic poultry or game or wildfowl.

The main groups of endoparasites are the unicellular animals (Protozoa), the roundworms (Nematoda), thorny-headed worms (Acanthocephala), tapeworms (Cestoda) and flukes (Trematoda). Only the more important pathogenic or commonly occurring genera or species will be mentioned.

Protozoa. These are single-celled animals, showing a wide variety of forms. Included in this group are the coccidia and the blood protozoa. The most important members of the group in Great Britain are the coccidia. Coccidian parasites of the genus *Eimeria*, for example *E. tenella*, may cause enormous economic loss in domestic poultry but such forms are not transmissible to wild birds, these being parasitized by distinct species. *Eimeria* species usually parasitize the intestine and heavy infections lead to enteritis, which may occasionally be haemorrhagic and fatal. However, immunity to infection is quickly established and usually this prevents the acquisition of overwhelming infections. Geese, Moorhens *Gallinula chloropus*, Kittiwakes *Rissa tridactyla* and cormorants *Phalacrocorax* spp. are among the hosts for such coccidia. A coccidian of the kidney *Eimeria truncata* occurs in geese. In domestic geese it may be highly pathogenic, especially in goslings. Its importance in wild geese is unknown but it is probably pathogenic for goslings.

While the genus *Eimeria* is host specific, the related genus, *Isopora*, common in passerines, is less so: for example *Isopora lacazii* is found in the intestine of about 50 species of birds including House Sparrows *Passer domesticus*, Goldfinches *Carduelis carduelis*, Skylarks *Alauda arvensis*, wagtails *Motacilla* spp. and Chaffinches *Fringilla coelebs*.

All the coccidia are microscopic and live within cells, usually of the intestine. The life-cycle is direct, infection of a bird occurring when it eats the infective stage (oocyst). These oocysts may remain infective on the ground for long periods, and large concentrations of them may accumulate around feeding and watering places. Artificial concentration of birds, e.g. due to hand-feeding in winter, may build up sites of marked contamination.

Lankesterella is related to the coccidia and is a common parasite of House Sparrows and other passerines. Developmental stages are found within cells of the spleen, bone marrow and liver and developmental forms may be seen in the blood. Transmission is probably by the red mite *Dermanyssus gallinae*. Occasionally, the parasite causes congestion and inflammatory foci in the liver and lungs of sparrows.

Previously *Lankesterella* has been confused with *Toxoplasma gondii*, a protozoan which occurs in a wide range of mammals, including man, and the definitive host of which is the cat. Toxoplasmosis, generally, is rare in birds but acute disease of domestic poultry has been recorded in Norway. A survey of *Toxoplasma* in pigeons in Washington D.C. showed 12% to be infected with a strain of organism which was closely related to a human virulent strain. However, there is no evidence that birds infected with *Toxoplasma* constitute an important source of infection for man.

Sarcocystis occurs as cysts, several millimetres long, in the muscles of the heart, legs and breast. It occurs in a range of ducks, grouse etc, though it is not known whether a single or several species of parasite are represented in this distribution. No obvious ill health results from the infection.

Trichomonads are flagellated protozoa. *Trichomonas gallinae* lives in the crops of birds, and in young pigeons it may cause disease and death, infection of the squabs being by contaminated 'pigeon's milk' from the parent (see CROP MILK). Wild and captive birds of prey may occasionally suffer severely from trichomoniasis, apparently from predation on infected pigeons.

Hexamita meleagridis is an intestinal flagellate and is a pathogen of domestic turkeys but may also occur in various wild gallinaceous species, infection in these serving as a source of infection for domestic poultry. *Hexamita columbae* is responsible for intestinal disease in pigeons *Columba livia*, the parasite affecting all parts of the digestive tract. It is distinct from the parasite of turkeys.

Trypanosomes occur in birds, *Trypanosoma fringillinarum* being found in Chaffinches, and *T. avium* in Rooks *Corvus frugilegus* and Jackdaws *C. monedula*. These trypanosomes are not, however, the cause of serious disease, unlike their relatives the trypanosomes of man and animals in Africa. Other blood protozoa include members of the genera *Haemoproteus* and *Leucocytozoon*, both being transmitted by blood-sucking flies. *Haemoproteus* species are found in many species, including thrushes *Turdus*, Blackbirds *T. merula*, Starlings *Sturnus vulgaris*, and birds-of-prey. *H. columbae* of pigeons and doves is transmitted by the louse-fly *Pseudolynchia canariensis*. Clinical signs include anaemia and enlargement of the spleen in young birds. *Leucocytozoon* species are transmitted to ducks by *Simulium* flies. Weakness and dypsnoea occur in heavy infections since cells of the lungs particularly, and the liver and brain, are parasitized. Light infections cause little or no harm.

The protozoan *Histomonas meleagridis* is the cause of the severe and often fatal disease of turkeys known as blackhead. It is transmitted from bird to bird by the caecal nematode *Heterakis gallinarum* (see below). Initially it causes an inflammation of the bowel, but later it affects the liver and produces marked damage and necrosis. Heavy mortality may occur in various species of gallinaceous birds, such as domestic fowl, Quail *Coturnix coturnix*, grouse Tetraonidae, partridges *Perdix* and *Alectoris*, pheasants Phasianidae and especially the Peacock *Pavo cristatus*.

Helminths. These are multicellular forms, generally referred to as 'worms' and include the forms mentioned below, the Nematoda, Acanthocephala, Cestoda and Trematoda. The majority are readily visible to the naked eye, frequently but not exclusively occur in the digestive tract and may require an intermediate host in which development occurs to the infective stage for birds.

Nematoda: Ascaroidea. Ascarids may have a direct or an indirect life cycle. Of those having a direct life cycle, the caecal worms *Heterakis* spp. and the intestinal worms *Ascaridia* spp. are extremely common. The caecal worm of domestic poultry, *H. gallinarum*, may occur also in a wide range of birds, including ducks, pheasants and crows. Infection is acquired by eating infective eggs, which may remain viable in the soil for long periods. Within the caecum of the fowl little direct damage is generally produced, but this parasite is of importance since it transmits the organism of blackhead (see above). Of the other *Heterakis* species, *H. dispar* occurs in ducks, frequently in large numbers, and *H. isolonche* is found in pheasants and causes a nodular disease of the caeca.

The genus *Ascaridia* is widely distributed in birds; *A galli* has a cosmopolitan distribution occurring in domestic poultry and game-birds, while *A. columbae* is a frequent parasite of domestic and wild pigeons. Heavy and sometimes fatal infections with the genus *Ascaridia* may occur in birds that feed in groups. These worms are some of the largest to be found in birds, and infection can be readily detected at post mortem; when in large numbers they may cause impaction of the intestinal tract.

Of the ascarids with an indirect life cycle, the genera *Contracaecum* and *Porrocaecum* are the most common. The larval stages of *Contracaecum* spp. occur in fish, and consequently fish-eating birds (and indeed mammals) are affected by them. *C. spiculigerum* is a very common parasite of the proventriculus and intestine of a variety of sea birds. The genus *Porrocaecum* has a wider host distribution. Some are found in birds of prey, in which case the intermediate stages occur in moles and shrews. *P. crassum* is particularly common in ducks and requires earthworms as its intermediate host, whilst *P. depressum* and *P. ensicaudatum* are widely distributed in many birds, the latter being particularly common in passerines.

Signs of infection include loss of weight, listlessness, loss of plumage and sometimes foamy diarrhoea.

Nematoda: Strongyloidea. The majority of these strongyles have a direct life cycle. The best known are the gizzard-worm *Amidostomum anseris* of geese, the gapeworm of poultry *Syngamus trachea* and the small strongyle of grouse and other birds, *Trichostrongylus tenuis*. *Amidostomum* spp. occur in many different species of ducks, geese and swans. The worms are relatively large and live under the horny coat of the gizzard, causing marked inflammation and severe ulceration that frequently ends in death. Young birds are particularly affected and *A. anseris* may be responsible for heavy mortality on breeding grounds.

The gapeworm occurs in the trachea and bronchi and often causes marked mortality in domestic and game birds, even a few worms leading to respiratory distress. The life cycle may be direct, or invertebrates such as earthworms and centipedes may act as transport hosts, infection being acquired by eating the latter. Earthworms also make the gapeworms of wild birds, particularly those of Rooks and Starlings, more readily transmissible to domestic poultry. It is thought that gapeworms of wild birds—and they occur in many species—are different strains from that found in poultry but the earthworm can modify them so as to produce infection in domestic birds. The gapeworm *Cyathostoma bronchialis* occurs in ducks and geese, and because of their size even one or two of these may occlude the trachea of young birds and cause death.

Trichostrongylus tenuis is a very small worm occurring in the caeca and intestine of ducks, poultry, pheasants, grouse and many other birds. This parasite is of particular importance in the Red Grouse *Lagopus lagopus*, in which it is a well known cause of death. In ducks, too, it may cause severe inflammation of the intestine.

Nematoda: Spiruroidea. All the spirurids require an intermediate host to complete their life cycles, this usually being an arthropod. A wide variety of parasites is included in this group, and they parasitize different sites of the body. One example is the genus *Oxyspirura*, which occurs in the conjunctival cavity of the eye.

One of the most important groups is the Acuariidae, containing several species which parasitize the gizzard or proventriculus of various birds, causing severe damage to the digestive system. *Echinuria uncinata* of ducks and geese may be responsible for heavy mortality in wildfowl kept in captivity; the intermediate host is the water-flea *Daphnia pulex*, which is abundant in stagnant and slow-running waters. Other genera of the Acuariidae include *Cheilospirura*, *Synhimantus* and *Dispharynx*, which occur in a range of galliform and passerine birds; they parasitize the upper digestive tract and have a marked pathogenic capacity.

A remarkable parasite in the Spiruroidea is *Tetrameres fissispina*, found in waterfowl. The female of this species becomes almost spherical and red in colour when mature, and since it lives in the glands of the proventriculus it causes marked dilatation and degeneration of glandular tissue.

Nematoda: Filaroidea. Adult worms live in body cavities and inner organs. They produce larvae, microfilariae, which occur in the blood. These, to complete their life-cycle, are taken up by blood-sucking insects and develop inside them to the infective stage. Infection occurs with the injection of infective larvae into the body of the bird with saliva from the insect.

Nematoda: Trichinelloidea. Capillarids are very thin small worms, difficult to see, but may occur in large numbers in various parts of the digestive tract. One of the commonest is *Capillaria contorta*, which occurs in the crop and oesophagus of domestic and many wild birds. When present in large numbers it causes marked thickening and inflammation of these organs.

Acanthocephala. Thorny-headed worms are small, generally sausage-shaped, and have a large retractable proboscis covered with numerous curved spines. This proboscis is used to anchor the worm to the bowel wall, being thrust into the tissues. The most common is *Polymorphus minutus*, occurring in many kinds of waterfowl, sometimes several hundreds or thousands being found, though in many cases causing no apparent ill health. This species is frequently bright orange in colour and in a heavily infected bird the inside of the bowel may be a continuous orange mass. The intermediate host of *P. minutus* is the freshwater shrimp *Gammarus*. The genus *Corynosoma* utilizes fish as an intermediate host, in addition to an arthropod, and consequently is found in fish-eating birds (and also in seals). In passerine birds the genera *Prosthorhynchus* and *Centrorhynchus* are commonly found.

Cestoda. Tapeworms have an interesting distribution in birds, in that certain groups of birds possess their own particular fauna of them. The family Hymenolepididae is perhaps the largest group occurring in birds, being common in the ducks. Many species occur, and their identification is a matter of great difficulty. The hymenolepid cestodes require intermediate hosts, and these vary from aquatic arthropods to beetles and annelids. Extremely heavy burdens of *Hymenolepis* spp. may occur in birds and are responsible, at times, for severe mortality. One of the commonest species, occurring in a wide variety of ducks and other waterfowl, is *H. anatina*.

The family Dilepididae is also a large group containing tapeworms which occur in a wide range of birds, but especially in the Turdidae and other passerines. Fish-eating birds are commonly infected with tapeworms of this family.

The tapeworm genus *Raillietina* is common in domestic poultry and in game-birds, also occurring in pigeons, sparrows and thrushes. The genus *Anomotaenia* is a large one and occurs in waders, gulls and passerines. The identification of tapeworms requires staining techniques and microscopic examination and is a task for a specialist.

All important species occur in the intestinal tract and the ill effects produced are much the same with all groups being loss of weight, diarrhoea and death in heavy infections.

Trematoda. A wide variety of flukes occurs in birds. Some are extremely small and difficult to see, some may occur in large numbers without causing any obvious ill health, whilst others may be pathogenic in moderate numbers. All undergo development within a snail, and in the majority of cases also require a second intermediate host for the infective stage of the fluke (metacercaria) to be reached, this occurring in a variety of animal life such as fish, snails, insects, crustacea, and annelids. Since many of the intermediate hosts are animals that live in or near water, it is not surprising that waterfowl and sea-birds in general frequently are parasitized by flukes.

The fluke family Echinostomatidae is very common in waterfowl. It is characterized by a collar of spines round the head, and includes some of the largest trematodes of birds and also some of the most highly pathogenic. *E. revolutum* is a common fluke of the intestines of ducks and geese, whilst the genera *Echinoparyphium, Hypoderaeum, Echinochasmus,* and *Himasthla* are common groups in water birds.

Members of the family Microphallidae are frequent in birds feeding on mudflats, saltings, and the seashore. These are very small flukes, and several thousand may be found in the intestine of a single bird. The family Plagiorchidae is chiefly found in sparrows, Starlings and Rooks, and one genus, *Prosthogonimus*, is found in the oviducts of such birds. There are other specific sites for flukes than the intestine; for example, in the gall bladder of passerines *Lyperosomum longicauda* is often found; the genus *Renicola* occurs in the kidneys of gulls; the genus *Clinostomum* occurs in the nasal passages of gulls and herons; and even the skin is affected by the genus *Collyriclum*, which causes cysts in such birds as warblers (Sylviinae), wagtails (*Motacilla* spp.) and sparrows.

One interesting group is the Schistosomatidae, the worms occurring in the vein draining the intestine. Birds such as ducks and swans, grebes, and gulls are parasitized by schistosomes. Infection of birds is produced by the infective stages (cercariae) penetrating the skin. Human bathers may be attacked by these cercariae, when a dermatitis called 'swimmer's itch' is produced. ENDOTHERMY: (= warmbloodedness, homoiothermy, homeothermy). The ability of birds and mammals to maintain a high, and usually near-constant, body temperature by the internal production of heat (see ENERGETICS; HEAT REGULATION; METABOLISM).

ENDYSIS: renewal of plumage after moult (ecdysis)—see MOULT.

ENERGETICS: a term broadly used to describe the various aspects of intake and utilization of energy. In practice the word is applied to the energy requirements of some phase of avian life history (e.g. egg-laying, moult, migration) or to basal or total energy utilization of a species under specific conditions, but the units measured are actually power units. Historically, avian energy utilization has been expressed in kilocalories per day either on a whole bird basis, or per unit body weight, or in relation to surface area. The International System of Units (SI system) suggests that the appropriate units to be used are joules ($j = 0.239$ cal) and watts ($859.8\,\text{cal}\cdot\text{hr}^{-1} = 1\,\text{j}\cdot\text{sec}^{-1}$ or $0.860\,\text{Kcal}\cdot\text{hr}^{-1} = 1\,\text{kJ}\cdot\text{sec}^{-1}$).

A variety of energy measurements have been used which focus on different levels of energy utilization. *Basal metabolism* is the minimum energy requirement of unfed, inactive birds at nonstimulatory temperatures. *Standard metabolism* is similar to basal metabolism but includes costs of thermoregulation. *Existence energy* is the energy requirement of caged birds in which activity is minimized but costs of thermoregulation and food utilization are included. *Metabolized energy* is similar to existence energy but includes possible energy requirements of moult, reproduction, growth, fat deposition, activity and other productive phenomena.

Basal metabolism. Basal metabolism, better termed standard thermoneutral metabolism, is the rate of energy utilization within the zone of thermal neutrality (i.e. at temperatures which do not stimulate metabolic rates) under certain standard conditions. Functionally, such values are determined by means of indirect calorimetry in which the oxygen consumption or carbon dioxide production of unfed (post-absorptive) birds is measured in unlighted chambers. Rate of oxygen consumption or CO_2 production can be converted to energy or power units by multiplying the volume of gas by the appropriate caloric equivalent (Table 1). The caloric equivalent to be used is judged from the *respiratory quotient* (RQ) which is the ratio of CO_2 produced to oxygen consumed and hence is an indication of the substrate (lipid, protein, carbohydrate or a mixture) that is being oxidized.

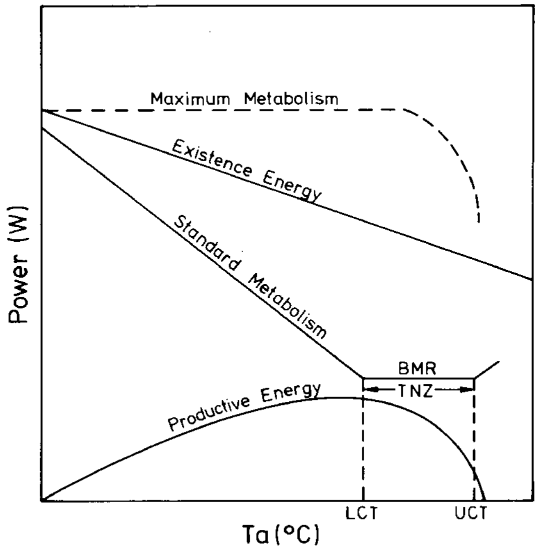

Fig. 1.

Use of oxygen consumption rather than carbon dioxide production as a measure of metabolism is usually preferred. A relatively large residual amount of carbon dioxide is usually present in the bodies of many organisms and this pool may easily increase or decrease, giving a false measurement of CO_2 production. Another problem is that the caloric equivalent of a litre of CO_2 varies widely with the type of substrate being oxidized; the equivalents of oxygen utilization vary less severely. It appears that birds undergo little anaerobic catabolism of energy substrate in comparison with other vertebrates and therefore do not usually accumulate significant 'oxygen debts'.

Allometry of metabolism. The relationship between body weight and standard thermoneutral metabolism is a curvilinear relationship such that the 'best fit' equations are exponential functions of the form:

$$M = aW^b \quad \text{or} \quad \text{Log } M = \text{Log } a + b \text{ Log } W$$

where M is $\text{Kcal}\cdot\text{day}^{-1}$ and W is in kg. Such equations are of considerable biological interest as the exponent or slope (b) of the equation reflects relative response of metabolism to increased body weight and the coefficient (a) indicates the relative magnitude of metabolism. These equations may therefore be used to compare metabolic rates of different phylogenetic groups.

Two principal equations have been presented that describe the relationship between body weight and basal metabolism (Lasiewski and Dawson, 1967). These are:

$$M = 129\,W^{0.724} \text{ (passerines)}$$
$$M = 78\,W^{0.723} \text{ (non-passerines)}$$

According to the Lasiewski-Dawson equations, the metabolic rate of a passerine bird can be expected to be 65% higher than that of a non-passerine bird of the same weight. It is obvious that individual species deviate from these 'best fit' lines, but the metabolic rate of several species or taxonomic groups is noteworthy. For example, metabolic rates of Accipitriformes, Falconiformes, Galliformes, and Strigiformes are lower than predicted by the non-passerine equation, while Apodiformes, Piciformes, Ciconiiformes, Anseriformes and Columbiformes are higher. In general 'primitive' birds with low body temperatures relative to other species have exceptionally low metabolic rates. This is particularly true of ratite species such as the Ostrich *Struthio camelus*, Rhea *Rhea americana*, Emu *Dromaius novaehollandiae*, and the kiwis (Apterygidae).

The allometry of metabolism may have more extensive significance than phylogenetic comparison (see Energy limits on body size, below). Since birds depend upon their territories for food and as energy needs vary allometrically with weight, it is logical that territory size will be an exponential function of size of the bird. Although specific exceptions must be considered, it appears that such a relationship generally exists. In addition, since some energy is lost in the exchange from one trophic level to the next, it is to be expected that carnivores (obtaining their food less directly from primary producers than herbivores) would have larger territories than primary consumers or herbivores. Exponential curves predicting territory size from body weight have exponents greater than 1.0, e.g. all birds, 1.09; carnivorous birds, 1.31 (Schoener 1968), and differ significantly between birds occupying different trophic levels.

Basal metabolism may be influenced by several factors that are not controlled or eliminated by the methodology. This involves measuring rates of oxygen consumption of individuals which have not recently been fed, are inactive and being held at temperatures in the thermal neutral zone (see Fig. 1). Cyclic differences in metabolic rates over the diurnal cycle, seasonal and sexual variations and ecotypic/climatic adaptation may all be influential in modifying the results obtained in particular tests. Before discussing the effects of such phenomena upon metabolism, metabolic rates obtained outside the zone of thermal neutrality must be examined.

Standard metabolism. The rate of energy utilization measured under the same conditions as basal metabolism but at temperatures that stimulate the production of heat is called standard metabolism (see Fig. 1). As ambient temperature decreases within the zone of thermal neutrality, increased heat loss is prevented by greater insulation provided by fluffing of feathers, reduced peripheral circulation and postural modifications. Below the ambient temperature (T_a) at which such physical insulation is at a maximum (the lower critical temperature), standard metabolism increases with decreased temperature, since increased heat loss must be replaced by metabolic heat production; alternatively body temperature (T_b) must drop in order to maintain a positive energy balance (see torpor below). The increase in metabolism is in proportion to $C(T_a - T_b)$ where C is 'conductance' (= the reciprocal of insulation) or the heat transfer coefficient. Minimum rates of heat transfer are largely a function of physical insulation provided by thickness of feathers. Although thickness of the plumage is difficult to measure, weight of feathers (F, in g) increases with body weight (W, in g) according to the equation:

$$F = 0.68\,W^{0.959}$$

This is nearly a direct relation of feather weight to body weight as the slope of the equation is not statistically different from 1.0. However, since surface area increases less rapidly than body weight, feather weight per unit surface area increases significantly with bird weight. As a result, the heat transfer coefficient decreases with body weight in an exponential fashion. From metabolic data this relationship has been determined to be:

$$C = 4.08\,W^{-0.51}$$

where C is in $\mathrm{cal \cdot g^{-1} \cdot hr^{-1} \cdot {}^{\circ}C^{-1}}$ and W is weight in g.

The heat needed to maintain constant body temperature is generated mostly from muscular activity. Shivering is the major source, but locomotor activity and specific dynamic action (see below) also contribute to a varying degree. Non-shivering thermogenesis, well known in mammals, apparently does not occur in birds.

The upper critical temperature marks the upper end of the thermal neutral zone. Above this temperature, the bird is no longer able completely to resist increases in ambient temperature by evaporation of moisture from respiratory surfaces. Standard metabolism increases as body temperature becomes elevated and heat death usually ensues quickly. At high ambient temperatures evaporative water loss increases sharply in a curvilinear fashion such that heat dissipation increases rapidly near upper critical temperatures. The heat of vaporization (H_v) is relatively large and therefore evaporation carries away substantial quantities of heat. H_v increases with the temperature at which evaporation takes place; the commonly used physiological constant is $580\,\mathrm{cal \cdot g^{-1}}$ water at 35°C (at 40°C, a temperature that more closely approximates the body temperatures of many birds, $H_v = 573\ \mathrm{cal \cdot g^{-1}}$). Water loss decreases to low levels at temperatures below thermal neutrality. This is energetically advantageous in that evaporative heat loss in cool environments would require energy and be of no benefit.

Birds that have fed shortly before metabolic tests have higher rates of energy utilization. For this reason, measurements of absorptive individuals under conditions of standard metabolism are termed resting metabolism. The calorigenic effect of food, usually called specific dynamic action, does not appear to vary with body size or species. Specific dynamic action is related to chemical composition and amount of food eaten. For example, pure protein elevates metabolism 20–45% in some species, while the effects of carbohydrate or fat may be significantly less. The calorigenic effect is associated mostly with the viscera and tests indicate that the heat arises from the catabolism of food, rather than increased activity of the digestive organs themselves. The apparent heat produced in specific dynamic action may vary with ambient temperature and appears partially to substitute for the heat produced in thermoregulation in the cold.

Energy demands may be modified by a variety of behavioural adaptations. Species which exhibit huddling or clumping together in tight groups may save significant amounts of energy during periods of inactivity at low ambient temperatures. Individual surface area and heat loss are reduced by the contact with conspecifics. Wrens (Troglodytidae), creepers (Certhiidae) and several other small passerines are particularly noted for huddling together at extremely low ambient temperatures. Use of cavities, winter nests, burrows and other protective sites may likewise conserve significant amounts of energy. Basking in sunlight may increase body surface temperatures and conserve energy by reducing heat loss from deeper in the body. A number of large, dark birds are known for their basking behaviour in which they may spread their wings and direct their ventral surfaces into the direction of the sun. American vultures (Cathartidae), cormorants and several diurnal birds of prey are among those noted for such behaviour. There is evidence that some of these species may deliberately overheat while basking, perhaps in an attempt to rid themselves of ectoparasites. Many other species also bask, often in a less obvious fashion.

Colour of the bird may be important in the amount of heat collected during exposure to solar radiation; in birds that vary in colour or have been artificially coloured, dark individuals may demonstrate energy savings of up to 20% over the energy requirements of light forms. GLOGER'S RULE states that, within endothermic species, black pigments increase in races from warm, humid areas, reds and yellow-browns tend to prevail in arid climates and pigments become generally reduced in cold regions. While much of this colour modification is probably a result of selection for individuals that more closely match background substrate and hence avoid being taken by predators, lighter colours may reflect greater amounts of solar radiation and reduce the tendency to overheat in arid environments. Darker colours conversely may more efficiently absorb solar radiation which assists in maintaining body temperature and reduces the energetic costs of thermoregulation.

Existence energy. The use of the bomb calorimeter in measuring the caloric intake and its utilization by birds was pioneered by S.C. Kendeigh in the late 1940s and gave rise to a means of making long-term evaluations of the energy balance of caged birds. The technique involves measurement of the caloric content of food and excreta of birds maintained under controlled or monitored temperatures, humidities and photoperiods. The term *metabolized energy* is applied to the energy utilized by birds not in a steady-state energy balance (i.e. those birds not maintaining constant weight or which are showing extensive activity other than simple maintenance processes). Functionally, metabolized energy (ME) is calculated as gross energy intake (GEI) minus excretory energy (EXE). GEI is the energy content of ingested food while EXE is the caloric content of the excreta (faeces + urine, since the two are difficult to separate in birds). The ratio (100 ME/GEI) has been variously termed coefficient of utilization, assimilation efficiency or energetic efficiency. The last is preferable, as 'cofficient of utilization' is misleading and assimilation is not being measured. The caloric contributions of faeces and urine are not experimentally separated in most tests. The faeces have not been assimilated but the calories in urine represent wastes that have undergone assimilation and catabolism. Energetic efficiency varies among species and with ambient temperature, photoperiod and composition of food. The effect of temperature and photoperiod may be a function of feeding rates and amount of activity. Energetic efficiency is usually lower at extreme cold temperatures and short photoperiods. Effects associated with composition of food are related to digestibility and the amount of specific dynamic action produced by the food. In general, carnivores have higher energetic efficiencies than seed-eaters or herbivores.

Existence energy is the metabolized energy utilized by individuals maintaining constant weight and which are expending negligible amounts of energy in activity or productive processes such as moult or egg-laying. The form of the relationship between existence energy and ambient temperature is similar to that of standard metabolism (Fig. 1) except that a thermal neutral zone appears to be lacking. Existence energy is usually greater on long photoperiods (i.e. light phase longer than dark phase). Equations that predict existence energy (EE) in $\text{Kcal} \cdot \text{bird}^{-1} \cdot \text{day}^{-1}$ from bird weight in g are significantly different for passerine and non-passerine birds (Kendeigh, 1970).

$$\begin{aligned} \text{EE} &= 1.572\,\text{W}^{0.621} \text{ (passerines, 30°C)} \\ \text{EE} &= 0.540\,\text{W}^{0.755} \text{ (non-passerines, 30°C)} \\ \text{EE} &= 4.337\,\text{W}^{0.530} \text{ (all species, 0°C)} \end{aligned}$$

In the zone of thermal neutrality, existence energy exceeds standard metabolism by 31% in passerines and 26% in non-passerines. The difference between existence energy and standard metabolism represents specific dynamic action and costs of activity.

Productive energy. The difference between maximum sustained rates of metabolism and existence energy is defined as productive energy (Fig. 1). It is generally assumed that maximum rates of metabolism are limited only by difficulties in heat dissipation as ambient temperature approaches body temperature, or by exhaustion of energy reserves or decreases in body temperature due to negative heat balance at low ambient temperatures. There are species-specific variations in the magnitude of metabolic maxima. Metabolic scope, an index of the capacity of organisms to mobilize energy, is expressed as a function of maximum metabolic rates as compared to minimum metabolic rates under standard conditions. Birds have metabolic scopes that range from approximately 10 to 20 times basal metabolic rates. As existence metabolism increases with decreased ambient temperature, lower lethal temperatures should be reached when existence metabolism is near or at the maximum sustained rate (i.e. productive energy = 0). If this model holds, then egg-laying or other productive activities would cease at some predictable temperature above the lower lethal limit and also increased physical activity would reduce the ability to survive low temperatures. These predictions have been confirmed by several independent investigations.

Table of combustible energy, oxygen consumption and carbon dioxide production for various foodstuffs.

	Kcal/g	$\text{cal} \cdot \text{ml O}_2$	$\text{cal} \cdot \text{ml}^{-1}\text{CO}_2$	RQ
Carbohydrate	3.8–4.3	5.1	5.0	1.00
Protein	4.3–5.7	4.8	5.8	0.83
Fat	9.0–9.5	4.7	6.7	0.71

Energy stores. Avian energy reserves consist largely of bodies of fat stored in masses beneath the skin and around the viscera. These so-called depot fats are composed of triglycerides. Upon hydrolysis, triglycerides yield fatty acids which may be oxidized (β-oxidation) with a relatively high yield of energy per g of fat (Table 1). Fatty acids provide the substrate that supports all prolonged avian activity. Carbohydrates such as glucose and glycogen are utilized in activities of short duration; the first few minutes of flight are fuelled by carbohydrates but, as flying continues, fatty acids become the major energy source. Fat is an advantageous energy store because of the high energy yield per unit weight. Not only is the caloric content greater, but deposition of fat depots requires little, if any, concomitant storage of water. Conversely, the storage of 1 g of carbohydrate is accompanied by additional storage of approximately 3 g H_2O.

Diurnal rhythms. The Lasiewski-Dawson equations presented above compare basal metabolism in passerine and non-passerine species and do not recognize significant differences that may occur between metabolic rates during the day and night (i.e. between activity phases and resting phases of the daily body temperature cycle). Separation of the relationship between weight and basal metabolism into activity (light or daytime) and rest (dark or nighttime) phases has produced the following equations (Aschoff and Pohl, 1970):

$$\begin{aligned} \text{Activity phase: } M &= 140.9\,\text{W}^{0.704} \text{ (passerines)} \\ M &= 91.0\,\text{W}^{0.729} \text{ (non-passerines)} \\ \text{Rest phase: } M &= 114.8\,\text{W}^{0.726} \text{ (passerines)} \\ M &= 73.5\,\text{W}^{0.734} \text{ (non-passerines)} \end{aligned}$$

Day-night variations in existence energy over the diurnal cycle need not be considered, as existence energy measurements are carried out over several days.

Daily cycles of body temperature and metabolism in birds have been known for many years. Highest body temperature and metabolic rate occur during the bird's activity period and are lowest during the rest phase of the diurnal cycle. These levels are reached independently of actual activity; measurements of basal metabolism are usually carried out with birds in darkened chambers and activity is usually negligible. Daily differences between high and low body temperature and metabolic rate in most species amount to only a few °C. However, a variety of species exhibit extensive decreases in body temperature and standard metabolism under conditions of low ambient temperature, darkness and/or shortage of food. Body temperatures below normal are termed hypothermia. Prolonged, severe hypothermia accompanied by relatively large decreases in heart, respiration and metabolic rates is referred to as torpor. The dividing lines between normal diurnal decreases in body temperature, moderate hypothermia and torpor are sometimes difficult to determine. However, the decrease in body temperature is reflected in an energy saving that is a function of the difference between active body temperatures and those of hypothermia. Reheating the body after a period of pronounced hypothermia or torpor may account for a substantial portion of the total energy demand of the period.

Climatic adaptation. Several widely distributed species are known to demonstrate intraspecific geographic variation in energy utilization probably as an adaptive response to local climate. In general, it appears that northern races and those from high altitudes are better insulated and less sensitive to cold than southern and low altitude races. For example, during the winter, the House Sparrow *Passer domesticus* in North America tends to be more heavily insulated in the northernmost part of its range and at high altitudes. The greater insulation found in northern birds results in smaller increases in metabolic rates with decreased ambient temperature and also results in lower critical temperatures that are shifted downward. Both modifications of metabolic response may contribute to a significant saving when northern individuals are compared with those from further south. Conversely, climatic adaptation may also be reflected in the ability of birds to produce heat; basal and standard metabolic rates may be slightly elevated in northern or arctic species but reduced in southern, tropical or desert forms.

Within many polytypic species of birds there are clines of increasing size northward (BERGMANN'S RULE) and/or decreasing appendage length (ALLEN'S RULE) which are functions of latitude or altitude or both. These ecogeographic rules may have thermoregulatory or energetic implications although considerable controversy has risen concerning the interpretation of the data. Such trends often are significantly correlated with isophane (an index of regional temperature regime calculated from latitude, longitude and altitude) or other measures of regional temperature. Increased size usually results in decreased sensitivity to low temperature; larger birds tend to be better insulated than small birds even when both have equivalent plumage thickness. However, larger birds also have greater overall energy requirements and it is difficult to demonstrate how natural selection might favour increased size in environments that demand more energy. Increased size probably produces other selective advantages such as increased foraging range, greater diversity of food items (as a result of increased bill size) or greater amounts of storage energy which permits survival of short periods of extreme energy demand.

The energetic implications of Allen's Rule lie in the use of extremities in the dissipation of heat. The extremities most important in avian heat loss are the legs and feet. Many species are capable of shunting blood flow to the legs under conditions of heat stress or may reduce blood flow to extremities in the cold. Temperate zone or arctic species may have tarsus and foot temperatures that are quite low in the cold; these may occasionally be as low as 1°C or less in the toes or webbing between them. Several species either extend the legs (sometimes in flight) or fully expose them when under heat stress. Herons wade in the water while panting and fanning themselves with their wings and the Wood Stork *Mycteria americana*, Turkey Vulture *Cathartes aura* and some Sulidae even squirt excrement on their legs and feet to increase the cooling rate. Obviously, increased length of extremities aids in heat loss. At the other extreme, at low ambient temperatures many species sit on their legs or hold them, one at a time, up within the body plumage to prevent heat loss. Several northern species have feathered tarsi which presumably reduce heat loss. In accordance with Allen's Rule, decreased leg length would serve the same purpose to a more limited extent.

Climatic adaptation may also be detected in comparisons of higher

Chestnut-banded Sandplover *Charadrius pallidus* illustrating heat loss by evaporative cooling while panting and by radiation from legs. (*Photo: J.F. Reynolds*).

taxonomic groups (e.g. in interspecific comparisons). Such studies have seldom indicated adaptive modification of basal metabolism when corrected for differences in body weight, except in interphyletic comparisons, but insulation and cold tolerance are often greater in northern members of related species.

Energy limits on body size. The evolution of passerine from non-passerine species has been accompanied by evolution of a higher rate of metabolism. As a result, the range between maximum and minimum size limits has been reduced (Kendeigh 1972). Difficulties in maintaining energy balance probably determine the minimum size limit in birds (about 5 g in passerines and 3 g in non-passerines such as hummingbirds). Minimum size becomes costly for small birds as the exponential relationship between body weight and metabolic rate per g increases sharply at very small sizes while the muscle mass necessary to produce heat becomes relatively small. Although they are also subject to similar limitations, hummingbirds have lower rates of metabolism and conserve energy by heterothermy (temperature regulation by recourse to external sources of heat). This apparently allows them to reach smaller sizes than passerines. Although the data are not unequivocal, it has been suggested that passerine species may have a limited potential for mobilizing energy; costs of existence energy and standard metabolism may be similar at low weights, suggesting that productive energy becomes severely limited. Maximum size in passerines may be limited by their inability to dissipate heat at high ambient temperatures. Non-passerines have lower metabolic rates and maximum size is not as severely restricted.

Seasonal variation in energetics. A variety of adaptive patterns of seasonal adjustment of metabolism are known. Acclimation refers to compensatory adjustments in response to maintained deviations of single environmental variables in the laboratory. Commonly, metabolic rates of birds that have been exposed to low temperatures (cold-acclimatized) in the laboratory are compared to rates obtained from birds maintained at warmer temperatures. Acclimatization is used to describe similar natural adjustments in response to complex deviations such as are found in seasonal changes in environment. Winter-acclimatized birds are often compared with summer-acclimatized individuals. As a result of cold exposure under natural conditions there is an increase in the ability of temperate zone and arctic species to sustain high levels of energy expenditure. This may be accompanied either by greater feather weight and/or subcutaneous fat or by tissue insulation, associated with reduced peripheral blood flow. Lower critical temperatures are theoretically shifted downward and slopes of metabolic curves below the lower critical temperature are more shallow in winter-acclimatized birds. Metabolic rates of species showing such adaptations usually take the configuration illustrated in Fig. 2A. In laboratory studies, there is metabolic adjustment in which rates of heat production after cold exposure are higher and insulation is not adjusted. Cold exposure for short periods of time appears to stimulate the capacity to produce heat and even the basal metabolism of cold-acclimatized individuals is usually enhanced (Fig. 2B). In fact, some students have maintained that enhanced survival in the cold is dependent upon development of a greater capacity to produce heat. However, studies of the plumage of wild birds under natural conditions indicate that natural winter acclimatization rarely if ever occurs without at least moderate increases in both insulation and some aspect of heat production.

Sexual variation in metabolism. In species that are dimorphic in body size there is usually a significant difference in basal and standard metabolism as a consequence of the allometry of metabolism associated with body weight. In monomorphic species the sexes are often metabolically indistinguishable outside the breeding season. Winter ranges of the sexes of dimorphic species in the temperate zone may only partially overlap for energetic reasons. In several North American finches, the males tend to winter further north and are apparently more cold-tolerant than the smaller females, probably because of their greater energy reserves. The separation of range would likewise decrease competition for food in which the larger males should dominate. If the birds tested in metabolic comparisons have previously experienced stimulatory photoperiods, then females may have higher basal and standard metabolic rates as a result of the costs of egg production.

Energy budgets and costs of free activity. Ornithologists have long desired to measure the costs of free existence in birds, but the technical difficulties involved have been hard to overcome. Three basic techniques currently exist that promise to solve this problem. These are time-energy budgets, measurement of metabolism by means of radioactive tracers (particularly doubly-labelled water), and telemetry.

Time-energy budgets are models of daily energy expenditure constructed from schedules of time spent at various activities. Each activity is converted to energy terms by assigning estimates of power costs. Few comprehensive budgets (i.e. constructed throughout the annual cycle) are available and seldom has the accuracy of the budgets been testable. A major difficulty is the assessment of many environmental factors, notably microclimatological ones; these should be included in the model and their effects evaluated upon each recognized activity. The instrumentation required and the complexity of the calculations needed become prohibitive for most researchers.

Doubly-labelled water, more precisely named deuterium oxide or D_2O^{18}, also provides a method for measuring total daily metabolism or costs of specific activity in free-living birds. As the oxygen of respiratory CO_2 is in isotopic equilibrium with the oxygen of body water, injection of D_2O^{18} allows us to monitor turnover rates of both hydrogen and oxygen. Since oxygen-18 is lost in CO_2 and H_2O, while deuterium is lost mainly through H_2O, CO_2 production can be calculated by measuring the difference between the turnover rates of deuterium and oxygen-18. Rate of oxygen consumption can also be computed if Respiratory Quotients (RQs) are known. Metabolic rates are then computed as described above

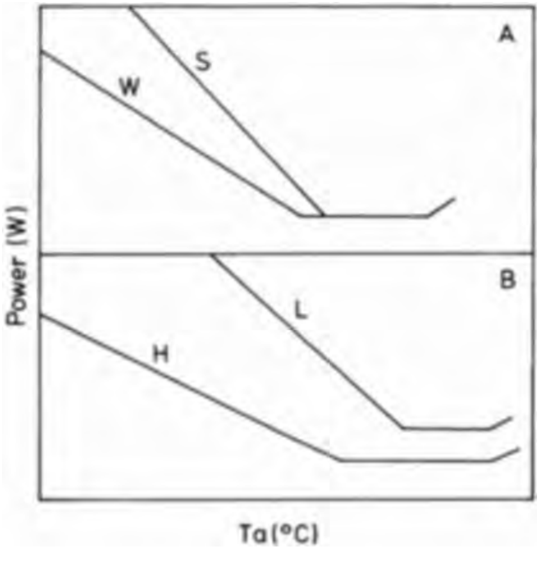

Fig. 2.

for other forms of indirect calorimetry; volume of CO_2 or oxygen must be multiplied by appropriate caloric equivalents indicated by the RQ (see above). In practice, RQs for free-living birds have not been measured and 'best estimates' (e.g. usually RQ = 0.8) have been used. Costs of activity or free existence measured by the D_2O^{18} technique are usually quantified as a function of basal metabolic rate. Estimates of metabolism under laboratory conditions by conventional calorimetry and the D_2O^{18} method are usually in close agreement and estimates of energy expenditure of free-living Purple Martins *Progne subis* from D_2O^{18} studies and a time-energy budget are quite similar. Other radioactive substances, such as phosphorus, iron, or more complex molecules, have not been used to any great extent for the measurement of avian metabolism. Because such substances may be potentially harmful, the difficulties in handling them and the dangers in releasing birds containing them have prohibited their use.

Various telemetry devices which transmit data on body temperature, heart rate or respiratory rates have been constructed and attached to or implanted within birds. Correlation of metabolic rates measured under controlled conditions with such variables could provide a means for estimating energy utilization by free-living birds. In one such experiment, the 'cost of free existence' of pinioned, free-living Blue-winged Teal *Anas discors* was an inverse function of ambient temperature and amounted to 0–18% of existence metabolism at ambient temperatures of 25° to −15°C.

Energetics of flight and migration. The energy demands of flight are a function of bird size and flight speed. Energy expended in flight increases with body weight, but larger birds have lower relative transportation costs (i.e. power needed to transport a unit weight over a given distance) than small birds. Both aerodynamic theory and empirical data indicate that power demands for flight at intermediate velocities are less than costs of slow flight (e.g. hovering) or more rapid flight (Fig. 3). Pennycuick (1969), in highly elegant quantitative analyses, has demonstrated the physical principles involved. In general, the power costs involve various aspects of drag, including the power needed to support the bird's weight in the air (induced power), to overcome friction and drag (parasite power) and the power requirements for overcoming the drag of flapping wings (profile power). Induced power costs decline with flight velocity, while parasite power increases and profile power remains proportional to the sums of induced and profile power. At intermediate speeds the power required is at a minimum since the sums of the power components are minimized.

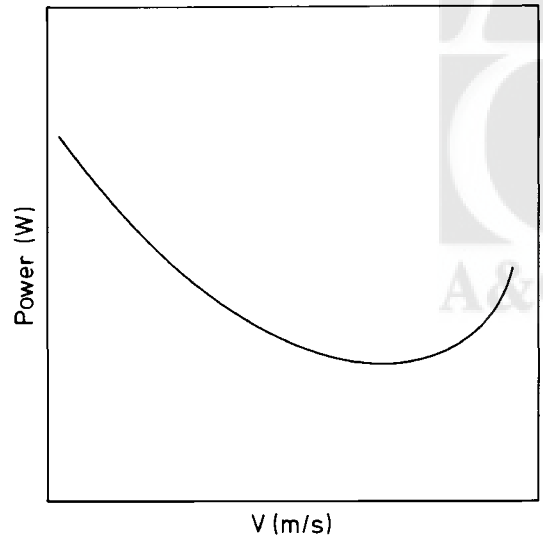

Fig. 3.

A variety of techniques have been used to measure the energetics of flight. Early successful attempts utilized indirect respirometry to measure metabolism of hummingbirds hovering in sealed containers. Tucker (1971) devised an ingenious technique in which birds are trained to fly in a wind tunnel while attached to respirometry equipment. Costs of flying at various velocities can be measured by changing the speed of the air passing through the tunnel, and Tucker has empirically confirmed many of the aerodynamic predictions of Pennycuick. Finally, the D_2O^{18} technique has been used to measure the costs of flight over known distances.

From studies of the cost of flight, a wide variety of observations and predictions about the costs of migration has been generated. For example, with increased body mass, minimum transportation costs occur at higher velocities. Larger birds should therefore migrate more rapidly than small birds. Additionally, the velocity of migration of individual migrants should slow near the end of migration as migratory reserves are depleted and weight drops. Larger birds with relatively similar reserves of premigratory fat should be able to make longer flights than small migrants. The major costs of migration are those of flight, but the temporal pattern and magnitude of deposition of depot fats are important features of energy utilization. Species making long, non-stop flights deposit large amounts of energy, in some cases amounting to several times the caloric content of their bodies, in a few days. The costs of fat deposition have not been extensively investigated, but undoubtedly exceed the caloric content of the fat itself (9.0–9.5 Kcal/g).

Energetics of moult. Energy demands during the moulting process are complex, as increased food demands are brought about by several factors. First, loss of feathers decreases insulation and metabolic rates must be elevated to replace heat loss. Secondly, the energetic requirements of synthesizing new plumage are superimposed upon the increased heat production. Finally, sufficient food must be processed to supply nutrients such as amino acids for the production of feathers. Although only a few studies are available, it appears that total costs of moult (E) vary with avian weight (W, in g) as:

$$E = 8.38\,W^{0.96}$$

or the energy costs of moult are very nearly a linear function of body size.

Reproductive energy. The energetics of reproduction may be divided into several components, including costs of reproductive activities such as territorial behaviour and nest-building, energy invested in production of sex cells and the costs of incubation and feeding of young (King, 1973; Ricklefs, 1974). The ability of the species to generate sufficient productive energy for these activities is a crucial central theme for avian biology. For example, below certain ambient temperatures, accumulation of sufficient productive energy may not occur; egg-laying is limited or ceases entirely. In some cases the geographic distribution of individual species may be limited by their ability to accumulate sufficient productive energy for reproduction.

Costs of egg formation. The energy content of eggs, expressed either as a function of adult body weight or basal metabolic rate, varies greatly among species. Passerines generally invest relatively small amounts of energy (45% of one day's basal metabolism); eggs of ducks (180%), shorebirds (226%) and gulls and terns (320%) contain relatively large amounts of energy. A similar ratio has not previously been calculated for the Brown Kiwi *Apteryx australis*, which lays eggs that weigh between 400 and 435 g. Since the adult weights only about 2,200 g this represents a considerable energy expenditure (rough calculations indicate the energy content = 1,162–1,337% of one day's basal metabolism).

In birds laying more than one egg, the caloric investment per ovum is spread over several days as yolk deposition may simultaneously take place in several ova. Energy requirements probably reach a maximum near the energy content of one egg at approximately the day that egg-laying begins. Production of eggs is inhibited by low ambient temperatures, probably as a result of increased costs of thermoregulation and the resulting decrease in productive energy.

Energy costs of incubation. The heat of incubation comes from the environment, the parents (except the megapodes) and the embryo itself. No complete energy budget exists for both eggs and parents during natural incubation, but it appears that the costs of incubation to the parents may be fairly large. In birds of small body weight, relative costs are probably highest and costs should increase with clutch-size and incubation temperature. Incubation costs also increase with decreased ambient temperature as heat losses from the eggs and nest increase, and must be replaced from increased heat production. Costs of incubation have been calculated or measured as amounting to 11–22% of adult resting metabolism in Zebra Finches *Poephila guttata*, 10–22% in the House Wren *Troglodytes aedon*, and 13–32% for Herring Gulls *Larus argentatus*. In some cases, the contribution of the eggs to their own incubation may be significant. Metabolism of avian embryos increases throughout incubation, but in a pattern that differs between altricial and precocial species. Rate of oxygen consumption of eggs of altricial birds increases exponentially throughout incubation. The metabolism of precocial birds increases through about 75% of incubation and then remains constant until hatching when metabolism again becomes elevated. During the latter stages of incubation, the embryos of the American Kestrel *Falco sparverius* may contribute 19–25% of the total heat required for incubation. In some shorebirds the contribution amounts to 35–40% or approximately 5% of the total energy required during the entire incubation period.

Nest structure and position are important factors in the energy costs of incubation and are usually related to degree of development of young at hatching. Nests of precocial species are often simply constructed and poorly insulated. Nests of altricial birds are more complex and probably provide better heat retention. Within both nest styles, species which have larger clutches usually build nests with greater insulative capacities.

There are very few data for assessment of the energetics of parents feeding young. Relatively crude calculations indicate that in some species the costs may amount to 50% or more of the total productive energy.

Energetics of growth. Increases in body weight from hatching to adulthood are energetically complex. As growth and maturity progress, the composition of young birds changes in a consistent fashion. Altricial species have low caloric contents per g body weight (caloric density) shortly after hatching and caloric density increases with growth mainly because of decreased water content of mature tissues and deposition of energy-rich materials such as lipid. The young of precocial species may have higher caloric densities at hatching, a generally slower growth rate, and smaller increases in caloric density as they develop towards maturity (Fig. 4). See photo HEAT REGULATION. C.R.B.

ENICURINAE: see THRUSH.

ENZYMES, DIGESTIVE: see ALIMENTARY SYSTEM.

EPAXIAL: see MUSCULATURE.

EPHTHIANURIDAE: family of the PASSERIFORMES, suborder Oscines; CHAT, AUSTRALIAN.

EPICARDIUM: see HEART.

EPIDEICTIC: term applied by Wynne-Edwards (1962) to communal displays and manoeuvres, particularly those that occur at special times such as dawn or dusk, the supposed function of which is to indicate to its members the numbers of a local population and therefore provide the feed-back enabling the level of the population to be adjusted.

Wynne-Edwards, V.C. 1962. Animal Dispersion in Relation to Social Behaviour. Edinburgh.

EPIDERMIS: the outer layer of the SKIN.

EPIDIDYMIS: in male birds, a compact body lying on the median side of each testis, consisting of convoluted tubules, in which the mature spermatozoa are accommodated before passing down the vas deferens to the cloaca.

EPIGAMIC: term applied to characters or actions tending to promote reproductive behaviour (see DISPLAY).

EPIGENETICS: the analytical study of the developmental process (ontogeny), a term implying the interaction of genetic factors—see DEVELOPMENT, EMBRYONIC; GROWTH.

EPISEMATIC: term applied to appearance or behaviour aiding recognition, applied particularly to coloration. 'Antepisematic' implies a threat; 'proepisematic' refers to social recognition; 'pseudepisematic' involves deception, e.g. the eggs of parasitic cuckoos (Cuculinae) may in a sense be protectively coloured in their mimicry, but the role is fundamentally aggressive. Compare APOSEMATIC; and in general see COLORATION, ADAPTIVE; RECOGNITION.

EPITHELIUM: see SKIN; TISSUE.

EPIZOOTIC: see DISEASE.

EQUILIBRATION: see HEARING AND BALANCE.

EREMOMELA: generic name used as substantive common name of *Eremomela* spp. (for subfamily see WARBLER (1)).

ERNE: archaic and poetic name, in Britain, for the Sea Eagle *Haliaeetus albicilla* (see under HAWK).

EROLIINAE: synonym of Calidritinae (see SANDPIPER).

ERROR, STANDARD AND PROBABLE: see BIOSTATISTICS.

ERUPTION: same, but in relation to area of origin, as IRRUPTION (see also MIGRATION).

ERYTHRISM: see PLUMAGE, ABNORMAL.

ERYTHROCYTE: see BLOOD.

ERYTHRURINI: see ESTRILDID FINCH.

ESOPHAGUS: American spelling of OESOPHAGUS (see ALIMENTARY SYSTEM).

E.S.S.: acronym for 'evolutionarily stable strategy', a term introduced by J. Maynard Smith in 1972. A strategy is simply some specified act, or trait, and an evolutionarily stable strategy is defined as a strategy that, if adopted by nearly all the members of a population, cannot be bettered by an alternative strategy.

The concept of the evolutionarily stable strategy was introduced for thinking about adaptations which have frequency-dependent fitnesses. Frequency-dependent FITNESS means that the number of offspring left by an organism adopting a particular strategy depends on the frequency of that strategy in the population. If the fitness of a strategy is negatively frequency-dependent, then an organism using the strategy when it was rare would leave more offspring than one doing so when it was commoner. The crucial idea in solving which strategy will be the ESS is that of evolutionary equilibrium. At equilibrium the fitnesses of all the strategies in the population are equal, so that natural selection is not altering the frequencies of any of them. Natural selection will cause the population to evolve until an equilibrium is reached, whence the population will be evolutionarily stable and the organisms of the population will be using the ESS. If all members of the evolutionarily stable population use the same strategy, it is called a pure ESS; if more than one strategy exists at equilibrium, it is called a mixed ESS.

Models of evolutionarily stable strategies have mainly been studied to clarify how natural selection might be expected to affect particular traits. For these purely theoretical studies, the strategies and their fitnesses (called 'pay-offs') are conceived by the modeller. One simple model by Maynard Smith, for example, showed how restrained fighting could be an ESS even though vicious fighters always beat animals that ran away. The reason for this result is the frequency-dependence of the fitness of vicious fighters. When vicious fighters are rare they do well because they usually meet animals they can beat; but when they are commoner they usually meet each other, inflicting detrimental injuries, so that animals that run away without fighting have higher fitness.

ESS models can also be used to find out equilibrial frequencies of real strategies in real populations. This has rarely been done so far, however, both because the models were only recently developed and because measuring the fitnesses of the animals requires large amounts of data.

ESTRILDIDAE: a family of PASSERIFORMES, suborder Oscines; ESTRILDID FINCH.

ESTRILDID FINCH: in the plural used for members of the Estrildidae (Passeriformes, suborder Oscines) which include the waxbills, grassfinches, and mannikins (not to be confused with the manakins); alternative name is weaver-finch. In addition, various special substantive names have been used such as 'parrot-finch', 'sparrow', and 'weaver'. They have been included in the family Ploceidae (weavers), for their outermost primary is reduced as in the true weavers, and the egg-white protein patterns of the 2 groups are similar (Sibley 1970). Other research has shown, however, that not all 'finches' are necessarily a monophyletic assemblage. There are marked differences, to name a few, between the estrildid or weaver-finches and true weavers in their plumage and egg coloration, clutch-size and nest construction, gape pattern of young, courtship behaviour, mode of parental care and begging of the young, and structure of the digestive tract.

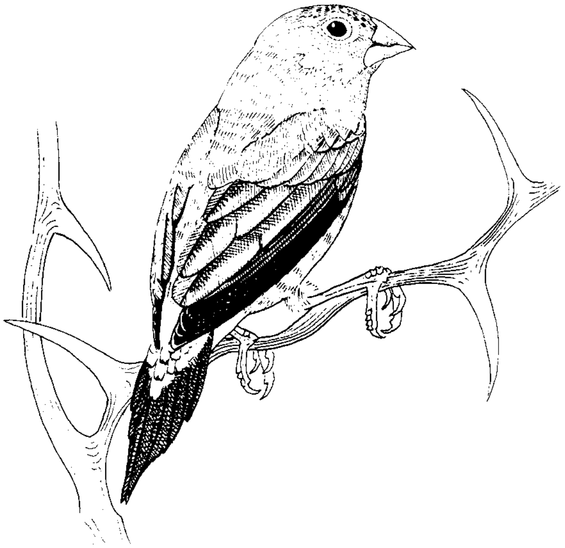
The number of species and genera that are recognized varies among authors. The latest revision (Goodwin 1982) recognizes 137 species and 27 genera. The family consists of 3 main groups, the waxbills, grassfinches and mannikins. Within the waxbills there is considerable adaptive radiation. There are about 60 species currently placed in either 16 or 17 genera by most authors. Some of the genera are poorly differentiated and those with few species, other than the monotypic genera, either form natural species-groups or superspecies (Hall and Moreau 1970). Many of them, particularly those in the genera *Estrilda, Lagonosticta*, and *Uraeginthus*, are small (length 90–108 mm); others, in the genera *Spermophaga* and *Pyrenestes* are larger (length 130–135 mm); and others, in the genera *Nigrita* and *Parmoptila*, are arboreal and eat insects instead of seeds. In all waxbills the juvenile palate markings consist of a series of spots, the commonest pattern consisting of 5 black spots (the so-called domino pattern). The grassfinches, length 100–130 mm, are a rather heterogeneous group and include the majority of Australian members of the family. The juvenile mouth markings range from a number of spots to a single continuous line in the shape of a horse-shoe. Finally, the mannikins are, in general, heavier looking than the others (length 95–120 mm), and the mouth markings in many consist of either one or two horse-shoe shaped lines.

Characteristics, habitat and distribution. The true waxbills, apart from 4 species, are confined to the Afrotropical Region where they are mostly found in open savannas and clearings within the forest areas. The Common Waxbill *Estrilda astrild* is widespread south of about 5°N and its range in East Africa extends northwards into Ethiopia. In addition, it has been introduced to many oceanic islands, to the South American mainland, and Portugal. It is distinguishable through the bright scarlet patch round the eye, also present in 3 other closely related species, but differs from these in having the lower abdomen and under tail-coverts black and the tail dark brown. Its place in West Africa and eastwards to Ethiopia is taken by the Black-rumped Waxbill *E. troglodytes* which has an essentially black tail and white under tail-coverts. Another attractive and common bird of forest clearings and swampy areas is the Orange-cheeked Waxbill *E. melpoda* which is found throughout West and Central Africa. The bright orange patch round the eye and on the cheek distinguishes it from other closely related waxbills. South of its range to about lat. 15°S and east of its range, its place is taken by the Fawn-breasted Waxbill *E. paludicola*. The males of all 9 species of fire-finch *Lagonosticta* are grey or brown, suffused in varying degree with red or pink, and some feathers on the breast and flanks are tipped white; the females are duller. Two of the most widely distributed are the Dark Fire-finch *L. rubricata* and the Red-billed Fire-finch *L. senegala*. The latter is more common, being found in towns and villages and frequently entering houses, whilst *rubricata* inhabits bush, woodland or forest edge. All 5 species of *Pytilia* are striking birds and usually found in thorny thickets and undergrowth in open savanna. The Melba Finch *P. melba* has a wide distribution and is probably the most beautiful. The male has an olive-green back and wings, crimson tail, grey head, barred underparts and brilliant red on the forehead and throat, merging into yellow on the breast. Some waxbills are forest species. Four crimson-wings *Cryptospiza* are found only in montane forest in East and central-southern Africa. The most widespread of these is the Red-faced Crimson-wing *C. reichenovii*. The male has an olive-brown head and underparts, blackish tail and wing, and bright scarlet on the flanks, upper tail-coverts, mantle and facial patch surrounding the eyes. The negro-finches (*Nigrita* with 4 species), and the flower-peckers (*Parmoptila* with 2 species) are both found in primary and secondary lowland forest. Although the negro-finches are not brightly coloured they are markedly different from each other, 2 having black, one white, and one chestnut underparts. The Red-fronted Ant-pecker *P. rubrifrons* also has chestnut underparts and the forehead and fore-crown are bright red.

Of the Asian waxbills, the Green Avadavat *Amandava formosa*, an endemic of India, is unique in being olive-green above and yellow underneath from chin to tail. In contrast, the male Red Avadavat *Amandava amandava* in breeding dress is crimson below spotted with white, red to brown above, and has brown wings. It is the only estrildid that moults into a duller non-breeding dress. It occurs throughout India, West Pakistan and southern Nepal, and its range extends eastwards to Cambodia, Saigon, and the lesser Sunda islands. It has been introduced into numerous islands such as Mauritius, Fiji, Sumatra, Singapore and the Philippines.

The grassfinches are predominantly found in Australia (15 species, placed in 7 genera). Most of them are birds of open grasslands and savannas, usually in the vicinity of water. Four species, however, occur in specialized habitats: the Blue-faced Parrot-finch *Erythrura trichroa* at the forest edge in northern Queensland; the Red-eared Fire-tail *Emblema oculata* in dense eucalypt forests in south-west Australia; and the Painted Finch *Emblema picta* and Zebra Finch *Poephila guttata* in semi-deserts in central Australia. In plumage they are extremely diverse. The parrot-finches *Erythrura* have iridescent green (unique in the family), reds or blues in their plumage; the Painted Finch has brilliant crimson, black, white, and brown in its plumage; and the Zebra Finch, in contrast, lacks bright colours and is pale brownish grey above and white below with a black band across its breast and black tips to the white feathers on the face. The parrot-finches (12 species) are widespread in the Philippines, Borneo, New Guinea and various islands in Melanesia, some of which have endemic species.

The mannikins are sombre coloured, mainly brown or nearly black with bars or shaft streaks, but some have large bold areas of black, white and brown. Five African species belong to the genus *Lonchura*, the Indian Silver-bill *L.* (= *Euodice*) *malabarica* also occurring in India and Sri-Lanka. Many more mannikins occur throughout the Oriental and Australian regions. There are 12 species in New Guinea, one of which, the Chestnut-breasted Finch *L. castaneothorax*, also occurs in Australia.



Indian Silverbill *Lonchura malabarica*. (*M.W.*).

On Madagascar is found the Bibfinch *Lepidopygia nana*, a species of uncertain affinity and considered by some to be closer to *Estrilda*. The largest of the group and best known is the Java Sparrow *Lonchura* (*Padda*) *oryzivora* which is believed to be native to Java and Bali but which has been introduced to many tropical areas including Hawaii, Seychelles and Tanzania. It is a popular cage bird as are many of the estrildids. Included in the mannikins are 2 African species (*Amadina*), the most widespread being the Cut-throat *A. fasciata*, but they differ from typical mannikins in having heavier heads, brighter colours and some differences between the sexes.

Movements. Estrildid finches are largely sedentary, but local movements may occur in the drier parts of their ranges. In Nigeria the Cut-throat migrates southwards in the dry and returns northwards in the wet season. Northern populations of the Aurora Finch *Pytilia phoenicoptera* and the Melba Finch *P. melba* in Nigeria, probably also have regular north-south movements. In Australia, the Zebra Finch is known to undertake large-scale, but irregular, nomadic movements during extended periods of drought.

Food. Estrildid finches are predominantly granivorous, feeding mainly on half-ripe and ripe grass seeds, which they either pick up from the ground or pull directly from the stalk. During the breeding season many of the granivorous species take insect food, and some of the parrot-finches also take fruit. The forest species of *Nigrita* and *Parmoptila* are apparently insectivorous throughout the year.

Several species of grassfinches, mainly in the genus *Poephila*, drink by sucking as do pigeons and doves. This is almost unique among passerines. The birds suck for several seconds at a time; up to 21 s has been observed in the Long-tailed Grassfinch *Poephila acuticauda*.

Behaviour. Estrildid finches seem to form very stable pairs and probably pair for life. Courtship behaviour shows great interspecific differences. It consists mainly of the male courtship dance, the basic movement of which is a vertical up-and-down bob, achieved by alternate stretching and bending of the legs. In some species the male, with rather stiff legs, actually leaves the branch, returning to the same spot each time; in others, rapid swings from side to side or combinations of both these vertical and lateral motions are involved. The ornamented areas of the plumage are usually erect and shown off. In many species the male may carry a piece of grass in his bill, and in most the male utters his courtship song while dancing.

Successful copulation is nearly always initiated by the solicitating female. In passerines this usually involves quivering of the wings, but in the estrildids the soliciting display involves the tail. Female cordon-bleus *Uraeginthus* adopt a horizontal posture and quiver or tremble their tails, which are usually slightly raised. At very high intensity the tail may make lateral and vertical movements up to an angle of 40° to the horizontal. In the grassfinches the quivering occurs in the vertical direction only.

Forest estrildid finches seem to be rather solitary, living in pairs or small parties. Open country species, on the other hand, may form big flocks, at least outside the breeding season, sometimes to pest proportions (the Spice Finch *Lonchura punctulata* and White-backed Munia *L. striata*). Some species, especially those inhabiting the arid parts of Australia, retain their sociability even during the reproductive season and tend to breed in loose colonies. Several times, each day, members of a colony, often joined by members of other colonies, gather together for 'social meetings' during which they feed together, bathe together, rest drowsily or preen each other. Special behaviour patterns such as social calls, peering behaviour (see below) and greeting ceremonies may serve to hold the group together.

Voice. Estrildids possess a considerable variety of calls, the largest number being found in the most sociable species. In the Australian genus *Poephila*, a number of different calls have been identified, including loud 'lost calls', low contact calls, mate and group greeting calls, as well as agitation, alarm, distress, fleeing, nest, copulation, and juvenile calls. They also have a song, not territorial in function nor used in aggression, but used mainly during courtship when it probably serves to attract and stimulate the female. In addition the males of many species utter a so-called 'undirected song' or 'jingle' the function of which is not entirely clear but which may contribute to maintaining the pair-bond. In some species, mainly in the genus *Lonchura*, other birds of a group sometimes respond to the 'jingle' song of a male by flying towards him and standing either beside or in front of the singer whilst peering into his face. If the singer edges away, he is followed by the other. This 'peering behaviour' has been noted in males and females, young and old, and its biological significance is not clear. In a few species, mainly African, the female also possesses a song phrase.

The songs of the estrildid finches are not loud, sometimes being inaudible only a metre away. They consist of high-pitched short and rather melodious phrases (some waxbills), of 'toy trumpet' notes (some grassfinches) or of unmelodious clucks, faint whistles and slurs (many mannikins).

Breeding. The reproductive season differs from species to species as well as between different climatic regions. It coincides with those parts of the year when half-ripe seeds and/or insects are most readily available. In the southern parts of Australia and South Africa, where winter temperatures are low and summers are very dry, estrildids breed mainly in spring but also at times in the autumn. In subtropical, semi-arid areas, they tend to breed during the second half of, and shortly after, the annual wet season(s). In tropical latitudes the breeding season is much more prolonged; thus nests of the Red-billed Fire-finch have been found in each month of the year in West Africa, and over a period of 9 months for the Dark Fire-finch. Finally, in the arid parts of central Australia and central southern Africa, where rainfall is somewhat erratic, estrildids are opportunistic breeders, reproducing whenever environmental conditions permit, the best known examples being the Australian Zebra Finch and the Red-headed Finch *Amadina erythrocephala*.

Most estrildids nest in bushes or small trees. Some, like the Red-eared Firetail, nest in the tops of tall trees, others among tall grass and reeds or right on the ground. A few species, like the Australian Gouldian Finch *Chloebia gouldiae* and the African Cut-throat, do not construct their own nests but use tree-holes or abandoned nests of other species respectively. The nests are domed, with a side-entrance and, in most cases, an entrance tunnel. In most species, the nest is a rather untidy structure, never woven in the manner of true weavers. Some species use feathers or other soft material for lining. Both sexes share in nest construction, the male usually collecting and carrying the material while the female sits inside the nest and builds it in. Some species build roosting nests outside the breeding season, often a co-operative task of several birds which use the roost nest together; others roost on twigs or use empty nests. Roosting behaviour is species-specific.

The clutch-size is usually 4–6. Larger clutches (sometimes as high as 9) have been recorded and are probably due to 2 females laying in the same nest. The eggs of all species are pure white. Both sexes incubate, with individual shifts of from 1.5 to 2.0 h. Incubation data for some genera are as follows: *Estrilda* 11 days, *Lagonosticta* 10–11 days, *Uraeginthus* 11–12 days, *Pytilia* 12 days, *Lonchura* 10–12 days, grass-finches 12–14 days. The nestling periods of those genera studied are: *Estrilda* 17 days, *Lagonosticta* 14–18 days depending on brood size, *Uraeginthus* 16–19 days, *Lonchura* 15–17 days, Australian grass-finches 21 days (very long for a small passerine bird). After the young leave the nest they are fed for another 1–2 weeks. During this time, some species lead their young back into the nest for roosting. Both parents feed the young by regurgitation.

In most species there is no specialized method of nest sanitation; the nestlings defaecate on the walls of the nest, and the faeces rapidly dry and stick there, so that the nestlings are not fouled.

The begging posture of estrildid finches is unique among passerine birds. The head is kept low and the neck is twisted to one side so that the beak is directed upward. The mouth is opened wide revealing the species-specific mouth markings of the nestlings (see above). The edge of the gape usually has white or black and white swellings, and in some species there are highly reflective spots at the base of the bill which presumably help the adults to locate the mouth in the dark cavity of the nest. The mouth markings are displayed conspicuously through lateral waving movements of head and tongue. Young estrildid finches mature very quickly and may breed at an age of a few months; mature gonads have regularly been found in 10-week-old Zebra Finches. This has been seen as an adaptation to the irregular climatic conditions in central Australia. Many African estrildids are parasitized by whydahs (*Vidua*); for details see WHYDAH (1). K.I.

ESTROGEN: same (American usage) as OESTROGEN; see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

ETHIOPIAN REGION: see AFROTROPICAL REGION.

ETHOLOGY: the scientific study of BEHAVIOUR.

ETIOLOGY: see AETIOLOGY.

EUPETES: substantive name sometimes used for the 3 New Guinea species of the genus *Eupetes* (see RAIL-BABBLER).

EUPHONIA: generic name used as substantive name of *Euphonia* spp. (see TANAGER).

EURING: the European Union for Bird Ringing, founded in Paris in 1963 as a loose federation of European ringing schemes—of which there are more than 30. Its aims are to promote and facilitate the exchange and use of ringing data and to this end it has established an international Data Bank of recoveries, currently located at Arnhem, Netherlands.

EUROPE: see under PALEARCTIC REGION.

EURYLAIMIDAE: family of PASSERIFORMES, suborder Deutero-Oscines; BROADBILL.

EURYOECIOUS: occupying a wide range of the habitats available in an area, i.e. showing 'wide habitat-tolerance'—contrasted with STENOECIOUS.

EURYPYGAE; EURYPYGIDAE: see under GRUIFORMES; SUNBITTERN.

EUSTACHIAN TUBE: see HEARING AND BALANCE; PALATE; and under SKULL.

EUTAXIS: see WING.

EUTROPHIC: rich in plant nutrients, usually referring to fresh water. Eutrophication can occur naturally or can be caused by residues of fertilizers draining into the water from farmland. The opposite term, referring to nutrient-poor waters, is 'oligotrophic'.

EVOLUTION: the theory that the present diversity of living organisms has originated from a much lesser diversity of organisms that existed in the past, by a process of gradual change from generation to generation. The original organisms are generally considered to have arisen from non-living materials. The development of this theory as part of modern science occurred mainly during the first half of the 19th century, particularly under the influence of Lamarck and of geologists concerned with the history of rocks and fossils. The theory was soundly established by Darwin, who not only marshalled a huge array of evidence for the theory but also, with Wallace, proposed a plausible mechanism for the process (see NATURAL SELECTION).

The fossil record provides good evidence for evolution—that is, it provides evidence which cannot be explained by alternative hypotheses except by special pleading, case by case. Thus, a general feature of the fossil record is that organisms tend to appear in the record in the order of their morphological similarity. A simple case of this is presented by Archaeornithes, which are not only morphologically intermediate between archosaurian reptiles and modern birds but which also make their first appearance in the fossil record in between the appearances of these two groups (see FOSSIL BIRDS). For groups of organisms that have been well-preserved in the record, detailed evolutionary lineages may be traced, with general consistency of the evidence of morphological similarity and that of position in time.

Systematic biogeography also provides evidence that is difficult to reconcile with hypotheses other than the theory of evolution, except by special pleading. Within a single geographical region, it is easy to recognize and delimit species in most animal groups: the species are distinct. But this is not so if one adopts a geographically broader approach. One then finds every gradation from species that are widespread but show little regional differentiation, through species that show gradual variation from place to place, species that show well-marked subspecies which interbreed freely, arrays of morphologically distinct forms that replace each other geographically and which hybridize only in a restricted region, groups of species which hybridize only occasionally even when sympatric, to groups of species which never interbreed (see SUBSPECIES, CLINE, SUPERSPECIES, SPECIATION). Geographically replacing populations will often hybridize freely with neighbouring populations but not with more distant ones, even though they are connected by a chain of hybridizing populations. Secondary overlap of the ends of such chains gives rise to RING-SPECIES. Such phenomena are to be expected if organisms have arisen by progressive diversification but not otherwise.

Biogeography also provides evidence of convergent evolution, the process by which species of unrelated and dissimilar groups in different parts of the world come to resemble each other because their evolution has been moulded by similar ecological circumstances. Thus although the diving petrels *Pelecanoides* belong to the order Procellariiformes and the small auks, e.g. *Plautus*, belong to the Charadriiformes, these birds look extremely similar and share many characters that are directly correlated with their way of life: swimming on the sea, diving deeply to feed, and using their wings for both submarine and aerial propulsion. There can be no doubt that the same ecological niche has been filled by evolution from two quite different stocks—the auks in the northern hemisphere, the petrels in the southern.

The biogeography of remote islands and archipelagos provides further evidence. The organisms of such places typically belong to fewer families and genera than do the organisms of equivalent continental areas. Yet the number of species is not reduced in proportion, because some of the families and genera have unusually large numbers of species. Furthermore, although these species are sufficiently similar to be placed in the same family or genus, they may inhabit a range of ecological niches that would be inhabited by species belonging to many different families in an equivalent continental area. The Geospizinae of Galapagos and Drepanididae of Hawaii are well-known examples (see DARWIN'S FINCHES, HAWAIIAN HONEYCREEPER). Selection favours individuals that are able to use empty niches so that, in this situation, it results in the rapid evolution of a diversity of species, each suited to one of the available niches. Since the original array of empty niches was great, the species are ecologically diverse, even though they are taxonomically similar.

Comparative studies show that animals that appear related, judged on general similarity or on the fossil record, tend to share basic underlying plans of parts of their anatomy, physiology, and behaviour. For example, the basic structure of the limbs is the same in amphibians, reptiles, mammals, and birds, even though that plan is modified to give an array of different types of limb, suiting the uses to which each is put. This is what one would expect if the theory of evolution was true. However, it may be that the similarities are explicable wholly in functional, rather than historical terms. Taking tetrapod limbs as an example, it may be that the similarities occur because there are certain basic similarities in the functional requirements for limbs in all tetrapods. We do not know enough about functional anatomy to be able to rule out this possibility. Thus comparative studies provide evidence that is fully consistent with evolution but which does not prove evolution, since there are other hypotheses which can be used to explain the data.

The same is true of the evidence provided by embryology. The early developmental stages of similar animals are generally more similar than the adult stages. If evolution has occurred by gradual change, this is to be expected. Genetic changes that affect processes occurring during the early stages in development are likely to have greater effects on the adult organism than changes that do not have any effect until late in development. Random changes in highly integrated systems, such as mutations in living organisms, are likely to be catastrophic if their effect is large. Thus most of the genetic changes incorporated during evolution will have been of small effect and, therefore, will tend to have been those affecting the later stages of development. Once again, however, functional constraints alone may be used to explain the greater similarity of embryos than of adults. It may be, for example, that the functionally best way of beginning the development of any vertebrate animal, given the similarity of the starting point in all species (the egg), is to proceed through the basic pattern of embryogenesis that the vertebrates display.

Biologists have no doubt that the theory of evolution is correct. Recently, it has come under attack mostly on philosophical and religious grounds. The main thrust of this attack has been that it is not a normal (i.e. hypothetico, deductive) scientific theory because it cannot be proved wrong. This is a mistaken view arising from three sources. One is that predictions of evolutionary theory are predictions about sets of individual phenomena, rather than about those phenomena themselves. For example, in east Asia we find forms of *Larus* gulls intermediate between *L. fuscus* and *L. argentatus*, the Lesser Black-backed and Herring Gulls. The theory predicts that we should find such transitional forms, but it does not allow us to predict which particular species pairs will display them: the prediction is about the whole set of species, not about particular species. Commentators used to the sciences of the laboratory bench have sometimes mistakenly concluded that such general predictions are not scientific predictions at all.

The same confusion about the scale of predictions is partly responsible for the second source of error. Evolutionists have proved ingenious at explaining away exceptions to the general predictions they make, resulting in the charge that the theory can explain anything and that its predictions are therefore unfalsifiable. However, although a few exceptions do not falsify a general evolutionary prediction, if the exceptions are abundant, then the prediction is falsified.

The third source of difficulty is that the major predictions that evolution makes are already known to be true. However, this was not true when Darwin established the theory. He was, for example, embarrassed by the apparent paucity of the transitional forms which the theory predicted and which were later discovered to be abundant. Furthermore, evolution theory continues to provide predictions which are testable in the standard way: many recent advances in the studies of feeding behaviour and social systems have resulted from making predictions based on Darwinian theory.

The modern theory of evolution, established by Darwin, goes further than the basic idea that organisms have evolved: it includes the belief that evolution has been mainly a result of NATURAL SELECTION. Various alternatives to this theory have gained considerable support in the past and some do so today. The theory of Lamarck was rejected when one of its premises, the inheritance of acquired characters, was found to be incorrect (except in some peculiar cases of little general significance). The theory of orthogenesis was shown to be inconsistent with the facts. This theory was that lineages became stuck in an evolutionary groove, evolving in a particular fixed direction, sometimes even developing characters to an extent that was detrimental and resulted in their extinction. However, the fossil record shows no long-continued unidirectional trends and it shows that organisms with so-called detrimental characters often persisted for millions of years.

A common misunderstanding of evolution, related to the orthogenetic view, is that evolution is goal-directed, that organisms evolve some character because they need it. Were natural selection exactly analogous with the artificial selection imposed by man on domestic animals and plants, this would be correct. Natural selection, however, does not occur in order to bring about the evolution that results from it, but simply because ecological circumstances lead to some genotypes reproducing or surviving better than others.

A common result of an evolutionary change, naively interpreted as the reason for evolutionary changes, is that the probability of the species' survival is increased, since characters increasing the survival of individuals are likely to increase the survival of the species to which the individuals belong. However, this is by no means always true. There may even be some characters which, although they decrease an individual's inclusive fitness (see NATURAL SELECTION), raise the viability of the population. For example, producing fewer offspring will often reduce an individual's inclusive fitness but, because a less rapidly growing population is less likely to overstretch the available food resources, reproductive restraint may increase the probability of the population surviving. It has been argued that such characteristics are found in some species and that, since natural selection cannot account for them, selection at the level of whole populations (group selection) must be invoked. This argument is not widely accepted because the existence of such 'self-sacrificing' characteristics is doubtful and because group selection appears to be generally incapable of prevailing against natural selection. The basic reason for this is that the rate of an evolutionary change under natural selection depends on the rate of turnover of generations of individuals (as well as on the strength of selection), whereas the rate of change under group selection depends on the rate of turnover of populations, i.e. the rate at which populations become extinct and are replaced by others. Since populations usually persist for many generations, evolution under group selection will be slower than under natural selection, so if the two forces are in opposition natural selection will prevail.

A more widely accepted alternative to the theory of evolution by natural selection is that most evolutionary change has come about through chance differences in survival of different genotypes ('the neutral mutation and random drift hypothesis'). The replacement of one genotype by another as a result of such chance differences requires that their fitnesses (see NATURAL SELECTION) differ by no more than one part in ten thousand, unless the species numbers less than a few thousand individuals. For characters that have been carefully studied, fitness differences more than one hundred times greater than this have commonly been identified. Because of this, the role of chance differences in survival appears to be limited.

Closely related to the neutralist hypothesis is the view that organisms have characters that are not selectively advantageous in themselves but are side-effects of other characters. Thus vertebrate blood may be red not because the redness is advantageous itself but because haemoglobin is an efficient oxygen-carrier for vertebrates and it happens to be red. Other characters may exist because, being advantageous in the past, they have become an integral part of the organism's constitution and so persist even though no longer useful. While it is undoubtedly true that some characters may exist as mere side-effects or historical hangovers, the recognition of this should not be taken as a licence to explain away any characters of which the selective importance cannot be demonstrated. Experience shows that the failure to demonstrate the selective importance of a character has usually been the result of human incapacity rather than the true lack of such selective importance.

If some characters are selectively neutral, their pattern of occurrence could be of great value in working out phylogenetic relationships, since their occurrence is not affected by the way of life of a particular species at a particular time. For this reason, phylogeneticists have commonly sought such characters. They have, of course, usually chosen those whose functional significance was obscure, biochemical characteristics having been especially popular recently. An approach that is more consistent with evolutionary theory is to consider the evidence as a whole, interpreting the data of comparative anatomy, biochemistry, embryology, palaeontology and biogeography in the light of the ecological circumstances that might have given rise to natural selection for particular characters. EXASPIDEAN: see under ENDASPIDEAN.

EXCREMENT; EXCRETA: see DROPPINGS; GUANO; GUANO, CAVE; and ALIMENTARY SYSTEM; EXCRETORY SYSTEM.

EXCRETION, EXTRARENAL: excretion, by the nasal (salt) glands, of excess salt present in ingested food and sea-water. The avian kidney possesses only limited ability to excrete sodium chloride and consequently excessive salt intake is harmful, or even fatal, to most birds. Obvious exceptions are those marine birds which are able to tolerate the high salt intake associated with their feeding habits, and Schmidt-Neilsen and his co-workers (1957) demonstrated that the nasal glands were not only particularly well developed in all marine species but were able to excrete salt in high concentration. Normal salt levels were therefore maintained in the blood and tissues of these birds even when large amounts of salt were consumed.

The nasal gland is present in all birds and consists of two or more lobes which lie on the skull above or anterior to the orbit (Technau, 1936). In terrestrial species the gland is small and inactive but correlation between degree of exposure to a marine environment and increasing activity of the gland in members of the Charadriiformes indicates that adaptive and, possibly, acclimative changes can occur (Staaland, 1967).

During secretory activity the duct of each lobe conveys the concentrated salt solution to the nasal cavity, whence it flows through the external nares to the tip of the bill. In some species of birds (e.g. cormorants *Phalacrocorax* spp. and gannets *Sula* spp.), the external nares are closed in the adult and the fluid then trickles from the internal nares in the roof of the mouth to the tip of the bill. Unlike the kidney, which functions continuously, the nasal gland is only active when the need to eliminate salt arises. There are, therefore, periods of intensive activity, e.g. after feeding at sea, interspersed with periods of quiescence.

The almost unique capacity of the salt gland to excrete a concentrated saline solution has interested many investigators and there is now an extensive literature on the physiological mechanisms involved in the secretory activity of the gland (see Peaker and Linzell, 1975). Most of this work has been done on the domestic duck *Anas platyrhynchos* and domestic goose *Anser anser* because these species are easy to handle and their nasal glands secrete readily when excess salt is administered.

The salt gland is derived from the nasal epithelium and consists of numerous tubular lobes each of which contains several thousand branched tubules radiating from a central duct. The distal portion of each lobule contains peripheral cells; these develop into the more numerous, and structurally more complex, secretory cells which occupy the remainder of the tubules. Conversion of peripheral cells to secretory cells appears to be dependent on a salt-water environment (Ernst and Ellis, 1969). The extensive blood supply to the tubules is so arranged that the blood flow in the capillaries is countercurrent to the direction of tubular secretion and probably facilitates the transfer of salt from the blood to the lumen of the gland.

Excessive salt intake by the bird results in increased salinity of the blood and subsequent passage of water from the tissues to the blood to maintain osmotic balance. The change in blood composition and the increase in blood volume have both been regarded as stimulants to nasal gland secretion but it is now clear that it is the former that is primarily responsible. Specialized nerve endings, sensitive to changes in blood tonicity, have been located in the large blood vessels close to the heart and messages from these structures are conveyed, via the brain, to the nasal glands where they initate secretion (Peaker and Linzell, 1975).

EXCRETORY SYSTEM: the organs responsible for excreting waste material containing nitrogen from the bird's blood and passing it out of the body, i.e. the paired, elongated kidneys each consisting of 3 main lobes in most birds; but 4 lobes are found in Ciconiiformes and Charadrii, while kiwis *Apteryx* spp. have 5. The kidneys lie symmetrically (except in Gaviidae and Podicipedidae) on the dorsal aspect of the body cavity below the synsacrum. The caudal lobes of the two kidneys are fused in the middle line in the Grey Heron *Ardea cinerea*, Chestnut-bellied Heron *Agamia agami*, Puffin *Fratercula arctica* and penguins (Spheniscidae), and may frequently be so in many other birds. Each kidney lobe is supplied with blood from a renal artery and a branch of the renal-portal vein (see VASCULAR SYSTEM). The subdivisions of the renal-portal veins (the interlobular veins) serve, together with the urine-collecting ducts that accompany them, to subdivide the kidney tissue into numerous lobules; the vessels run round the periphery of each lobule, and in the central region of each lobule there is a relatively large intralobular vein. The kidney tissue proper consists of a large number of convoluted and looping uriniferous tubules, which at one end join the peripheral urine-collecting ducts and at the other terminate in a Malpighian body or glomerulus, each tubule and its Malpighian body being known as a nephron. The Malpighian bodies encircle the intralobular veins: they are very small and very numerous in birds compared with mammals, varying from 400 per mm^3 in some African weavers (Ploceidae) to about 90 per mm^3 in the Rook *Corvus frugilegus*—whereas in mammals there are only about 4–15 per mm^3. The total number of nephrons present in both kidneys may vary from nearly two million in ducks (Anatidae) to some 30,000 in small passerines; the kidneys tend to be larger in aquatic and marsh birds than in others. The renal arteries break up into fine intralobular arteries that entwine the uriniferous tubules and ultimately join the interlobular veins. Capillaries from these veins also ramify amongst the uriniferous tubules and enter the intralobular veins, which in turn finally unite to form the renal vein.

The fluid extracted from the blood by the nephrons—the urine—passes into collecting ducts that unite to form the ureters, and through them the urine reaches that part of the cloaca known as the urodaeum, to be voided by the bird to the exterior (see ALIMENTARY SYSTEM; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM). There is in birds no urinary bladder as there is in mammals.

Avian urine, although subject to considerable variation, is normally cream-coloured and rich in mucoid substances and urates. The high concentration of urates (uric acid) accounts for over 60% of the total nitrogen excreted and is highly characteristic. After some resorption of water in the cloaca, uric acid is deposited as whitish crystals that are frequently seen mingled with the faeces of birds (see DROPPINGS; GUANO).

EXOCCIPITAL: a paired bone of the SKULL.

EXOCRINE: see under ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

EXOGENOUS: see ENDOGENOUS.

EXOTIC: applied to species, etc., meaning that these are in the natural course alien to the area under reference.

EXPECTATION OF LIFE: see AGE.

EXPLOITATION: see UTILIZATION BY MAN.

EXTERMINATION: see EXTINCT BIRDS.

EXTEROCEPTIVE: the senses involved when what is perceived is external (see HEARING AND BALANCE; SMELL; TASTE; TOUCH; VISION).

EXTINCT BIRDS: for the purposes of this article, restricted to species or subspecies that ceased to exist after 1600 AD, the boundary date for historic extinctions accepted by the IUCN Species Survival Commission. Except for rock drawings and preserved feathers of some moas (Dinornithidae; see MOA), we have no evidence of the external appearance of species that died out before that date. See also EARLY EVOLUTION OF BIRDS; ENDANGERED BIRDS.

Of the birds that have become extinct within the span of ornithologically recorded history, the Dodo *Raphus cucullatus* of Mauritius, last recorded in 1662, is the proverbial example. The Passenger Pigeon *Ectopistes migratorius* of eastern North America, whose population of hundreds of millions declined to extinction in less than a century, is perhaps the most spectacular. Other well-known vanished birds are the flightless Great Auk *Pinguinus impennis* of the North Atlantic; the Labrador Duck *Camptorhynchus labradorius*, which became extinct before its breeding range could be discovered; the Carolina Parakeet *Conuropsis carolinensis*, the only parrot native to eastern North America; and the Huia *Heteralocha acutirostris* of New Zealand, in which the sexes differed remarkably in bill shape (see WATTLEBIRD (2)).

Systematic survey. The accompanying table lists all species extinct after 1600 for which tangible remains have been preserved. Although skins survive for most, some are known only from subfossil bones. These can often be correlated with travellers' descriptions. A number of species are known from descriptions or illustrations only. Although some of these, such as a macaw from Jamaica, undoubtedly existed, most must be considered hypothetical. A rail from Tahiti (*'Rallus pacificus'*) and an unidentifiable passerine from Raiatea (*'Turdus ulietensis'*) were named from inadequately described specimens long since lost. Other birds, such as a megapode from the Kermadec Islands, vanished before specimens could be collected, and remain unnamed.

With the loss of the species listed, 29 genera (19 non-passerine, 10 passerine) and the families Aepyornithidae (see ELEPHANT-BIRD), Dinornithidae (see MOA), Raphidae and Pezophapidae (see DODO), and Turnagridae (see THRUSH, NEW ZEALAND) have ceased to be represented among living birds. Of surviving families, the ducks (Anatidae), rails (Rallidae), pigeons (Columbidae), parrots (Psittacidae), starlings (Sturnidae) and Hawaiian honeycreepers (Drepanididae) have lost heavily in representation.

This list is probably incomplete. Some species not seen for many years may already be extinct, although their disappearance has not been confirmed. These may include the Glaucous Macaw *Anodorhynchus glaucus* of South America, last seen (in captivity) before 1905; the Uluguru Bush Shrike *Malaconotus alius* of eastern Tanzania, unrecorded since 1961; and possibly Semper's Warbler *Leucopeza semperi* of St Lucia, West Indies, last seen in 1972. One species, the Socorro Dove *Zenaida graysoni* of Socorro I., Mexico, is extinct in the wild but survives in captivity (Jehl and Parkes 1983).

Other species, listed here as extinct, may prove to survive. In the past, several birds have been confidently recorded as extinct, only to be brought back from the dead by new explorations or more extensive field surveys. Well-known examples are the Takahe *Porphyrio mantelli*, a flightless gallinule from New Zealand, unrecorded between 1898 and 1948; the Seychelles Scops Owl *Otus (magicus) insularis*, lost between 1906 and 1959; the Noisy Scrub-bird *Atrichornis clamosus* of Western Australia, last collected in 1889 and, despite a report in 1920, presumed extinct until its rediscovery in 1961; and the Eyrean Grasswren *Amytornis goyderi* of the central Australian deserts, unseen from 1875 to 1961. The Cahow or Bermuda Petrel *Pterodroma cahow* was rediscovered in 1916, having gone unnoticed since its populous days in the early 17th century. Recent rediscoveries include the White-winged Guan *Penelope albipennis* of Peru, the Fiji Barred-wing Rail *Nesoclopeus poecilopterus*, the Night Parrot *Geopsittacus occidentalis* of Australia, and the Long-legged Warbler *Ortygocichla (Trichocichla) rufa*, also of Fiji. The Molokai O'o *Moho bishopi* was apparently found again in 1981, not on Molokai where it had last been seen in 1904 but on Maui, where no species of O'o has ever been collected.

In addition to full species, over 60 subspecies and many unnamed populations have become extinct since 1600. Perhaps the best known of these is the Heath Hen *Tympanuchus c. cupido*. Despite concerted conservation efforts, the last bird died on or after 11 March 1932, on Martha's Vineyard, Massachusetts, USA.

Extinction dates. For most of the vanished birds listed here, the 'extinction date' is actually the date of the last reliable record. For the 3 moas (Dinornithidae), it is the most recent radiocarbon date. Many of these birds may have survived for years afterwards, particularly those 10 species observed or collected only once, or at most by a single expedition. The Cook Pacific voyages recorded at least 5 birds that were never seen again (nos. 32, 47, 75 and 2 subspecies), and Kittlitz found 3 in the Pacific in 1828 (24, 63, 73).

For some species, the date of extinction can be determined exactly. What were probably the last survivors of 4 species (11, 39, 50, 53) died in captivity. The last Passenger Pigeon died in the Cincinnati Zoo, probably at 1 p.m. (local time), 1 September 1914. Although they were not in captivity, the hour of doom of the last pair of Great Auks is known almost as exactly—the afternoon of 3, or, more probably, 4 June 1844 (though there are later, doubtful, sight records).

Causes of extinction. Extinction is invariably the result of a species' inability to adapt to changes in its environment. Species whose initial populations are small, either because of large home ranges or specialized habitat requirements, are particularly vulnerable to extinction (Diamond and May 1976). So are colonial species having large, concentrated populations, and species dependent on intermittently available resources, rendering them subject to drastic population fluctuations (see ENDANGERED BIRDS). Birds confined to oceanic islands have proved highly prone to extinction; 80 of the 90 species listed here were island dwellers, and some island groups, such as Hawaii, the Mascarenes, and the Bonins, have lost large proportions of their land bird faunas. Among birds with similar feeding behaviours, the largest species have tended to disappear first. In the Hawaiian Islands, 5 of the 7 largest nectar-feeders surviving into historic times (67, 68, 69, 88, 89) have become extinct. The largest, the Kioea *Chaetoptila angustipluma*, was among the first to disappear.

Man's effect on avian extinction certainly goes back far beyond 1600. Hunting has been implicated in the extinctions of the moas and of 5 subfossil species of waterfowl in New Zealand (Williams 1964), and of the flightless scoter *Chendytes lawi* of western North America, which died out about 3,700 years ago (Morejohn 1976). Habitat destruction by the Malagasy probably was responsible for the extinction of the Elephant-birds. Recent discoveries of the subfossil remains of at least 45 species of birds on the Hawaiian Islands suggest that perhaps 2/3 of the original Hawaiian avifauna may have disappeared as a result of human activity before the arrival of Europeans. The vanished species include at least 7 flying and flightless geese, 2 flightless ibises, 7 flightless rails, 3 owls and at least 15 Hawaiian honeycreepers. The Polynesians hunted, introduced dogs, rats and pigs, and, perhaps most fatally, destroyed much of the lowland forest for agriculture (Olson and James 1982).

In historic times, the spread of western civilization to the remotest parts of the world has had a catastrophic effect. The worst period for recorded extinctions since 1600 was the late 19th and early 20th centuries, when many oceanic islands were rapidly developed and altered. Between 1885 and 1907 approximately 21 species became extinct, 8 from the Hawaiian Islands alone. Most of the 10 extinct continental species vanished in the early years of the 20th century. All but one of these lived in North America (including Mexico), India and Australia, areas greatly altered by western settlement in the preceding decades.

But human activity is not solely to blame for all historic extinctions. On rare occasions, a catastrophic natural event has wiped out a population. The unnamed Kermadec megapode and the San Benedicto Rock Wren *Salpinctes obsoletus exsul* disappeared after volcanic eruptions destroyed their habitats, in 1876 and 1952 respectively. More often, however, a variety of factors, both natural and human-induced, has contributed to each extinction. The European population of the Waldrapp *Geronticus eremita* (see IBIS) appears to have been restricted in both range and numbers by climatic deterioration after the mid-16th century, rendering it more vulnerable to the human interference which presumably wiped it out by 1621 (Schenker 1977). Banks (1977) has proposed that a shift in the prevailing winds in the early 19th century may have forced the Eskimo Curlew *Numenius borealis* to alter its migration route, bringing much of the population over New England where hunters brought it to the point of extinction. On the other hand, hunting drove the Auckland Island Merganser *Mergus australis* from most of its New Zealand range, but is not directly responsible for its disappearance from Adams Island, its final refuge (Williams 1964). Similarly, although the precipitous decline of the Passenger Pigeon was largely due to overhunting, its final disappearance cannot be so simply explained. It may have been so specialized for colonial breeding that, after its once immense flocks had been reduced below some critical size, it became unable to fledge enough young to maintain its numbers (Halliday 1980).

The human factor. The most severe effects of man on the extinction of birds have been:

Direct hunting pressure. This has affected mostly the large edible species, such as pigeons, parrots and the hapless Dodo. The last Great Auks were pursued by scientific collectors. The Guadalupe Caracara *Polyborus lutosus* is perhaps the only bird to have been deliberately exterminated, by goat-herders who claimed it took kids.

Introduction of predators and diseases. Feral cats, rats and pigs prey on both nests and adults, and have probably been chiefly responsible for the extinction of several flightless rails and other ground-nesting island species. Black Rats *Rattus rattus* released by a shipwreck on Lord Howe

Island in the Tasman Sea, in 1918, may have wiped out one endemic species (no. 66) and 4 subspecies of song-birds, most of which were ground- or hole-nesters. Ground-nesting birds are particularly vulnerable. Feral cats on Socorro Island, Mexico, probably killed off the endemic dove *Zenaida graysoni* and have driven the endemic mockingbird *Mimodes graysoni* to the brink of extinction. Both birds are ground-nesters. Tree-nesting birds on the same island have not been affected (Jehl and Parkes 1983). In the Hawaiian Islands, introduced mosquitoes possibly contributed to extinctions of birds by spreading avian pox, avian malaria and other diseases to which the endemic birds had lost immunity (Warner 1968).

Introduction of potential competitors. Introduced species may be able to out-compete residents for food or other limited resources. They may even destroy such resources. Rabbits, introduced on Laysan in the Hawaiian Islands in 1903 or 1904, destroyed almost all of the island's vegetation over a 20-year period. During this time, 3 of the 5 resident land birds—a rail, a warbler, and a Hawaiian honeycreeper—disappeared. The rail (no. 22) survived until 1944 on Midway, where it had been introduced.

Habitat destruction. Habitat destruction, particularly the cutting of mature forest, has been the major contributing factor in the extinction of many species. It has meant doom for many island endemics unable to adapt to secondary growth of vegetation or man-made conditions. On the Philippine island of Cebu, which was almost completely deforested in the 19th century, 16 of the 26 resident forest species had disappeared by 1947. These included 9 of the 10 endemics (no. 65 and 8 subspecies). The only surviving endemic, the Black Shama *Copsychus niger cebuensis*, has apparently adapted to secondary growth (Rabor 1959).

Island vulnerability. The particular vulnerability of island endemics has been explained by their long isolation from predators and competitors, with a correlated loss of both defence mechanisms and adaptability. The extinction of almost 20 flightless island species, including 11 of the 18 known flightless rails, provides a classic example.

Subtler factors may, however, be involved in island extinctions. Island endemics are often sedentary, confined to mature forest and other restricted habitats. Species diversity is directly related to the area of available habitat. Therefore, partial destruction of an area of mature forest may lead to loss of some of its bird species even if the remaining area is undisturbed. If the patch of forest is isolated, the species lost may not be able to recolonize it (Diamond and May 1976; but see Boecklen and Gotelli 1984). Despite its relatively undisturbed condition, Barro Colorado Island has lost 16 rain-forest bird species since its isolation by the Panama Canal (Willis and Eisenmann 1979). Even if island endemics could survive by adapting to secondary growth, the rapid spread of introduced birds already adapted to such habitats may prevent the residents from doing so. This may be true even if the endemics are perfectly able to out-compete the new arrivals in their own habitats.

These factors have, until now, had their most drastic effect on the small populations and localized habitats of island endemics. They are, however, increasingly important for the conservation of birds elsewhere. As continuing destruction of natural areas reduces continental habitats to a series of island-like pockets, mere preservation of remaining patches is unlikely to save all species. It is particularly unfortunate that tropical mature forest, the habitat with the largest number of bird species, many of which are highly sedentary, is today the subject of rapid destruction everywhere. A wave of extinctions of continental species much greater than the 19th century wave of island extinctions may be difficult to avoid. James Fisher wrote in 1964: 'It certainly seems likely that an insurance man can give a better quotation for a species' life now than he could at any time in the last graceless quarter of a millennium.' It is difficult now to be so optimistic (see King 1980). (J.F.) R.O.

Full species of birds believed to have become extinct since 1600. Only those species for which specimens survive have been included. Modified from Greenway (1967), Luther (1970), and King (1979), and other sources (including H.D. Pratt). See Greenway (1967) for hypothetical species.

Species (with approx. date of extinction)	*Range in historic times*
AEPYORNITHIDAE	
1. *Aepyornis maximus*[1] F (*c.* 1649?)	Madagascar
DROMAIIDAE	
2. *Dromaius minor* (*diemenianus*) F (1803–36)	Kangaroo and King Is., Australia
DINORNITHIDAE	
3. *Megalapteryx didinus*[1] F (1785)	South Island, New Zealand
4. *Euryapteryx geranoides* (*gravis*)[1] F (1640)	New Zealand
5. *Dinornis torosus*[1] F (1670)	South Island, New Zealand
HYDROBATIDAE	
6. *Oceanodroma macrodactyla* (1912)	Guadalupe Island, Mexico
PHALACROCORACIDAE	
7. *Phalacrocorax perspicillatus* (*c.* 1852)	Bering Island, USSR
ARDEIDAE	
8. *Nycticorax* (?) *megacephalus* F? (*c.* 1730)	Rodriguez, Mascarene Is.
ANATIDAE	
9. *Cygnus sumnerensis*[1] (*c.* 1590–1690)	Chatham Is., New Zealand
10. *Tadorna cristata** (1943; 1964?)	North-east Asia
11. *Rhodonessa caryophyllacea** (1944)	Indian Subregion
12. *Camptorhynchus labradorius* (1875)	Eastern North America
13. *Mergus australis* (1905)	Auckland Is., New Zealand
FALCONIDAE	
14. *Polyborus lutosus* (1900)	Guadalupe Island, Mexico
PHASIANIDAE	
15. *Coturnix* (*n.*) *novaezelandiae* (1875)	New Zealand
16. *Ophrysia superciliosa* (1868)	Himalaya Mountains
RALLIDAE	
17. *Gallirallus wakensis* F (1945)	Wake Island, Pacific
18. *G.* (*philippensis*) *dieffenbachii* (*c.* 1842)	Chatham Island, New Zeland
19. *G. modestus* F (*c.* 1900)	Pitt and Mangare Is., New Zealand
20. *Tricholimnas lafresnayanus** F (1904; 1961?)	New Caledonia
21. *Atlantisea elpenor*[1] F (1656)	Ascension Island
22. *Porzana palmeri* F (1944)	Laysan, Hawaiian Is.
23. *P. sandwichensis* F (1884)	Hawaii, Hawaiian Is.
24. *P. monasa* F (1828)	Kusaie, Caroline Is.
25. *Aphanapteryx bonasia*[1] F (*c.* 1675–1700)	Mauritius, Mascarene Is.
26. *A. leguati*[1] F (*c.* 1730)	Rodriguez, Mascarene Is.
27. *Porphyrio albus* F? (*c.* 1834)	Lord Howe Island, Tasman Sea
28. *Gallinula* (*n.*) *nesiotis* (1861)	Tristan da Cunha
29. *Pareudiastes pacificus* F (1874)	Savai'i, Western Samoa
30. *Fulica newtoni*[1] (*c.* 1863)	Mauritius (and Reunion?), Mascarene Is.
GLAREOLIDAE	
31. *Cursorius bitorquatus* (1900)	Andhra Province, India
SCOLOPACIDAE	
32. *Prosobonia leucoptera* (1777)	Tahiti and Moorea
ALCIDAE	
33. *Pinguinus* (*Alca*) *impennis* F (1844)	North Atlantic
COLUMBIDAE	
34. *Ptilinopus mercierii* (1922)	Nuku Hiva and Hiva Oa, Marquesas Is.
35. *Alectroenas nitidissima* (1830)	Mauritius, Mascarene Is.
36. *A. rodericana*[1] (*c.* 1670)	Rodriguez, Mascarene Is.
37. *Columba versicolor* (1889)	Nakondo Shima and Chichi Shima, Bonin Is.
38. *C. jouyi** (1936)	Ryukyu Is., Japan
39. *Ectopistes migratorius* (1914)	Eastern North America
40. *Microgoura meeki* (1904)	Choiseul, Solomon Is.
RAPHIDAE	
41. *Raphus cucullatus* F (1662)	Mauritius, Mascarene Is.
PEZOPHAPIDAE	
42. *Pezophaps solitaria*[1] F (1791)	Rodriguez, Mascarene Is.
PSITTACIDAE	
43. *Charmosyna diadema** (1860; 1970?)	New Caledonia
44. *Nestor* (*meridionalis*) *productus* (*c.* 1851)	Norfolk and Philip Islands, Tasman Sea

45. *Psephotus pulcherrimus** (1927)	Eastern Australia
46. *Cyanoramphus zealandicus* (1844)	Tahiti, Society Is.
47. *C. ulietanus* (*c.* 1773–74)	Raiatea, Society Is.
48. *Lophopsittacus mauritianus*[1] F (1638)	Mauritius, Mascarene Is.
49. *Necropsittacus rodericanus*[1] (1731)	Rodriguez, Mascarene Is.
50. *Mascarinus mascarinus* (*c.* 1834)	Reunion (and Mauritius?), Mascarene Is.
51. *Psittacula* (*eupatria*) *wardi* (1881)	Mahe and Silhouette, Seychelles
52. *P.* (*krameri*) *exsul* (1875)	Rodriguez, Mascarene Is.
53. *Conuropsis carolinensis* (1914; 1938?)	Eastern North America
54. *Ara tricolor* (1864)	Cuba (and Isle of Pines?)
CUCULIDAE	
55. *Coua delalandei* (*c.* 1834–37; 1930?)	Madagascar
STRIGIDAE	
56. *Sceloglaux albifacies** (1914; 1950? 1982?)	New Zealand
57. *Athene murivora*[1] (1730)	Rodriguez, Mascarene Is.
CAPRIMULGIDAE	
58. *Siphonorhis americanus* (1859)	Jamaica
ALCEDINIDAE	
59. *Halcyon miyakoensis* (1887)	Miyako Shima, Ryukyu Is.
PICIDAE	
60. *Campephilus imperialis** (1958)	Mexico
ACANTHISITTIDAE	
61. *Xenicus lyalli* F? (1894)	Stephen I., New Zealand
TURDIDAE	
62. *Turdus ravidus* (1938)	Grand Cayman, W. Indies
63. *Zoothera terrestris* (1828)	Chichi Shima, Bonin Is.
SYLVIIDAE	
64. *Acrocephalus* (*f.*) *familiaris* (1916)	Laysan, Hawaiian Is.
DICAEIDAE	
65. *Dicaeum quadricolor* (1906)	Cebu, Philippines
ZOSTEROPIDAE	
66. *Zosterops strenua* (1918)	Lord Howe I., Tasman Sea
MELIPHAGIDAE	
67. *Moho nobilis* (1934?)	Hawaii
68. *M. apicalis* (1837)	Oahu, Hawaiian Is.
69. *Chaetoptila angustipluma* (1859)	Hawaii
CALLAEIDAE	
70. *Heteralocha acutirostris* (1907)	North Island, New Zealand
TURNAGRIDAE	
71. *Turnagra capensis** (1955; 1963?)	New Zealand
STURNIDAE	
72. *Aplonis pelzelni** (*c.* 1930–35)	Ponape, Caroline Is.
73. *A. corvina* (1828)	Kusaie, Caroline Is.
74. *A. fuscus* (1925)	Lord Howe and Norfolk Is., Tasman Sea
75. *A. mavornata* (*c.* 1774)	unknown (Pacific)
76. *Fregilupus rodericanus* (1832)	Rodriguez and Ile-au-Mat, Mascarene Is.
77. *F. varius* (*c.* 1862)	Reunion, Mascarene Is.
PLOCEIDAE?	
78. *Neospiza concolor* (1888)	São Tome, Gulf of Guinea
FRINGILLIDAE	
79. *Chaunoproctus ferreorostris* (1890)	Chichi Shima, Bonin Is.
DREPANIDIDAE	
80. *Paroreomyza flammea** (1964)	Molokai, Hawaiian Is.
81. *Hemignathus* (*Loxops*) *sagittirostris* (*c.* 1900)	Hawaii
82. *H. obscurus* (*c.* 1895)	Hawaiian Is.
83. *H. procerus** (*c.* 1968–69)	Kauai, Hawaiian Is.
84. *Rhodacanthis palmeri* (1896)	Hawaii
85. *R. flaviceps* (1891)	Hawaii
86. *Chloridops kona* (1894)	Hawaii
87. *Ciridops anna* (1892)	Hawaii
88. *Drepanis pacifica* (1898)	Hawaii
89. *D. funerea* (1907)	Molokai, Hawaiian Is.
ICTERIDAE	
90. *Quiscalus palustris* (1910)	Mexico

EXTRALIMITAL: occurring only outside the boundaries of the area under consideration.

EYAS: special term (also 'eyass'; plural 'eyasses') for a nestling falcon or hawk, used especially of those species taken by falconers for training (see FALCONRY).

EYE: see VISION.

EYELASH: a bristle (modified feather) resembling a mammalian eyelash (hair) in situation and appearance; such eyelashes occur in a few groups of birds, e.g. conspicuously in hornbills (Bucerotidae), many species of cuckoos (Cuculidae), eagle owls *Bubo* spp., and the Ostrich *Struthio camelus*. See also PLUMAGE.

EYREAN: see AUSTRALASIAN REGION.

EYRIE: term (also 'eyry', 'aerie', 'aery') for the nest of a bird-of-prey, often an eagle *Aquila* sp., etc. (see also under FALCONRY).

F

FABULOUS BIRDS: kinds of birds that the human imagination has conjured up as religious, magical, or poetic symbols. This is apart from the role played by real species of birds in folklore, heraldry, witchcraft, and totemism (see FOLKLORE; HERALDIC BIRDS; OMENS, BIRDS AS).

The concept of fabulous birds, as of all zoological symbols, originated in primitive man's personification of the forces of nature. As his mind evolved he became increasingly aware of his aloneness in a mysterious and often hostile universe. Abstract concepts of a god or protecting power were at this time beyond his range, and it was thus natural that he should take the familiar creatures of his environment as the basis of elaborate symbols representing the good and evil powers that ruled his life. The more sinister zoological symbols, such as the dragon, belonged to the earth, and especially to the dark subterranean world of evil spirits. Birds, on the other hand, belonged to the sky—an ethereal region of purity and light. Fabulous birds were thus generally symbols of hope and regeneration, representing benevolent forces and the highest aspirations of mankind.

The first fabulous birds of any importance appeared in the Middle and Far East. The chief was Garuda, a gigantic bird-of-prey who, in Hindu mythology, was believed to bear the sun-god Vishnu on his daily journey across the sky. The earliest concepts of Garuda were almost certainly purely avian, and it seems probable that he was a composite symbol derived from observations of such real birds as Pallas's Fishing Eagle *Haliaeetus leucoryphus*, the Crested Serpent Eagle *Spilornis cheela*, the Lämmergeier *Gypaetus barbatus*, and the Brahminy Kite *Haliastur indus*. Later, however, he began to be depicted with human arms and legs, the avian characters being restricted to a white face, a golden body, and red wings. Garuda was a relentless enemy of serpents, which were a symbol of evil, and he was also supposed to carry elephants and tortoises to the summits of high mountains to devour them. The cult of Garuda spread eastward from India and he became a much venerated symbol in Indo-China, Siam, and Cambodia. In Malaya he was known as Gerda, and according to Ingersoll the men of Perak still say when a cloud obscures the sun; 'Gerda is spreading his wings to dry.' The cult of Garuda even reached Japan, where he was variously known as Gario, Bingacho, or Karobinga; but here he changed his sex and became half woman, half bird, a sort of feathered angel with the legs of a crane.

Westwards from India several bird-gods and demi-gods shared affinities with Garuda, and many have been descended from him. The most important was the early Persian Senmurv, half bird, half mammal, which was regarded as an elemental connecting link between heaven and earth. The wings, body, and tail of the Senmurv were those of a bird, but it was also supposed to have teeth; and the female of the species was believed to suckle its young. Like Garuda, it was an enemy of serpents and a benefactor of mankind, making its home in a tree of which the seeds would cure all evil. Every time the Senmurv alighted in the tree its branches used to shake and thousands of these seeds were scattered through the world.

In later Persian mythology the Senmurv was replaced by the Simurg. This was a giant bird which made its nest on Mount Alburs, on a peak that touched the sky. It was regarded as a symbol of strength and wisdom, a friend of the sick and the poor, and a comforter of mankind. Some beliefs concerning the Simurg show affinities with the Phoenix legend. For instance, it was reputed to live 1,700 years, and when at the end of that time the young was hatched, the parent of the same sex (some versions of the legend say the opposite sex) burnt itself to death. The Simurg may also be identified with the Anka of Arabic lore, and it shares some of the characters of the Rukh or Roc. The latter was a huge bird which inhabited an island in the Indian Ocean (usually identified with Madagascar), and was reputed to carry off elephants in its claws. The fronds of the exceptionally large palm *Sagus ruffia* were once regarded as the feathers of the Rukh, and the giant eggs of the extinct Madagascan bird *Aepyornis maximus*, each of which will hold over 10 litres of liquid (see ELEPHANT-BIRD), may also have played a part in the development of the legend as recounted in the *Thousand and One Nights*, the second and fifth voyages of Es-Sindibad of the Sea.

The most famous and poetic of all fabulous birds is the Phoenix. Pliny describes it as being the size of an eagle, with a gold neck, purple body, azure tail, and crested head. It has been identified by different ornithologists with the Purple Heron *Ardea purpurea*, the Bateleur Eagle *Terathopius ecaudatus*, the Golden Pheasant *Chrysolophus pictus*, or one or other of the various species of parrots (Psittacidae) or birds-of-paradise (Paradisaeidae), but like other fabulous birds it is probably a composite symbol derived from many sources. There was said to be only one Phoenix in the world at a time, and it dwelt in paradise, a land of infinite beauty lying beyond the eastern horizon. Every 1,000 years (some versions of the legend say 350, 500, or 1,461 years) the Phoenix left paradise and flew westwards to die. It collected aromatic plants on the way from the spice groves of Arabia, and built itself a nest in the top of a tall palm tree. Here, on the first dawn after its journey, it sang a song of such surpassing beauty that the sun-god stopped his chariot to listen. When he whipped up his horses again sparks from their hooves set fire to the nest of the Phoenix, and it died on a blazing aromatic funeral pyre. The new Phoenix grew from a worm which was found in the ashes of the nest, and flew back to paradise for its own allotted life span of 1,000 years.

The fabulous birds of the west were in general less benevolent than their eastern counterparts. In Greek times the hideous harpies, with their birds' faces and claws, were universally regarded as evil and destructive beings; even the glamorous sirens, variously depicted as birds with womens' heads or women with birds' legs, used their charms to lure mariners to destruction rather than to succour them in their dangerous calling. More lethal still were the Stymphalian birds, which were dealt with so effectively by Hercules in the sixth of his labours. These were man-eating birds, a mixture of stork, crane, and eagle, armed with arrow-like feathers that wounded all who came within their range.

In conclusion a few less publicised fabulous birds must be briefly mentioned. One of the most magnificent was the Fung-whang, or Feng Huang, the Chinese Phoenix. This was known by the Taoists as the scarlet bird, and was one of the four fabulous creatures symbolizing the four quarters of the heavens. Representations of the Fung-whang on Chinese screens and elsewhere suggest that its ancestry owes a good deal to the Peacock *Pavo cristatus*.

In Japan there is still a belief in a race of fabulous birds known as Tengus. The king of the Tengus is said to have the wings and claws of a giant eagle, a long red beak, and exceptionally piercing eyes. The Tengus are nature spirits, not positively evil but decidedly mischievous. They are very skilled in dancing and the use of arms, and sometimes take possession of human victims who, although half-demented, acquire their prowess in these activities while under their influence.

In ancient Sumer a huge divine eagle named Imgig was the royal symbol of Ur. The bird-god Horus of ancient Egypt, almost certainly derived from the Egyptian form of the Black Kite *Milvus migrans aegyptius*, was perhaps the most ancient god of the Egyptian pantheon. In Russia violent winds are still said to be produced by the wings of the colossal eagle-demon Vikhar flying overhead. Similar associations between violent winds and fabulous birds are found in the folklore of many primitive peoples and peasant communities, especially in northern Europe and among the North American Indians. FACIAL DISC: a well defined, relatively flat, forward-facing part of the head as seen in some owls. It probably helps the bird in locating prey by sound, focusing the sounds made by the prey on the owl's ear openings (see OWL). See photo VISION.

FACIES: among other meanings in biology, the general appearance of a species without regard to details; comprises size, shape, posture, or movement, perhaps with general hue and any conspicuous features (see JIZZ; SIZE).

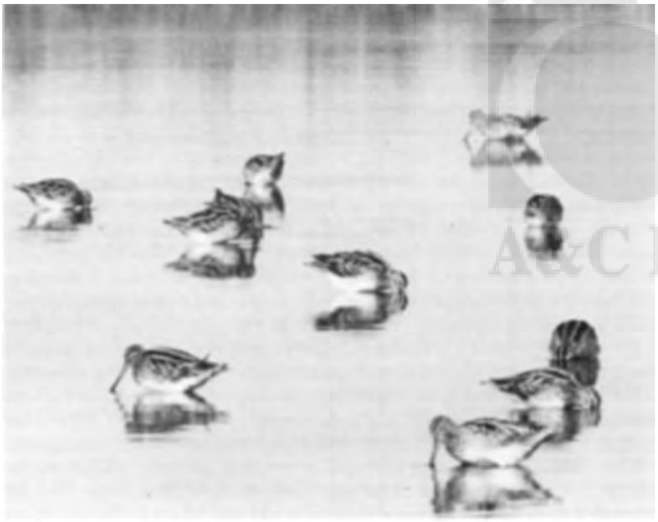
FACILITATION, POSTURAL: postural facilitation can best be defined by referring to an example. When a bird preens, it tends to work systematically from one region of the body to another. For example, preening the tail might be most often followed by preening the tail-coverts, rump or lower back. In other words transitions between successive preening acts occur in such a way that the bodily posture of the preceding act is similar to that of the following act.

The theory of postural facilitation predicts that changes between acts involving fewer body moves should occur more commonly than those involving many body movements. This is advantageous for the animal because it minimizes time and energy expenditure. J.R.K.

FACILITATION, SOCIAL: the term is not used very precisely, but a broad and a narrow sense can be distinguished. In its broad sense, social facilitation is the increase in frequency of a pre-existing activity caused by the presence or actions of another animal. In its narrow sense, it is an increase in the frequency of a particular activity caused by another animal's performing that very activity. The standard example from human behaviour is yawning: the sight of yawning causes other people to yawn.

Social influences on animal behaviour are multifarious, but not all such influences involve social facilitation. Social facilitation is an increase in the frequency of an activity; decreased frequency would be attributed to social interference. Social facilitation refers only to activities that are already established in the animal's behavioural repertoire. If an animal produces a novel act after seeing another animal do it, this would be a case of imitative learning, not of social facilitation.

Social facilitation has been documented for many kinds of behaviour. For example, in gulls, rates of visual and auditory displays, preening and copulation are all increased by the presence of other gulls doing the same. An example of social facilitation in the broad sense is the increase in male display rates that often occur in the presence of a female. M.R.



Snipe *Gallinago gallinago* feeding together. (*Photo: F. Pölking*).

FAECAL SAC: a white jelly-like 'envelope' in which the FAECES of the nestlings of nidicolous birds are enclosed. It is easily removed from the nest by the parents, thus promoting efficient nest sanitation. (See PARENTAL CARE).

FAECES: see ALIMENTARY SYSTEM; DROPPINGS; for nest sanitation see PARENTAL CARE.

FAILED BREEDER: a bird which nests but does not manage to fledge young.

FAIRY: substantive name of *Heliothryx* spp. (for family see HUMMINGBIRD).

Fairy-bluebird *Irena puella*. (*C.E.T.K.*).

FAIRY-BLUEBIRD: substantive name of the 2 species of the genus *Irena*, family Irenidae (Passeriformes, suborder Oscines).

Characteristics. Wholly arboreal passerines, 25–30 cm long, weighing approximately 60–80 g, with relatively small toes, short, thick tarsi, a moderately heavy beak with slightly curved culmen, finely notched tip and covered nostrils, and wings and tail of moderate length. The tail of some subspecies of *Irena puella* is overlaid almost to its tip by full upper and lower coverts. Fairy-bluebirds resemble leafbirds (Chloropseidae) and bulbuls (Pycnonotidae) in profusely shedding feathers when handled.

From the crown to the upper tail-coverts, exclusive of the back of *I. cyanogaster*, adult males are a brilliant, enamel-like ultramarine to turquoise or cobalt blue, this colour extending ventrally over the lower tail-coverts. Elsewhere they are velvety black or, in most forms of *cyanogaster*, deep blue. Females of this species differ only in being duller while those of *I. puella* are more or less uniform dull verditer blue. Immatures resemble females but lack the conspicuous carmine-red iris of adults.

Plumage and other external features have variously placed fairy-bluebirds near or with the bulbuls, leafbirds, drongos (Dicruridae) and cuckoo-shrikes (Campephagidae), and on osteological grounds they have been proposed as a subfamily of the Oriolidae. Their egg-white proteins support an affiliation with this general assemblage of passerine families but have provided no independent clue to a nearest relative. Ecologically, fairy-bluebirds most resemble leafbirds and the more frugivorous bulbuls.

Distribution. They comprise one of two bird families endemic to the Oriental biogeographical region, *I. puella* being distributed from the wetter parts of the Indian subcontinent, formerly also Sri Lanka, through South-east Asia to the Andamans, Nicobars and the larger islands of the Sunda Shelf, including Palawan. *I. cyanogaster* occurs allopatrically over most of the rest of the Philippines.

Habitat. Although occasionally tempted by a fruit supply into nearby disturbed habitats, fairy-bluebirds are normally found only in tall semi-deciduous or evergreen forest, ranging at times to an altitude of 2,000 m though they may not breed in montane biotopes.

Movements and food. *I. puella* is everywhere at least locally nomadic, dispersing over the forest canopy in search of suitable fruiting trees, although unlike some other Oriental forest frugivores it has not been recorded moving at night. Fruit, especially figs, forms the bulk of the diet and is taken mainly, but not exclusively, at canopy level. Certain tree flowers are regularly probed for nectar and fairy-bluebirds also take arthropods.

Behaviour. Typically, fairy-bluebirds disperse and forage in pairs or small, loose parties, which may show some temporary cohesion in their comings and goings at a fruit-source. In areas of extensive forest a mass fruiting may attract considerable numbers but such gatherings are short-lived only. No true flock movements or communal roosting behaviour have been recorded.

Voice. *I. puella* has various loud, liquid, incisive calls: *wait, wait-wait, wi-it, whi-tu*, uttered mainly while perched, and a sharp flight call *chichichichik*, repeated every few seconds.

Breeding. *I. puella* builds, usually several metres up, in the forks of saplings and subcanopy trees. The nest is a rough platform of long, often thick twigs capped by a layer of rootlets and green bryophytes in which is formed the open cup. The 2 eggs (occasionally 3 in India) are greenish white to olive-grey or buff to reddish grey, with irregular streaks of brown, grey and purplish coalescing into a cap over the broad end. Only the female has been recorded building, incubating and brooding. Both parents feed the young. D.R.W.

FALCATED: sickle-shaped, as in some of the scapular feathers.

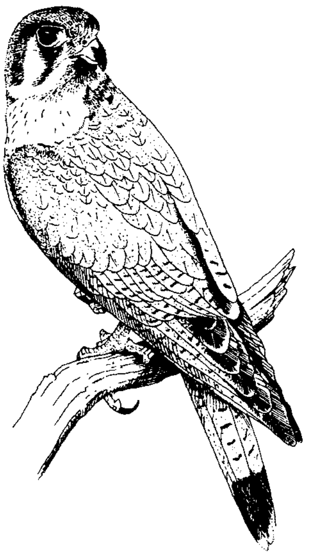
FALCON: substantive name of many species of the Falconidae (Falconiformes); in the plural, general term for *Falco* spp.—or, more loosely, for the whole family. Similar to the Accipitridae (see HAWK), with sharp curved talons and hooked bills, and remarkable powers of sight and flight; they differ, however, in details of skeletal structure, sequence of moult of primaries, and chemical composition of eggshells. As in other birds-of-prey, the females are larger than the males. The family contains about 60 species, divided among 4 subfamilies.

Forest Falcons. The Micrasturinae contains 5 species in the genus *Micrastur*, restricted to the New World tropics. Sometimes known as harrier-hawks, these birds are in general appearance between a harrier *Circus* sp. and a Goshawk *Accipiter gentilis* (see HAWK)—long-tailed, long-legged, and with a partial facial ruff. They were formerly placed close to the Circinae by some authors on that account, but are in fact primitive falcons which have become adapted for life in dense forests, where they prey largely on birds. Little is known of their habits. (The term 'harrier-hawk' is also applied to the subfamily Polyboroidinae of the Accipitridae—see HAWK).

Laughing Falcon. The Herpetotherinae contains one species, *Herpetotheres cachinnans*, which is falcon-like in appearance, dark above with white underparts and a striking white crown set off by a black mask. It inhabits forests in tropical America, where the birds sit on the tops of trees overlooking open ground and make their presence known by their loud calls. They nest in cavities in trees, but have been little studied.

Caracaras. The Daptriinae, comprising about 9 species in the genera *Milvago*, *Phalcobaenus*, *Daptrius*, and *Polyborus*, is a New World (mainly Neotropical) group of large (buzzard-sized) long-legged birds that look quite unlike falcons. They inhabit open country, forest or savanna, and are insectivorous or omnivorous, with a strong taste for carrion. Caracaras are very common in parts of Central and South America, and are in general rather sluggish birds, spending much of their time perched, or walking about on the ground; but they can run swiftly. They associate with vultures (Cathartidae) at carrion and sometimes force these and also other caracaras to disgorge in the same way as skuas will rob gulls. Unlike the true falcons, caracaras build their own nests; they lay 2–3 eggs, but otherwise little is known of their breeding habits. One species, the Guadeloupe Caracara *Polyborus lutosus*, has become extinct within historical times.

True Falcons. The subfamily Falconinae comprises the genera *Spiziapteryx* (one species, Argentina), *Polihierax* (2 species, Africa and south-east Asia), *Microhierax* (6 species, tropical Asia), and *Falco* (37 species, all continents). The first 3 genera are all very small falconets and pygmy falcons, the smallest of all the birds-of-prey and restricted to the tropics of Old and New Worlds. The Philippine Falconet *Microhierax erythrogonys* is only 15 cm long, black above and white below, and hunts insects from the tops of trees in the manner of a flycatcher (Muscicapinae); it breeds in old holes of woodpeckers (Picidae). The African Pygmy Falcon *Polihierax semitorquatus* is likewise very small, but within its limits it is a bold and dashing little predator, capable of killing small birds as well as the large insects which form the major part of its food. It breeds in the huge communal nests of Sociable Weavers *Philetairus socius* in South Africa, and in East Africa in the thorny nests of buffalo-weavers *Bubalornis* and *Dinemellia* spp. The Sociable Weavers do not object to the presence of the little falcon, which does not molest its hosts.



Red-headed Falcon *Falco chicquera*. (*K.J.W.*).

The genus *Falco*, containing the small to medium-sized typical falcons, is the largest genus in the Falconiformes. It can be conveniently divided into a number of adaptive types on physical characteristics and general habits. The falcons are found throughout the world, mainly in open or fairly open habitats.

The large true falcons are stocky, powerful birds of exceptionally swift flight, the wings being pointed and the tail relatively short. They are among the most accomplished fliers of all birds, and habitually kill their prey, principally birds, in full flight, either striking them dead by a blow or seizing them in the foot and coming to ground with them. Owing to the speed of their attack they rarely kill on the ground. Although they chiefly eat birds they will occasionally take mammals, and are fond of flying insects, such as termites or locusts, when available.

The largest of all falcons, the Gyrfalcon *Falco rusticolus* (length 50–60 cm), is a magnificent species inhabiting Arctic America and Eurasia and feeding largely on ptarmigan *Lagopus* sp. One of its colour forms is almost pure white, with a few black spots, but more commonly it is grey and white. The Peregrine Falcon *F. peregrinus* (length 36–48 cm), which typifies the larger falcons, is one of the world's most spectacular birds. Cosmopolitan in distribution, with 17 races, it is a perfect performer in the air, capable of feats of speed and precision flying scarcely to be equalled by any other bird. It is par excellence the falconer's choice, and has been used in all countries where the pursuit is followed (see FALCONRY). In most of its range it was much reduced in numbers during the 1950s and 1960s by DDT and other organochlorine pesticides (see EGG-SHELL THINNING; TOXIC CHEMICALS). Peregrines breed on tall buildings in towns in several countries, possibly attracted by the large numbers of domestic pigeons found there, but the habit has never become widespread. Other large falcons of the same general type are the Lanner *F. biarmicus* of Mediterranean countries and Africa, the Laggar *F. jugger* of India, the Saker *F. cherrug* of eastern Europe and central Asia, the Prairie Falcon *F. mexicanus* (closely related to the Lanner) of western North America. Most of these have been used for falconry to a greater or lesser extent. The Taita Falcon *F. fasciinucha*, a rare inhabitant of Africa, is probably close to the peregrine group although only half the size of a Peregrine. All these species nest solitarily, usually with 2 km or more between pairs.

The hobbies are a group of small (length 28–36 cm), long-winged, exceedingly swift falcons which live largely upon insects but can take some small birds, including swifts, in flight. They catch almost all their prey on the wing. They occur all over the world, and include *Falco subbuteo* of Europe, *F. severus* of India, *F. longipennis* of Australia, *F. cuvieri* of Africa, and *F. albigularis* and *F. femoralis* of South America. Eleonora's Falcon *F. eleonorae* (length 36–40 cm) and the Sooty Falcon *F. concolor* (length 33–36 cm) are conveniently placed close to hobbies. *F. eleonorae* is a very localized bird, breeding in loose colonies in late summer on certain Mediterranean and other islands, preying on the migrant streams of passerines on southward passage at that time, and thereafter migrating to Madagascar. *F. concolor* inhabits the North African deserts, and preys on birds and bats, as does *F. albigularis*.

The Merlin *F. columbarius* (length 25–30 cm) is a Holarctic species, inhabiting forest bogs, open moorland and grassland and preying on small birds caught on the wing; it is migratory throughout its range, moving mainly to temperate regions for the winter. With it may be placed *F. chicquera*, a dashing little falcon inhabiting Africa and India, also feeding on birds, and commonly associated (in Africa at any rate) with the Borassus Palm *Borassus flabellifer*. Both these falcons are solitary while breeding. They can be trained for falconry, but will not kill anything larger than a small dove.

The Grey Kestrel *F. ardosiaceus* and Dickinson's Kestrel *F. dickinsoni* of tropical Africa and *F. zoniventris* of Madagascar form another group. They are not true kestrels, having some of the habits of kestrels but being more like merlins in other respects. They kill a good deal of their prey on the ground, and eat small mammals, lizards, and insects as well as birds; they sometimes hover, but can fly very swiftly also. The Grey Kestrel has the strange habit of appropriating the huge domed nests of the Hamerkop *Scopus umbretta* in which to breed, ejecting the rightful owner. Dickinson's Kestrel breeds in the hollow tops of dead palm trees.

The Red-footed Falcons *F. vespertinus vespertinus* and *F.v. amurensis* are small (length 29–31 cm), migrant, insectivorous falcons of striking colouring, with red feet and (in the males) black and grey plumage set off with chestnut under-tail coverts. They are highly gregarious both on migration and when breeding, roosting in hundreds together in selected trees, and breeding in colonies in the nests of Rooks *Corvus frugilegus* after the Rooks have flown (*F. v. vespertinus*). In winter they migrate from central Europe and Asia to southern Africa. They are commonly to be found feeding on swarms of flying termites. The Lesser Kestrel *F. naumanni* (length 29–32 cm), although very like the Kestrel *F. tinnunculus* in plumage, is perhaps best placed with these two, being insectivorous and gregarious on migration and breeding in colonies on cliffs and buildings.

The kestrels are a large group of small falcons, cosmopolitan in distribution, and having the habit of hovering with gently fanning wings to assist in finding their prey, which is largely small mammals and insects taken on the ground or in long grass. They rarely take birds in flight and are typified by *F. tinnunculus* (length 32–35 cm), which has numerous races occurring all over Europe, Asia and Africa, and is closely related to *F. sparverius* (length 19–21 cm) of America. Other kestrels, *F. moluccensis*, *F. newtoni*, *F. araea*, and *F. punctatus*, inhabit islands in the Pacific and Indian Oceans; *F. punctatus*, inhabiting Mauritius but reduced to less than 5 pairs, is the rarest of all falcons. *F. cenchroides* is the Australasian representative, and to complete the group there are 2 rather larger species in Africa—the Fox Kestrel *F. alopex* and the Greater Kestrel *F. rupicoloides*, which are like other kestrels in many of their habits but seldom if ever hover; they eat small mammals, reptiles, and insects caught on the ground. Many of the kestrels are strongly gregarious when on migration, but breed apart and well separated. In all kestrels the plumage is mainly chestnut and grey in the male, with black spots, and in the female pale reddish-brown with black streaks and bars.

Falco berigora of Australia, known as the Brown Hawk and formerly placed in a separate genus '*Ieracidia*', is one of the commonest birds-of-prey on that continent, having many of the habits of kestrels but being much larger and generally darker in colour. It does not hover, but catches most of its prey on the ground (insects, lizards, and small mammals), and is both gregarious and migratory.

In their breeding habits members of the genus *Falco* vary greatly, but none of them build their own nests, although they may improve an existing structure. They either breed in a scrape on a rock crag, which may be resorted to year after year, or they appropriate the old nest (and sometimes the occupied nest) of some other bird, such as a large eagle or a buzzard or one of the crows. Some species use tree cavities. Their eggs are all very handsome, being generally buffish in ground colour, thickly speckled with dark red-brown, sometimes so as to obscure the ground colour completely; they are fairly round. Clutches are usually 2–3 in hobbies, 3–6 in other small falcons and 3–5 in large species; eggs are laid at 2–3 day intervals. Incubation periods range from 25–32 days in small species to 32–35 days in large ones; nestling periods from 25–32 days in small species to 40–49 days in large ones; and post-fledging dependency periods from 2–3 weeks in small species to 2 months in large ones. In all falcons while breeding, the male provides most of the food and the female does most of the incubation and tending the young.

As expected in such spectacular fliers, most displays take place in the air, though others are centred on nest-sites. Vocalizations are heard mainly in the breeding season, and consist of screams or chattering notes. Many species protest loudly when the nest is visited. (L.H.B.) I.N.

FALCONET: substantive name of some small species of Falconinae (see FALCON).

FALCONIDAE: see FALCONIFORMES; FALCON.

FALCONIFORMES: an order, comprising the sole family Falconidae (see FALCON; CARACARA). In Wetmore's system treated as one of 4 families in the suborder Falcones in the order Falconiformes *sensu lato* (see ACCIPITRIFORMES), but anatomical features and probably isolated, radiating development of South American members considered as primitive, have led to raising the family to ordinal rank.

FALCONRY: also known as hawking, the use of trained birds of prey for taking wild quarry. It originated in the Far East, possibly as long as 4,000 years ago although the first indisputable written evidence is from Japan in 244 AD, and spread to Europe with the Germanic tribes. Falconry was widely practised in Britain before the Norman Conquest, and the Bayeux Tapestry depiction of soldiers carrying hawks is thought to symbolize a readiness for recreation or peace. There is a long and continuing Islamic tradition of falconry, with an injection of eastern techniques to Europe being noticeable immediately following the Crusades. Falconry flourished during the Middle Ages, being practised by people in all walks of life, although painting and literature have often associated it with the aristocracy who sponsored these arts. With the development of firearms, the enactment of land reforms and the evolution of a town-based industrial society, falconry declined throughout Europe. It was maintained during the 19th century by a handful of enthusiasts, with a succession of small British clubs playing a vital role. Increased leisure time and interest in birds of prey since about 1950 have produced a renaissance in western falconry, including its establishment throughout North America. There are now several hundred active falconers in Britain alone, mostly members of either the British Falconers' Club or the Welsh Hawking Club. Falconry clubs throughout the world combine to form the International Association for Falconry and Conservation of Birds of Prey.

Birds used. The birds most commonly trained are hawks (*Accipiter*), known to falconers as 'short-wings', falcons (*Falco*) called 'long-wings', and buzzards (*Buteo*) or eagles (*Aquila*, *Hieraaetus* and *Spitzaetus*) which are sometimes grouped as 'broad-wings'. The word 'falcon' is often applied only to the female Peregrine *Falco peregrinus*, while Gyr Falcon *F. rusticolus*, Saker *F. cherrug*, Lanner *F. biarmicus*, Merlin *F. columbarius* and Sparrowhawk *Accipter nisus* are used for the females of those species, whose males are the jerkin, sakret, lanneret, jack-merlin and musket respectively. The word 'tiercel', originally meaning the male Peregrine, but now also used for the male of many other species, is thought to derive from the male being about a third smaller than the female, although it may also have been believed that males came from the third egg in a clutch. Falconers often prefer to fly females, which are better able than males to subdue the largest prey.

Until the 1970s, all falconers' birds were obtained from the wild, birds taken from the nest being known as 'eyasses' to distinguish them from birds trapped as 'passagers' or 'passage-hawks' in first year plumage or as adult 'haggards'. After a moult in falconers' hands the birds are 'intermewed'. An 'intermewed eyass goshawk tiercel' would be a male Goshawk *Accipiter gentilis* of more than one year old which had been obtained as a nestling. Eyasses are usually taken when about to fledge, and then kept loose in a large shed without sight of man until their feathers are 'hard penned'. Otherwise, some birds start to scream at their handler for food, an irritating type of 'imprinting' which may continue through the bird's life. Eyass falcons are sometimes flown 'at hack', to practise their flying skills by fledging, from an isolated 'hack house' at which food is provided and where they can later be trapped for training. Similarly, trained birds may later be 'hacked back' to the wild, and the technique is also used for re-introductions in areas where wild stocks have been eliminated by persecution or pollution.

In the 1960s, as severe population declines became apparent among Peregrines and small accipiters in Europe and North America, many falconers turned to importing falcons and hawks from Asia and Africa, where birds of prey had been less affected by organochlorine or heavy metal contamination. Because these supplies often became commercialized, and some dealers sought to profit by robbing protected populations, many countries eventually prohibited or severely restricted exports. Other falconers had responded to the disappearance of favoured species by starting projects to breed them in enclosures, and restrictions on supplies of non-threatened species later encouraged further effort in this direction. Peregrines had first been bred by a German falconer, Renz Waller, in 1941, but there was no successful postwar domestic breeding of this species until 1970. By the end of the 1970s, falconers working alone or in research institutes had bred at least 12 species of falcons, 6 of broadwings and 3 of accipiters. About 200 Peregrines were being produced annually, and in several western countries there were more of some falcon species being bred domestically than were being allocated under licence from the wild.

Basic equipment. Extending 10–20 cm from each leg of a falconer's bird is a strap-like 'jess', usually made of strong yet supple leather, with a slit in the free end for joining both jesses via a metal swivel to a leather or nylon leash. A jess may be one continuous piece of leather round the leg, or be threaded through an eyelet in a much shorter anklet. The anklet system is called 'Aylmeri', after a forestry officer who promoted its use in Britain, but is eastern in origin. Since a bird with Aylmeri can be flown free wearing slit-less 'field-jesses', or the anklets alone, instead of the longer 'one-piece' jesses whose slits may snag on vegetation, Aylmeri jesses are now replacing the others. Traditionally, the only other equipment on a bird in the field is a small but amazingly loud bell, of beaten brass or other resonant alloy, attached to each leg by a leather 'bewit' or mounted on the tail. Bells help to locate birds which are out of sight in the field, and by their sound alone a falconer can tell much about the wearer's behaviour at any time. A tiny radio transmitter fixed to a leg or to the tail is a more modern location aid.

When not being flown, birds are often put to 'weather' outside, with the 1–2 m leash linked to the jesses and fastened at its other end, with a one-handed 'falconers' knot', to a running line or suitable fixed perch. The outside perch for falcons is a 'block', typically 20–40 cm high and shaped like an inverted cone in the west, but more mushroom-like as used by eastern falconers. Shortwings and broadwings are most commonly given a 'bow-perch', like a stout and very convex bow with its ends embedded in the ground. A shallow bath is provided, and large birds kept permanently outside have a shelter against inclement weather.

Inside quarters are called a 'mews', in which the bird may be secured to a 'screen-perch'. This is a 1–1.5 m high long, horizontal perch, with material stretched vertically beneath to help the bird regain its position if it 'bates' off the perch. Blocks and bow perches are often used inside too, and many falconers leave their birds loose in the mews to choose between different perch types.

Right-handed western falconers have a leather gauntlet on their left hand for carrying a bird, thus keeping the more versatile hand free. Eastern falconers tend to carry on a padded sheath, known as 'dastri' or 'maukala', round the right wrist. Other falconry accessories are for IMPING to mend broken feathers, for 'coping' overlong beaks and talons, for medical treatment of parasitic or other infections, for vitamin or mineral supplementation of the diet, and for weighing the bird to determine its feeding regime. Those who fly falcons use a light leather hood to protect a bird from sights which might frighten it, or to discourage attempts to leave the fist too early in the field. A hooded falcon will settle quietly as if asleep. 'Austringers', who fly hawks, use hoods less often.

Training. In the first stage, known as 'manning', a falconer must initially gain the bird's trust and then get it used to other people, animals, machines and strange places. The bird is gradually exposed to each new phenomenon while feeding on the fist. The second stage, 'calling off', is of encouraging the bird to fly increasingly long distances to the falconer. A light line, the 'creance', is attached to the bird's swivel in the early stages. Training is done at feeding times, which may be arranged a little later each day to ensure that a bird is 'sharp set'. The trainee must not be brought into low condition by under-feeding, which could lower its resistance to disease.

Falcons are introduced to the 'lure', a leather bag decked with feathers of an intended quarry and with a reward of food attached. Once off the creance, falcons are taught to 'stoop' at the lure, which is swung on a short line, to provide exercise and to call them back from a distance when hunting. Hawks and broadwings may be called to a lure pulled along the ground, but are usually expected to return direct to the fist.

Flying at quarry. Perhaps the most spectacular flights are those of falcons at game. 'When game hawking, i.e. flying at grouse or partridges, a wide-ranging setter or pointer is put down. When game is found, the falconer, having removed her leash, swivel and hood, puts his falcon in the air. She flies in a spiral, ringing until she has gained her pitch over the dog. The higher she mounts the better. There she will wait on until the falconer serves her by putting up the game, down wind, under her. On sighting the rising game she will stoop at it and either bind to it in mid-air or put it in to covert, over which she will make her point and wait on once more until the falconer can put out the quarry to her again. Having taken the quarry she will be allowed to plume it quietly, that is to pluck or even break into it, before the falconer makes in to her and takes her gently on fist again. There, sitting on his glove, she will assuredly be rewarded with a titbit before being hooded up and replaced on the cadge, a light wooden framework used to take falcons into the field. Not all flights are successful however. She may fly at check at other quarry, i.e. rake away after, say, a distant pigeon. Then must the falconer, his best foot foremost, follow her and endeavour to take her down with his lure.' (A.G. O'Carroll Scott).

Thrilling flights are also to be seen when two falcons are flown together, as a 'cast', and stoop alternately at a particularly wily prey, or when a Rook *Corvus frugilegus*, for instance, tries to outfly a falcon by 'ringing' up into the sky. 'Waiting-on' flights are uncommon in the east, where falcons are flown at game straight from the fist, and this style is usual in the west too for some quarry. In the east, large falcons are flown mainly at bustard and hares, whereas western falconers concentrate on partridge, grouse, pheasant and duck, sometimes also pursuing Rooks and crows. In Britain Merlins have traditionally been flown at Skylarks *Alauda arvensis*.

Flying falcons requires wide open spaces, in which prey seek safety in flight rather than by diving into the nearest cover, and over which wide-ranging flights can be kept in view. Accipiters, on the other hand, have the high acceleration and agile turning suitable for flights off the fist in more wooded country, where prey may often seek to hide or out-manoeuvre the hawk in the vegetation. Such flights tend to be short, but well-trained birds may accept long 'slips' at distant prey. If unsuccessful, the hawk can be called back to the fist, but may also be encouraged to follow overhead from tree to tree. Using these techniques, Goshawks are flown at pheasant, partridge, duck, rabbits, hares and other natural prey. Sparrowhawks have traditionally been flown at sparrows *Passer* and Blackbirds *Turdus merula*, or quail in the east.

Broadwings (buzzards and eagles) may be flown at similar prey and can sometimes be trained to wait on. The tribesmen of Central Asia still fly Golden Eagles *Aquila chrysaetos* at wolves from horseback. Unlike the sister art of fishing with cormorants, trained birds of prey do not carry their quarry back to the falconer, but must be 'taken up' from the kill. The bird may then be flown again, but it is unusual for more than two or three kills to be made in a day.

Conservation aspects. Falconry has a long tradition of studying and protecting birds of prey. Emperor Frederick II, who wrote the 13th century falconry treatise *De Arte Venandi cum Avibus*, has been called the father of modern ornithology. There were medieval laws to protect birds of prey in the name of falconry, and for most of the last two centuries falconers were considered eccentric in their desire to preserve these predators. Falconers such as the American Craighead brothers and Dr Heinz Brüll of Germany provided the first modern books on raptor ecology, and falconer-vets have ensured that raptor diseases are better understood than for any other group of wild birds. By release and inadvertent loss of birds falconry has re-introduced the Goshawk to Britain, and the development of domestic breeding with release techniques provides an insurance against extinction for endangered birds of prey. On the negative side, illegal procurement of birds for falconry increased human pressure on some populations which had been reduced by pollution. Falconry is recognized by law in many modern states, including the United Kingdom. It is to be hoped that the recent tightening of controls on obtaining or possessing birds, through national legislation and the international Washington Convention on Trade in Endangered Species, will prevent further irresponsible activities and preserve the beneficial aspects of this ancient art.

FALCUNCULINAE: see PACHYCEPHALIDAE; THICKHEAD.

FALL: a sudden arrival of large numbers of birds at a certain point, usually coastal. Falls may occur when migration is interrupted by the rapid onset of adverse weather, such as gales or fog (see MIGRATION).

FALSE PREENING: see DISPLACEMENT ACTIVITY.

FAMILY: a primary taxonomic category (or a particular example thereof), being a subdivision of an order and a grouping of genera. Secondary categories may be interpolated between these levels when considered necessary—suborder and superfamily as higher divisions of the order, subfamily and tribe as subordinate groupings of genera (see TAXON). Although the category was not used by Linnaeus (whose genera were very wide), it has become one of the most important. It is a level at which the taxonomist demands a high degree of probability that the taxon is monophyletic; though less so and with a less amount of certainty than in that of the genus. It is also one at which he expects to find gaps between the taxon and its neighbours, sufficient in magnitude to make each of them plainly distinctive; the gaps may have originated through either the reaching of different ecological levels or the extermination of intermediate forms. The grouping of families in higher taxa tends to become progressively even more speculative; the subdivision of a family into subordinate taxa (above species level) comes more and more to depend on points of minute detail.

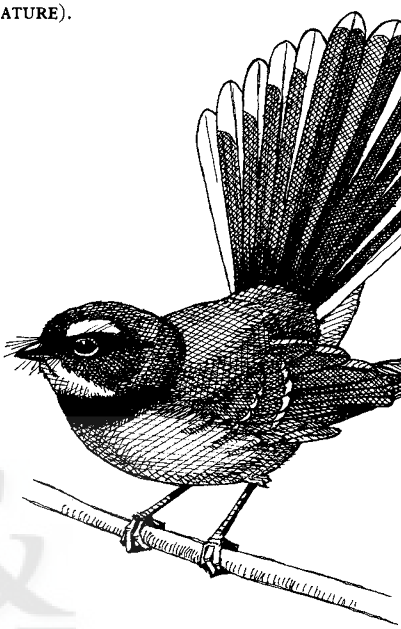
There are, of course, exceptions. On the one hand there are groups of rather similar families—so little different that some authors regard them as subfamilies of a single family, and that at least ordinal relationship is indisputable. On the other hand, there are families—as at the moment recognized—that include such diverse elements as to raise doubt about their monophyletic character; these groupings can be considered as no more than provisional, pending further evidence. And again, there are families that fail of distinctiveness because they are linked to others by species of apparently intermediate character; in this event, the present tendency is to reduce the families to subfamilial level, where a certain lack of distinctiveness can be more readily accepted. The whole question of familial status and interfamilial relationships is particularly difficult in respect of the passerine birds (see PASSERIFORMES), particularly the so-called Nine-primaried Oscines including the families of finches (Fringillidae), Hawaiian Honeycreepers (Drepanididae), American Warblers (Parulidae), Bananaquits (Coerebidae), Tanagers (Thraupidae), American Sparrows, Buntings and Cardinals (Emberizidae), American Orioles (Icteridae).

Subfamily and Tribe; Superfamily. Secondary categories that are sometimes interpolated between family and genus are subfamily and tribe. These may be useful where the genera within the family are sufficiently diverse and appear to fall into groups. The criteria of degrees of difference are necessarily subjective; so what one author may regard as a number of separate families, another may treat as subfamilies, or even tribes, of a single family. The tribal category is regarded as superfluous by some authors (e.g. Wetmore 1960), but it may help on occasion in breaking up a large family showing relatively little diversity. If the cladistic method of classification is strictly followed, however, a number of interpolated taxa may be obligatory (see CLADISTICS).

The names of superfamilies end in '-oidea', those of families in '-idae' (the 'i' is short), those of subfamilies in '-inae', and those of tribes in '-ini'. In all cases the stem of the name is taken from the name of the type genus. Each of the 3 higher taxa has a subordinate 'nominate' taxon at the next level below, with the same type genus and a name identical except for the termination. The names of nominate subfamilies and tribes are not used as separate entry words in this work, as they derive obviously from the name of the higher taxon.

A.L.T.

FAMILY GROUP: with reference to the ranks of taxa, term embracing those taxa that are based on, and are co-ordinate with, the family (see NOMENCLATURE).



Grey Fantail *Rhipidura fuliginosa*. (*N.W.C.*).

FANTAIL: substantive name for a passerine group (suborder Oscines) of unsettled limits and relationships, regarded by Beecher (1973) and Boles (1979) as no more than distinctive MONARCH FLYCATCHERS, but here given familial status as Rhipiduridae. Though yet to be rigorously investigated and defined anatomically, the fantails, like the monarchs, are already known to differ from the true flycatchers (see FLYCATCHER (1)) in lacking both the 'turdine thumb' on the syrinx (Ames 1975) and 'process D' of the carpometarcarpus (Harrison 1969).

The nucleus of the group is the Indo-Pacific genus *Rhipidura*, of some 39 spp. Associated with this have been *Chelidorhynx* (1 species, India and SE Asia, sometimes regarded as congeneric) and *Culicicapa* (2 species, India, SE Asia, Philippines, Sulawesi; Parker 1964). The African genera *Erythrocercus* and *Elminia*, currently listed in the Monarchidae appear similar to the fantails, as do 3 of the 5 species of the African '*Trochocercus*' (Hall and Moreau 1970).

Characteristics. *Rhipidura*: small to medium songbirds, 14–20 cm, with long, rounded, fan-shaped tails (more than half of total length) and moderately broad bills, the gape armed with rictal bristles; most species also have relatively short tarsi and small feet (not so in the atypical partly terrestrial Willie Wagtail *R. leucophrys*, see Harrison 1976). Plumage generally lacking in bright colours, predominant tones being greys, browns, white, rufous and black; a few species with strong bluish tones, e.g. Blue Fantail *R. superciliaris* (cf. the fan-tailed African monarchines *Elminia* and '*Trochocercus*' spp.); some species are strikingly patterned, e.g. the Black-and-Cinnamon Fantail *R. nigrocinnamomea*, and the black-and-white Willie Wagtail and Cockerell's Fantail *R. cockerelli*. *Chelidorhynx* is similar to *Rhipidura* but much smaller (8 cm) and bright yellow beneath, mainly greyish olive above. *Culicicapa* (9 cm) also has much yellow in the plumage, but the tail squared and of moderate length. There is little or no sexual dimorphism in the family. The young are unspotted but feathers of the upperparts, especially the wing-coverts, may be tipped cinnamon to buff.

Habitat. Forests, woods and thickets, including primary rain-forest, second-growth, mangroves, sclerophyll woodland, gardens; usually within or not far from the cover of canopy or dense shrubbery, though some species more frequently venture into the open than others, the

Willie Wagtail actually favouring open ground in the vicinity of trees and bushes.

Movements. As with many other groups, there is a tendency for populations breeding furthest from the Equator to be the least sedentary. For instance, at least some of the Tasmanian and south-eastern Australian populations of the Grey Fantail *R. fuliginosa*, and all the south-eastern Australian populations of the Rufous Fantail *R. rufifrons*, move north in autumn and winter. In addition, some high-altitude breeders may descend to lower altitudes in winter, e.g. Himalayan populations of the Grey-headed Flycatcher *Culicicapa ceylonensis*.

Food. Chiefly small insects, including termites, dragonflies, bugs (including lerps), beetles, flies, moths and their caterpillars, bees, wasps and ants; also spiders; emphasis on small winged insects. In addition, the Willie Wagtail has been recorded taking worms.

Behaviour. Fantails occur chiefly singly or in pairs, also in family groups; many species also form mixed feeding parties. The method of hunting, characteristic of many species, is to flit actively from branch to branch with tail fanned and wings drooped, fluttering against the foliage to dislodge insects (Harrison 1976) and sallying out to snap up prey in mid-air; in addition, the versatile Indian White-browed Fantail *R. aureola* has been recorded working up tree-trunks and boughs, flushing insects from crevices in the bark (cf. the monarch *Arses*), and attending and perching on grazing livestock, snapping up the tiny insects disturbed by the animals; the Willie Wagtail habitually indulges in this last practice. Some species are less active, perching more and fanning the tail less, e.g. the Dusky Fantail *R. tenebrosa* and Cockerell's Fantail, both of the Solomons, and the Northern Fantail *R. rufiventris* of Australia, New Guinea, Solomons and Indonesia. The African 'monarchines' *Erythrocercus*, *Elminia* and the 3 bluish '*Trochocercus*' spp. also hunt actively and fan the tail like the more typical *Rhipidura* spp. (Chapin 1953). *Culicicapa* hunts like a fantail, but tends to spread its shorter, squared tail less. As in the monarchs, some species of *Rhipidura* are reported to hold larger prey under the foot and eat it piecemeal.

Possible courtship display has been noted in *Culicicapa ceylonensis*, the presumed male flying continuously in a rough circle in front of a second, perched bird, which flew out to it once each circuit, there being at least 15–20 circuits in all (Lister *in* Ali and Ripley 1972). Agonistic display is common in the aggressive and strongly territorial Willie Wagtail, in which rival males expand their white eyebrows, submission being signalled by the defeated bird relaxing its feathers to hide the eyebrow completely.

Voice. Calls are simple chips, clucks and grating notes. The song is typically a weak, high-pitched but melodious phrase consisting of short clear whistles, and climbing and tumbling strophes of shorter notes. A few species have atypically loud forceful songs, e.g. Willie Wagtail.

Breeding. Fantail nests are deep cups compactly made of mosses, bark, fine grasses and lichens, the exterior plastered with spiderweb, some species of *Rhipidura* appending a 'tail' of nest-material to the bottom. The nest is placed in a fork (usually more or less horizontal) or on a horizontal branch; the Willie Wagtail will also build on man-made bases such as clothes-lines. The clutch-size is 2–4; in *Rhipidura* and *Culicicapa* the eggs have a pale or rich cream ground, with markings of brownish and greyish spots and blotches concentrated in a ring around the larger end or equator (eggs of the African *Elminia* and bluish '*Trochocercus*' spp. are similar to this); in *Chelidorhynx*, however, the eggs are cream or pinkish cream with pinkish-brown stippling that tends to form a solid cap at the larger end. In *Rhipidura* spp., the incubation period is 12–14 days, nestling period 13–15 days; the scanty information available indicates that both sexes build, incubate and care for the young. In *Culicicapa* nothing appears to be recorded save that the female alone builds the nest. S.A.P.

FASCIA: a sheath of connective tissue.

FASTING: see FEEDING HABITS; PENGUIN; TORPIDITY.

FAT DEPOSITION: see METABOLISM; MIGRATION.

FAULT BAR: see PLUMAGE, ABNORMAL.

FAUNA: the total animal life of an area, the vegetable life being the 'flora' and the two together being sometimes known as the 'biota'; the 'avifauna' is the part of the fauna consisting of birds. Faunistic studies are those that deal with the occurrence, prevalence, and distribution of the different forms of birds or other animals in particular geographical areas (see DISTRIBUTION, GEOGRAPHICAL).

FAUNAL REGION: see DISTRIBUTION, GEOGRAPHICAL.

FAUNISTICS: the study of faunas, especially their composition, origin and history, and their relationships one with another.

FEAR: see BEHAVIOUR, DEVELOPMENT OF; PANIC; TAMENESS.

FEATHER: the component unit of the plumage and a structure outstandingly and uniquely characteristic of birds as a class (see also PLUMAGE; MOULT).

Development. The surface of the body of any vertebrate animal is covered by a skin, a highly organized structure consisting of two separate parts (see SKIN): a thick underlying dermis with muscles, blood vessels, and nerves in it, and an overlying epidermis. The epidermis consists, in the adult, of many layers of cells the deepest of which may be distinguished as a single layer of active cells lying upon a basement membrane which is firmly attached to the dermis. Each cell of this layer at intervals divides into two, and the products of these divisions lie, as a rule but not always, one outside the other. The cell remaining in the basal layer divides again, and so also may the one pushed outwards. In this way the products of these divisions generally find themselves progressively farther and farther from the underlying dermis and therefore from their only source of nourishment and of oxygen. Thus they die off. As the cells die they become filled with a horny substance called KERATIN. A feather is simply an astonishingly elaborate and specialized product of the epidermis of a bird, and it is made of practically nothing but keratin.

At about the fifth day of incubation the embryo of a fowl may be seen to have rows of pimples, in well-marked patterns, on its surface. Each pimple is a consequence of an increase in the rate at which epidermal cells are multiplying at that particular site. The dermis here also proliferates and there is thus a finger of dermis pushed out, covered by a thimble of epidermis, as is shown in Fig. 1. This is a feather germ. (See also DEVELOPMENT, EMBRYONIC).

Further localized growth now serves to push this feather germ down into a deepening depression. While this is happening, the feather germ continues to lengthen greatly, so that, instead of a pimple on the surface of the embryo, there is now a pit with a long cylinder projecting out of the mouth of a follicle (Fig. 2). The cylinder slopes backwards, so that obverse ('dorsal') and reverse ('ventral') sides can be distinguished.

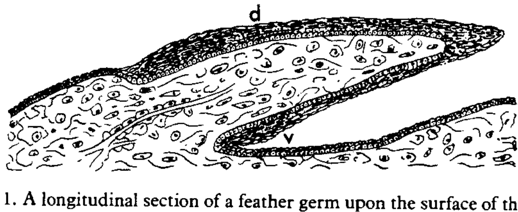

Fig. 1. A longitudinal section of a feather germ upon the surface of the skin of a developing chick (*Gallus*) at about 10 days incubation. A thimble of epidermis can be seen to enclose a finger of dermis. (*P.G. 'Espinasse*).
d. dorsal (obverse); v. ventral (reverse).

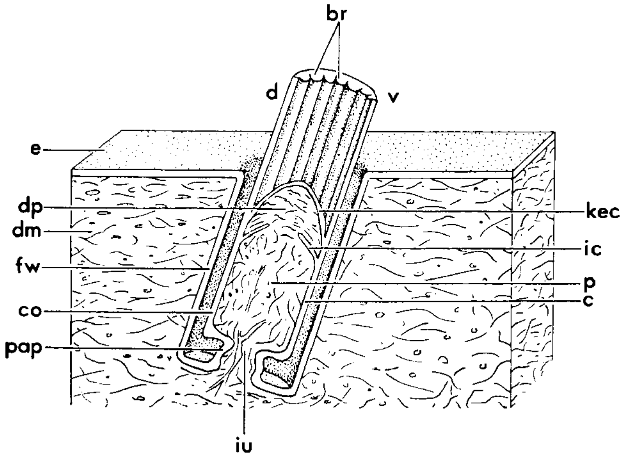

Fig. 2. A diagrammatic representation of a block cut from the skin of a bird during its development. The plane of the section nearest the observer cuts a developing feather in half longitudinally. The half of the feather remaining in the block is alone shown. The barb-ridges on the near aspect of the cylinder can be clearly distinguished. (*P.G. 'Espinasse*).
br. barb-ridges; **c.** calamus or quill; **co.** collar; **d.** dorsal; **dm.** dermis; **dp.** dead pulp; **e.** epidermis; **fw.** follicle wall; **ic.** incipient cap; **iu.** inferior umbilicus; **kec.** keratinised epidermal cap; **p.** pulp; **pap.** papilla; **v.** ventral.

A 'napkin-ring' of epidermis towards the lower end of the cylinder is distinguished and named the 'collar'. Beneath this again is the persistent papilla. It is within the collar that nearly all the growth leading to the production of a feather takes place. By this growth, which in an adult bird may continue at a high rate for weeks, the cylinder of epidermis is lengthened. Within the cylinder is the dermal pulp with nerves and blood vessels, which supply the nutrients.

The cells forming the outside of the cylinder, when they keratinize, are joined together to constitute a resistant sheath. This sheath is destined later to split and to be lost, so freeing everything it had been holding together.

The inner aspect of the lengthening cylinder becomes longitudinally pleated or ridged (Fig. 2). These ridges contain the developing barbs. Within the substance of the barb-ridges many cells fall away individually and take no part in the structure of the finished feather, but some become firmly joined to each other and form the rami of the barbs. Other cells become joined in columns, each column sloping downwards towards its barb, to which proximally it becomes firmly fixed. Two series of such columns are differentiated in each barb-ridge, and these columns of single cells will be the barbules when they have become fully keratinized.

In the developing contour feather the barb-ridges each take a half-spiral course. Each pair of barb-ridges is initiated ventrally, and one of them proceeds, as the cylinder lengthens, to be differentiated downwards and around the cylinder towards the dorsum on one side of the cylinder while its mate goes round the other side. The two fail to meet dorsally, and the strip down the cylinder dorsally thus left intact is the site of the developing rachis (Fig. 3).

Contour feathers. Different types of feathers can be recognized, of which the contour feather quantitatively is the most important and probably the fundamental type (see ARCHAEOPTERYX).

Contour feathers consist of a shaft on each side of which a long series of sidebranches (barbs) are attached (Fig. 4). A barb consists of a ramus which bears two rows of sidebranches, the barbules. The part of the shaft which bears the barbs is the rachis and it consists of an outer layer of solid cells (the cortex) and a core of air-filled cells (the medulla, pith). The lower part of the shaft, without attaching barbs, is known as the calamus. This is a hollow cylinder, the lower part of which sticks into the feather follicle. At both ends there is an opening, the inferior and superior umbilicus. The ramus also consists of cortex and medulla, while the barbules are solid.

A barbule is divided into a lamella-shaped base and a pennulum. The latter is usually as long as the base, tapers, and ends as the pointed tip of the barbule. In some cases the pennulum is thread-like and much longer than the base. Those barbules attaching to the side of the ramus closest to the feather tip are termed distal, those on the other side proximal. Two neighbouring barbs are locked together when the hooklets present on the distal barbules catch upon the obverse edges of the proximal barbules (Fig. 5). This interlocking system, together with the fact that rami and barbules all lie in the same plane, is what characterizes the pennaceous feather structure, of which the continuous-looking vanes (vexillum) of a typical contour feather, e.g. a flight feather, are constructed. The vanes are light, strong and almost air-tight and represent the basic structure enabling birds to fly.

In addition to this, the pennaceous part of a contour feather, a smaller or larger plumulaceous (downy) part is also present basally (Fig. 4).

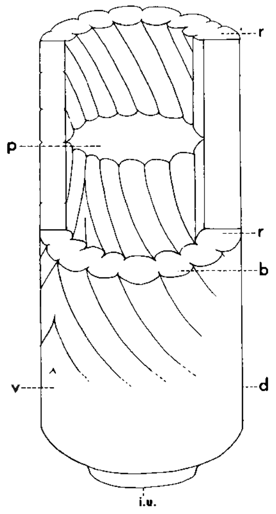

Fig. 3. A perspective view of a model of a developing feather. The barb-ridges instead of running straight up and down as in the first down feather can be seen in this to follow a half spiral course, so that each barb-ridge runs into a developing rachis dorsally, thus giving the form of a normal feather. (*P.G. 'Espinasse. Reproduced by permission of the Zoological Society of London*).

The variation in contour feathers is almost endless. The upper tail coverts of the Peacock *Pavo cristatus* are exceptional, not only because of the 'eyes' but also because of their shape and length (*c.* 1.5 m). The central tail feathers of the Great Argus Pheasant *Argusianus argus* measure *c.* 1.2 m and the longest primaries in larger vultures may measure 0.7–0.8 m.

The smallest contour feathers are found on the eyelids. In the smallest bird species, the hummingbird *Calypte helenae*, they measure *c.* 0.4 mm, but even in the domestic hen they are only *c.* 1 mm long.

Contour feathers of bizarre shape are e.g. the elongated primaries of some nightjars (Caprimulgidae) (Rutschke 1965) and the very long flag-bearing head feathers of the King of Saxony Bird-of-Paradise *Pteridophora alberti* (Lüdicke 1969).

Many modifications of feathers are related to colour. In most feathers the ramus is laterally compressed, usually pear-shaped in cross-section, and of the lamella-shaped barbules little more than the edges are visible. Where the feathers are structurally coloured, this normal situation may be markedly changed (see photos).

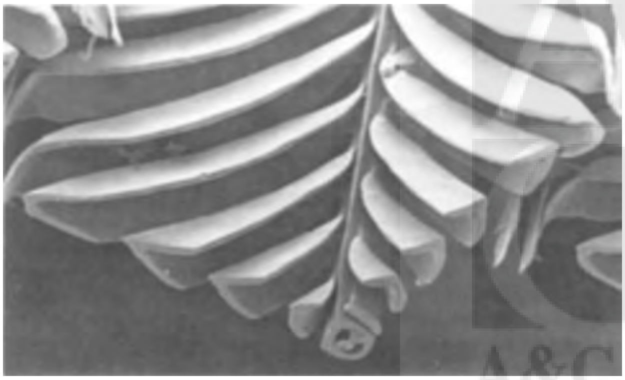

Photo (a). In iridescent feathers the barbules, which contain the colour-producing structure, are enlarged and their upper parts expanded. Together the barbule cells form an almost mirror-like surface which is responsible for the brilliancy of the structural colour. Scanning electron microscopical picture of a small part of a green feather of a hummingbird *Chlorestes notatus*.

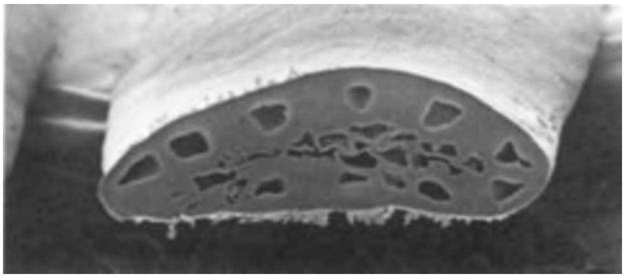

Photo (b). Where the colour-producing structure resides in the ramus, the barbules may be absent altogether, and the ramus is much expanded laterally. The ramus has been cut crosswise, so that the interior of the cells can be seen. The cells appear solid, but do in fact contain minute air-filled cavities which are of importance for the production of the turquoise colour. The large holes (one per cell) are formed when the cells dry up during feather formation. The irregular holes in the centre are medullary cells, which are empty except for some melanin granules. Scanning electron microscopical picture of a single ramus of a turquoise small wing covert of *Pitta sordida novaeguineae*. (*Photos: Jan Dyck & Bent Rasmussen*)

Down. Down feathers have a loose, fluffy texture, instead of the firm, closely-knit texture characteristic of contour feathers. This is in particular due to the structure of the barbules, which are more or less circular in cross-section, so that they may bend in all directions. Where two adjoining barbule cells meet there are usually some, e.g. 4, short projections (prongs). Some prongs of one barbule may become entangled with some spines on another nearby barbule. When this happens in several places a stabilized three-dimensional network is formed, which is the basic feature of the downy structure and the one which gives it its insulative properties.

The rami of down feathers are more flexible than those of contour feathers and they are sometimes branched; factors which also contribute to the down's fluffy structure. Natal down is mostly more simply built than the down of later plumages. A shaft is usually lacking so that the barbs are attached to the upper rim of the calamus (Fig. 6), the barb tips lack barbules and the barbules are shorter than in adult down.

The microscopic structure of down barbules varies considerably in different groups of birds, probably more so than that of pennaceous barbules. This variation may be used for the identification of feather remains.

Semiplumes. Down feathers, whether with a shaft or not, are usually short compared to contour feathers. But some feathers are long like contour feathers and have a downy structure throughout. They are termed semiplumes and are defined as downy feathers in which the longest barb is shorter than the shaft. There is a continuous intergradation between down, semiplumes and contour feathers, with a larger or smaller downy portion.

Powder down. These are feathers which produce a fine powder. In e.g. pigeons the powder grains are derived from cells that surround the future barbules in a growing feather. In other birds, e.g. herons (Ardeidae), parts of the feathers themselves also disintegrate to produce powder. At its most specialized, the powder feather consists of little more than barbules, attached by strips to the calamus, and clogged with powder. Possibly they grow continuously. The particles have an irregular shape, are colourless and *c.* 1 μm (1/1,000 mm) in diameter.

Bristles. These are best described as contour feathers which lack barbs in their distal portion, so that the shaft becomes the dominating feature. In an extreme case, e.g. the rictal bristles of the Band-winged Nightjar *Caprimulgus longirostris*, the bristle consists of nothing but shaft and calamus. The shaft tapers distally to a fine point, and this portion of the shaft in nearly all bristles is dark brown or black (Stettenheim 1974). It is probable that the melanin pigment responsible for the colour enhances the stiffness and hardness of the tip.

The bristles of passerines are mostly 2–8 mm long, with the longest ones on the rictus. A feather type intermediate between contour feather and bristle is the semibristle.

Filoplumes. These constitute the most aberrant feather type. If a domestic pigeon is plucked, the filoplumes will remain and can be observed as very thin and hair-like structures. Filoplumes are always situated beside other feathers, never by themselves. They may be as long as their host feather, but are much more simply built.

A filoplume consists of a calamus, a long, thin shaft and, at the tip, a short tuft of barbs (sometimes a few barbs are present also lower down on the shaft).

It has been suggested that filoplumes are degenerate structures without function, but it is now considered probable that their function is as sensors of the movements of the larger feathers. If the position of a primary is changed by the wind, the primary may displace the tips of some of its filoplumes, which in turn transmit the displacement to their

ca. calamus; **r.** rachis; **su.** superior umbilicus.

bases where nerve endings register it. Such a function is supported by the fact that the shaft of a filoplume is thicker at the tip than at the base and that remiges and rectrices usually have more filoplumes (8–12) than have body feathers, which make simpler movements.

Feather muscles. Feathers can be elevated, depressed or rotated by feather muscles (*musculi pennati*). These are unstriated (see MUSCULATURE) and are attached to the outer surface of the feather follicle wall by elastic tendons. In many regions feather muscles join together neighbouring follicles so that regular patterns of feather muscles arise.

FEATHERS, NUMBER OF: although the numbers of typical contour feathers, plumulaceous TELEOPTILES and true down feathers on adult individuals of various bird species have been determined, virtually nothing is known about the number of filoplumes which are present. The total number of NEOSSOPTILES on newly-hatched passerine nestlings has also received attention. However, since passerine neossoptiles may (at least in some species) be degenerating structures without any embryonic or postnatal functions, this account is restricted to the plumage of adult birds. (See also FEATHER; PLUMAGE; PTERYLOSIS.)

Feather counts. In general, large birds have more feathers than small birds but this correlation with body size is by no means absolute. Feather counts published by different workers are not all directly comparable, since the totals given by some authors are for contour feathers only. The lowest number of contour feathers recorded to date is 940 for a Ruby-throated Hummingbird *Archilochus colubris*; and the highest is 25,216 for a Whistling Swan *Cygnus columbianus*. Eighty per cent of the feathers were found on the head and neck of the swan. Examples of feather counts for single specimens of other species are: Pied-billed Grebe *Podilymbus podiceps*—15,016; Green-winged Teal *Anas crecca*—11,450; Clapper Rail *Rallus longirostris*—7,224; American Coot *Fulica americana*—13,913; Least Sandpiper *Calidris minutilla*—4,480; Bald Eagle *Haliaetus leucocephalus*—7,182; Barred Owl *Strix varia*—9,206; Common Nighthawk *Chordeiles minor*—3,332; Red-bellied Woodpecker *Melanerpes carolinus*—3,665; Yellow-fronted Tinker Barbet *Pogoniulus chrysoconus*—2,210; Laughing Dove *Streptopelia senegalensis*—4,207; Brown-headed Cowbird *Molothrus ater*—4,297; Blue Jay *Cyanocitta cristata*—3,773; Eastern Meadowlark *Sturnella magna*—4,607; Green White-eye *Zosterops pallidus*—3,307. What limited information there is on distribution of feathers on the body suggests that in a land bird approximately one third are on the head. Future feather counts should record numbers of feathers by pterylae. This might contribute to better understanding of the function of feathers.

Individual variation. No marked differences in feather numbers occur between individuals of the same species and sex living in the same area at the same season; nor has significant sexual variation in numbers yet been recorded. However, in the species examined to date, there have not been marked differences in plumage complexity or body size between male and female, for which differing feather totals might be expected.

Seasonal variation. No thorough investigation of the total number of feathers comprising the plumage of individuals of a species at different seasons has yet been undertaken. Contour feather counts made on birds of the same species at different times of the year in the United States at Ann Arbor, Michigan and at Washington D.C., respectively, revealed a definite seasonal variation in the number of feathers present, more being found on a bird during the winter, when protection against cold would be required, than during the summer. For example, a loss from winter to summer of 11.5% of the total number of contour feathers was recorded for the House Sparrow *Passer domesticus* and the figures showed a progressive seasonal change. The gradual loss of feathers during the breeding season could be an adaptation for thinning of the bird's insulating layer in warm weather.

A small series of Laughing Doves from Pretoria, South Africa, was examined but no seasonal variation in feather number was detected. Further research is needed in order to determine whether the feathers of various species living in an equable climate remain relatively more constant in number all the year round than do the feathers of those birds inhabiting regions with marked seasonal changes in temperature.

FEEDING HABITS: behaviour exhibited in obtaining or utilizing food (see also FOOD SELECTION). Few species of birds are so much specialists as to be limited to one prey or to show a distribution coincident with that of a single food item; the Everglade or Snail Kite *Rostrhamus sociabilis* lives entirely on gastropods of the genus *Pomacea*, and the distribution of the Limpkin *Aramus guarauna* in the south-eastern United States is coincident with that of the same molluscs. The breeding haunts of the Slender-billed Nutcracker *Nucifraga c. caryocatactes* are largely defined by the occurrence of the 'cedar' *Pinus cembra* (see FOOD STORING). Some species are, in parts of their range, so dependent upon one out of many possible foods that the lack of that prey may inhibit breeding or compel migration; this is the case with the Snowy Owl *Nyctea scandiaca* and the Long-tailed Skua *Stercorarius longicauda* in lemming (*Lemmus*) areas. But many groups—notably the crows and the gulls—can only be described as omnivorous, perhaps having preferences but able to subsist upon a remarkable variety of foods. In some species there is a marked change in diet with age—Partridges *Perdix perdix* and other seed-eaters are almost entirely insectivorous when young, though the adult birds are largely vegetarian. In the estrildid finch *Poephila guttata* the two sexes have been shown to have different food preferences; in the Sparrowhawk *Accipiter nisus* the females kill larger preys than do the more lightly built males; and in the extinct Huia *Heteralocha acutirostris* the marked difference in bill structure was correlated with a difference between the feeding habits of male and female (see BILL; WATTLEBIRDS (2)).

The feeding habits of any species may be divided into two components—the general dietary and hunting methods of the genus, family or order and the characteristic specific habits or preferences that give at all times a measure of ecological isolation by ethological means, and enable more than one closely related species to live within a single habitat (see ECOLOGY). The tits, with varied preferences for hunting at different heights, in different trees and in different parts of those trees, provide a notable example of specific distinctions within a genus. These ethological isolating mechanisms have not necessarily any anatomical basis; there is nothing structural to indicate that the Song Thrush *Turdus philomelos* has the innate capacity to crack open the shells of snails and that the Blackbird *Turdus merula* has not.

Methods of obtaining food. Birds have exploited all that grows or moves upon the surface of the earth or in the upper layers of its waters. The fossorial habit is the only feeding method not represented among birds, although the snow burrows of arctic grouse might be cited as an exception to this statement. Many short-billed species, notably among the Galliformes, will delve a little below the surface of the ground, with bill or feet or both, to obtain prey; longer-billed birds, notably among the Charadrii, probe in earth or sand or mud. The Starling *Sturnus vulgaris* thrusts the closed beak into the turf and then opens the mandibles, peering into the cavity so formed. Fallen leaves, moss and litter are tossed aside by many birds to reveal hidden morsels, and between tide-marks the Turnstone *Arenaria interpres* lives up to its name.

Common Sandpiper *Actitis hypoleucos* extracting ragworm *Nereis diversicolor*. (*Photo: J.B. & S. Bottomley*).

Growing herbage and the leaves of trees are cropped by some pigeons, gallinaceous birds (Galliformes) and geese (*Anser* etc.), and a parrot, the Kakapo *Strigops habroptilus*, is said to 'graze like a rabbit'; but in general birds depend more upon fruits, nuts and seeds—and in hummingbirds and sunbirds, so far as they may be regarded as vegetarian, upon nectar—than upon foliage. The kernels of armoured fruiting bodies are reached by bills adapted for crushing (Hawfinches *Coccothraustes coccothraustes*) or shearing (macaws Psittacinae) or by the crossed tips of the highly specialized bills of Crossbills *Loxia* spp., which first fray and then probe between the scales of fir-cones. The large, light bills of toucans enable these relatively heavy birds to pluck fruits without performing gymnastic feats or taking wing.

Just as stout or arched bills usually bespeak an herbivorous habit, long and light bills can generally be correlated with a diet wherein arthropods, annelids and other invertebrates predominate. The wide, lamellate bills of flamingos and of some surface-feeding ducks provide filter-feeding mechanisms for very minute food particles.

In the owls and the diurnal birds of prey (Falconiformes and Accipitriformes) the taloned feet are used to seize and often to kill the prey; if the formidable grip or lacerating impact be not sufficient to give the coup-de-grâce, the beak comes into action, usually attacking the base of the victim's skull. The long-winged falcons (Falconidae) rely upon speed

Broad-tailed Hummingbird *Selasphorus platycercus* male about to visit flower. Note protruding tongue. (*Photo: L. Rue Jr.*).

to secure their prey; the owls, harriers (Circinae) and round-winged hawks (Accipitrinae) depend more upon surprise. The eagles (also Accipitrinae) show a great variety of hunting methods, but usually capture their prey upon the ground. The falcons, which strike their prey in mid-air, will often kill birds larger than themselves; but in general the birds of prey, with their relatively fragile wing feathers, do not risk the rough and tumble with large victims that is so often undertaken by hunting mammals. The birds of prey, the tits (Paridae), the crows (Corvidae) and some 'minor raptors' hold their food with the feet while dismembering it; shrikes may hold prey with the feet or rend it after impalement upon a thorn. The parrots and—surprisingly, the Purple Gallinule *Porphyrio porphyrio* use one foot very much as a 'hand' to hold up morsels to be bitten.

The herons and all the fish-eaters with the exceptions of the Osprey *Pandion haliaetus* and the fishing eagles (*Haliaeetus* etc.) use the beak alone to secure their prey; but the Reef Heron *Egretta gularis* will extend a foot to stir a tuft of weed and then stab at the bolting fishes. The Black Heron *Egretta ardesiaca* when fishing converts itself into a 'peripatetic umbrella' by bringing the fully spread wings forward and downwards until the tips of the remiges touch the water; it is suggested that small fish take refuge in the shade, and so are caught.

Turnstone *Arenaria interpres* scavenging mussel *Mytilus*. (*Photo: J.B. & S. Bottomley*).

The shallows of the world's waters are worked by a great variety of methods—wading with beak or head submerged to skim or sieve or snatch, or walking wholly submerged along the bottom, aided by the pressure of the current (and sometimes by the action of the wings) as is the habit of the dippers. The phalaropes and the smaller petrels, swimming or flitting with paddling feet, feed largely upon organisms from the very surface of the sea. Swimming under water with wings or feet may follow a leap clear from the surface, a brisk downward tilt or a submersion so gradual that it can scarcely be described as a 'dive'. Birds that depend upon the impetus of a headlong plunge to carry them below the surface may dive from forward flight, after a hover or from a perch (see SWIMMING AND DIVING). The skimmers fish entirely upon the wing, ploughing the surface with the blade-like lower mandible and snapping down upon any fish that comes in contact with it; skimmers are said to work back over their tracks, seeking preys that have been attracted by the disturbance of the surface at the first passage.

In the air swallows, swifts and nightjars make many successive captures in the course of sustained flight, while the flycatchers (Muscicapinae) hawk from look-out posts for single victims. Both methods of aerial feeding are used by the bee-eaters. The hummingbirds are the outstanding exponents of stationary hovering while feeding, but many species of birds hover with more or less skill to obtain nectar, insects or fruit. Many small insectivores 'glean' their prey from leaves and twigs.

Among the woodpeckers there is a startling variety of diet and habit—sap-feeding of the sapsuckers *Sphyrapicus* spp., the ant-eating (with the aid of a long and mobile tongue) of the ground-feeding species, and the splitting of hard nuts or the demolition of fir-cones by the pied woodpeckers *Dendrocopos* spp. The kingfishers are remarkable for the inclusion of a number of tropical species which live far from water and feed entirely upon insects and other small terrestrial animals. Some food preferences and habits would never be suspected upon anatomical grounds—the aquatic hunting of the dippers, the fondness of the Palm-nut Vulture *Gypohierax angolensis* for the fruit of *Elaeis guineensis*, the berry eating of the Curlew *Numenius arquata* and the liking of the Turnstone *Arenaria interpres* for carrion.

Bewick's Swans *Cygnus columbianus* upending to feed, and Pochards *Aythya ferina*. (*Photo: A. Christiansen*).

Preparation of food. The preparation of prey ranges from bolting the victim whole to a careful plucking (often at some favourite stance) or rejection of some part—the heads of snakes by the Secretary-bird *Sagittarius serpentarius*, the bills of Starlings by Sparrowhawks, the albumen gland of the snail *Helix aspersa* by the Song Thrush and the stings of wasps by shrikes. Slugs are wiped to and fro in grass by thrushes or carried to dusty ground to be cleared of the slime which may be toxic; there is a record of a Mistle Thrush *Turdus viscivorus* treating a hairy caterpillar in the same manner.

Some of the straight-billed scavengers, such as the gulls and storks, depend upon a bird with a hooked beak or a mammalian carnivore to open up a carcass. Food invested in a hard shell is usually opened up by strength of beak, as is the habit of the Oystercatcher *Haematopus ostralegus*, which may also take limpets by surprise. The method of breaking open snails on anvil stones has been evolved at least twice—by the Song Thrush and by a bowerbird *Scenopoeetes dentirostris*. The

Daurian Starling *Sturnus sturninus* male feeding on nectar. (*Photo: M.A. Omelko*).

Everglade or Snail Kite extracts the body of *Pomacea* by waiting until the gastropod is partially emerged and then crippling it with a stab of the sharp, slender beak—apparently into a nerve ganglion, showing an innate 'anatomical knowledge' more reminiscent of a hunting wasp than of a bird! That tortoises are dropped by the Lammergeier *Gypaetus barbatus* has been known since classical times, but it has been suggested that the victim may not be so much deliberately dropped as let fall during an effort to prize it open in the air. The dropping of bones (presumably for the marrow) has been confirmed in this species. Gulls and crows drop crustaceans, echinoderms and molluscs to break them open; often it seems a matter of chance whether the prey falls on hard or soft ground. The Pacific Gull *Larus ('Gabianus') pacificus* is credited, however, with carrying gastropods of the genus *Turbo* to selected dropping places.

Blue-cheeked Bee-eater *Merops superciliosus* with dragonfly. (*Photo: A.A. Karavaev*).

The employment of an anvil whereon prey is hammered or dropped may, perhaps, be regarded as the use of a 'tool' as may the wedging of nuts into crevices in bark by the Great Spotted Woodpecker *Dendrocopos major* and the impaling of victims by shrikes. A Grey Heron *Ardea cinerea* which has caught a large eel will quickly carry it some distance back from the water's edge to dispatch it in a place whence escape is difficult. There are two truly remarkable instances of the use of a tool in obtaining food. The Woodpecker Finch *Camarhynchus pallidus* of the Galapagos probes with a thorn into crevices in the bark of trees and thereby evicts insects which are beyond the reach of the somewhat short bill. Egyptian Vultures *Neophron percnopterus* break open the eggs of ostriches by throwing stones at them (see TOOLS, USE OF). Smaller eggs are picked up and dashed on the ground. In both Africa and America the Green-backed Heron *Butorides striatus* has been observed to use a white bait to attract small fishes.

Both corvids and ducks will carry hard food to water to soften it; and the Redshank *Tringa totanus* may carry large, muddy preys to the tide edge to wash them.

Frequency. The frequency of feeding activities range from the almost uninterrupted hunting of small passerines during daylight hours, through the one meal a day of the Red Grouse *Lagopus lagopus scoticus* and the one meal in 48 hours of Great Black-backed Gulls *Larus marinus* during the East Anglian herring fishery, to the fantastic fast two months long by the male Emperor Penguin *Aptenodytes forsteri*. The meal times of birds of prey that can obtain a day's supply in one or two kills often show a clock-like regularity.

American Robin *Turdus migratorius* swallowing mulberry. The seeds will later be dispersed. (*Photo: E.J. Hosking*).

Blackbirds in autumn and Starlings in spring seek earthworms early in the morning and other foods later in the day. Night and day dictate the major rhythm of hunting routine, but in some herons and ducks and many wading birds (Charadriiformes) the ebb and flow of the tide has an important influence on feeding routine. In feeding behaviour two components may be detected—the drive to forage and actual appetite. Hunger may be appeased before the drive to hunt is exhausted: when this happens a bird will capture and at once abandon prey. An unsatisfied foraging drive may be responsible for 'food storing' in many species—Jays *Garrulus glandarius*, woodpeckers, tits and shrikes. Very little is known of the frequency with which hidden food is recovered by many species, but in the Nutcracker the accumulation of stored food is of real biological importance. Nutcrackers rely upon hazel nuts gathered in the autumn for the bulk of their winter food and of supplies for the young in the following spring. The Acorn Woodpecker *Melanerpes formicivorus* drills long series of holes and stores them with acorns. 'Paper tearing. by tits in the autumn is probably an expression of frustrated or misdirected foraging activity as is the placing of a pebble by Acorn Woodpeckers in a hole for which no acorn is available.

Interrelations. The robbing of birds of other species of their prey

Fulmars *Fulmarus glacialis* and gulls *Larus* scavenging at sea. (*Photo: F. Pölking*).

(PIRACY or kleptoparasitism) is the regular custom of the skuas and frigatebirds. Black-headed Gulls *Larus ridibundus* frequently harry Lapwings *Vanellus vanellus* on pasture or plough-land, and on the coast may so persecute Sandwich Terns *Sterna sandvicensis* that the terns are able to fledge no young at all. Most species of birds will at times attempt to rob others of their food. There is an inter-specific order of dominance among the tits, though as between Great Tits *Parus major* and Blue Tits *P. caeruleus* much depends upon the élan of the displacing attack. In the thrushes the Song Thrush is always subordinate to the Blackbird: in one April in Suffolk a group of Song Thrushes lost 9% of their worm harvest to the heavier species.

It has been suggested that in a mixed feeding flock each bird acts unwittingly as a beater for the other members. Parties of members of a single species of pelican, or cormorant, will make concerted fishing movements, hunting strung out in line across a creek or shoal or (pelicans) dipping their heads in unison while swimming in compact formation.

Commensalism is most often practised by the use of some larger species as 'beaters' for the disturbance of insects or other small prey—horses, cattle, large game of many kinds and even railway trains are thus exploited. The Cattle Egret *Bubulcus ibis* is an outstanding example of this behaviour, but there are many other—Robins *Erithacus rubecula* are commensals of wild boars, moles and man. The use of foraging troops of monkeys as 'beaters' has been described for such different birds as hornbills in Africa, drongos in Asia, fairy-bluebirds in the Philippines and trogons in Panama. Off the south coasts of Arabia the driving of 'sardines' into dense shoals by tunny and sharks is the signal for the assembly of a company of screaming terns to swoop and plunge in the turmoil of spray and fish; and all over the world fishing boats are followed by gulls and other snappers-up of unconsidered trifles. Indeed, it has been advanced that the refuse of the fishing and whaling industries has been responsible for the great increase of the Fulmar *Fulmarus glacialis* within the last century. The strange relationship between honeyguides and ratels *Mellivora capensis* or man is symbiotic rather than commensal (see HONEYGUIDE). For the association between some birds and crocodiles, see CROCODILE-BIRD.

Commensalisms between birds are less common than these relations between birds and members of other classes. The most delightful avian example is that of Carmine Bee-eaters *Merops nubicus* riding on the backs of Abdim's Storks *Sphenorhynchus abdimii* and Kori Bustards *Ardeotis kori* and swooping in pursuit of the insects disturbed by their mounts. Chaffinches *Fringilla coelebs* will eat the seeds of crab-apples hacked open by Fieldfares *Turdus pilaris*, and House Sparrows *Passer domesticus* collect the legs deliberately knocked off cockchafers by thrushes.

The only birds to show parasitic feeding habits in the true sense of the words are one of DARWIN'S FINCHES, *Geospiza difficilis*, which, on two Galapagos islands only, take blood from the developing feathers of moulting boobies, and the OXPECKERS *Buphagus* spp., which take blood and perhaps tissue from wounds on large mammals (but feed primarily on the ticks which initially cause some of these sores).

Methods of study. Until comparatively recently the usual and, indeed, almost the only method of studying bird foods was the examination of gut contents. The value of the technique remains as great as ever, but it has been supplemented by other methods that are especially necessary when the rarity of a species forbids the collection of adequate samples; in the Hawaiian Goose or Nene *Branta sandvicensis* for example, much has been learned from the examination of droppings. The examination of pellets has long been of use in the study of hawks and owls, but is of very limited value in the investigation of such birds as herons which have very great powers of digestion (see PELLET). Feathers, fur and bones at plucking places have yielded much data. Of recent years photography has provided valuable results, both qualitative and quantitative. Much can be learned from the direct observation of such easily identified foods as wild fruits, seeds and carrion.

The food of nestling birds has been studied by direct observation from hides; by retrieving samples from the gullets of young birds fitted with collars tight enough to prevent the swallowing of meals; by inducing young herons, cormorants and hawks to disgorge by fright or massage; and by persuading parent birds of hole-nesting species to feed an 'artificial nestling' (see also BEHAVIOUR, DEVELOPMENT OF).

FEEDING NICHE: see ECOLOGY; NICHE.

FEEDING OF YOUNG: see GROWTH; PARENTAL CARE.

FEMUR: the 'thigh-bone' (see LEG; SKELETEON, POST-CRANIAL).

FERAL: literally 'wild', but applied only to populations of domesticated species that have reverted to a free existence.

FERAL PIGEON: a bird descended from domestic stock of *Columba livia* but living in a wild state. These birds are common both in towns and in the countryside and may be called 'domestic', 'London' or 'town' pigeons as well as 'feral' pigeons.

FERNBIRD: *Bowdleria punctata* (see WARBLER (1)).

FERN-WREN: the Australian warbler *Oreoscopus gutturalis* (see WARBLER, AUSTRALIAN).

FERTILITY: see HYBRID; ISOLATING MECHANISM.

FERTILIZATION: the union of the male gamete (spermatozoon, or spermatozoid) with the female gamete (ovum), taking place in the upper part of the oviduct following copulation (see COPULATION; DEVELOPMENT, EMBRYONIC; EGG; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

FIBULA: a bone of the leg (see LEG; SKELETON, POST-CRANIAL).

FIELD CHARACTER: a distinctive feature which enables a particular species to be identified in the field.

FIELDFARE: *Turdus pilaris* (see THRUSH).

FIELD GUIDE: see Regional articles.

FIELD-TYRANT: substantive name of the ground-living tyrant-flycatcher *Muscigralla brevicauda* of the arid west coast of South America (see FLYCATCHER (2)).

FIGBIRD: substantive name of *Sphecotheres* spp. (see ORIOLE (1)). See also BECCAFICO.

FIGHTING: see under AGGRESSION; DOMINANCE (2); TERRITORY; also COCK-FIGHTING. See photo AGGRESSION.

FILOPLUME: a type of feather resembling a fine, thin hair (see FEATHER; PLUMAGE).

FILTRATION FEEDING; see FLAMINGO.

FINCH: term used for the family Fringillidae (Passeriformes, suborder Oscines), or more generally for any small seed-eating song-bird, with a stout bill. Thus the word has been applied to at least 11 different groups of birds of varying degrees of affinity, namely the subfamilies Fringillinae (chaffinches and allies), Carduelinae (goldfinches and allies), Emberizinae (buntings), Thraupinae (tanagers), Geospizinae (Galapagos finches), Cardinalinae (cardinal-grosbeaks), Bubalornithinae (buffalo-weavers), Estrildinae (estrildid or weaver-finches), Viduinae (whydahs), Ploceinae (weavers) and Passerinae (sparrows). All these birds have the same specializations for dealing with hard seeds: stout conical bills, strong skulls, large jaw muscles and powerful gizzards. Yet they differ so much in the other details of their anatomy and their behaviour that they are without doubt derived from several ancestral stocks, providing an example of convergent evolution. Many of these groups are now given the rank of family, and are described elsewhere in this book. This article is concerned with only 2 of these subfamilies, the Fringillinae and the Carduelinae, which are usually grouped to form a single family, the Fringillidae. From now on the word finch will be used only for members of this family. They are distinguished from the various other seed-eating birds by certain details of skull structure, the presence of 9 (instead of 10) large primary feathers in each wing, 12 large tail feathers, and the fact that the hen is responsible for building the cup-shaped nest and for incubating the eggs. Some of these features are shared with other groups; it is the combination of characters that distinguishes the Fringillidae. The family contains a variety of species, ranging between 10 and 100 g in weight, some of them richly coloured and, within the limits imposed by a seed diet, showing great variation in the shape of their beaks, according to the types of seed they eat.

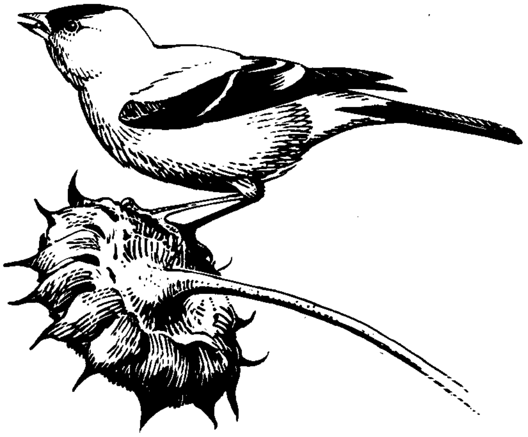
Characteristics. The Fringillinae contains only 3 species, the Chaffinch *Fringilla coelebs* and Brambling *F. montifringilla* of Eurasia, and the Blue Chaffinch *F. teydea* of the Canary Islands. All 3 are of similar shape, about 15 cm long, with fairly long tails, peaked heads, and prominent shoulder patches and wing markings. The Carduelinae contains around 122 species, of which 16 are found in Europe. The smallest ones are about 11 cm long, and the largest about 19 cm; they vary greatly in colour, but generally have prominent wing and tail markings; many species are streaked, especially in juvenile plumage.

Habitat and distribution. Among the Fringillinae, Chaffinches breed in all kinds of woodland, and over much of Europe are one of the most numerous birds, usually comprising between one-fifth and two-fifths of the total woodland bird population. The Brambling replaces the Chaffinch as a breeding bird in the sub-Arctic birchwoods of northern Europe, and also extends across Asia to Kamchatka, migrating south for the winter, and concentrating in areas with beechmast. The Blue Chaffinch is found only on the Canary Islands, and is a rare inhabitant of high altitude pine forests. The Carduelinae are widespread, represented naturally in North and South America, Europe and Africa (except Madagascar) and by introductions in Australasia. These finches occupy a range of habitats from closed forest, through scrubland and savanna, to open tundra, steppe and desert, though no one species is so widespread. In some regions, certain species have successfully colonized man-modified environments, and breed commonly in town parks and gardens, and in farmland. They are thus some of the most familiar birds in western Europe and in eastern North America. Populations of arctic and temperate regions tend to be migratory, and others resident.

Food. The beak of all finches is modified internally for holding and shelling seeds. Each seed is wedged in a special groove at the side of the palate and crushed by raising the lower jaw on to it. The husk is then peeled off with the aid of the tongue and discarded, thus releasing the kernel, which is swallowed. In cardueline finches the bill is also used for extracting seeds from the seed-heads of plants. Species differ in the size of seeds they prefer, and in the types of seed-head they can best exploit, corresponding with differences in the size and shape of their bills, and in the way the bill is used. Hawfinches *Coccothraustes coccothraustes* have big powerful bills for crushing large hard tree-fruits; Goldfinches *Carduelis carduelis* and Siskins *C. spinus* have long tweezer-like bills for probing into thistles and other seed-heads; Bullfinches *Pyrrhula pyrrhula* and Pine Grosbeaks *Pinicola enucleator* have rounded bills adapted for bud eating; while crossbills *Loxia* have crossed mandibles which help them extract seeds from hard closed cones. Moreover, the 4 species of crossbills in

Differences in breeding behaviour between the fringilline and cardueline finches. From Newton 1972.

	Fringillinae	*Carduelinae*
	Chaffinch and Brambling *(Fringilla)*	Goldfinches, siskins, linnets, redpolls, serins, rosefinches and crossbills *(Carduelis, Serinus, Carpodacus, Loxia)*
Food of young	Insects, fed frequently from parent's bill.	Mainly seeds, fed infrequently by regurgitation.
Nesting dispersion	Large territories. Elaborate fighting involving special postures.	Small territories, grouped into colonies.
Food obtained	Within territories, solitarily.	Outside territories, in flocks.
Sequence of behaviour	(1) establishment of territory. (2) pair-formation. (3) selection of nest site.	(1) pair-formation. (2) selection of nest site. (3) establishment of territory.
Type of song	Stereotyped, short, loud and clear.	Less stereotyped, prolonged and less loud.
Sexual behaviour	Inside territory.	Inside and outside territory.
Pair-formation	Sudden, hen attracted by song of cock in territory.	Prolonged, cock approaches hen in flock; courtship involves 'bill-scissoring'.
Courtship feeding	Absent.	Present.
Display flights over breeding area	Absent.	Present.
Incubation	By hen, feeds herself.	By hen, mainly fed by cock.



American Goldfinch *Carduelis tristis*. (*D.A.T.*).

Europe have different sized bills and feed primarily from different cones: the slender-billed Two-barred Crossbill *Loxia leucoptera* eats mainly the small soft cones of larch, the medium-billed Common Crossbill *L. curvirostra* feeds mainly from the medium cones of spruce, and the large heavy-billed Parrot Crossbill *L. pytyopsittacus* and Scottish Crossbill *L. scotica* mainly from large hard cones of pine. The various finches also differ in the proportion of food they obtain directly from vegetation, as opposed to the ground, and in the extent to which they use their feet in feeding, both being connected with differences in body weight and leg structure (Newton 1972). The feet are used mainly to clamp seed-heads to a firm perch, while they are worked with the bill.

Although the main food of all finches is seeds, the Fringillinae feed their young entirely on insects (especially caterpillars), while the Carduelinae feed their young either on a mixture of seeds and insects or on seeds alone. The raising of young entirely on a seed diet is comparatively rare among birds, but has been recorded for crossbills, Siskins, Redpolls *Carduelis flammea* and Linnets *C. cannabina*. Also, while the Fringillinae carry insects to their young one or a few at a time in the bill, the Carduelinae carry large quantities of seeds in their gullets and regurgitate them to the young. Some species have special throat pouches for this purpose.

Behaviour and voice. It is in their dispersion and social behaviour that the fringilline and cardueline finches differ most markedly (Table 1). The fringilline finches defend large territories while breeding, and pairs spread themselves fairly evenly through the habitat. The food is obtained from the territory itself, and the young are fed at frequent intervals (say every 5–10 minutes). The carduelines nest solitarily or in loose colonies, within which each pair defends only a small area around its nest; they forage away from the colonies in flocks, wherever food happens to be abundant at the time. They pack large amounts of seeds into their crop, and feed their young at infrequent intervals (say 20–60 minutes).

Chaffinches are noted for their strong melodious songs, which differ slightly from bird to bird, and form local dialects (Thorpe 1961). These arise because young male Chaffinches, taking a territory in their first spring, learn certain elements in their song from their neighbours. Individuals tend to return to the same territories year after year, so that dialects are perpetuated. Each cock, moreover, may have several slightly different songs in his repertoire, usually 2–3, but occasionally up to 6. This singing serves to attract hens and to repel cocks, and is loud, clear and easy to locate. An unmated cock Chaffinch on territory will sing every 7–15 s for most of the day—or 6 times a minute, 360 times an hour and more than 3,300 times in a 12-h day, feeding between times. Once he has found a mate, a cock sings less often, partly because one of the functions of the song has been fulfilled. Among cardueline finches, the song is generally quieter, but in some extremely melodious; it seems to be used as a form of advertisement, but is not restricted to the nesting territory. Many species have special song flights over the breeding areas.

Breeding. Like other birds, finches breed when their food is most plentiful, but this occurs at a different time in different species, according to what they eat. The Chaffinch, which needs caterpillars, has a short breeding season in late spring; while the cardueline finches, which need seeds, have long and varied seasons, in which individual pairs often raise more than one brood. Thus the Greenfinch *Carduelis chloris*, Linnet and Bullfinch, which in Britain eat a variety of seeds, breed for almost the whole growing season, continually changing their diet as different plants come into seed. The European Goldfinch, which likes the seeds of thistles and related plants, breeds later in summer, while the American Goldfinch *C. tristis*, which depends even more on thistles, breeds later still. The crossbills nest in any month, whenever conifer seeds are most available: in larch forests this is mainly in late summer or early autumn, in spruce forests in autumn to winter, and in pine forests in spring. If spruce and pine are available in the same area, breeding can occur continuously for 10 months.

The female is responsible for building the nest, incubating and brooding the young, and during this period is fed on the nest by the male. When the young are feathered and can keep warm, both parents collect food. All species build open, cup-shaped nests, mostly in trees or shrubs, and lay 3–6 eggs, which in most species are whitish with brown spots. Incubation takes up to 2 weeks, and the young then stay in the nest for another 2 weeks or so (longer in crossbills). Predation on eggs and young is often heavy but, in most areas, more than one brood is raised in a season. The young are born naked, but can fly within a few days after leaving the nest.

Moult. After breeding, adult finches undergo a complete moult, and at the same season the juveniles have a partial moult, replacing only the soft body feathers and retaining the large flight and tail feathers for another year.

Captivity. Because of their song, bright colours, engaging habits and simple seed diet, finches have for centuries been kept in cages as pets. Some species breed readily in captivity, and from the wild Serin *Serinus canarias* of the Canary Islands all the various strains of domestic Canary were derived. Certain finches are also important as pests, especially the Bullfinch which eats buds of fruit trees, sometimes devastating orchards and causing a major problem to the industry.

Newton, I. 1972. Finches. London.
Thorpe, W.H. 1961. Bird-song. Cambridge.

FINCH-LARK: substantive name of *Eremopterix* spp. (see LARK).

FINCH, PLUSH-CAPPED: *Catamblyrhynchus diadema*, a species that some authors place in a family of its own, the Catamblyrhynchidae (Passeriformes, suborder Oscines), and others treat as belonging to the Thraupinae (see TANAGER). The allocation is in either event provisional, as not enough is known about the relationships of this peculiar bird. It is found in the Andes of South America, from Venezuela to Bolivia, where it is apparently resident in the humid upper subtropical and temperate zones. It is a finch-like bird *c.* 15 cm long, mostly dark grey above, with black markings on the head, and reddish below. The forepart of the crown carries golden-brown feathers that are erect and stiff to the touch, like plush. The Plush-capped Finch is rarely found far from bamboos, and is apparently specialized for foraging on bamboos; it clings to and works along the stalks actively, adopting tit-like positions, foraging by probing into the axils of leaf whorls. Both insects and vegetable matter are taken. It is possible that the plush-like feathers of the fore-crown are adapted to this method of foraging, being less subject to abrasion, and perhaps also to soaking, than ordinary plumage. The species is usually seen accompanying mixed feeding parties, and its nesting biology is undescribed.

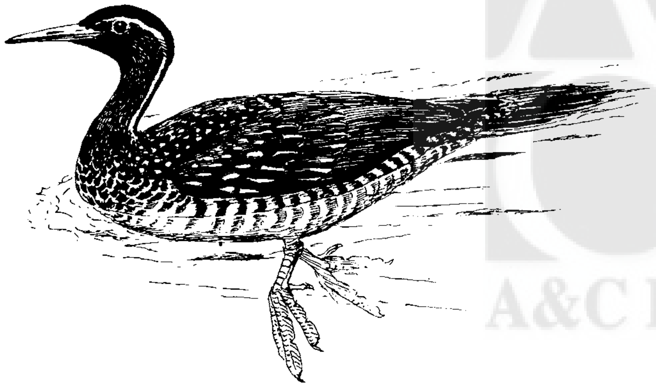
FINCH, SNOW-: substantive name of *Montifringilla* spp. (see SPARROW (1)).

FINCH, WEAVER: see ESTRILDID FINCH.

FINFOOT: (plural ‘finfoots’): name of the 3 species of Heliornithidae (Gruiformes); in the Americas still often called ‘sungrebes’. Confined to the tropics and subtropics, they recall in certain features of their structure, appearance and habits a number of other families of waterfowl, notably the grebes, cormorants, darters, ducks (especially torrent ducks *Merganetta* spp.) and rails (especially coots *Fulica* spp.). Egg-white protein analysis has, however, confirmed the balance of other evidence suggesting they are most nearly allied to the rails.

Among the distinctive anatomical characters of the finfoots are the elongated head and neck, very broadly lobed and brightly coloured toes, and strongly graduated long stiff tail. Of special interest is the possession by all 3 species, though its function has only been observed in the African bird, of a claw on the first digit of each wing. Resembling a fairly large thorn, it is doubtless used to assist the bird to scramble through vegetation in the manner of the HOATZIN. Unlike that species however, finfoots often seem to retain and use the claw when adult, which can perhaps be construed as another sign of their archaic origin.

Characteristics and distribution. The differences between the 3 widely separated species of finfoots are less remarkable than the similarities, indicating that the family is of great antiquity and once had a far wider and more continuous distribution. Smallest and least specialized of the survivors is the American Finfoot *Heliornis fulica*, only about 30 cm in length, and certainly the least known until 1969, when its nest was first found and a breeding population came under study for the next two years. It ranges from southern Mexico to north-eastern Argentina but is probably most common on Guianan rivers. Its predominantly pale olive brown colour is exactly matched in the intermediate-sized Masked Finfoot *Heliopais personata*, *c.* 53 cm in length, which ranges from north-eastern India to Cambodia, peninsular Malaysia and Sumatra. The third and largest species, some 60 cm in length, is the African Finfoot *Podica senegalensis*, which ranges from Senegal to Ethiopia and south to the Cape Province. The brown of its plumage lacks the olive tinge of the other two but in the adult is more or less noticeably washed with peacock green or blue. Suitable habitats within its range are often far apart and climatically distinct, so not surprisingly some 4 races are recognized (mainly on size criteria). All 3 species are sexually dimorphic, the smaller females tending in peak breeding plumage to be more conspicuously marked and brightly coloured.



African Finfoot *Podica senegalensis*. (*C.J.F.C.*).

Due to the difficulties of observation, the function and survival value of several morphological peculiarities of finfoots remain obscure. Thus the stiffer shafts of the tail feathers and a knob on the carpal joint in *Podica* may or may not indicate that it is more prone than the others to scramble through or over thick vegetation. A knife-edged erectile ridge or wattle at the base of the culmen in the male of *Heliopais* presumably has some unknown role in courtship since it disappears at the end of the breeding season. The significance of the 'zebra-striped' toes of *Heliornis*, the pea-green yellow-lobed ones of *Heliopais* and the scarlet of *Podica*'s is quite uncertain, but in the muddy waters which are perhaps most typical in finfoot habitats, display or recognition factors rather than aid to flushing or attracting prey seem likely to be involved.

The finfoot's mastery of its aquatic habitat is shown by its ability to float high in the water or so low that only the head and part of the neck are visible (a feat possibly aided by the absence of the water-repellent flexules at the tip of the breast feathers typical of many waterfowl). But it is also agile on land, preferring when alarmed to bolt into a thicket, body at a 40° angle to the ground, after scuttering coot-like round a bend in the river, rather than take wing, though it can fly swiftly. However, the principal factor in its inconspicuousness is undoubtedly its chosen habitat.

Habitat and food. The habitat is remarkably uniform for all 3 species, despite the great distances separating them. It consists essentially of the margins of perennial waters, large or small, fresh or brackish, placid or, more rarely, fast flowing, provided they are overhung by forest or thick vegetation. In such secluded and inaccessible surroundings single birds, pairs or family parties occupy and defend a length of the relevant bank and adjacent water as their territory, swimming, scuttering or clambering in pursuit of the insects that form the bulk of their food. Well adapted for diving, they have seldom been observed doing so, though fish, unreliably, and more often frogs, crustaceans and molluscs have been noted in stomach contents. Some vegetable matter (leaves and seed), mud and grit are also swallowed.

Movements. Although finfoots generally avoid taking wing, circumstantial evidence suggests that *Heliopais* is at least partly migratory.

Voice. There appear to be some differences in the voices of the 3 species. Although a variety of barking, growling or even booming notes have been recorded, and a soft clucking by birds engaged in nesting activities, *Heliopais* is said to produce a rather high-pitched bubbling, like air being blown through a tube into water. To judge from the recent study of *Heliornis*, it is likely that finfoot calls are mainly associated with agonistic behaviour on the part of males seeking to establish and defend their territories, and with subsequent courtship activities. At other times of year they seem generally very silent, another reason why an unusually interesting family of birds is so often overlooked and still poorly known.

Breeding. The nest, a shallowly indented platform of twigs, 30–40 cm in diameter and lined with leaves, is placed a metre or so above water on a horizontal branch or fallen tree, sometimes on refuse left by floods. Breeding, however, seems more often to coincide with the early part of the rainy season. The eggs, which are remarkably spherical but generally ralline in appearance, are cream-coloured with reddish-brown or purple markings. So far as is known *Heliornis* lays only 2 eggs, *Podica* also lays 2, very rarely 3, but *Heliopais* differs from both by laying 5 eggs, and sometimes as many as 6 or even 7. The incubation periods for *Heliopais* and *Podica* are unknown, except that a nest of *Podica* on the Athi river in Kenya contained 2 eggs which were thought to be on the point of hatching, or even already hatched, 14 days after their discovery. They or the chicks were, however, then taken by a Nile Monitor *Varanus niloticus*. The incubation period for *Heliornis* is only 10–11 days, an exceptionally short period for so large a bird. The naked young chicks are somehow deposited by the male in pockets of skin under his wings. The adjacent flank feathers are fanned to help hold the chick in place though its beak and head can be spotted as the finfoot flies past. This astonishing habit was first reported as long ago as 1830, and was confirmed in the early 1970s. The clutch of only 2 eggs is in keeping with its unique arrangements for transporting the young to safety. H.F.I.E.

FIREBACK: substantive name of some *Lophura* spp. (see PHEASANT).

FIRECREST: *Regulus ignicapillus* (see WARBLER (1)).

FIRECROWN: substantive name of *Sephanoides* spp. (for family see HUMMINGBIRD).

FIRE-EYE: substantive name of *Pyriglena* spp. (see ANTBIRD).

FIREFINCH: substantive name of some waxbills *Estrilda* spp. (see ESTRILDID FINCH).

FIRETAIL: name popularly applied to various red-tailed species in different parts of the world; in Australia one of the recognized names for *Zonaeginthus* spp. (for family see ESTRILDID FINCH).

FIREWOOD-GATHERER: *Anumbius annumbi* (see OVENBIRD (1)).

FISCAL: substantive name, alternatively 'fiscal shrike', of some African *Lanius* spp.; used without qualification for *L. collaris* (see SHRIKE).

FISH-HAWK: American name for the Osprey *Pandion haliaetus* (see HAWK).

FISHING: see FEEDING HABITS.

FISSIPALMATE: term applied to a foot that is discontinuously webbed, with lobes or fringes on the separate toes.

FITNESS: a term used in evolutionary contexts, with a range of meanings from general to more specific. It may simply denote how well designed an organism is for its way of life. This is the meaning of 'fitness' in Spencer's phrase 'the survival of the fittest'. More precisely, in recent evolutionary theory fitness of a specified kind of organism (or genotype) is the ratio of the proportion in one generation to the proportion in the previous generation. This is loosely equivalent to the number of offspring left by an individual of the specified kind. Finally, an individual's *inclusive fitness* is its effect on the reproduction of all of its genetic relatives, including its own production of offspring as only one class among many classes of relatives. To calculate the inclusive fitness of an act, the appropriate coefficient of relatedness is needed. This is, for example, half between parents and offspring and between siblings, and a quarter between an organism and its grandchildren. The effect of an act on each class of relatives is multiplied by the individual's coefficient of relatedness to that class, and then the resulting weighted effects are added up to give the inclusive fitness. See also NATURAL SELECTION. M.R.

FIXATION (1): in the nomenclatural sense, a general term for all methods of determining the type species of a genus or subgenus (see TYPE SPECIES).

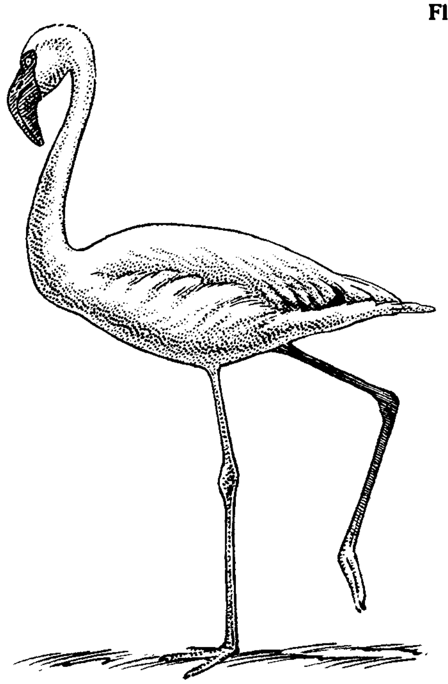
FIXATION (2): in behaviour studies, a term sometimes used to describe an abnormal attachment of one individual to another of a different species, usually caused by conditioning in early life.

FIXED ACTION PATTERN: translation, abbreviated to 'FAP', of the term 'Erbkoordination'; a behaviour pattern which, as defined by Lorenz, (i) is invariant; (ii) is relatively independent of external stimuli once started; (iii) has its own specific motivation revealed in vacuum performances; and (iv) shows specific exhaustion, in that one performance makes an immediately subsequent performance less likely. See BEHAVIOUR, HISTORY OF.

FLAMINGO: substantive name of the species of Phoenicopteridae (Phoenicopteriformes); in the plural (-gos). Here the order is assigned between Ciconiiformes and Anseriformes, but evidence of relationship is contradictory. Flamingos have usually been considered as a suborder of Ciconiiformes. On anatomical evidence they have been supposed to have affinities with the storks (Ciconiidae) and ibises (Threskiornithidae), while work with egg-white proteins appears to place them close to the herons (Ardeidae). On the basis of behaviour and Mallophaga, they have seemed most like the waterfowl (Anseriformes). Recently, affinity with the waders (Charadriiformes) has been stressed, and familial status in the suborder Charadrii next to Recurvirostridae proposed (Olson and Feduccia 1980). This suggestion is based on similarities between flamingos and the Australian Banded Stilt *Cladorhynchus leucocephalus*. A comparative ethological study in the field is required, and new evidence can be expected.

All flamingos are very similar and, although 3 genera are usually recognized, this is not based on widely accepted taxonomic evidence. The 5 species are placed in 2 groups on bill morphology: *Phoenicopterus*, which has a relatively primitive feeding apparatus, and *Phoenicoparrus* (Andean and James') and *Phoeniconaias* (Lesser) which are more specialized. The last 2 genera are separated only by the presence or absence of the hind toe. Possibly a single genus *Phoenicopterus* would suffice; however, the older nomenclature has been retained here. *Phoenicopterus r. ruber* (also called the Caribbean) and *P. r. roseus* (*'antiquorum'*) are usually regarded as races of the Greater Flamingo, while *P. chilensis*, the Chilean Flamingo, is felt to be sufficiently different to have specific status.

Characteristics. Flamingos form a remarkable and ancient group, and are easily recognized. They are large birds (90–180 cm long) with a long sinuous neck, long legs ending in webbed feet, an 'upside-down' bill and rosy pink plumage. Because they may occur in huge numbers they have been called 'the most impressive and colourful of all bird spectacles' (Brown 1973). Flamingos swim and upend with ease and extend the neck and legs in flight. Males are larger than females, but they are almost indistinguishable.



Lesser Flamingo *Phoeniconaias minor*. (*R.G.*).

Habitat. Being specialized ecologically, they are often superabundant in certain habitats and entirely absent from others. They are confined to shallow soda lakes and salt lagoons with a high pH (up to 10.5), usually barren of vegetation and surrounded by almost desert-like wastes.

Distribution. From fossils it is known that flamingos were once widespread in Europe, North America and Australia as well as in areas where they are found today. They are now a relict group occurring in isolated pockets, mainly in the tropics and sometimes at high altitudes.

The very bright pink Caribbean Flamingo *Phoenicopterus r. ruber* numbers about 60,000 and occurs in the West Indies with a small outlying population in the Galapagos Islands. The paler, Old World form of the Greater Flamingo *P.r. roseus* is the largest, weighing on average 3.0 kg; it is more common, at an estimated 790,000, and is the most widespread species, ranging from West Africa to south-east India, and from southern France and Kasakhstan to the Cape Province of South Africa. The Chilean Flamingo *P. chilensis* numbers about 500,000 and is found from central Peru southwards along the Andes to Tierra del Fuego and from sea level to 4,500 m. *Phoenicoparrus andinus*, the Andean Flamingo, differs from the others in having yellow legs. It is restricted to the high Andes, mainly above 2,500 m, from southern Peru to central Chile and northwest Argentina. Its population is estimated at 150,000. James' Flamingo *P. jamesi* has the most restricted range of all, from 15°–26°S in the Andes and mainly above 3,500 m; it is the rarest species, numbering only about 50,000 individuals. The smallest species, at 1.9 kg, is the Lesser Flamingo *Phoeniconaias minor*. It is also the most numerous, with about 2.5 million birds in Africa in the rift valley, Namibia, Botswana, and in Mauretania, and an unknown number breeding in north-west India, probably numbering some tens of thousands.

Movements. Birds breeding at high latitudes or altitudes move to warmer climates in the winter, the young travelling separately from their parents. Other irregular movements, often at night, are thought to be in relation to changes in food supply.

Food. The feeding methods of flamingos are characteristic and peculiar. The bill, which is held upside-down in the water, has 'the lower jaw large and trough-like and the upper small and lid-like' (Jenkin 1951). Jenkin has described the bills of flamingos in detail, and has pointed out that their filter feeding is comparable with that of whale-bone whales (Mysticeti) and otherwise unique among adult vertebrates. *Phoenicopterus* has the upper mandible 'shallow keeled' with only parts of the mouth equipped with filtering lamellae, while in the 'deep keeled' bills of *Phoenicoparrus* and *Phoeniconaias* the lower jaw is deep and swollen and the upper mandible is narrow. In both, the tongue is enlarged and acts as a piston. Water and mud are taken in along the whole gape and expelled, 3 or 4 times a second, past the filtering devices. In the more specialized forms, coarse particles are kept out by stiff excluder lamellae and finer particles, such as algae, are caught. The Caribbean, Greater and Chilean Flamingos feed mainly on invertebrates (brine fly *Ephydra*, shrimps *Antemia*, and molluscs *Cerithium*) from the bottom mud, normally wading in shallow water, more rarely swimming or upending like ducks. They are thus usually found feeding at a shoreline or on mud banks. The smaller Lesser Flamingo feeds on the erratic but occasionally dense blooms of the planktonic blue-green alga *Spirulina* which is rich in protein, and on benthic diatoms. It is a primary user of the lake and spends 60% of the daylight hours extracting its food from the top 6 cm or so, often while swimming. It can therefore coexist with the Greater Flamingos, and does so in large numbers, without competition. The feeding habits of *Phoenicoparrus* are less well-known, but both species are algivorous, and James' has a bill designed for taking smaller food items than the Andean Flamingo. The brilliant red colour of flamingo plumage reflects rich sources of carotenoids in their diets, and great efficiency in the metabolism of these labile compounds. All 5 species have been found to carry canthaxanthin as the predominant pigment in blood and feathers.

Voice. The flamingo's voice is rather goose-like and loud and may be important in keeping the flock together.

Behaviour. Flamingos are among the most social of birds, and display in large groups with sometimes hundreds of birds taking part. Both sexes participate, although displays are usually initiated by the males whose performances may be more intense and protracted. Many of the ritualized displays are similar to the preening and stretching movements that the birds adopt in everyday activity. The displays are only more stiffly performed, more contagious amongst members of the group, and given in typical, predictable sequences. Head-flagging followed by wing saluting is common: a bird in or near the displaying group suddenly stops headflagging, spreads its wings and folds them again. The effect is a flash of black in a pink field. A twist-preen may then follow: the bird twists its neck back, flashing a wing downward to expose the black primaries, and appears to preen behind the wing with its bill. In the inverted wing salute, the bird bends forwards and the wings are flashed partly open and held above the back. Marching is a display in which flamingos gather in a tight mass, and walk backwards and forwards in synchronized quickstep, sometimes making feeding movements with the bill in the water. Displaying occurs months before, as well as after, actual nesting.

Breeding. In areas with seasonal climates, nesting usually occurs at the beginning of the rains, such as in late November or early December in the Andean altiplano of South America. Flamingos nest in huge colonies: indeed, they seldom breed in flocks smaller than 10 pairs. Nesting is synchronized, presumably in relation to food abundance for the laying females and the chicks. Only the nest site is defended vigorously with various threat postures and the nest mounds themselves are usually two neck-lengths apart. Nests are built with movements similar to those of waterfowl and waders; both sexes pick up mud and stones within reach and place them beneath their bodies to form a circular pile with a shallow depression at the top. Nest mounds may be 30 cm high and presumably give protection from flooding and from the excessive heat often experienced in the mud at ground level. A single white egg, the yolk of which is blood-red, is laid and both male and female incubate it for 28–30 days. After hatching, the chick, unlike young waterfowl and most waders, remains in the nest until 5–8 days of age. It has grey down and a straight, pink bill and swollen pink legs both of which turn black within a week. While in the nest, the chick is fed by both parents on a secretion formed by glands in the upper digestive tract. Initially, this crop-milk is dark red in colour due to a high canthaxanthin content; after a while this fades and the secretion appears to be a pale straw colour. The length of time for which the chick is dependent for food varies: the Caribbean Flamingo can feed itself from 4–6 weeks but in the Greater and Lesser Flamingos parental feeding continues until fledging, by which time the bill is hooked, as in the adult. After they leave the nest, the young form into large crèches up to 30,000 strong, and the parents apparently find their own chick in the group and feed it alone. The young of most species are fledged within 3 months. The first plumage is grey, with brown and pink markings, and the legs and bill are black. Most are fully pink at 2 years of age, the richest red being on the wing-coverts. Individuals may breed when 3, but presumably many do not nest for several years. Flamingos are long-lived and have been estimated to reach an average of 25–60 years in the rift-valley of East Africa. Predation levels are normally low, and there is little response to terrestrial predators. (L.H.B.) J.K. (1)

FLANGES: enlarged light coloured margins of the gape found in some nidicolous species (see PARENTAL CARE).

FLANK: see TOPOGRAPHY.

FLATBILL: substantive name of *Rhynchocyclus* spp., sometimes applied also to other genera (see FLYCATCHER (2)).

FLAVOUR: see PALATABILITY OF BIRDS AND EGGS.

FLEAS: see ECTOPARASITE.

FLEDGING: term usually applied to the acquisition by a young bird of its first true feathers; when the process is complete the bird is 'fledged', and may for a short time be described as a 'fledgling' (see PLUMAGE; YOUNG BIRD).

FLEDGLING: a young bird which has just left the nest (fledged). The term is used of nidicolous young, which leave their nests only when they are fully feathered and ready to fly.

FLICKER: substantive name of *Colaptes* spp. (see WOODPECKER).

FLIGHT: the form of locomotion especially characteristic of birds as a class; even flightless species show unmistakable signs that their ancestors once flew. Birds are not the only flying animals, but their wings are constructed on an entirely different mechanical principle from those of bats and pterosaurs, the only other vertebrate groups to achieve powered flight. In birds the lifting surface is formed by the flight feathers, which are stiff, and need to be supported at one point only, the base of the shaft. The entire force from the wing is transmitted to the body through the shoulder joint, whereas the flexible membrane forming a bat or pterosaur wing has to be supported between the wing skeleton, the side of the body, and the hind leg. See WING.

The performance of bird and bat wings in flight is not very different, and indeed bats are generally more manoeuvrable than birds of similar size. The importance of the bird arrangement is indirect. Because the legs are not involved in the wing structure, they have continued to evolve as completely separate locomotor organs. Birds have two locomotor systems, which usually serve different types of locomotion. Typical birds fly with their wings, keeping the legs tucked up under the flank feathers. On the ground, the wings are folded up, and the legs are used for walking or perching. There are many variations on this. Water birds use their wings or feet, or both, for swimming. Birds of prey use the feet for catching and manipulating food, and so on. In all cases the legs and feet remain clearly recognizable as the bipedal walking legs of the birds' close relatives, the dinosaurs. The vast range of adaptations seen in birds has been achieved with only minor modifications of the original dinosaur-like body plan. The development of FEATHERS has enabled birds to fly without the drastic modification of the legs seen in bats and pterosaurs.

Power required to fly. Any flying animal (or machine) has to support its own weight in a thin medium, and overcome the drag caused by its own forward motion. The weight is supported by constantly pushing air downwards. To be exact, the rate at which downward momentum is imparted to the air has to equal the weight. This means that if the bird is flying slowly, or hovering, it has to accelerate a stream of air to a high downward speed. If it is flying fast, a more copious supply of air is streaming past, and less downward velocity has to be imparted to it. This is reflected in the rate of energy expenditure (power) required. Supporting the weight is most expensive in terms of rate of energy expenditure in hovering, and gets progressively cheaper as speed is increased, roughly as shown in Fig. 1.

The opposite is true of the power required to overcome the drag of the body. The faster the body moves forwards through the air, the larger is the drag force tending to hold it back. The power required to overcome this is zero when the speed is zero and builds up with approximately the cube of the speed, as in Fig. 1.

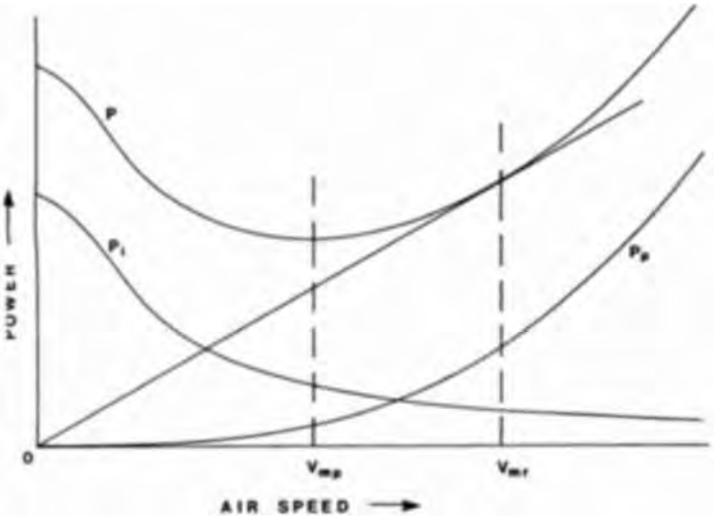

Fig. 1. The induced power P_i is that needed to support the weight in air. It declines with increasing speed. The parasite power P_p is that needed to overcome the drag of the body. It starts at zero, and increases with speed. The total power P has a pronounced minimum resulting from adding these two components together, even though various other components also have to be added. The two speeds marked are for minimum power and maximum range.

The horizontally flying bird has to supply both components of power at the same time. Consequently, hovering flight is strenuous, because of the high cost of supporting the weight, and so is high-speed flight, because of the cost of overcoming the drag. There are also other components of power which have to be supplied, but there is always some moderate speed at which the power required to fly is less than at either slower or faster speeds (Fig. 1). If the bird chooses to fly at this 'minimum power speed', the rate at which it consumes fuel and oxygen will be a minimum.

In most circumstances, and especially when migrating, birds normally fly faster than the minimum power speed. This is because a migrating bird needs to minimize the energy consumed per unit distance, rather than that consumed per unit time. This is achieved at the speed at which the ratio of power to speed is a minimum, which can be found from the power curve by drawing a tangent from the origin as in Fig. 1.

Speed in different birds. In general the speeds at which birds fly are faster in larger than in smaller birds. This is because each unit of wing area has to carry more weight in a large bird, since the ratio of surface area to volume is less. Therefore the air has to flow faster over the wing, and the bird achieves this by flying at a higher forward speed. As a rough guide, the speeds at which birds of different sizes fly vary with the square root of the body length, but there are wide variations about this general trend. At any particular size, birds with thick bodies and small wings (like auks), fly faster than those with slender bodies and large wings (like terns).

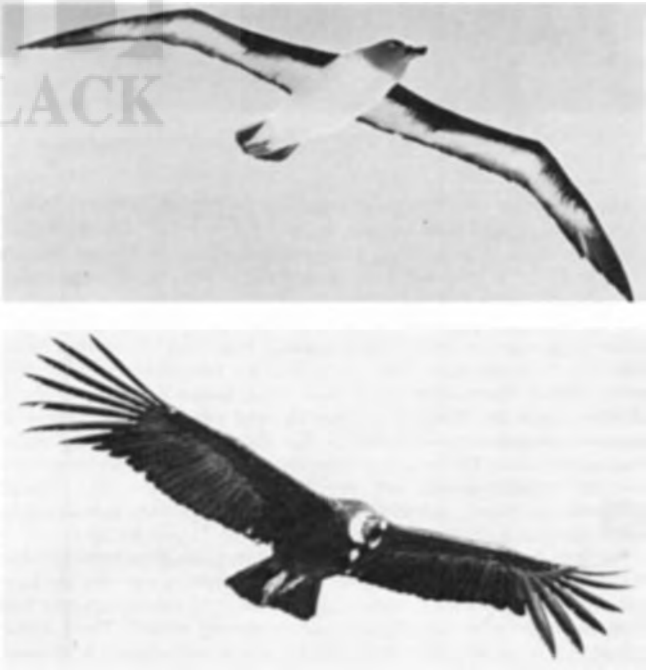
Many methods have been tried for measuring the speeds of free-flying birds, including radar, various optical methods and following with a car or aircraft. The results are usually assumed to be representative of the maximum range speed. Accuracy is difficult to achieve, besides which there is much variation between different species, and indeed in the same species depending on the weather and on what the bird is doing. As a general guide, small passerines cruise at 6–8 m/s (22–29 km/h), small gulls at 9–10 m/s (32–36 km/h), large gulls and small waders at 10–12 m/s (36–43 km/h), and the faster ducks and waders at up to 20 m/s (72 km/h) (see FLIGHT, SPEEDS OF).

The power source. The mechanical power required for flight comes from the flight muscles, of which the most important is the pectoralis, the large breast muscle which pulls the wing down (see MUSCULATURE). In birds other than hummingbirds most of the work in flapping flight is done during the downstroke, in which the fully spread wing is swept downwards and forwards. The wing is normally flexed at the elbow and wrist joints during the upstroke. At high forward speeds the lift developed by the wing is sufficient to carry it up without a great deal of help from the muscles. In slow flight the humerus is raised by the supracoracoideus muscle, and the manus flicks up somewhat later, in a complicated motion which usually causes the flight feathers to separate from each other. It is generally agreed that the function of this type of upstroke is just to get the wing into position for the next downstroke, and that not much aerodynamic work is done by the supracoracoideus muscle.

Limits of body mass. The pectoralis muscle more easily satisfies the demands made on it in small birds than in large ones, for two reasons. First, the power required to fly would be directly proportional to the weight if all birds flew at the same speed, but since the larger ones have to fly faster, it follows that the power required from each gram of muscle is greater in a large bird than in a small one. The second effect aggravates the first. The power available from each gram of muscle is less in a large bird than in a small one. The work done per unit mass of muscle is roughly constant, and the power is this work times the flapping frequency. Vultures are obliged to flap their wings at a lower frequency than hummingbirds, and consequently get less power out of each gram of muscle.

These two effects acting together mean that the power requirements for flight become more difficult to satisfy as birds become larger, and there is therefore a definite upper limit to the mass of flying birds. This limit seems in practice to be in the region of 10–15 kg. Birds of around this mass are found in several unrelated groups, notably the American vultures (Cathartidae), storks (Ciconiidae), swans (*Cygnus*), cranes (Gruidae), bustards (Otididae) and albatrosses (Diomedeidae). The largest members of all these groups show obvious signs of lack of power in flight. In particular condors (*Gymnogyps*, *Vultur*), flap horizontally only with the greatest reluctance and difficulty.

At the opposite end of the scale, the tiny hummingbirds are the only birds capable of continuous hovering (the most strenuous form of flight) over periods of many minutes. Their wing beat frequencies are in the region of 30 Hz in normal flight, giving the characteristic audible hum when they fly, and go over 50 Hz in maximal exertion. Hummingbirds do not suffer from lack of power, but are prevented from reducing their size still further by the still higher wing beat frequencies that would be required. The muscles would not be able to react quickly enough. Hummingbirds overlap in mass with the larger insects, whilst smaller insects have a special type of muscle, which is able to operate at frequencies far higher than any vertebrate muscle can attain.



Grey-headed Albatross *Diomedea chrysostoma* (upper); Andean Condor *Vultur gryphus* (lower). Contrasting wing shapes in large soaring birds. The albatross showing streamlined body, and narrow wings with pointed tips; the Condor showing broad wings, with slotted tips characteristic of birds which soar in thermals over land. (*Photo: C.J. Pennycuick*).

Sand Martin *Riparia riparia* about to enter nest hole. (*Photo E.J. Hosking*).

Galapagos Hawk *Buteo galapagoensis* about to land on tortoise. (*Photo: F. Pölking*).

Puffin *Fratercula arctica* about to land. (*Photo: H.E. Grenfell*).

Great White Pelican *Pelecanus onocrotalus* landing on water. (*Photo: E.J. Hosking*).

The difficulties resulting from large size are partially offset by differences in body proportions between birds of different size. Although there is great variation of wing shape at any particular size, the general trend is for large birds to have relatively longer wings than small ones, which helps to reduce the power required by large birds to fly.

Long distance flight. Powered flight has provided birds with the means of prodigious feats of long-distance migration. Some land birds make very long passages over water, the best known being the Pacific Golden Plover *Pluvialis dominica fulva* which makes a crossing of about 2,600 km from the Aleutians to Hawaii, and the Greenland Wheatear *Oenanthe oenanthe leucorrhoa* which flies about 4,100 km on the trans-atlantic route from Greenland to Morocco. Many small passerine species cross the Mediterranean and the Sahara in a single 'hop' (about 3,000 km), and there is another route of similar length from north-eastern North America over the western Atlantic to the Lesser Antilles.

The long-distance migrants are mainly small to medium-sized species. The distance a bird can fly without landing to feed is not very strongly dependent on body size. It is determined mainly by two factors, the first being the fraction of the take-off mass consisting of fuel. The fuel for migration is invariably fat, and migratory species are adapted to increase their food intake just before departure, so as to lay down massive deposits of fat, up to half the total body mass. A 'fat fraction' of this order is typical of small and medium-sized birds, but large birds cannot carry so much, because of the limitations on muscle power, mentioned above. Therefore the range attainable in flapping flight begins to decline as body mass increases above about 1 kg.

The second factor affecting migration range is the 'effective lift-to-drag ratio', a quantity which expresses the energy needed to propel unit mass of bird unit distance. This lift-to-drag ratio has mechanical and metabolic components. The mechanical part is simple. If the wings are long in relation to the width of the body, the effective lift-to-drag ratio is high, and so is the attainable range. Furthermore, for a given fat fraction, birds of the same shape should go the same distance, irrespective of absolute size. This simple rule has to be modified when the energy expended on basal metabolism is taken into account. Basal metabolism is a larger fraction of the whole in small than in large birds. Also small birds fly more slowly, spend longer in the air when flying a given distance, and use more energy for basal metabolism while they do so. Small birds therefore go less far than larger ones on the same fat fraction, because a bigger fraction of the energy is expended on basal metabolism. This effect might give a medium-sized wader, say, twice the range of a small passerine, on the same fat fraction.

The result of these effects is that the longest-distance fliers are medium-sized birds such as waders and plovers (Charadrii). Smaller birds are at a moderate disadvantage because of their higher metabolic rates and lower speeds, whilst large birds are unable to lift large amounts of fat.

Changes during long flights. On the longer migratory routes, small birds spend 2–3 days and nights in continuous flight. At the end of such a flight, the bird has consumed half its take-off mass, but still has the same wings. Speed and power therefore have to be progressively reduced in the course of the flight. Migrants also climb gradually in the course of long flights. As the cruising speed and power decline, the bird can maintain them in progressively thinner air. Flying higher increases the cruising speed, and to some extent offsets the loss of speed caused by using up fuel. Passerine migrants typically climb to heights of 1,000–2,000 m soon after take off, and then climb gradually, reaching 6,000 m or so towards the end of a long flight. The cross-current arrangement of the avian lung allows birds to extract an adequate supply of oxygen from thinner air than would be usable by equivalent mammals. Keeping warm at high altitudes is not a problem, as the exertion of flight causes excess heat to be generated. (See RESPIRATORY SYSTEM.)

Take-off and landing. Small birds jump straight into the air when they take off, whereas large ones need a take-off run. The reason lies in the relationship of power required to power available (Fig. 2). Small birds can generally muster enough muscle power to fly at zero speed (hover), at least for a short time, whereas large ones can only fly over a limited range of speeds, between some minimum and maximum. They have to run over the ground or water until the minimum speed is attained. The speed in question is the air speed, not the speed relative to the ground. Therefore birds always face into wind when taking off and landing, so that the wind speed contributes to the air speed. Large land birds perch on a tree or slope whenever possible, as they can then acquire the minimum flying speed by dropping from the perch. Seabirds achieve a similar result by accelerating down the windward slope of a wave.

When taking off from level ground, large land birds run with steps synchronized with the wing beats. Both the Old World vultures (Aegypiinae) and their New World equivalents (Cathartidae) run with a curious asymmetrical, sidling gait, for reasons unknown. Most water birds use their webbed feet in a running motion to push themselves forward through the water, but those of the order Pelecaniformes use a rowing motion with both feet together, synchronized with the wing beat.

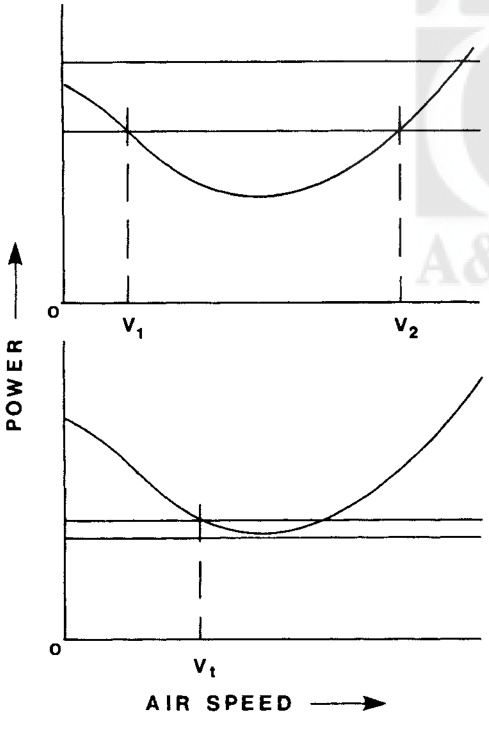


Fig. 2. The curves show total power required to fly, as in Fig. 1. The upper horizontal line represents the maximum power available from the muscles in a brief sprint, whilst the lower line is the maximum power which can be continuously supplied, without incurring an oxygen debt. A small or medium-sized bird (upper) can fly briefly at zero speed, and can therefore take off from a standing jump. It has sufficient power available to fly continuously only in the speed range between V_1 and V_2. Some very large birds (lower), such as condors, have insufficient power to fly continuously at any speed, and have to accelerate by running or diving to a take-off speed V_t before they can fly at all.

Large birds also have to contend with high landing speeds. One method of dealing with this is to use a 'ballistic approach', in which the bird dives to a high speed a little below the intended landing spot, then pulls up into a steep climb. If correctly judged, this results in the speed dropping to zero just above the perch. Large birds use this method to land on trees or cliffs, as do some smaller ones with heavy bodies and small wings, such as auks (Alcidae). A high landing speed is less of a problem for water birds. Most of them hydroplane to a halt on their large webbed feet, whilst a few such as gannets (*Sula*), always dive into the water, however slow their ground speed. Some water birds such as divers (Gaviiformes) land only on water, and can therefore accept a high landing speed and posteriorly placed legs. In most water birds these adaptations are not carried to such extremes as in divers, to allow acceptable landing performance on land. Albatrosses are able to alight on land, but are notably clumsy when doing so, as indeed are many of the smaller Procellariiformes.

Uses of the tail and feet. Birds do not have the long, jointed tails seen in other vertebrates, including their own reptilian ancestors. The tail consists of a fan of stiff feathers, which can either be furled, or spread out sideways, so varying its area by a factor of 3 or more. A bird's tail does not have the same function as that of an aircraft, in which loss of the tail renders the aircraft uncontrollable. Birds can still fly without their tails, but have difficulty in manoeuvring at low speeds, and particularly in landing. The tail is spread in low-speed flight, and helps to deflect air downwards over the wings. The effect is to augment the lift developed by the wings, and to keep the air flowing smoothly over them at lower speeds than would otherwise be possible.

Birds with small wings and tails, and large webbed feet, such as auks, augment their tail area when flying slowly, by spreading the feet on either side of the tail. A more common use for webbed feet in flight is as airbrakes. When extended below the body, the feet generate a large amount of drag, enabling the bird to descend at a steep angle without excessive speed. Cliff-nesting birds such as fulmars *Fulmarus* use the feet in this way to soar level with the cliff-top, and avoid being carried above it by the wind. Gulls depress the furled tail for the same purpose, but it is unusual for birds to use the tail as an airbrake in this way. The spread tail, seen in birds about to land, is usually not acting as an airbrake, as often stated, but in a manner more akin to an aircraft's flaps.

Birds' feet do not have to be webbed to make effective airbrakes. The long legs of storks and cranes are extremely effective as drag generators. The legs of vultures and even pigeons are sufficiently effective to be of major importance as airbrakes.

Adaptations for powered flight. Scale effects impose general trends which make birds of different size fly in different ways. At any particular size, there is a wide range of adaptations in which one feature is developed at the expense of others. For example birds with very long wings are adapted to minimize the power required to fly at low speeds, or to hover, as in terns and frigatebirds. Swifts are commonly thought of as fast-flying birds, and indeed they can attain quite high speeds in a dive. The primary function of their long wings, however, is to enable them to fly and manoeuvre slowly in pursuit of flying insects, and also to remain airborne day and night, flying slowly and expending energy at a low rate.

Hummingbirds are the only birds able to hover continuously without incurring an oxygen debt. When they hover, their wings beat to and fro almost horizontally. The wings are nearly symmetrical in cross section, and are inverted on the backward stroke, so producing about the same amount of lift on both the forward and backward strokes. This mode of hovering is more characteristic of insects than of birds, other kinds producing lift mainly on the downstroke when hovering. The hummingbird method produces a smoother downward flow of air, which is less wasteful of energy than the more intermittent flow produced by other birds.

Those water birds which use their wings under water tend to develop small wings in relation to their body size, because the denser medium requires this. Some, such as the auks and diving petrels (Pelecanoididae) continue to fly in air, with wings which also perform much the same motion under water. Such birds fly fast and with high wing beat frequencies. When they come ashore to breed, they rely heavily on ballistic landing and take-off techniques. The fact that such an awkward compromise is retained in so many living water birds testifies to the selective value of retaining the power of flight. Penguins, by breeding in places inaccessible to terrestrial predators, were able to dispense with flight long ago, and so to specialize entirely on aquatic locomotion

Kestrel *Falco tinnunculus* female wind-hovering. (*J.B. & S. Bottomley*).

(incidentally removing the restriction on maximum body mass). More recently individual species of other groups have embarked on the same course, sometimes successfully as in the Flightless Cormorant *Nannopterum harrisi* and sometimes, as in the Great Auk *Pinguinus impennis*, with disastrous results.

Short wings allow high wing beat frequencies to be attained, and are found in birds which need bursts of high power output from their muscles. Game birds, with their short, rounded wings, are adapted for good take-off performance rather than for sustained cruising flight. The smaller ducks have well streamlined bodies and relatively small, pointed wings, giving fast and efficient cruising at the expense of rather high speed landings and take-offs. Swans are of special interest as the largest birds which undertake substantial migratory flights without soaring. Unlike other large birds (except albatrosses—see below), their bodies are well streamlined, and their wings are of an efficient, pointed shape.

Soaring. A bird's own muscles are not necessarily the only source of energy for flight. Energy can often be extracted from the air in which the bird flies. Flight based on this principle is called soaring. For various reasons it is more advantageous to large birds than to small ones.

Soaring depends on exploiting motions in the atmosphere which are non-random, and therefore predictable. The simplest method is slope soaring, which depends on the fact that the wind is deflected upwards when it blows against a vertical obstruction such as a hillside or a line of trees. By flying back and forth along the windward side of the obstruction, the bird can remain continuously in rising air. If the vertical speed of the air exceeds the sinking speed of the bird when gliding, the bird can maintain height, or climb, without flapping its wings. Gulls and other seabirds make extensive use of slope lift along sea cliffs. In Britain Kestrels *Falco tinnunculus* can often be seen using motorway embankments to slope soar in a fixed position over the ground, looking for food below, while the American Turkey Vulture *Cathartes aura* is adept at using trees for slope soaring. Slope lift is easy to find because it is always over the slope, but for that very reason is limited in its usefulness. It is also usually limited vertically, seldom extending far above the top of the slope, even on a high mountain ridge.

Lee waves, which form on the downwind side of an obstruction, and remain stationary relative to the ground, provide the basis of another method of soaring. Lee waves extend to much greater heights than slope lift, but are more difficult to use because their location is less obviously related to the landscape. The European Gannet *Sula bassana* and Andean Condor *Vultur gryphus* have been reported using lee waves on a small scale, and this method may be important for the latter.

Most bird soaring is done in thermals, which are vortex structures in the atmosphere, usually triggered off by solar heating of the ground. Cumulus clouds are caused by thermals, and serve as indicators of their presence, although thermals can also occur in a clear blue sky. Thermals normally have a zone of rising air in the middle, surrounded by a zone of rotating or sinking air. To exploit the thermal, the bird flies in circles of small radius, so that it remains inside the central zone of lift, or 'core'.

Thermals are used extensively by birds of prey, simply to keep them airborne for long periods, while they patrol in search of food. Migratory species also use thermals for cross-country travel, by alternatively climbing in a thermal, then gliding off, losing height, in the required direction. Because of the time taken for the climbs, during which no progress is made, this method of travel is slower than continuous powered flight. On the other hand the energy consumption is less, especially in large birds, whose basal metabolism is relatively low. In small birds the time lost climbing in thermals would lead to an undue increase in the energy consumed in basal metabolism. As the basal metabolic rate is large compared to the power required to flap the wings, it is metabolically cheaper for small birds to migrate by flapping, and they soar only incidentally. The smallest soaring birds are the swifts, but they soar to remain airborne in pursuit of their insect prey, rather than for migration as such.

Thermals occur where relatively cool air is heated from below by a hot land surface, and are consequently most reliable as a source of lift in the drier parts of the tropics and sub-tropics, and in inland continental areas at higher latitudes in summer. The seasonal occurrence of good soaring conditions is exploited in both the Old and New Worlds for the annual migrations of birds of prey and storks. These birds make a detour around the Mediterranean Sea, in order to take advantage of better thermals over the land. During the autumn migration they converge in spectacular concentrations to cross isthmuses and narrow straits, as at the Bosphorus and Suez. Similar concentrations of migrating birds of prey and Turkey Vultures are seen on the isthmus of Panama. The European Crane *Grus grus* also migrates by using thermals, but is less dependent on them. It crosses the Mediterranean in flapping flight, and reverts to thermal soaring further north.

Thermals, accompanied by characteristic cumulus clouds, also occur over the sea in the trade wind zones, in which the air converges continuously towards the Equator from both north and south, and is therefore heated from below by the progressively warmer sea surface. Unlike thermals over land, which generally cease as the surface cools at night, these trade wind thermals continue with little variation during the night. Frigatebirds are adapted for soaring in these weak but consistent thermals. Although primarily coastal in their distribution, they are regularly seen several hundred km from land, and are apparently able to soar by day and night, as they never alight on the water.

A variety of coastal and freshwater birds, including gulls and pelicans soar in thermals over land, but rely mostly on flapping flight over the sea. The Procellariiformes are a truly pelagic group using various methods of soaring over the open sea. Being most abundant in the windy middle latitudes of the southern hemisphere, petrels and albatrosses rely to a large extent on slope soaring along waves. The larger members of the group, from albatrosses down to medium-sized petrels and shearwaters, also make use of the variation in the horizontal wind speed in the bottom 15 m or so of air, caused by friction with the sea surface. It is possible to extract energy from this wind gradient by pulling up against the wind. The wind speed progressively increases as the bird climbs, so offsetting the decline in its airspeed. A further gain can be made by gliding downwind through the wind gradient, which has the effect of flattening the angle of glide.

Storm petrels have a special method of soaring, which they use for feeding at the surface. The bird points into wind with its wings extended, but with its feet in the water acting as a sea anchor.

Adaptations for soaring. Gaining height in thermals or slope lift calls for gliding at a low air speed, and a low rate of sink. This is achieved by a low wing loading (large wing area relative to body weight), long narrow wings, and a well streamlined body. Frigatebirds are specialized in this way, being adapted to remain airborne in weak thermals for long periods, without any requirement for fast cross-country progress. Those birds which migrate by thermal soaring, or make long daily forays in search of food, as some vultures, need to glide fast between thermals, in addition to flying slowly when climbing. These needs are difficult to reconcile, as fast gliding calls for a high wing loading. Wing loadings are higher in migratory species than in those which use thermals purely for patrolling a small foraging range.

Birds which use thermals over land do not, in general, show the long narrow wings which would be most efficient for this. They have characteristically broad, rectangular wings, in which the primaries are emarginated to form a series of slots at the tip. The gliding performance resulting from this shape is not impressive by comparison with that of sailplanes. The broad, slotted wing characteristic of eagles and hawks (Accipitridae), American vultures (Cathartidae), storks, cranes and pelicans is most probably adapted primarily to the requirements of take-off on land, rather than to those of soaring as such. Water birds seem to have less difficulty with take-off, and the long, narrow, glider-like wing is seen most highly developed in the albatrosses. Their wing loading is relatively high, and they skim fast along waves, following the zone of slope lift.

Many marine and freshwater birds habitually fly as close to the surface at they can, with their wing tips almost touching the water. The close proximity of the surface results in a significant increase in the efficiency of the wing, a phenomenon known as 'ground effect'. Some birds such as skimmers *Rynchops* use ground effect as the basis of their foraging technique.

Body measurements. Reliable predictions about birds' capabilities in flight depend on accurate body measurements, but these are less easy to come by than might be supposed. The wing measurements traditionally made by ornithologists are of little value for flight calculations. It is not difficult to collect more useful measurements, and much could be learned if those who regularly trap and handle birds would do so. The following three measurements supply a foundation for the more basic flight calculations.

Body mass. This can be measured in the usual way, but not forgetting to note whether the bird is fat or thin, and whether its crop is full or empty.

Wing span. The wings should be extended to their fullest extent, without actually straining the structure, and the extreme distance measured, from tip to tip. 'Wing length' as usually recorded is not a useful measurement (see WING SPAN).

Wing area. This is a more time-consuming measurement, in which the bird's body is held by the edge of a table, one wing is spread out to its fullest extent over a sheet of paper, and the outline is carefully traced. The area required is the projected area of both wings, including the section of the body in between them, as in Fig. 3a. To achieve this, the tracing of one wing must be extended to the midline, by measuring a distance equal to half the span, inwards from the tip (Fig. 3b). The area can then most easily be measured by counting squares on a grid overlay, made by ruling a grid on a sheet of transparent plastic.

A collection of masses, areas, and wing spans is always worth publishing, provided explicit details of the methods of measurement are given.

FLIGHT FEATHERS: general term for the primary and secondary feathers of the wing (see REMEX; WING).

FLIGHTLESSNESS: a condition whereby the flight apparatus is reduced or absent, rendering the adult form totally unable to fly. This phenomenon, widespread among various orders within the Class Aves, occurs in two totally different adaptive zones, the aquatic and terrestrial environments. In both, however, all flightless forms have been derived from flying ancestors (see EARLY EVOLUTION OF BIRDS).

In the water two very different types of swimmers and divers have become flightless. These are foot-propelled and wing-propelled divers. Flightless foot-propelled divers are ancient, with one form, *Enaliornis*, from the early Cretaceous, going back nearly to the time of the first known bird, *Archaeopteryx*. *Enaliornis* is the earliest of the toothed, foot-propelled hesperornithiform birds (order called Hesperornithiformes: genera *Enaliornis*, *Hesperornis*, *Baptornis*, *Neogaeornis* and *Coniornis*). These flightless divers ranged in size from that of a moderate sized grebe to over 1½ m in length (*Hesperornis regalis*), and although not related to the living divers or loons, resembled them through convergent evolution. Modern foot-propelled divers that are flightless occur in a variety of orders. Among the ducks (Anatidae) 2 of the 3 steamer ducks *Tachyeres* spp. are flightless or nearly so. They are more heavily built than their flying congener: when speed is necessary, the wings are flapped to aid progress over the surface of the water (see DUCK). A recently extinct flightless goose *Chendytes* from the Pacific coast of America is another example of anatid flightlessness. Among the grebes (Podicipedidae) we also see a tendency to become flightless or nearly so, with examples such as the nearly flightless *Podiceps gigas* of Lake Atitlan, or the flightless *Centropelma micropterum* of Lake Titicaca. Finally, among the cormorants (Phalacrocoracidae), the foot-propelled diver *Nannopterum* (*Phalacrocorax*) *harrisi* of the Galapagos Islands is completely flightless.

Flightless Cormorant *Nannopterum harrisi* with small chicks on Galapagos. (*Photo: F. Pölking*).

The case of wing-propelled flightless divers is quite different. Here evolution has led to adaptation for a largely marine existence, with modification of the wings as flippers for swimming (see PENGUIN; SWIMMING AND DIVING). This use of the wings requires strong pectoral muscles and a carinate sternum, as in the case of flying birds, since these birds literally fly through the water, and may be considered among the 'best' flyers. Penguins, thought to be derived from procellariiform ancestors, are the only totally flightless wing-propelled divers known from the Southern Hemisphere, but from the Northern Hemisphere the recently extinct Great Auk *Pinguinus impennis* evolved from alcid stock. Its ancestor *Pinguinus alfrednewtoni*, known from the lower Pliocene of North Carolina, was slightly less specialized for wing-propelled locomotion. The Lucas auks, intermediate in structural specialization for wing-propelled diving, are also flightless forms from the upper Miocene to Pleistocene deposits of California. Finally, there are the recently discovered plotopterids (Plotopteridae), Northern Hemisphere pelecaniform derivatives that converged on the extinct giant penguins of the Southern Hemisphere. These, the largest swimming birds known, with one species over 2 m in length, occur in the late Oligocene and early Miocene of Japan, Washington and California. Their extinction occurred at the same time, the early Miocene, as that of the giant penguins of the Southern Hemisphere. They are thought to have occupied the pelagic niches for endotherms the size of seals and porpoises, both of which were undergoing adaptive radiation at that time.

Equally, or perhaps more diverse are the myriad of terrestrial birds that have lost their flying powers. In almost all of these cases we see the evolution of flightlessness as a case of arrested development or neoteny, though the reasons for the evolution of flightlessness may be quite different.

The earliest flightless terrestrial forms are the diatrymas from the Paleocene and Eocene of North America and Europe. These were giant forms, 2 m or more tall, with a head the size of a modern horse's. *Diatryma* and its allies (*Gastornis*, etc.) apparently took over the niche for a bipedal carnivore left vacant by the extinction of the flesh-eating dinosaurs. Another group of birds evolved in South America from the Oligocene to the close of the Pliocene, a period during which South America was totally isolated from the rest of the world and therefore isolated from the invasion of advanced mammalian carnivores. These were the phorusrhacids (*Phorusrhacos*, *Brontornis*, *Andalgalornis*, and allies) which were more lightly built than the diatrymas. They ranged in size from 1½–2½ m, with the speed to run down their prey, unlike the diatrymas which probably were not capable of great speed. One giant phorusrhacid, *Titanus walleri*, which was larger than the African ostrich, is known from the Pleistocene of Florida.

Another flightless flesh-eater was the giant owl *Ornimegalonyx oteroi* from the Pleistocene of Cuba which, standing over 1 m tall, had a tarsometatarsus twice as long as that of the modern *Bubo virginianus*.

Another avian order to have given rise to flightless forms is the order Columbiformes, the pigeons and doves. Flightless derivatives include the now extinct DODO *Raphus cucullatus* of the island of Mauritius; it weighed about 23 kg. A flightless cousin of the Dodo, and presumably derived from the same stock, was the Solitaire *Pezophaps solitarius* on the neighbouring Mascarene island of Rodriguez. They became extinct in the 17th and 18th centuries.

Among the Psittaciformes, the Owl Parrot (or Kakapo) *Strigops habroptilus* of New Zealand is flightless, although it sometimes opens its wings when pressed or while climbing in trees and may glide to the ground from heights. Several other parrots, although not flightless, are primarily terrestrial; these include the Ground Parrot *Pezoporus wallicus* and the Night Parrot *Geopsittacus occidentalis* of Australia (see PARROT).

Within the heterogeneous order Ciconiiformes two flightless ibises are now known: from the Quaternary of Jamaica *Xenicibis xympithecus*, and from the Pleistocene of Hawaii *Apteribis glenos*. *Apteribis* coexisted with a large flightless Hawaiian goose, *Thambethochen chauliodus*, characterized by possessing blunt, bony, toothlike projections on both jaws. A larger extinct flightless goose *Cnemiornis calcitrans* is known as a subfossil from New Zealand, and was no doubt contemporaneous with man and the moas.

Among the Passeriformes there are also a few flightless members, including the now extinct Stephen Island Wren *Xenicus lyalli* of New Zealand. The Central American Wren-thrush *Zeledonia cornonata* is also flightless or nearly so, as are a number of species of the Neotropical family Rhinocryptidae, in which the sternal keel is nearly wanting. Within the coraciiforms, a recently extinct flightless hoopoe *Upupa antarios* is known from the island of St Helena in the South Atlantic Ocean.

However, it is within the rails of the order Gruiformes that we see the greatest proclivity to become flightless; nearly one fourth of all island rails, living or recently extinct, having lost their powers of flight. Some of the more notable are the wekas *Gallirallus* spp. of New Zealand, the Takahe *Notornis mantelli* (at one time thought to be extinct) of the same country, *Porzanula palmeri* of Laysan Island, *Gallinula nesiotis* of Tristan da Cunha (subspecies extinct) and Gough Island, and the very small *Atlantisia rogersi* of Inaccessible Island. Rails prove that: (1) flightlessness may evolve in a very short period of time (e.g. generations), and (2) their flightlessness in all cases is a result of arrested development or neoteny. Even after hatching, the flight apparatus of flying rails is only poorly developed. Neotenic features of flightless rails (which also characterize other flightless birds and the RATITES) include a keelless sternum, an obtuse angle between the scapula and coracoid, and a large opening of the ilioschiatic fenestra. Flight is an energetically expensive ability to maintain, and in island rails, as well as other flightless birds, it appears that, if there is no strong and continual selection to maintain the flight apparatus, it will tend to disappear, along with the extensive pectoralis muscles and the entire flight architecture.

Other gruiforms to become flightless include the KAGU *Rhynochetos jubatus* of New Caledonia, the sole member of the family Rhynochetidae. There are a number of extinct flightless gruiforms known, including the highly cursorial ergilornithids from the mid-Tertiary of Mongolia, and the large Pleistocene gruiform *Aptornis* from New Zealand.

None of the 3 species of Mesitornithidae (see MESITE), a gruiform family of ground-dwelling birds peculiar to Madagascar, is known to fly; although they have fair-sized wings the clavicles are much reduced.

Perhaps the most notable of the living flightless birds are the so-called 'ratites'. Whatever the relationships of the various ratite groups (e.g. monophyletic or polyphyletic) they show similar neotenic features to those found in other flightless birds, and most have evolved in the direction of large size, very strong legs, and a wholly terrestrial mode of life (see CASSOWARY; ELEPHANT-BIRD; EMU; MOA; OSTRICH; RHEA). The KIWIS of New Zealand are exceptional in having attained only moderate size and in having developed nocturnal habits instead of relying on fleetness of foot for safety. The ratites are thought by some to be allied by their common possession of a peculiar conformation of the palatal bones known as the palaeognathous PALATE, but this feature may be either primitive within birds or neotenic, or both.

The large living ratites include the South American rheas (2 species), the African Ostrich *Struthio camelus*, the Australian Emu *Dromaius novaehollandiae*, the Australian and New Guinea cassowaries, and the smaller New Zealand kiwis. Extinct forms include the large ELEPHANT-BIRDS of Madagascar, a great variety of Australian dromornithids (Dromornithidae: Miocene to late Pleistocene), one of which may have equalled or exceeded in size the largest elephant-bird, and the 13 or so species of greater and lesser moas of the Quaternary of New Zealand.

FLIGHT LINE: see MIGRATION.

FLIGHT, PRECOCIOUS: flying by young birds well before they have attained full size. The general rule is that a bird does not fly until it is practically full grown, which is usually at a very early age; and it is clear that the flight feathers appropriate to an adult would, in the partly grown bird, be out of proportion to the other factors involved in flying (see FLIGHT). It is, however, characteristic of the Galliformes that a miniature set of remiges is grown by the chicks so that they can fly when quite small. This is no doubt a useful safety-device for ground-living birds; on the other hand, it may on occasion lead to undue scattering of the brood while its members are still of an age to need parental protection. Precocious flight reaches its extreme in the Megapodiidae (where the question of scattering does not arise); for instance, the chick of the Mallee-fowl *Leipoa ocellata* can fly almost as soon as it leaves the egg (see MEGAPODE). More often, in other families of the Galliformes, flying does not begin until later, e.g. 3–4 days in curassows (Cracidae) and 12–14 days in the Pheasant *Phasianus colchicus*. Precocious flight is also found in the gruiform family Turnicidae (see BUTTONQUAIL).

FLIGHT, SPEEDS OF: dictated by many factors in different situations. Since flight ability is closely related to ecological success the selection of speed is of crucial importance. Flight is used by birds predominantly to gather food, to search for mates (and to display for them) and to move to more favourable habitats (including migration). Optimal flight performance is that which gives the best contribution to evolutionary fitness in return for the effort expended. However, the measure of 'best return' must be defined in relation to the particular circumstances of an individual and its behaviour, and there is no general definition of optimum flight strategy or speed. Powered flight is demanding in the quantity of energy required, and generally the flight pattern is selected so that the energy consumed is minimized, or that (while foraging) the nett energy gain is maximized. The rate of energy consumption in flight (power) depends strongly on speed, and there is strong pressure on any bird to choose an optimum speed; it is in flight speed measurements that we can expect to see the response of an animal to varying ecological and environmental conditions. An individual will not always fly at the same air speed, regardless of what it is trying to achieve or of environmental conditions, and flight speeds are not dictated by wing size and proportions alone; on the other hand as a result of evolutionary specialization the wing morphology of any species is best adapted for the predominant flight conditions encountered.

Flight performance. Power consumption in level flapping flight can be depicted as a U-shaped graph (see FLIGHT); curves of this kind have been obtained from aerodynamic theory and from measurements of gas exchange for birds flying in wind tunnels. The detailed shape of the curve depends on the aerodynamic characteristics of the bird and on wing morphology, and has important consequences for the speed of flight.

Hovering—flight at zero air speed—is demanding in energy as there is no forward air velocity contributing to support of the animal's weight and therefore all air currents must be generated by the wings; it is only used continuously by birds which can exploit a rich or high-energy food reserve guaranteeing sufficient return for the energy expended. As speed is increased the energy needed for lift (weight support) decreases, and power consumption falls; at higher speeds still the frictional drag of body and wings becomes important, and power must rise (Fig. 1). Since there are physiological limitations on the rate of steady oxygen supply to the muscles and on the rate at which muscles can develop force there must be a fixed upper limit to the metabolic power available, and hence to the speed range. The same constraint can also set a lower limit: indeed, few birds are capable of sustained hovering for this reason, although many can 'hover' very briefly for a few wing strokes while landing or manoeuvring. Although frequently described as 'hovering', birds such as the Kestrel *Falco tinnunculus* and Rough-legged Buzzard *Buteo lagopus* cannot sustain the high power output this would entail, and they remain stationary relative to the ground while hunting by flying into moderate winds. In larger birds slow flight speeds can also be difficult or impossible to achieve because a minimum speed is required for lift generation; this can be particularly important in take-off, and can frequently demand a long run to build up sufficient air speed.

The most common criterion by which speed is determined is the reduction of energy for a given flight. Assuming that any flight speed (within the range set by metabolism) can be obtained by variation of the wing-beat geometry, then presumably the bird selects a speed primarily according to this rule. The shape of the power-velocity curve shows that two important characteristic speeds can be defined: V_{mp} at which power (energy/time) is least, and V_{mr} at which cost of transport (energy/distance) is least, or equivalently at which flight range is greatest for given fuel. (In the largest birds physiological factors may limit the maximum available speed to less than V_{mr}.) If the intention is to remain in the air for the longest possible time (roosting of swifts, some forms of hunting) a bird will fly at about V_{mp}, while if pressure is to maximize distance flown (migration, flying to feeding site) it will fly at V_{mr}. In some situations reducing time becomes important (escape from predation, foraging to feed young), and the bird will then fly as fast as possible. Typical flight speeds relative to the power curve for different flight conditions are summarized in Fig. 1.

Migration. Perhaps the most important situation demanding best possible flight performance is migration. As a contribution to the animal's annual energy budget the extra flight energy consumed must be more than balanced by improved energy intake in the more favourable habitat, and by the associated increase in reproductive fitness. The large distances involved place strong pressure for a strategy that minimizes total energy for the distance covered, and migrants can be expected to fly (in still air) at speed V_{mr}. If the bird is influenced by wind, as is often the case in migration, ground speed and air speed will not correspond, and air speed must be adjusted so that ground distance is as large as possible. Theory suggests that in head winds air speed should be increased by about 30% of wind speed (up to the maximum set by metabolism, beyond which forward progress is impossible), while in tail winds the bird should reduce air speed by the same amount. Several migrants (e.g. Chaffinch *Fringilla coelebs*) have been observed to respond in this way when the wind is parallel to the flight path and does not drift the bird to the side of its goal. In crosswinds the situation is more complex, but one possible response is for the bird to fly at high altitude in a strong wind without compensation for drift or wind speed until abreast of its goal, then to descend to lower altitudes where the winds are weaker and to fly direct to its destination: in this way the total energy needed can be minimized. The large fuel reserves stored as fat at the start of migration by many small birds also affect flight strategy: as the flight proceeds, fuel is consumed and mass decreases, and speed should be reduced: at all times, however, the bird should fly at V_{mr} (with appropriate compensation for wind etc.), and the change in mass alone dictates the change in speed.

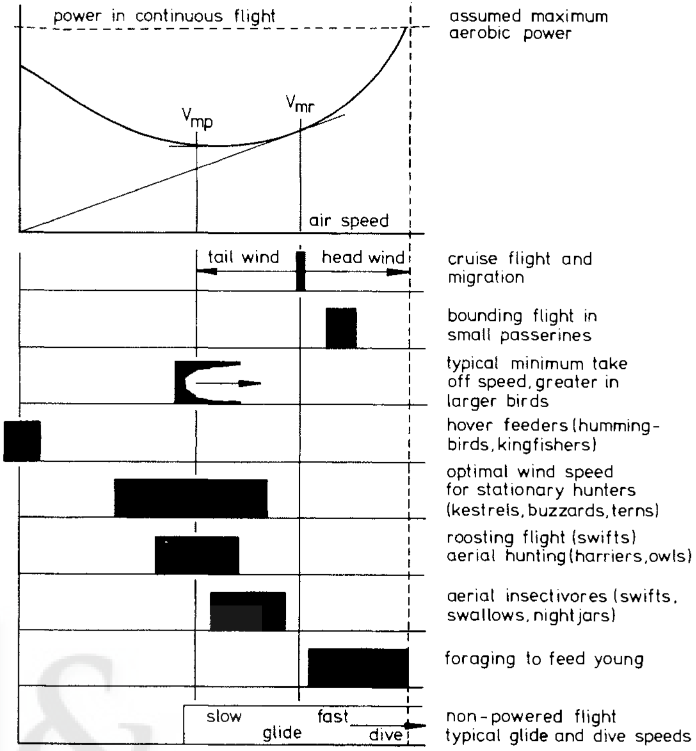

Fig. 1. Typical graph of power against speed for level flapping flight in birds, showing characteristic speeds V_{mp} and V_{mr}, together with the likely ranges of flight speed in different flight conditions, as they are related to the characteristic speeds and to the shape of the curve. Morphology adapts so that power is minimum at the appropriate speed range.

Morphology. The active selection of flight speed according to the demands of performance allows a bird to optimize flight behaviour, but the speeds available to it are dictated by the aerodynamic features of the animal and by the size and shape of the wings. Selection favours the development of wings specialized for the type of flight pattern associated with the animal's behaviour and ecology, and as the design of wings becomes more extreme, allowing less flexibility in flight behaviour, so the animal becomes more specialized not only in its flight but also in ecology and ethology. Wing size is described by wing loading (weight supported by unit wing area), and wing shape by aspect ratio (wing span squared, divided by area), and the major trends of flight adaptations may be distinguished with these parameters. Measurements of air speed in level flapping flight for a number of species are shown in Table 1, together with body mass, wing loading and aspect ratio. The considerable variation in speed even between birds of the same mass is the effect of wing morphology: speed rises with both mass and wing loading since higher speeds become necessary if lift is to be sufficient to support weight, while speed shows a slight decrease as aspect ratio rises since longer wings are more efficient. Birds which fly slowly or hover while foraging (e.g. Kestrel, terns, kingfishers, hummingbirds), and aerial insectivores (swifts, swallows), have long, high-aspect-ratio wings so that V_{mp} (and also V_{mr}) is low and power at that speed is as small as possible, even though the penalty of low maximum speed is unavoidable. On the other hand divers, ducks, geese and some waders have short, high-aspect-ratio wings allowing high speeds without unduly high power, because their feeding behaviour is dramatically influenced by weather and tide, and high speeds are of great importance to their success, as many of these species breed in arctic latitudes where the season is short and weather can be unfavourable. Many small passerines have short, rounded wings of large area and low aspect ratio. The low wing loading permits the large increases in weight prior to migration without flight becoming impossible, and these birds compensate for the high wing drag

Table of speeds of flight for a sample of birds, with average mass and wing morphology for each species. Speeds, obtained from radar measurements from a variety of sources, are cruise speed (V_{mr}) in light winds or still air.

		Mass	*Aspect ratio*	*Wing loading*	*Speed*	
		(kg)		(N/m^2)	(m/s)	(km/h)
Red-throated Diver	*Gavia stellata*	0.96	12.2	106	17	61

House Sparrow	*Passer domesticus*	0.028	5.5	26.4	8–11	29–40
Starling	*Sturnus vulgaris*	0.076	7.2	36.6	9–10	32–36
Crow	*Corvus corone*	0.46	6.8	36.7	14	50

by adopting bounding flight, in which the wings are closed for about half the time they are airborne, and speed is rather higher than V_{mr}. In every flying bird morphology is best adapted to suit performance largely so that speed and energy are optimized: flight is so demanding on energy consumption that selection will ensure that no resources are wasted and that food is gathered in the optimum way.

Speed measurement. In view of the numerous factors involved in the selection of flight speed and the great difficulties inherent in measuring it, it is hardly surprising that published bird speed records show little coherence. Many methods have been used with remarkably little success; techniques such as triangulation or pacing from cars, trains or aircraft are particularly unlikely to produce meaningful data. The best method is probably low-range Doppler radar tracking of a known individual; with tracking radars the bird may not be accurately identified, and exact wind strength and direction are rarely known. High-speed cinematography can be valuable if the camera used and distances are accurately calibrated, but with every technique it is vital to record wind velocity and to take note of what the bird is trying to achieve. Because many observers have been prevented from doing this, published speed records, such as those tabulated by Meinertzhagen, are often misleading and inaccurate. Table 1 lists recent radar measurements of cruise (usually migration) flight speeds in still air or light winds. These are believed to be reliable, and in most cases represent flight at or near V_{mr}.

Considerable popular interest is devoted to records such as the 'fastest' bird, and to this end many fanciful estimates of speed have been published. Comparisons of this kind between species are invidious, but from the table it can be seen that speeds rarely exceed 20 m/s (72 km/h), and doubt must be expressed over air speeds for steady powered flight much in excess of this. The fastest speed for any type of flight probably occurs during the stoop of the Peregrine *Falco peregrinus*, but no accurate determination of speed has been made, and it is probably no more than about 50 m/s (180 km/h). In steady flight the fastest bird reliably clocked as yet is the Eider *Somateria mollissima* at 21 m/s (76 km/h); this bird has the highest recorded wing loading. Contrary to popular opinion, swifts are among the slowest of birds, as is consistent with their long, thin wings; speeds for the Common Swift *Apus apus* in foraging (6.5 m/s, 23 km/h) are slightly higher than V_{mp}, at the expected optimum for an aerial insectivore; in migration they fly at about 11 m/s (40 km/h), that is at V_{mr}. FLIPPER: term applied to the modified wing in the Spheniscidae (see PENGUIN; SWIMMING AND DIVING).

FLOCK: see ASSEMBLY, NOUN OF.

FLOCKING: term for the positive social behaviour of individual birds that results in their joining into groups (flocks), as distinguished from aggregations of animals resulting from the influence of ecological factors alone.

Characteristics of flocks. Flocks may consist of one to several species, the latter usually referred to as mixed-species flocks. Dominance hierarchies may exist in both single and mixed-species flocks, and an individual's ranking may affect its access to food. In the tropics flocks exist year-round, while at higher latitudes they are confined to the non-breeding season and to non-breeding birds. Flocks range in size from a few birds to thousands of individuals, as seen in some icterid or finch flocks. Many flocks are constantly on the move, showing a loosely coordinated, unidirectional movement that distinguishes them from chance aggregations. They may cover as much as several hundred metres within an hour, even when their individuals are successful in finding food. Members of compact open-country flocks frequently exhibit conspicuous 'leap-frog' movements, in which birds at the rear fly over and land in front of the other members. In this way they minimize the probability of encountering just-exploited areas.

Although flocks result in a large-scale clumped distribution of birds, at a smaller scale these birds are evenly spaced. Members of open-country flocks are usually spaced much more closely than those of forest-dwelling flocks, sometimes not over a body-length apart. Birds in forest-dwelling flocks usually remain at least several metres apart, but their minimal tolerated distances (individual distances) vary among species or at different times. Half of the advances by Black-capped Chickadees *Parus atricapillus* to within 3 m of a conspecific resulted in a supplanting action or retreat; in Blue Tits *Parus caeruleus*, the corresponding distance was one metre.

Flock members may either roost communally or apart. Icterid and starling flocks sometimes remain as units within large roosts. Members of forest-dwelling flocks, however, usually roost in holes or other sites independently of each other and join shortly after becoming active in the following morning.

Flock members obtain one or more general advantages: feeding, predator-avoidance, and reproductive. In most cases, reproductive advantages (*sensu stricto*) may be separated from the others and they will not be further discussed here (see NATURAL SELECTION). Bird flocks bear many functional similarities to fish schools and mammal herds or troops.

Feeding advantages. Foraging flocks are a common phenomenon among birds. Hypothetically, birds may obtain several food-related advantages while in them.

Facilitation of food-finding. Probably the most frequently suggested feeding advantage is that participating in a group facilitates food-finding. One bird may observe another foraging and join it if the original forager is successful. For this to be advantageous, food must be so abundant that one individual can not consume it all quickly. Alternatively, an individual may simply forage at a site similar to one where another individual is foraging successfully. The only experimental evidence supporting either alternative is from the laboratory studies using Great Tits *Parus major*. Several field studies have also produced evidence consistent with this advantage. Rather than increasing the amount of food that an individual will find, flocking may lessen the danger of an individual going without food for long periods. Given the severe conditions often experienced by birds at high latitudes during the winter, and the tendency for flocking to increase as climatic conditions grow more severe, this hypothesis has merit.

Minimizing duplication of effort. If flock members deplete an area other birds must avoid that site. They may obtain this advantage by watching the movements of others, although little direct evidence exists that they do this. This pattern would be advantageous if food were evenly distributed in parcels too small for more than one individual to exploit.

Success from numbers. Individuals may have access to certain resources by sole virtue of their numbers. If Cedar Waxwings *Bombycilla cedrorum* enter a Mockingbird *Mimus polyglottos* territory, the Mockingbird will attempt to drive them out, but if their flock consists of several score individuals, the Mockingbird may be able to evict only a small minority of them. In this way the Waxwings can exploit the rich berry sources often defended by a Mockingbird during the winter.

Beating. It is often suggested, particularly in the older literature, that a major advantage of flocking lies in the insects that are flushed (and subsequently captured) by the participants. Some individuals may so benefit when insects are active; however, the advantage cannot occur in all cases, since flocks of small insectivorous birds are most prominent at high latitudes during winter, when insects are inactive. Further, unless birds can capture flying insects, they are unlikely to benefit. For beating to be a direct advantage of flocking, rather than an advantage only to certain members, more flushed prey must be captured by birds when in groups than when alone, and this advantage must hold for all members. Such conditions are not met in most flocks of small insectivorous birds, and certainly not in flocks that feed on non-motile prey. However, Cattle Egrets *Bubulcus ibis* feeding in groups may obtain this advantage, although their foraging success is lower than when they follow cattle. Flocks of pelicans, cormorants and mergansers may also drive schooled fishes into shallow water where these birds can capture their prey more readily than in deep water.

Predator-avoidance advantages. Flock members may enhance their ability to escape predators in several ways.

Increased awareness of predators. Individuals should be apprised of predators more rapidly in groups, because many eyes are present. Predation is less severe on members of wader and Woodpigeon *Columba palumbus* flocks than on single individuals. Vulnerability decreases as flocks become larger up to a certain point. In the case of waders and corvids, detailed observations have shown that more birds were taken from larger flocks than from smaller ones. If flocks become too large, an individual on one side of the flock may not see a predator approaching from the other. Alternatively, individuals might get in each other's way during an escape. Evidence on these points is not available for most bird flocks, and some workers have argued that the increased conspicuousness of flock members may negate any advantages. Members of many flocks call nearly continuously, including notes that may not be given at other times. Thus, although the percentage of successful attacks might decline, the number of attacks might increase.

Confusion effect. A mass response, whether a sudden flight or calling, may confuse a predator, at least temporarily, giving flock members the opportunity to escape. When confronted with many simultaneous stimuli, a predator may find it impossible to separate out a single individual. When attacking a flock, a predator's typical strategy is to separate an

Oystercatchers *Haematopus ostralegus* flocking. (*Photo: H.E. Grenfell*).

individual if possible. Many, although not all, flocking species give characteristic calls upon detecting a predator. These calls have been considered difficult to localize because of their acoustical properties. However, at least some avian predators can localize them; but in any case the fact that it is calling means that the flock member is aware of the predator. As a consequence, the predator may not attempt to capture it.

Discouraging predators. Some animals may repel predators as a consequence of their numbers, by posing a threat. Flocks in flight tighten their formation, thereby providing a target that may be dangerous to any predator that attempts to fly into the middle of it. Starling *Sturnus vulgaris* and Red-winged Blackbird *Agelaius phoeniceus* flocks may even turn on their attackers, forcing them on to the ground or into the water. Alternatively, if being in a flock makes individuals more difficult to capture, it may not be worth the predator's efforts to attack, though no data known to the writer support the existence of this effect in bird flocks.

Cover-seeking. A given flock member might obtain protection from predators by hiding behind other members, or at least by positioning itself so that one or more flock members lie between it and the predator. This behaviour would favour central individuals over peripheral ones and would tend to result in a compact group. Little direct evidence exists for this in birds. In flocks with widely-spaced individuals, such as mixed-species insectivorous flocks, such a hypothetical advantage would seem confined to maintaining a core position, thus keeping other individuals between the actor and the periphery, from which an attack would normally come. However, even if these effects were demonstrated, they could not be considered a primary advantage of flocking, unless all members benefited from it. Thus, if peripheral individuals suffered increased predation as a consequence, they would be continually peeled off the outside. More likely, peripheral individuals would stop flocking before severe predation ever took place.

Decreasing the probability of discovery. Several workers have suggested from mathematical formulations that animals in groups should be discovered less frequently than if they were solitary. However, it is questionable whether such advantages exist in the real world. These models assume random movement on the part of the flocks and predators and do not account for possible behavioural changes of members between solitary and social situations. Flock members and their predators, at least when in heterogeneous habitats, concentrate their activities in certain places. Further, they perform various behavioural patterns that are not typically given by solitary individuals. For instance, tits in flocks regularly produce calls that are not given elsewhere. If a flock member becomes temporarily separated from other individuals, it often calls loudly from a conspicuous perch. Both these behaviours make flocks conspicuous to human observers, and probably to flock predators as well.

Single-species and mixed-species flocks. Both single-species and mixed-species flocks may share the non-reproductive advantages discussed above. However, differences should exist in the magnitude of advantages obtained. Although members of mixed-species flocks overlap with each other in foraging, this overlap is lower than that among members of the same species. Thus, if food is scarce, individuals of different species would not be disadvantaged as greatly as members of the same species. However, any food-related advantages should not be as great as those obtained in a single-species flock.

If the energetic stakes are lower in mixed-species flocks than in single-species flocks, some other factor should account for the existence of mixed-species, as opposed to single-species, flocks. Anti-predator advantages should be relatively greater in mixed-species flocks, by virtue of the greater variety of eyes brought to bear, the wider range of locations often exploited at a given time, and the larger size often possible in mixed-species groups, a probable consequence of lowered competition.

Certain species often sound anti-predator warnings first. Carolina Chickadees *Parus carolinensis* usually sound the warning in mixed-species forest flocks in eastern USA. It is not clear whether they are thus being parasitized by other species, or whether the sentinels obtain special advantages in return. However, species sharing relatively little foraging similarity to other members of flocks sometimes move with them for considerable distances. For instance, Eastern Bluebirds *Sialia sialis*, Dark-eyed Juncos *Junco hyemalis*, and Chipping Sparrows *Spizella passerina* often follow tit flocks through open woodlands, spending much of their time foraging on the ground. If individuals in the trees sound warnings, these 3 species fly rapidly to cover. They probably take advantage of the others' elevated locations to lessen the danger of being captured unaware. If so, this relationship is a commensal one; that is, one in which they benefit and the other members are unaffected.

Migrants in flocks. Flock function has been little studied during migration, although migrants often move in groups or join other flocks between their flights. Migrants might find rich food sites or protection from predators by following resident groups. Since migrants are unfamiliar with their surroundings, their potential reward from joining residents should be large.

Evolution of flocking. Many workers have argued that either foraging or anti-predator advantages are responsible for the evolution of flocking. These arguments are fraught with danger, because it is unlikely that either advantage will exist in the absence of adaptations associated with the other. Thus, if individuals commenced to form flocks that enhanced foraging, they would quickly become vulnerable to predation, unless they simultaneously developed anti-predator adaptations lowering predation at least to a point where feeding advantages outweighed the increased risk of predation.

Alternatively, if individuals formed flocks that enhanced avoidance of predators, they would be likely to incur feeding disadvantages as a consequence. Strong pressure would consequently develop to minimize foraging disadvantages. In either case, if one capability develops, the other should quickly follow.

Flock size. A close relationship may exist between energetic conditions, aggression levels, predation pressure, and consequent flock size. When energetic demands are stringent, foraging occupies so much of flock members' time that they have little time left to fight. This might happen at a time of deteriorating food supply, or when cold weather makes high energetic demands. Flocks increase in size and cohesion at such times, and individuals simultaneously decrease their frequency of scanning for predators, permitting an increased proportion of time to be spent searching for food, presumably with no added danger of predation. If conditions become less stringent, more time is available for fighting. Flock size declines at such times, probably because subordinate birds are harassed so frequently that it no longer benefits them to participate in the flock. However, certain reports are not consistent with these observations. For instance, increased fighting for food accompanies extremely severe conditions in corvid and tit flocks. Whether or not flock sizes in extremely large groups follow this pattern remains to be explored. The flocks discussed here are of modest size, within the range in which individual recognition remains possible.

Other groupings. In practice it may be difficult to distinguish between flocks and other groupings (see ROOSTING; COLONIALITY). Some of the flocks discussed above have clearly-defined commensals attached to them, such as the bluebirds *Sialia* and sparrows (Emberizidae) that follow tit flocks. It is not a great jump from these associations to two-species feeding associations, such as those between grebes and ducks or coots, in which the former obtain food dislodged by the latter. Similar associations may even form between birds and other animals, such as squirrels that follow bird flocks, or monkeys that follow hornbills.

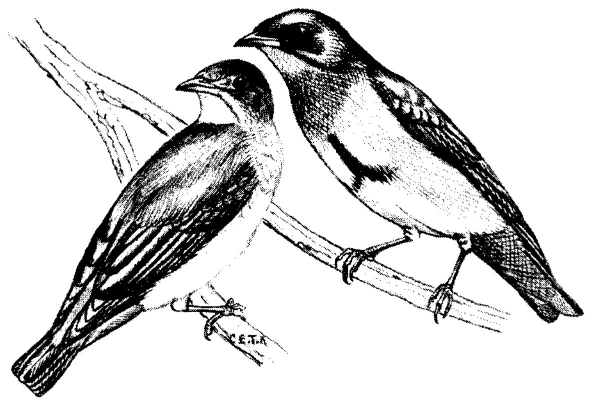
FLORA: the total plant life of an area (contrasted with FAUNA); see HABITAT.

FLORICAN: substantive name (also spelt 'floriken') of 2 Indian species of Otididae (see BUSTARD).

FLOWERPECKER: substantive name of some species of Dicaeidae (Passeriformes, suborder Oscines); in the plural, general term for the family. This is a group of small or (rarely) medium sized arboreal birds (7.5–19 cm long) of Oriental and Australasian distribution.



Mistletoebird *Dicaeum hirundinaceum*, female (left) and male. (*C.E.T.K.*).

Characteristics. Most (40 out of 55 species) are grouped within the 2 widely distributed genera *Prionochilus* and *Dicaeum*. These typical flowerpeckers are small birds, with a wing length in adult individuals of 4.0–7.5 cm, and with short, stumpy tails. The bill, in which the edges of the distal third are serrated, is short, varying in structure between a stout and blunt type like that of tits (Paridae) and a thin, attenuated, more or less decurved type like that of warblers (Sylviinae) or short-billed sunbirds (Nectariniidae). The short tongue has, in its deeply cleft distal half, the edges curled to form two slender semitubular tips; this somewhat resembles the tongue structure in sunbirds and is probably an adaptation to nectar feeding. The plumage coloration in some species is plain, similar in both sexes; in other species the males are brightly coloured, often with contrasting patches of red and with glossy areas, the females as a rule being more dully coloured. The outermost (tenth) primary is well-developed in *Prionochilus*, but vestigial in *Dicaeum* except in *D. melanoxanthum*.

Habitat. Habitat selection is very varied. Some species frequent lowland rain-forest, others the montane mossy forests, and *Paramythia montium* ascends even to the stunted trees of the timberline. Many species prefer second growth, bamboo groves, and cultivated areas, and may, as in the case of the Scarlet-backed Flowerpecker *Dicaeum cruentatum* of Burma and Malaya, be common inhabitants of village and town gardens. The New Guinean endemic genera mainly frequent forest understory. The Mistletoebird *Dicaeum hirundinaceum* of Australia occurs in diverse habitats, ranging from rain-forest to arid *Acacia* woodland.

Distribution. The distribution of the family covers the whole Oriental Region westwards to the drier parts of India, and the Australasian Region (not New Zealand) eastwards to the Solomon Islands. Two species, *Dicaeum ignipectus* and *D. melanoxanthum*, range into the Palearctic parts of the Himalayan area and south-western China. Richest in species are the Philippines (13 species, of which 11 are endemic) and New Guinea (11 species, all endemic).

The New Guinean genera *Melanocharis* (with 5 species) and *Rhamphocharis* (monotypic) are more primitive and have a rather simple structure of the tongue, but in many ways show relationship to *Prionochilus*. The New Guinean monotypic genera *Oreocharis* and *Paramythia*, as well as the Australian genus *Pardalotus* (pardalotes or diamond-birds) with 7 species inhabiting the Australian continent and Tasmania, are more aberrant, and their relationship with the typical flowerpeckers is obviously remote. They share with *Dicaeum* the vestigial outer primary, but differ in having simple tongue structure and in lacking the serration of the bill. Even in habits they differ strikingly. The Tit Berrypecker *Oreocharis arfaki* resembles a large tit, while the Crested Berrypecker *Paramythia montium* is the size of a thrush *Turdus*. The pardalotes come nearest to the typical flowerpeckers in appearance. They are small birds with short tails, tit-like bills, and a variegated plumage in which a spotted pattern is very conspicuous and has given rise to the common names. Nevertheless, the pardalotes may probably belong to a separate family, the Pardalotidae, as protein analysis indicates they are closer to other Australian families than to the Dicaeidae.

Movements. All flowerpeckers are sedentary in high degree, except the Mistletoebird *Dicaeum hirundinaceum*, which has nomadic habits and is a powerful flyer with long swallow-like wings.

Food. The food of the typical flowerpeckers consists of berries (chiefly those of the family Loranthaceae), nectar, and insects. The pardalotes are almost entirely insectivorous, while the 4 New Guinean endemic genera are fruiteaters.

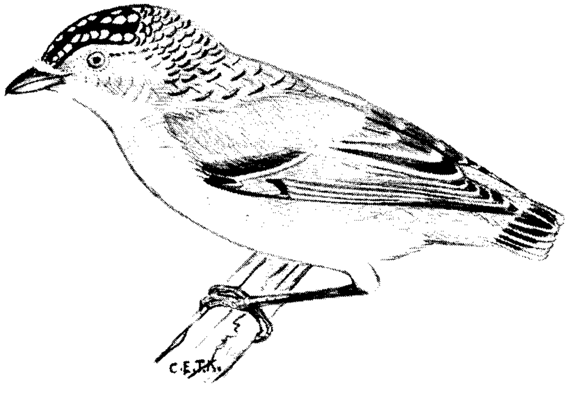
Behaviour and voice. The typical flowerpeckers resemble sunbirds in appearance and general habits. They usually frequent high trees, where they fly restlessly around in search of food, their favourite hunting grounds being flowering epiphytes, strangling figs, or, particularly, clumps of parasitic plants growing high up in the branches. They are energetic and noisy birds that turn and twist about in every kind of attitude and constantly twitter when feeding. During flight they utter rather sharp call notes that can be rendered as *chip*, *chip*. Some species have modest warbled songs. The flowerpeckers are not especially gregarious, but appear in pairs or family parties.

Breeding. The pendent, domed nests of the typical flowerpeckers are similar to those of sunbirds. They are pear-shaped structures, suspended by the stalk from a twig, with the entrance high on one side, built of vegetable fibres, rootlets, grass, and cobwebs, lined with silky down. The nest of the Thick-billed Flowerpecker *Dicaeum agile* (Indo-Malayan) differs in its peculiar felt-like fabric. The pardalotes place their nests in holes in trees or hollows or crevices in the ground, or in a tunnel excavated by the birds themselves, usually in the side of a bank. The nest itself is elaborately built of bark and grass, and is usually cup-shaped—but domed in some species. Nests of the endemic New Guinean *Paramythia* and *Melanocharis* are cup-shaped and placed in dense bushes.

Most flowerpeckers lay white eggs, only *Paramythia*, *Melanocharis* and a few species of *Dicaeum* have spotted eggs. The clutch size is 1–4 (usually 2) in *Dicaeum* and *Prionochilus*; 2 in *Melanocharis*, one only in *Paramythia* while *Pardalotus* lays 2–5, usually 4. In the species investigated the female alone builds the nest and incubates the eggs, while both sexes participate in the feeding of the young. In *Pardalotus* it is known that the excavating of the nesting tunnel is shared by both sexes.

Ecological relations. A close association exists between certain flowerpeckers and the mistletoes (chiefly Loranthaceae: *Amyema*, *Lysiana*, *Muellerina*, *Dendrophthoe*, *Viscum*). Many species among the typical flowerpeckers feed almost exclusively on the fruits of these plants (apart from insects), and at the same time they constitute by far the most effective disseminators of the mistletoe seeds. In this way a mutual dependency, highly specialized, has evolved between the plants and the birds. In spreading these harmful parasitic plants, which are a serious pest in many areas, the flowerpeckers become important birds from an economic point of view.

The method of eating the mistletoe berries differs according to the structure of the bill. The thick-billed species, such as *Dicaeum agile*, use the bill to separate the fleshy epicarp from the seed, swallowing the former and getting rid of the latter by scraping it off on a twig. The thin-billed species, such as Tickell's Flowerpecker *Dicaeum erythrorhynchos* of India, swallow the berries whole and void the viscous seeds after an astonishingly short time, usually a few minutes. The seeds are able to germinate in both cases, i.e. whether they have passed through the alimentary canal of the birds or not. The extraordinary rapidity with which the mistletoe fruits pass through the intestines is due partly to the laxative effect of the berries, but mainly to a special structure of the stomach. The muscular stomach has developed into a blind sac with a sphincter at its opening, which construction allows the easily digestible



Red-browed Pardalote *Pardalotus rubricatus*. (*C.E.T.K.*).

berries to pass directly from the oesophagus to the intestine without entering the stomach; on the other hand, insects and spiders, which need grinding and a more thorough treatment before the digestible parts can be assimilated, are not prevented from entering the muscular stomach. The alimentary canal of *Melanocharis* and *Paramythia* is not so specialized, but more closely resembles that in other fruit-eating passerines.

Owing to their nectar feeding, many flowerpeckers are of importance as pollinators of various flowers, but in this respect play a lesser role than honeyeaters (Meliphagidae), sunbirds (Nectariniidae), and some other groups (see POLLINATORS; SEED DISPERSAL.) F.S.

FLOWER-PIERCER: substantive name of *Diglossa* spp., a group of specialized Neotropical passerine birds (suborder Oscines) formerly included in the family Coerebidae but now treated as members of the tanager subfamily, Thraupinae (see HONEYCREEPER (1); TANAGER). Relationships within this large passerine assemblage are still uncertain, and future research may well modify the arrangement adopted here. The most striking character of the flower-piercers is the form of the bill and associated feeding method. The upper mandible has a sharply hooked tip and is notched along the cutting edge, while the lower mandible, which is a little shorter, ends in a very sharp point. Flower-piercers extract nectar from flowers by hooking the upper mandible round the corolla tube, thus holding it in position while the lower mandible pierces the tube and the tongue, which is unusually long and U-shaped in cross-section, is inserted into the slit. By this means flower-piercers are able to visit and take the nectar from small flowers in very rapid succession, as well as extracting more slowly the more copious nectar from larger flowers. Since they do not come into contact with the reproductive parts of the flower they are 'nectar thieves' rather than pollinators, and where they coexist with hummingbirds they may be important ecological competitors. On occasion, however, they may also extract nectar in the 'legitimate' manner, by inserting the bill into the mouth of the corolla tube if the mouth is wide enough. Not all species of flower-piercers are equally specialized; in some the bill is less highly modified and fruit may be an important part of the diet. Probably all the species also take insects.

Distribution. The flower-piercers have their centre of abundance in the Andes, where they are a characteristic element in the avifauna of woodland and shrubby country at subtropical and temperate levels. One species extends to the highlands of Central America, and 2 endemic species occur in the isolated highlands of southern Venezuela. The total number of species of *Diglossa* is problematical, as there has evidently been much recent diversification of populations isolated in different parts of the Andes, and it is in several cases not clear whether the isolates have diverged sufficiently to qualify as separate species; 11 species are currently recognized.

Characteristics and breeding. Flower-piercers are mainly dull-plumaged birds, largely slaty grey or black in the male and paler grey and olive in the female; but dark shining blue plumage occurs in some species, and in another the black plumage is set off by a conspicuous tuft of white feathers on each flank. Their voices are generally weak and high-pitched. The nest of the only species that has been well studied, the Slaty Flower-piercer *D. baritula* in Central America, is a substantial cup placed in a shrub or sapling, and the 2 eggs are bright blue spotted with brown. The nestlings are fed by regurgitation, and receive the food into a large protuberant crop, in which respect they resemble the hummingbirds. D.W.S.(1)

FLUKES: see ENDOPARASITE.

FLUSH: disturb bird, usually into flight.

FLUVICOLINAE: subfamily of Tyrannidae (see FLYCATCHER (2)).

FLYCATCHER (1): substantive name of the family Muscicapidae (Passeriformes, suborder Oscines), comprising about 150 species distributed throughout the Old World.

Characteristics. The species in this large group are very variable in plumage and behaviour but most are about 10–20 cm in length and are characterized by broad, flattened bills surrounded by rictal bristles and short, weak legs that are used mainly just for perching. Most of the larger species have long wings and are good fliers, feeding by hawking flying insects in mid-air or by diving from a perch on to insects on the ground. Some of the smaller species feed like warblers (Sylviidae), hopping amongst vegetation and picking insects from the foliage. In the New World the flycatcher ecological niche is occupied by the tyrant-flycatchers of the family Tyrannidae (see FLYCATCHER (2)).

Habitat and distribution. The family includes the *Ficedula* and *Muscicapa* flycatchers of Europe, Africa and Asia, the *Melaenornis* and *Bradornis* flycatchers from Africa, and the *Niltava* and *Eumyias* flycatchers from Asia.

The habitats occupied come under two broad categories related to foraging behaviour. Some species inhabit parks, orchards, gardens and woodland edges where they sally forth from prominent perches and capture flying insects or prey on the ground, often returning to the same perch again after a capture attempt (e.g. Spotted Flycatcher *Muscicapa striata* and Verditer Flycatcher *Eumyias thalassina*). Other species inhabit woodland where they capture insects on the wing amongst the branches or pick up prey from the foliage in the canopy (e.g. Pied Flycatcher *Ficedula hypoleuca*). Some species may join mixed-species flocks in the foliage of forest trees. In the Himalayas, for example, the Rufous-bellied Niltava *Niltava sundara*, is frequently seen with small parties of tits, warblers and babblers, snapping up small insects disturbed by the flock as it moves through the trees.

Populations and movements. As might be expected from their specialized insect diet, flycatchers are migratory. All the Palearctic species winter in the tropics. The Pied and the Collared Flycatcher *F. albicollis* winter in Africa south of the Sahara, probably mainly in evergreen forest in the canopy and along forest edges. The Spotted Flycatcher winters from Kenya south to the Cape in thorn country, forest edges and gardens. The Red-breasted Flycatcher *F. parva* winters in India and Sri Lanka. Species breeding in the Himalayas show altitudinal migration, moving down into the valleys in winter.

In the breeding season the Pied Flycatcher inhabits deciduous, and sometimes coniferous, woodland in western and northern Europe. In south-eastern Europe it is replaced by the very similar Collared Flycatcher and there is an area of overlap in central and eastern Europe and on the island of Gotland in the Baltic where the 2 species occasionally interbreed. On Gotland, the Collared Flycatcher is 10 times as abundant as the Pied Flycatcher and the 2 species hybridize (4% of all matings) at frequencies less than predicted for random mating (13%). Mixed pairs produce just as many offspring as same-species pairs but fewer hybrids breed than would be expected from the proportion of hybrid fledglings in the population, probably due to poorer survival after fledging and also, perhaps, to the inefficiency of hybrids at mate attraction.

Food. Pied and Collared Flycatchers feed their young on both adult and larval insects, particularly caterpillars collected from the tree canopy. The Spotted Flycatcher takes mainly large flying insects, especially Diptera (Muscidae, Calliphoridae, Scatophagidae, Syrphidae), Lepidoptera and Coleoptera. They also eat bees (*Bombus*) and wasps (*Vespula*) and beat these against a perch to remove the stings before swallowing them or giving them to their nestlings. Early in the morning or during cold, wet days, when large flying insects are scarce, they feed up in the tree canopy on swarms of small insects, especially Chironomidae and Aphididae. During the egg laying stage the female seeks out calcium-rich prey including snails (Mollusca) and woodlice (Isopoda) presumably to help her form the egg shells. These prey are also given to the nestlings, probably to help bone growth. Nestlings are given larger prey than the adults eat themselves because it is more economical to carry large prey back to the nest.

Spotted Flycatcher *Muscicapa striata*. (R.G.).

Behaviour. Most species are territorial in the breeding season. Pied Flycatchers defend their nest holes and Spotted Flycatchers defend their nest sites and favourite feeding perches presumably to avoid interference in prey capture from conspecifics. Male and female within a pair may also avoid interference by feeding in different parts of the territory. Other species, including the Pied Flycatcher, defend feeding territories even during the short stop-overs on migration when they spend a week or so fattening up prior to the Sahara crossing.

In the breeding season the nest defence behaviour of the Pied Flycatcher is beautifully adapted to the dangers presented by particular predators. Woodpeckers and squirrels, which are only a threat to the brood, are attacked with swooping dives accompanied by snarling calls. Owls and Red-backed Shrikes *Lanius collurio* on the other hand prey upon both the adults and the young and are merely mobbed from a safe distance. Experiments with hand-reared, naive birds showed that recognition of these predators is innate. The Spanish population of the Pied Flycatcher, *F. hypoleuca iberiae*, reacts to owls but not to Red-backed Shrikes, which are absent from Spain. Therefore geographical variation in enemy recognition matches the occurrence of the predators.

Voice. Some species have songs consisting of musical warbles but in others the song is very weak and is just a few thin, squeaky notes. Many species utter loud alarm calls, much heard when the young have fledged.

Breeding. Some species build neat, open cup-shaped nests in crevices in walls or against tree trunks (Spotted Flycatcher). Others breed in holes in trees (Pied and Collared Flycatchers) and will regularly occupy nest boxes. The Black and Orange Flycatcher, *Ochromela nigrorufa*, of southern India builds an enclosed nest of moss, with a side entrance, under tree roots on the forest floor. Sometimes the old nests of other species are used, for example old thrush and blackbird *Turdus* nests (Spotted Flycatcher), old weaver bird nests (Swamp Flycatcher *Alseonax aquaticus*) and old woodpecker holes (Pied Flycatcher).

The eggs of flycatchers are blue, brown, red, yellow or white in background with spots and mottling. In tropical or subtropical species the clutch is usually 2–3 eggs but in temperate regions it is larger (usually 5–7 but up to 10 in the Pied Flycatcher and usually 4–5 in the Spotted Flycatcher). In *Ficedula* spp. it is usually the female who incubates alone but in other species both sexes take part. Both parents feed the young. Incubation and nestling periods are both about 10–15 days.

In the Spotted Flycatcher the male may provide up to 30% of the female's food by courtship feeding during the egg-laying period and he also feeds her while she is incubating on the nest. In the Pied Flycatcher the male may provide the incubating female with half her food requirements. There have been several detailed population studies of the Pied Flycatcher with densities of up to 4 nests per hectare. Early broods are more successful than late broods, reflecting the decline in the abundance of the caterpillar food for the young. There is a seasonal decline in clutch size; for example in the Forest of Dean in England, mean clutch size is 7.5 at peak in May and 4.5 in the middle of June.

In both the Pied and the Collared Flycatcher, some males are successively bigamous and some first year males fail to breed. A male increases his reproductive success through polygamy but his second female suffers because only the first female gets the male's help with chick feeding. A male goes a long way from his first nest site (up to 3.5 km) in order to attract a second female, perhaps to deceive her into thinking that he is unmated.

In Britain, the Spotted Flycatcher is one of the last summer visitors to arrive and breed, usually laying at the end of May. This is probably because it is not until fairly late in the summer that there is a guaranteed supply of large flying insects on which this species feeds its young.

FLYCATCHER (2): substantive name of most species of Tyrannidae (Passeriformes, suborder Deutero-oscines, infraorder Tyranni); in the plural forms 'tyrant-flycatchers' or 'New World flycatchers', general name for the family; a diverse assemblage of 375 species in about 90 genera, entirely restricted to the New World, predominantly the Neotropical realm where it is numerically the dominant land-bird family. Other major substantive names for members of the family include 'tyrant', 'tyrannulet', 'kingbird', 'phoebe', 'pewee', 'flatbill', and 'elaenia'.

Systematics. Closely related to Cotingidae and Pipridae, with which its taxonomic boundaries have been enigmatic. Presently considered to contain at least 3 subfamilies, Elaeniinae, Fluvicolinae, and Tyranninae; by some authors, a fourth subfamily, Tityrinae, is provisionally moved to this family from Cotingidae. The family is defined primarily by cranial, syringeal, and tarsal characters.

Characteristics. In its great diversity of body forms and foraging styles, the family replaces numerous Old World families, principally the Muscicapidae (see FLYCATCHER (1)). The family includes ecological counterparts of warblers, wrens, vireos, jays, shrikes, pipits, thrushes, and certain icterids, as well as many sorts of aerial flycatching species of various families. Body sizes range from the smallest passerine species (Short-tailed Pygmy-Tyrant *Myiornis ecaudatus*; total length 5 cm, wing length (3.0–3.5 cm) up to medium-sized birds in the genera *Agriornis*, *Xolmis*, *Tyrannus* and their relatives (wing lengths 11–14 cm). Body weights span from 4.5–80 g. Sexual dimorphism in size is minor, males averaging slightly the larger.

Variation in body form is primarily associated with the diversity of foraging styles. Wings are short and rounded among the tody-tyrants (*Todirostrum*, *Hemitriccus*, and related genera), which glean prey with short hops in dense foliage. Wings are long and pointed in the many genera that forage with powerful aerial sallies in open places, such as the kingbirds *Tyrannus* spp. and pewees *Contopus* spp. Deeply forked and greatly elongated tails occur in many of these 'aerial hawkers', including the genus *Tyrannus* (contains Scissor-tailed *T. forficatus* and Fork-tailed *T. savana* Flycatchers, formerly genus *Muscivora*), in the Streamer-tailed Tyrant *Gubernetes yetapa*, Long-tailed Tyrant *Colonia colonus*, and others. Tarsi vary from extremely short in the Cliff Flycatcher *Hirundinea ferruginea*, to long and strong in several terrestrial genera such as *Muscisaxicola*, *Muscigralla* and *Machetornis*. Bills tend to be broad at the base, but great variation is evident in this character as well; the longest and broadest bill is that of the Boat-billed Flycatcher *Megarhynchus pitangua*; specialized, wide and spatulate bills occur in the spadebills *Playtrinchus* spp., flatbills *Rhynchocyclus* spp., and relatives; narrow, warbler-like bills occur in several genera (e.g. *Ornithion*, *Camptostoma*, *Inezia*) that probe and glean for insects without sallying from perches.

Rictal bristles are in general well developed, excessively so in *Onychorhynchus*, *Myiobius* spp. and relatives; in species that are either heavily frugivorous (e.g. *Elaenia* spp.) or do not sally while foraging (e.g. Southern Beardless Flycatcher *Camptostoma obsoletum*), rictal bristles are reduced or absent.

Overall coloration typically is drab; the most common pattern is olive-green above, bright or pale yellow to whitish below, with or without pale superciliary eye rings, stripes, or wingbars. Other colours include browns, greys, black and white. Bright colours besides yellow are rare, and blue is virtually absent. Eight tyrannine genera share a common colour pattern of bright yellow underparts, dull olive back, and contrasting black or grey and white stripes on the crown. Many species show slight to well developed crests. Semi-concealed red, orange, yellow, or white crown patches occur in 30 of the 90 genera. The most extreme crown ornamentation is a long, erectile crest of brilliant orange feathers tipped iridescent blue, in the Royal Flycatcher *Onychorhynchus coronatus*. Pronounced sexual dimorphism in plumage is rare except in one group of fluvicoline genera, in which males typically are black or black-and-white, and females are brownish (e.g. *Knipolegus*, *Fluvicola*, *Alectrurus*). The male Vermilion Flycatcher *Pyrocephalus rubinus* is predominantly brilliant scarlet, unique in the family. The Many-coloured Rush Tyrant *Tachuris rubigastra*, a marsh-dwelling species of Argentina and the high Andes, shows a harlequin pattern of reds, yellows, blue, green and black.

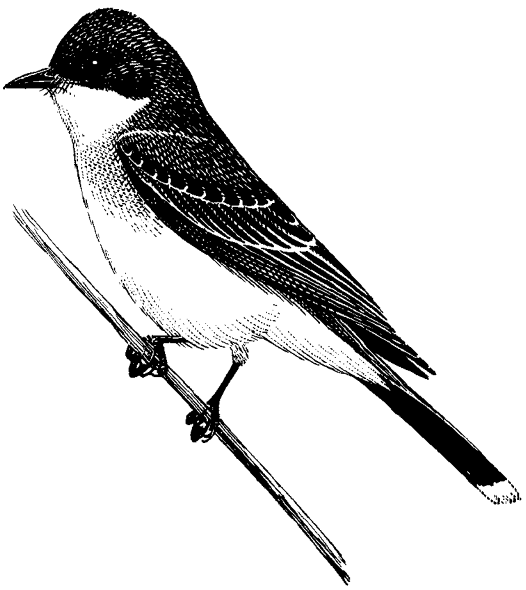
Habitat. Foliage-gleaning species, which predominate, occur in all vegetation types from temperate woodlands and tropical desert scrubs to dense deciduous and evergreen forests, from treeline to sea-level. Aerial hawking flycatchers occupy open, forest-edge habitats, water margins, and cliff faces. Terrestrial species, such as the Cattle Tyrant *Machetornis rixosus* and various ground-tyrants (genus *Muscisaxicola*), predominantly occupy savanna or bare, rocky alpine habitats. Many species dwell along stream, river, and lake margins, where they may take aerial prey (e.g. Black Phoebe *Sayornis nigricans*), aquatic prey from the surface (e.g. Lesser Kiskadee *Pitangus lictor*) or even from underwater (e.g. Greater Kiskadee *Pitangus sulphuratus*, a frequent fish-eater).

Distribution. Found virtually throughout the New World, tyrant-flycatchers occur from the taiga of Alaska and northern Canada (where all species are migratory) south through the Americas and West Indies to the southern tip of South America and adjacent islands, including the Galapagos Archipelago (2 species). Only about 30 species occur north of Mexico. Greatest diversity is reached in the Amazonian and eastern Andean forests. More than 70 species have been found together at several localities in western Amazonia.

Many lowland species occur throughout the forested Neotropics. Certain open-country species such as the Tropical Kingbird *Tyrannus melancholicus* and Vermilion Flycatcher occur from southern North America south to central Argentina. Others, especially those inhabiting cloud forests or oceanic islands, show greatly restricted distributions.

Movements. All species that breed in North America are at least partially migratory, wintering primarily in Central and northern South America. In some species only the northernmost populations migrate. The Eastern Kingbird *Tyrannus tyrannus* migrates in huge flocks from as far north as Alaska and northern Canada south as far as Bolivia and northern Argentina. Many long-distance migrants, such as the Eastern Wood Pewee *Contopus virens*, maintain exclusive territories on their wintering grounds. Many, perhaps most, of the temperate-zone species of Patagonia, southern Argentina, and even southern Brazil migrate northward to equatorial latitudes. The Piratic Flycatcher *Legatus leucophaius* migrates entirely within tropical latitudes, apparently in response to seasonal patterns of fruiting by tropical forest trees. Local movement patterns within tropical forest regions by Olive-striped and Ochre-bellied Flycatchers and relatives (*Mionectes* spp.) have been recently documented, but remain poorly understood.

Food. Feeding habits vary enormously within the family, but nearly all species are predominantly insectivorous. Insects of all kinds are eaten, most frequently snatched from the air or from leaf surfaces during a rapid, sudden flight (sally) from a stationary perch. Some species, like the shrike-tyrants *Agriornis* spp. and the monjitas *Xolmis* spp., drop to the ground from exposed perches in the manner of bluebirds (*Sialia*). Others, mentioned above, take various invertebrates while walking on the ground. The larger species, especially the Greater Kiskadee, frequently feed on fish, tadpoles, frogs and lizards as well as large moths, orthopterans and other arthropods. Many tropical species regularly eat fruit from vines, mistletoes, or trees. The Piratic Flycatcher and several species of *Elaenia* and relatives are almost entirely frugivorous during much of the year.



Eastern Kingbird *Tyrannus tyrannus*. (R.G.)

Behaviour. Most species live as monogamous pairs on territories, in a relatively simple social structure. Some migratory species, such as the Variegated Flycatcher *Empidonomus varius*, and the Fork-tailed Flycatcher *Tyrannus savana*, congregate in flocks of up to several hundred individuals during the non-breeding season, but no true coloniality is known to occur in any species. Intra- and interspecific communal roosting occurs among some tyrannine species. Helpers at the nest occur in a few species, especially the White-bearded Flycatcher *Conopias inornatus*, but this, too, is uncommon. The Piratic Flycatcher breeds within large colonies of caciques (Icteridae), whose nests it takes over through harassment. Members of the genus *Mionectes* (incl. '*Pipromorpha*' spp.) are known to exhibit loose LEK behaviour in their forested habitats, associated with their highly frugivorous diet. Some sexually dimorphic grassland species, especially the Cock-tailed Tyrant *Alectrurus tricolor*, may be polygynous. This and numerous related species have peculiar and highly stereotyped aerial displays. The Spectacled Tyrant *Hymenops perspicillata*, in which the all-black male has wide, fleshy yellow eyerings, performs spectacular aerial loops and somersaults over its marshy habitat during courtship. Tail flicking or pumping is common, particularly among terrestrial forms such as the Masked Water Tyrant *Fluvicola nengeta*. The tail is cocked and spread like a fan during active foraging by *Myiobius* spp. Wing-stretching, flicking, whirring or buzzing are featured in the territorial or courtship displays of almost all species. The Common Tody-Flycatcher *Todirostrum cinereum* cocks its tail vertically and hitches sideways along a perch during such a display.

Voice. Tyrant-flycatcher vocalizations are notably simple and weak, with only a few exceptions. Most species whistle uncomplicated single syllables, phrases, or short trills. These include some of the least conspicuous advertising songs of any species of Passeriformes. The most remarkable vocal feature of the family is the propensity of nearly all its members to utter repetitive 'dawn songs', at or before first light during breeding seasons. These typically include more extended and complicated versions of the simple, daytime advertising songs, but in some species certain vocal patterns are restricted to this period of active calling. Thus, in the Neotropics, flycatchers of many species are frequently the first birds to be heard vocalizing as dawn breaks. Aerial displays are accompanied by special flight songs in some fluvicoline species and in the kingbirds.

Breeding. Nest structure varies considerably. Most typical is a simple cup placed in a forked twig or stem, as in the genera *Empidonax* and and *Tyrannus*. Cups may be elaborately decorated with mosses and lichens, as in *Contopus* and *Elaenia*. Bulky, ball-shaped globular nests of grasses and twigs are built by Greater Kiskadee, Masked Water Tyrant, Social Flycatcher *Myiozetetes similis*, and others. Pendulous, purse-shaped nests with side entrances characterize the tody-flycatchers (*Todirostrum*) and numerous related genera. All members of the genus *Myiarchus* nest in natural cavities, and line their nests with soft animal matter, virtually always including pieces of shed snake skin. Other cavity-nesters include the genera *Rhytipterna*, *Attila*, *Myiodynastes*, *Machetornis*, and the White-ringed Flycatcher *Conopias parva*.

Clutch size varies from 3–5 in North America (but up to 8 in Great Crested Flycatcher *Myiarchus crinitus*), and is usually 2–3 in the Neotropics. Incubation time typically ranges from 14–20 days, followed by nestling periods of 14–23 days. Independent young of many tropical species remain with their parents to form family groups for nearly a year after fledging. With rare exceptions, both sexes construct the nest and feed the young. Only females incubate eggs or brood young. Many species regularly attempt more than one brood in a single season.

FLYCATCHER-SHRIKE: alternative substantive name of some species of Campephagidae (see CUCKOO-SHRIKE).

FLYCATCHER, SILKY: see SILKY FLYCATCHER.

FLYCATCHER-WARBLER: name sometimes given to *Seicercus* spp. (see WARBLER (1)).

FLYEATER: *Gerygone sulphurea*, the only south-east Asian member of the predominantly Australian genus *Gerygone* (see WARBLER, AUSTRALIAN).

FLYWAY: a major route for birds on migration (see MIGRATION).

FODI; FODY: substantive name of *Foudia* spp. (see WEAVER).

FODITANY: substantive name applied to two Madagascan BULBULS of the genus *Phyllastrephus*, and to the aberrant Madagascar BABBLER *Oxylabes madagascariensis*.

FOLIAGE-GLEANER: substantive name of species in several genera (e.g. *Automolus*) of Furnariidae (see OVENBIRD (1)).

FOLKLORE, BIRDS IN: folklore is a term of somewhat imprecise application, mingling as it does with myth, legend, fable and oral literature, and reaching out toward magic and religion. For present purposes bird folklore may be defined as the total corpus of beliefs, half-beliefs, tales and sayings, fanciful or otherwise, orally transmitted and of undetermined authorship, which are referable to genuine species. (For discussion of wholly invented or composite species see FABULOUS BIRDS.) Its origins lie in observation as well as imagination, with misinterpretation in between.

It may be assumed that birds have been the concern of men for as long as humankind has existed: on the material side as a food source for the hunter and later as a competitor for food with the farmer; as a supplier of plumage for adornment and for warmth, and of such accessories as feathers for arrows and bones for beads and whistles; and as practice targets for apprentice hunters (see ORNAMENTATION, BIRDS IN HUMAN). Although true domestication has been accepted by very few species, the keeping of birds as pets may go back to the remote past, to judge by the fondness of 20th century Stone Age peoples in Amazonia for their shoulder-tame macaws *Ara ararauna*, or the young cassowaries *Casuarius* spp. running loose in Papuan villages. On the non-material side, the readiness of men to ascribe human characteristics to other creatures is with us yet. In the minds of preliterate peoples, for whom the barrier between natural and supernatural hardly exists, all animals and often plants must needs live on the spiritual as well as the earthly planes. Thus a bird that is notably wily or swift or cruel or nutritious must possess particular powers, to be courted, countered, revered or borrowed; and upon such relationships myths are built. The antiquity of this preoccupation is illustrated by palaeolithic cave-paintings of bird-men (whether gods, decoys, disguised hunters or all three is not always clear), and its refinement by Horus the Hawk God of dynastic Egypt, who personified the rising sun.

Some myths have the force of religious tenets. For the Hebrews a dove discovered dry land after the Flood, and for the Crow Indians in Montana diving ducks sent down by the Creator brought up mud from below the primaeval waters to make the Earth—to give but two examples of a widespread theme. Over much of native North America rainfall is controlled by the Thunderbird, conceived of usually as an eagle but sometimes as a hawk, and in the interior of British Columbia as a grouse. In all cases it is the flashing eye that generates lightning and the flapping wings that reverberate. As has been said, other creatures besides birds have their mythic roles and, despite his luxuriant plumage, Quetzalcóatl the Plumed Serpent, god of wind and scholarship in ancient Mexico, appears to have been a reptilian rather than an avian mutant. He is much, much older than the eagle with a serpent in its talons which was the sign for the 14th century Aztecs that they had reached their Promised Land.

Not all bird lore is so portentous. Tales told purely for entertainment have abounded in both Old and New Worlds, wherein birds appear as protectors, tricksters or comics. A favourite genre, echoed in Kipling's *Just So Stories*, recounts the origins of particular shapes or plumages: in Europe the Robin *Erithacus rubecula* scorched its breast bright red while stealing fire from the sun, and the Crossbill *Loxia curvirostra* twisted its beak on the nails of the Cross; in Manitoba the Sapsucker *Sphyrapicus varius* acquired its many hues as consolatory gifts from other birds because it had been too tipsy on birch juice to attend the official distribution of colours.

In the Orient some birdlike beings of no clear faunal affinity have entrenched themselves in the great religions (see FABULOUS BIRDS). In the West the bird spirits have been banished by Christianity or diminished, sometimes by way of witchcraft, into mere harbingers of good or bad luck. The dove (when not pronounced 'pigeon') and the crowing cock have maintained an odour of reasonable sanctity, and the Swift *Apus apus* has about lived down a reputed collusion with the Devil, but the superstitious still know that any bird—especially a black-as-night corvid—that strikes at a window is summoning a human soul to the grave.

Attitudes to birds as expressed in British folklore are not always consistent. The Wren *Troglodytes troglodytes*, which shares with the Goldcrest *Regulus regulus* and Firecrest *R. ignicapillus* a variety of ironic European names denoting petty kingship (*Regulus*, Latin; *Roitelet*, French; *Reyezuelo*, Spanish—sometimes downgraded to *Abadejo*, petty abbot), is traditionally killed and paraded on St Stephen's Day in England and Ireland to a satirical refrain dubbing it King of All Birds. This despite the West Country warning that 'Who kills a Robin or a Wran, shall never prosper, boy or man', and similar minatory verses current in Scotland. The Magpie *Pica pica* likewise enjoys a mixed reputation, 'One for sorrow' offset by 'One's a wish'. Owls, highly regarded in Classical Athens and relied upon to deflect lightning in England as in China, are associated with the black arts in both hemispheres and can still induce the crossing of fingers in the role of Shakespeare's 'fatal bellman, that gives the stern'st goodnight'. Perhaps darkness has something to do with it; by daylight the wise old owl is among the most popular of avian symbols.

An important branch of bird folklore is that which may be classed as alternative ornithology, based on day-to-day observation, but leaning heavily on conjectural explanations of what was not, in pre-'scientific' conditions, observable. The empirical approach has engendered some sound proverbs or 'country' sayings; the hypothetical conclusions have been shrivelled by science. It is probably good if expensive husbandry to plant one bean for the rook and one for the crow in addition to the one to grow. It is certainly true that the first Swallow *Hirundo rustica* may arrive in England before the last cold snap, so that one alone does not indeed make a summer. On the other hand it is no longer averred that swallows spend the winter dormant beneath the streams they skim over in autumn; that the Cuckoo *Cuculus canorus* and the Merlin *Falco columbarius* are the summer and winter phases of one and the same species; that the 14 halcyon days during which the seas remain calm are those needed by the Kingfisher or Halcyon *Alcedo atthis* to safeguard the eggs in its floating nest of fish bones; nor yet that the cirriped barnacle is the embryo of the Barnacle Goose *Branta leucopsis*.

Vicariously related to bird lore proper are the Gabriel Hounds, the nocturnal pack whose funereal baying overhead has been explained away as the flight calls of Brent Geese *Branta bernicla*. The ominous function of some other species, notably owls and corvids, has been touched on above; the institutionalized role of birds in augury in S.E. Asia is treated in detail under a separate heading (see OMENS, BIRDS AS).

A wealth of perception, imagination, whimsy and onomatopeia resides in English local or folk-names of birds, and some of it is intriguing. The erroneous reason for calling the Nightjar *Caprimulgus europaeus* a Goatsucker is familiar enough, but why also Corpse-hound (a distinction shared with the Whimbrel *Numenius phaeopus*)? The Wryneck *Jynx torquilla* is Cuckoo's Mate because it arrives a day or two ahead to prepare the way for the Cuckoo—which name itself, amended with the pejorative termination '-old', bespeaks the bird's involvement with fertility. Association with wet weather belongs equally, for differing reasons, to the Green Woodpecker *Picus viridis* and the Red- and Black-throated Divers *Gavia stellata* and *G. arctica*, which are Rain-bird and Rain-geese respectively. The Hooded Crow *Corvus corone cornix* is called a Kentish Crow in Norfolk, an Isle of Wight Crow in Sussex, a Danish Crow in East Anglia and a Dutch Crow in Yorkshire; the North Country's Wetwang Greyback sounds less discriminatory. Storm Witch for the Storm Petrel or Mother Carey's Chicken *Hydrobates pelagicus* reflects the mariner's belief that the bird lived totally invisible until the onset of tempest. The stripling Oxfordshire cronies who taught me Bumbarrel for the Long-tailed Tit *Aegithalos caudatus* cared naught for semantics.

It is very desirable that ornithologists who come across any local or traditional sayings, stories or customs to do with birds should make sure that they are, or that they already have been, recorded. As a counterbalance to the histogram, folklore provides insights both valuable and entertaining into Man's long association with the world of birds. Mainly, to be sure, as it has been in the past—but Her Britannic Majesty's Government still takes precautions against the disaster that would befall the realm were the Tower of London to lose its Ravens *Corvus corax*.

FOOD PASS: aerial food presentation by the male raptor to the female, usually taking place during the periods of courtship, incubation, and brooding of the young.

FOOD SELECTION: an aspect of behaviour (see FEEDING HABITS), of interest also from the evolutionary and ecological points of view in that closely related species living in the same habitat do not compete for food (as postulated first by D. Lack and now generally accepted). Although some avian species are specialized for selecting a particular type of food, e.g. the FLAMINGOS, many are rather catholic in their choice and take a variety of items. This wide range of food items is apparently due to an initial response to a few generalized stimulus situations, each characteristic of a variety of objects. The effective stimuli are later narrowed by learning, the course of which is determined not only by the food within the environment, but also by the behaviour patterns, sense organs and body structures available for finding it.

Distantly related species may show marked innate differences in the stimuli that elicit their feeding responses. Between closely related species, however, such innate differences are often more difficult to detect. Sometimes competition is avoided by differences in habit selection or in the selection of the feeding niche within the habitat. In other cases, small differences in behavioural or physical characteristics prevent overlap in diet. Thus tits, but few other species, learn to open milk bottles because they have the necessary motor patterns; and the size of seeds taken by finches is determined in large part by the size of the bill—each species learning to take the most suitable seeds. The ability of many birds—including Jays *Garrulus glandarius*, Magpies *Pica pica*, some finches and tits—to use the foot with the bill is often characteristic of the species, but learning helps towards its perfection. It enables food sources to be tapped that would otherwise be unavailable: thus Magpies pull down and stand on grass stems while they peck out the seeds, and Goldfinches *Carduelis carduelis* use both bill and foot to feed on thistle seeds. The BILL and other structures used in feeding are adapted to conditions in the localities inhabited by the species. Populations adapted to different conditions and meeting later may therefore select different diets, not because of innate differences in responsiveness, but because they learn to eat those foods to which they are structurally adapted (Hinde 1959).

The first appearance of pecking in the young of nidifugous birds is not dependent on learning: they may peck at a number of different items, provided that they contrast with the background, and accuracy improves with experience. Should the object be of a suitable size, it may be swallowed. If the effect is not then unpleasant, the action may be repeated and the animal comes to distinguish the edible from the inedible. In the food selection of most birds, the visual sense is paramount; TASTE and TOUCH are also important, but the other senses less so (although nocturnal birds such as owls hunt by sound, and at least the kiwis and Oilbird *Steatornis caripensis* use an ability to detect ODOUR—see also SMELL).

The stimuli that elicit the greatest pecking response have been tested in a variety of birds. In particular, the newly-emerged young of species that hatch with their eyes open have been found to peck selectively at objects that differ in size, shape, height and in speed of movement. Young birds with little visual experience and no opportunity for direct learning have been tested also for their differential response to colour. It is known that closely-related species tend to have similar colour preferences, and in many cases these preferences have selective advantages. Hence gulls and terns peck at red and orange, and these colours often, but not always, appear on the parents' bill at which the young bird pecks for food. The chicks of the Oystercatcher *Haematopus ostralegus* and Moorhen *Gallinula chloropus* also select red, as does the Coot *Fulica atra* although the adult bill is white. In studies of young ducks and pheasants, which obtain their own food from the start, it has been shown that almost all species prefer green. The preferences of some adult birds can be inferred through a study of bird-pollinated flowers and bird-distributed fruit (see POLLINATORS; SEED DISPERSAL). Some 84% of the former are red or orange, while red, orange and black berries are vastly more common than those of any other colour.

The Browers (1964) suggest that food has a variety of flavours that conveys no information to the naive bird who will accept initially a wide range of items. If the animal eats and then vomits, it will associate the taste of the food being expelled through the mouth with an uncomfortable 'gut reaction'. Originally a gourmand, the bird is now a gourmet, and taste will thereafter convey useful information. Once conditioned, the bird judges potential food by taste. Obviously the next, more efficient, stage is to recognize prey by sight alone before it needs to be caught and tasted.

The complexity of food selection is illustrated by the work of Krebs (1978) among others, on OPTIMAL FORAGING (see also OPTIMALITY THEORY). The hypothesis here is that an animal searching for food must make decisions that maximize its rate of food absorption: it must decide which type of food it will eat, where it will hunt, and what search path it will adopt. Any item eaten has a cost in terms of time taken to find, catch and consume it, and a benefit in terms of net nutritional intake. Predators should (a) prefer more nutritious (profitable) prey, (b) be more selective when such profitable prey items are uncommon and (c) should ignore unprofitable items no matter how common they are. These predictions have been tested and it can be shown that (c) does not apply if the time taken to recognize unprofitable prey lowers the overall rate of food intake. Thus caged Great Tits *Parus major* do not completely ignore unprofitable items if they are abundant and mixed at a high density with profitable ones. Either the birds require time to recognize prey or they need to sacrifice a certain amount of efficiency to acquire information by 'sampling' the relative nutritional value of each food type. Active birds will search where food is clumped or patchy in distribution but, again, the need to collect information through sampling may cause them to deviate from optimal behaviour. In considering the search path that the foraging bird will take, it can be predicted that a non-random route is most likely, at least in situations where the prey is not replenished rapidly, if only so that the bird does not waste time crossing its own path. Blackbirds *Turdus merula*, for instance, will alternate left and right turns in their search path, but after finding an earthworm, tend to make successive turns in the same direction. In a fluctuating environment (and most environments do change with time), the bird's problem is to update continually its estimates of capture rate and availability so that it can always make the 'best' decisions.

Many temperate-latitude species are known to change their diet with the seasons, coinciding with the onset of breeding, migration, the feeding of young, the moult and a changing climate. To some extent this is a matter of food availability, but preferences are governed by internal changes. Domestic hens can learn to select food so as to correct for some deficiencies, and Red Grouse *Lagopus lagopus scoticus* have been found to prefer 3–4 year old heather that is richer in nitrogen and phosphorus.

Parental example and social experience are likely to affect food selection, the latter especially in flocking species. Most parent birds provide potential dietary guidance. Ducks and geese lead their young to suitable feeding grounds, and most gallinaceous birds pick up and drop a morsel of food apparently to draw it to their chicks' attention. Young rails follow their parents and are fed from their bills, and even sometimes obtain food from juveniles of the previous brood. In many other species, the parents bring food to their offspring. The importance of this early experience is not known; in parasitic species, at least, it sometimes appears to be slight. Cuckoos and honeyguides do not parasitize host species that give 'unsuitable' foods or cannot collect enough. Eggs laid by female Cuckoos *Cuculus canorus* 'taken short' in the nests of 'wrong' species often hatch but the young one seldom fledges. Yet no host brings the food that makes the diet of adult cuckoos and honeyguides unique: hairy caterpillars on the one hand and beeswax on the other.

The feeding behaviour of flocking species may be influenced by companions in three ways: by SOCIAL FACILITATION, by imitation and by what has been called 'local enhancement'. Social facilitation usually affects the quantity of food that the individual takes and, apart from vocal mimicry, there is not a lot of evidence for direct imitation in birds. Normally it is 'local enhancement' that accounts for the spread of new feeding habits among birds: one bird happens upon a previously untapped food source and others are led in that direction. Examples are the opening of milk bottles by tits and the appearance of Great Spotted Woodpeckers *Dendrocopos major* at bird tables. Often prolonged severe weather and food scarcity seem to encourage searching and lead to the discovery of new food supplies. Such novel behaviour patterns perhaps originate with young birds during the first year of life; their actions are observed by other juveniles and eventually by their offspring. Thus new habits become traditional, without the usual limits of acquired behaviour that disappears with the death of the individual. The tendency for new feeding behaviour to arise varies from species to species and differences in adaptability seem to be genetic in origin.

Possibilities for interaction between the members of a flock are obviously influenced by the proximity of feeding individuals. Crook (1965) showed how the social organizations of birds are related to the type of food eaten and to its dispersion within the habitat. Food that is scattered or cryptic, difficult to find and difficult to catch, must be searched for by stealth, speed and skill. Birds dependent on this type of food, such as birds-of-prey (Accipitriformes, Falconiformes), are solitary feeders because any gregarious behaviour interferes with individual methods of acquisition, and their feeding methods in consequence tend to be stereotyped. If food is commoner in some parts of the environment than in others, congregation by the birds may be advantageous in increasing the ability to locate and exploit it effectively. In this group are swifts and many nectar-feeders, insectivores with broad diets such as tits, and ground-feeders. These birds normally tolerate other feeding individuals close by, although a change of feeding habit (to feed young, for instance) may change the closeness of foraging, and territorial behaviour develops. It is when food is found sporadically in patches within the habitat and does not require skill to catch it that the greatest gregariousness occurs. Foraging in a flock prevents repeated sampling of areas already covered and this may be of especial value when food is scarce. A member of the flock, by the very act of feeding, indicates where there is food and other birds move towards it—a precise example of 'local enhancement'. This applies especially to fruit-eating birds, such as many parrots, whose frequently bright colours and raucous voices indicate to their own and other species the locality of clumps of ripe fruit which are shared. It is in these social groups that the greatest possibility for change in food selection by demonstration exists. J.K.(1)

FOOD STORING: temporary storing ('hoarding') of food in sites other than where it was collected. The time between storing an item and eating it may vary between a few hours in tits and up to a year in certain woodpeckers and corvids. Storing in different forms is well developed among several bird families, notably crows and their allies, tits, nuthatches, shrikes, woodpeckers and also among certain diurnal raptors and owls. For example, Thick-billed Nutcrackers *Nucifraga c. caryocatactes* during autumn collect large numbers of hazelnuts *Corylus avellana* several km from their nesting territories in coniferous forest, storing loads of 15–20 nuts in many different locations on the ground, and carefully covering the sites with vegetation. During winter and spring, the Nutcrackers subsist and raise their young on the stored nuts, which they recover with great precision. Swanberg (1951) found that 86% of the attempts at digging up nuts through thick snow-cover were successful, and the precision did not decrease over the winter. Nutcrackers hence memorize the storing sites, and also which caches they have previously emptied. Food storing is also important in *N. c. macrorhynchos*, and in the North American Clark's Nutcracker *N. columbianus*.

Another species with advanced food storing is the Acorn Woodpecker *Melanerpes formicivorus*. Territorial groups of up to a dozen birds store large numbers of acorns in a few granary trees, in which the woodpeckers have excavated suitable storage holes. The group members communally defend the 'larders' against food competitors of the same and other species. The social organization of Acorn Woodpeckers is related to the feasibility of acorn storage: when food cannot be hoarded in sufficient quantity, the birds do not form social groups but nest in solitary pairs and migrate during winter, a remarkable social flexibility.

Ecological factors promoting hoarding. The survival value of food storing should usually increase with, among other things, the likelihood that (a) food withstands extended storing without decay; (b) food will be less abundant in the period ahead, or the forager will then require more food, for example during reproduction; (c) the storing individual itself will be able to recover the food.

Hoarding seems to fit such a pattern. (a) The most commonly stored items are energy-rich seeds or nuts with protective cover, which are sometimes preserved for over one year without serious decay. Bird's eggs are often hoarded by crows, foxes and martens. Tits store insects mainly during autumn, and low temperatures during the following winter may

Great Spotted Woodpecker *Dendrocopos major* storing cones. (*Photo: H. Schouten*).

retard their decay, but it is doubtful whether hoarded insects remain unused for such a long period. Raptors and owls store small mammals and birds for short periods of usually a few days, both outside and during the breeding period; so do certain shrikes with insects and small vertebrates. (b) Most storing species occur in North Temperate areas, with great differences in food abundance between the autumn storing season and the recovery period during winter and spring. The few known cases of storing in the tropics occur among highland species, for which food abundance may vary due to seasonal fluctuations in rainfall. Further studies in the tropics are needed to test whether hoarding is less common in stable environments with little seasonal variation.

Nesting raptors, owls and shrikes which store food over brief periods might gain two advantages: (1) buffering against temporary food shortage due to, for example, inclement weather which impedes hunting; (2) boosting the growth of chicks when their food requirements are highest and they consume food faster than the parents can gather it. (c) The chances that the hoarder itself will recover the food should be greatest in sedentary species with individual or pair territories. Food storing seems to be crucial for the non-migratory habit in the Acorn Woodpecker. Most hoarding birds are resident species which forage on individual, pair, or group territories. Among colonially nesting birds, the Rook *Corvus frugilegus* regularly and the Jackdaw *C. monedula* sometimes hoard food.

Scatterhoarding and larderhoarding. 'Scatterhoarding' the food in numerous small and dispersed caches, and hiding it in the ground, below vegetation, in bark crevices or tree holes is common among hoarding birds, also among species which live in groups. Scatterhoarding reduces the risk that competitors will discover and consume the stored food.

'Larderhoarding' of food in concentrated, more conspicuous stores occurs in some species which are well equipped to chase away food competitors. Acorn woodpeckers, where the members of a social group store thousands of acorns in one or two prepared trees, jointly defend the larders. Shrikes and birds of prey are morphologically well adapted to protect their larders from other species.

Recovery of stored food. Careful hiding of food reduces the risk that competitors will find it, but also makes recovery by the hoarder more difficult. In some species, this problem is solved by a remarkable memory: several hundred or even thousand storing sites spread over sometimes more than 10 ha are remembered fairly precisely for more than half a year by Thick-billed Nutcrackers and European Jays *Garrulus glandarius*. The jays use conspicuous objects such as saplings and tree trunks as beacons in recovering food. There is strong evidence that the birds do not use smell, but rely on visual cues in recovering stored food. Nutcrackers and jays, like most birds, appear to have poor sense of smell.

Hoarding in groups. Tits, Rook, Clark's Nutcracker, Pinyon Jay *Gymnorhinus cyanocephalus* and several other species hoard in conspecific groups in 'communal areas' where the group members tolerate each other. Hoarding in such situations raises a special problem. Since harvesting and storing food requires time and energy, it has a certain cost which a group member might avoid by refraining from hoarding, yet exploiting the food stored by other group members. When stored food is easily available to each group member, as in the Acorn Woodpecker, such 'cheating' seems particularly likely. In this species all group members except yearlings hoard, but there is no quantitative study of the distribution of storing and consumption of the food among the different members.

In group-living birds which scatterhoard and hide food, cheating may not be advantageous if the hoarder of an item is more likely than any other group member to recover it. This could come about either if individuals remember their own caching sites, or if individuals differ in preferred types of sites. Among group-living tits, both mechanisms may operate. Individual Marsh Tits *Parus palustris* differ in their types of hoarding sites, and have a fairly precise memory of the storing places during at least 24 hours. Contrary to what has been suggested, stored food in many group-living species may not therefore be 'communal property' which all group members have equal chances to eat; the hoarder of an item is often most likely to recover it. Therefore, KIN SELECTION is not necessary for the evolution of hoarding in groups. After juvenile dispersal in late summer, groups of food-storing tits consist of genetically unrelated individuals. But kin selection has possibly been important in other hoarding, group-living birds, as it has apparently been for the evolution of advanced food-storing among bees and other hymenopterous insects.

Evolution of food storing. Among species which do not hoard, a bird, after finding a food item, may move to eat it in a more convenient or protected place, for instance to reduce the risk of discovery by predators or competitors. Food-storing may have evolved from such transportation of food. Woodpeckers and nuthatches often fix their food in holes or bark crevices to make eating easier. Fixation of more food than is immediately needed should be a further easy step in evolution. Many predators may continue hunting even when they have just eaten and will not consume more food. 'Surplus killing' is common among carnivorous mammals, and some birds of prey continue to hunt and store food after they are satiated.

Coevolution of hoarders and food plants. There are several beautiful examples of mutualism and coadaptation between hoarding birds and their food plants. The latter offer the animal a rich food source, while the hoarder 'pays back' by dispersing the seeds (see SEED DISPERSAL). Since the hoarder does not recover all stored seeds, it helps propagate the plant. In some well developed hoarder-plant systems, the bird has evolved a specialized bill and an extensible oesophagus or sublingual pouch for efficient seed transport, and the plant has evolved seeds or fruits which are large, nutritious, easily available, protected against mould by a cover, and otherwise suitable for hoarding. Two examples are Clark's Nutcracker-Piñon Pine *Pinus edulis* and European Jay-Pedunculate Oak *Quercus robur*. But the habits of hoarders are not always advantageous for their food plants; Acorn Woodpeckers and other melanerpine species seldom drop Piñon seeds or acorns, and store them in sites unsuitable for germination. These woodpeckers may therefore be 'parasites' on mutualistic systems developed between other hoarding birds and plants.

FOOD-WEB: see ECOLOGY.

FOOL HEN: popular name for the Spruce Grouse *Dendragapus canachites* (see GROUSE).

FOOT: see under LEG; SKELETON, POST-CRANIAL.

FOOTEDNESS: a physiological dominance of one foot over the other, comparable with right-handedness or left-handedness in human beings. There is some evidence of this in a few groups of birds.

In 7,259 landings of 11 Domestic Pigeons *Columbia livia*, 7 used the right foot, 3 the left foot, and one showed no particular preference for either (Fisher 1957); biometric analysis revealed a slight departure from bilateral symmetry in the leg bones of the pigeon (McNeil and Martinez 1967). The right leg as a whole, and most of the right limb segments, are significantly longer than the left.

In the Accipitriformes, Bond (1942) found that a young Goshawk *Accipiter gentilis* would sleep on both feet, but would hold its food with the left talon. Hosking (1943) describes the same behaviour for several species of hawks and owls. The parrots manifest a similar type of handedness. Of 20 birds belonging to 7 genera and 16 species observed using right or left foot to bring food to the beak (Friedmann and Davis 1938), the percentage of left-handedness exhibited by the birds as a whole was 72.2%; 3 individuals of *Brotogeris jugularis* were 100% left-handed. Of the genus *Amazona*, 7 species showed 66.97% left-handedness, while the 10 individuals involved were 70.5% left-handed. In *Amazona amazonica*, which is 75% left-handed, McNeil and Martinez showed a significant predominance in the length of the left limb as a whole and in most of the left limb segments. A similar type of left-handedness was reported for the Carolina Parakeet *Conuropsis carolinensis* (Allen 1939). It may be concluded that many genera and species of Psittacidae are left-handed. However, observations on 56 individuals of *Aratinga pertinax* when bringing food to the beak (McNeil *et al* 1971) showed that half the birds were left-handed and half were right-handed. A biometric analysis revealed a slight departure from bilateral symmetry in hindlimbs as a whole and hindlimb segments in close relationship with handedness (left and right).

Among Passeriformes, the occurrence of foot preferences is not well documented. It has been reported (Dobie 1936, and others) that in the Crossbill *Loxia curvirostra* the use of a particular foot to hold a cone is correlated with the direction of crossing of the mandibles. If the lower mandible twists to the right, then the left foot is used and vice versa. When the cone is held with both feet, if the lower mandible twists to the right, the base of the cone lies under the left foot and its tip under the right foot and vice versa. Great Tits *Parus major* showed marked preferences, about half the birds being right- and half left-footed, when holding insect food (Vince 1964). The preferences were however more marked in some individuals than others and broke down in the more complex task of string-pulling.

There is no evidence to show whether such foot preferences are individually acquired or not. A close relationship between skeletal bilateral asymmetry and footedness has been shown but the results do not demonstrate any causal relationship. McNeil and Martinez (1967) believe that bilateral symmetry in external organs (limbs and sense organs) may be interpreted as a locomotor adaptation in the sense that it would make it easier for an animal to reach its goal directly, while departures from bilateral symmetry may have other functions in, for example food handling or prey catching. FOOT-PADDLING: see FEEDING HABITS.

FOOT PAPILLAE AND PADS: thickenings of plantar skin; pads are covered with papillae and are separated from other pads by furrows. In various birds pads and papillae, making contact with the substrate, show great variety in structure as adaptations to the way of living. The papillae are often called scales or reticulate scales. In embryonic studies they are called radially symmetrical scales in contrast to the overlapping scales of tarsometatarsus and toes. The morphology, histology, and function of papillae deviate from scales and justify the term papilla.

Embryonic development. Pads, furrows, and papillae develop by three separate processes in the embryo (see Fig. 1). The furrows develop through a thickening of epidermal cells, followed by a folding; they appear during days 10–12 of the domestic chick's embryo development. Pads swell by cell proliferation in the deep dermis; the large pad in the centre of the foot appears on day 8 of the embryo, and the pads in the toes on days 10–12. The papillae develop through a condensation of dermal cells close to a thickening of epidermal cells; they appear on days 11–14. The embryonic development of papillae shows similarities to that of scales and feathers; factors in the dermis control the differentiation of the skin.

Papillae. Tree-living birds often have papillae with the microscopic structure shown in Fig. 2. The primary dermal papilla is divided into several secondary dermal papillae. This implies an increased surface of

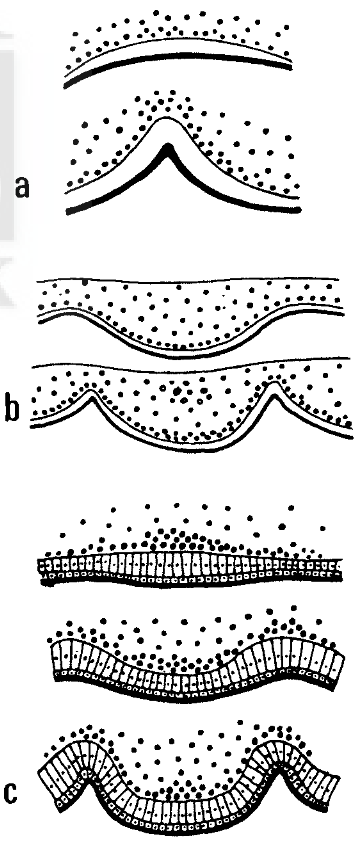

Fig. 1. Development of (a) furrow, (b) pad, and (c) papilla. The periderm is indicated black; the basal epidermal cells are unshadowed in (a) and (b); the epidermis is two-layered in (c); the superficial dense dermal cells are indicated by dots, and the deep dermal cells by rings. A line in (b) shows the deep border of the dermis.

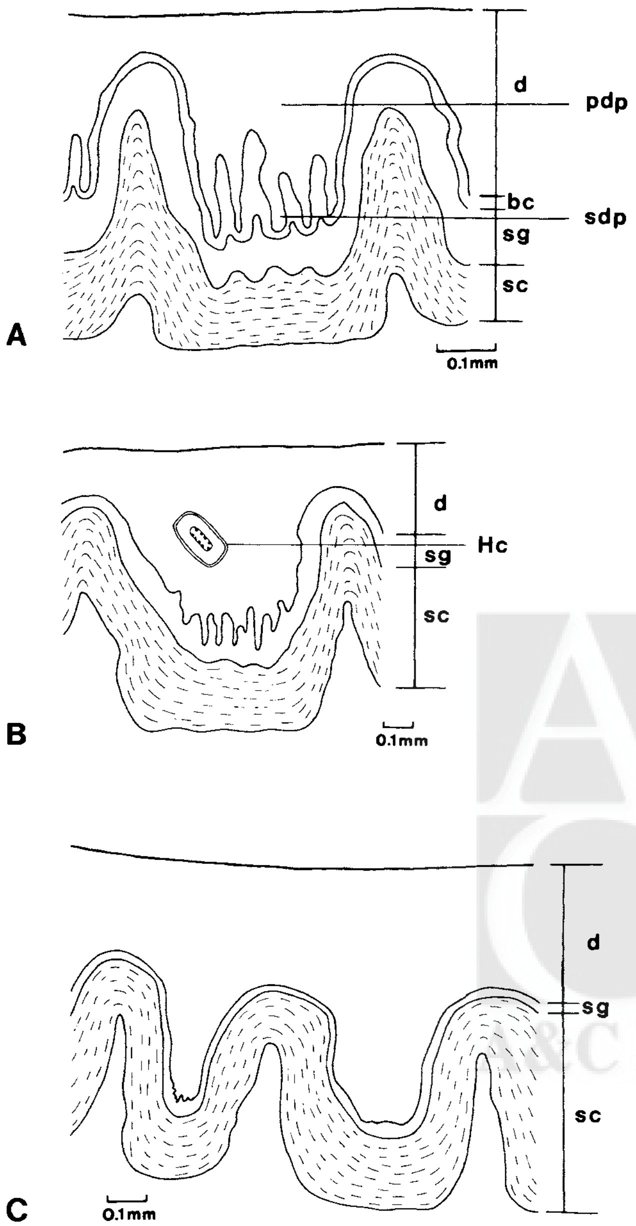

Fig. 2. Diagrams of papilla in (a) a passerine, (b) a parrot, and (c) an owl. The skin consists of the dermis (d), which projects into the papilla with a primary dermal papilla (pdp) and several secondary dermal papillae (sdp). The epidermis has a basal cell layer (bc) where mitotic activity renews the epidermis, the cells moving through the stratum germinativum (sg) and the stratum corneum (sc) to be worn off at the surface. Many papillae in parrots have Herbst sensory corpuscles (Hc). Scales 0.1 mm.

contact between dermis and epidermis and space for a large number of basal epidermal cells, which divide and renew the epidermis. Papillary arteries and veins branch from a network of blood vessels in the dermis and continue as capillaries to the top of the secondary dermal papillae. Arteriovenous anastomoses occur at the base, regulating the blood flow to the papilla. There is obviously a heat exchange between arteries and veins, generating a temperature gradient in the papilla.

The pads and papillae of tree-living birds are often subjected to strong external forces when the bird lands or grasps a branch. They are connected to each other by a thick layer of stratum corneum, forming a thick skin which covers the pad. This skin is flexible but only slightly stretchable. The distal end of the papillae in some birds projects and is pointed, suitable to penetrate roughnesses in the substrate.

Ground-living birds such as waders, bustards, cranes, grouse and storks have a similar connection of papillae to a skin plate, although the surface of the papillae is flat.

Parrots have separate papillae. Many papillae have Herbst sensory corpuscles in the dermis. The free papillae and the sensory corpuscles indicate a touch function of the papillae, comparable to the touch function of the epidermal ridges in primates.

Birds-of-prey have separate or connected papillae. The stratum germinativum is often thin and the stratum corneum is thick, indicating a different condition of wear and renewal. Herbst sensory corpuscles are sparse and scattered in the dermis of owls *Asio* and buzzard *Buteo*. The Osprey *Pandion* and the fishing owls *Ketupa* and *Scotopelia* have pointed, spiny papillae adapted to grasping slippery fishes.

Palearctic passerines wintering within the region have generally few and large papillae, whereas passerines of similar size wintering in tropical Africa have many and small papillae. The Redpoll *Carduelis flammea* and the Goldcrest *Regulus regulus* have exceptionally few papillae, but some of them are very large and the stratum corneum is thick. This reduces the area of contact with the substrate during cold winter conditions. Some birds wintering in temperate climates have a thicker stratum corneum in winter than in summer, an insulative acclimatization. Passerines living on the ground such as the Skylark *Alauda arvensis* also have few papillae.

Pads. The pads are defined by the furrows: gaps between the papillae, which open and close when the digits are bent. Some furrows are developed in the early embryo and occur in every individual of the species; other furrows develop later in the embryo or early in the nestling, and they show individual variation in occurrence.

The pads in the toes are anchored by connective tissue to the phalanges or to the joints and are therefore termed phalanx pads and joint pads. One pad in the central part of the foot is close to the trochleas of the tarsometatarsus: the central pad.

Figure 3 shows the feet of 6 birds. The Grey Heron *Ardea cinerea* has small joint pads and long narrow phalanx pads. This pattern occurs in

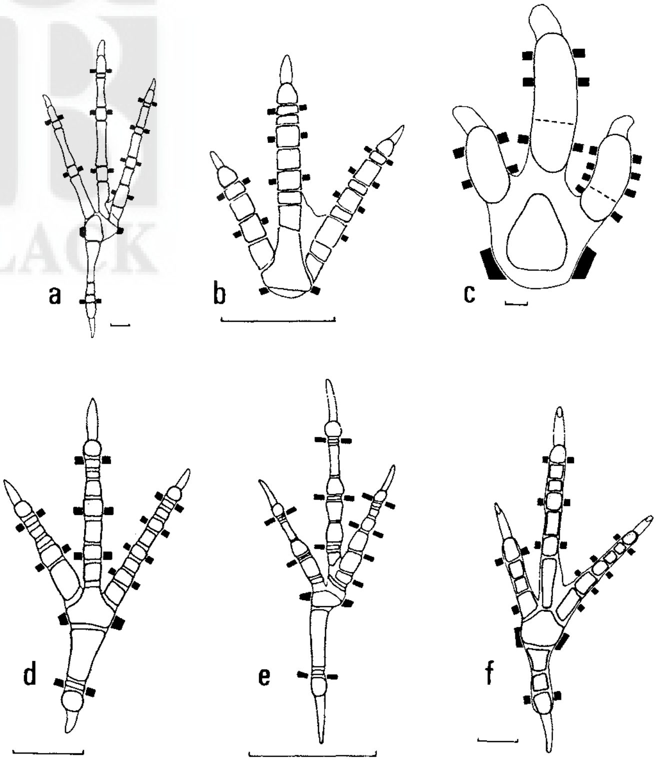

Fig. 3. Pads in the feet of 3 ground-living birds (upper row) and 3 tree-living birds (lower row): (a) Grey Heron *Ardea cinerea*; (b) Ringed Plover *Charadrius hiaticula*; (c) Kori Bustard *Choriotis kori*; (d) Roller *Coracias garrulus*; (e) Redstart *Phoenicurus phoenicurus*; (f) Sparrowhawk *Accipiter nisus*. Each pad is represented by a line showing the margin of the pad. Black areas at the side of the digit show the position of joints. Scales 1 cm.

many ground-living birds such as waders and gamebirds. Some of them, such as the Ringed Plover *Charadrius hiaticula*, walking mostly on hard substrates, have phalanx and joint paids about equal in size. This also occurs in the Little Bustard *Otis tetrax*. The great Kori Bustard *Ardeotis kori* has only 4 pads: one in the centre of the foot and one in each of the anterior toes, the latter being fusions of several pads. Similar fusions of pads occur in sandgrouse and in flightless birds such as the Ostrich *Struthio camelus*.

Many ducks and gulls have joint pads and a central pad but lack furrows. The Eider *Somateria mollissima* has a large phalanx pad at the base of the second toe, obviously important in standing. The Scaup *Aythya marila* and the divers have only a central pad and no sign of pads in the toes. The papillae and pads of the petrels are very similar to these groups.

The Roller *Coracias garrulus* has phalanx and joint pads; some phalanx pads in the distal part of second and third toe are divided into 2 or 3 pads. Kingfishers and other birds with toes connected by skin have fewer pads due to fusions. Pigeons and doves have pads comparable to those in the Roller, but certain species have fewer pads.

Passerines, e.g. the Redstart *Phoenicurus phoenicurus*, have a basic pattern of 12 phalanx pads and one central pad. The joint pads are reduced to folds, which have a few papillae or a smooth skin surface without any papillae. Certain joints may even lack folds. Woodpeckers and cuckoos have prominent phalanx pads and small folds at many joints.

Many diurnal raptors have phalanx and joint pads, but not so many as in the Roller. The Sparrowhawk *Accipiter nisus* has some projecting joint pads in the third and fourth toe adapted to penetrate the feathers of its prey. The owls have joint pads, but the furrows are unclear or absent.

Pads and papillae are mostly characteristic of the species. In fragments of birds including the leg, e.g. from a raptor's prey, the species may sometimes be recognized by comparison with wet-prepared museum specimens. I.L.

FORAGING STRATEGY: see STRATEGY.

FORAMEN: an aperture (plural 'foramina') in a bone or other bodily structure (see SKELETON, POST-CRANIAL).

FOREHEAD: see TOPOGRAPHY.

FORENECK: see TOPOGRAPHY.

FORKTAIL: substantive name of *Enicurus* spp. (see THRUSH).

FORM: in taxonomy, a loose or deliberately neutral term for a species or a subdivision thereof, non-committal as regards the rank or status to be assigned to it; sometimes used more precisely to embrace subspecies and monotypic species, e.g. in giving the total number of 'forms' included in a genus or found in an area. For nomenclatural purposes, however, it is now (after 1960) assumed that a 'form' or 'variety' designated as such is infrasubspecific (presumably where the context admits).

FORMENKREIS: term introduced by Kleinschmidt in 1900 for a taxonomic grouping between the wide Linnean genus and the narrowly defined species of his own day; the nearest equivalent in current parlance is 'superspecies'. The author's views, although based on theoretical considerations that are unacceptable, had a useful influence on the development of taxonomic thought. See also SUPERSPECIES.

Stresemann, E. 1936. The Formenkreis-theory. Auk 53: 150–153.

FORMICARIIDAE: see under PASSERIFORMES, suborder Deutero-Oscines; ANTBIRD.

FOSSA: a depression in a bone, e.g. temporal fossa, tympanic fossa (see SKELETON, POST-CRANIAL).

FOSSIL BIRDS: any members of the class Aves whose remains have been preserved in a palaeontological context. Fossil birds range in age from the Jurassic Period up to only several hundred years old and may be taken to include all avian remains that are not accompanied by written historical documentation. Bone, both mineralized and unmineralized, is the most common and the most important type of avian fossil, although feathers, feather impressions, eggshells, gizzard stones, footprints, and mummified skin and bare parts have also contributed to our knowledge of birds of the past.

Chronological framework. A clear understanding of geological time and its associated biological events is essential to interpret the fossil record of birds. Recent years have witnessed great advances in geochronology and biochronology, especially through the application of radiometric and palaeomagnetic dating methods to many fossil localities. Figures 1 and 2 present a synthesis of much recent information on

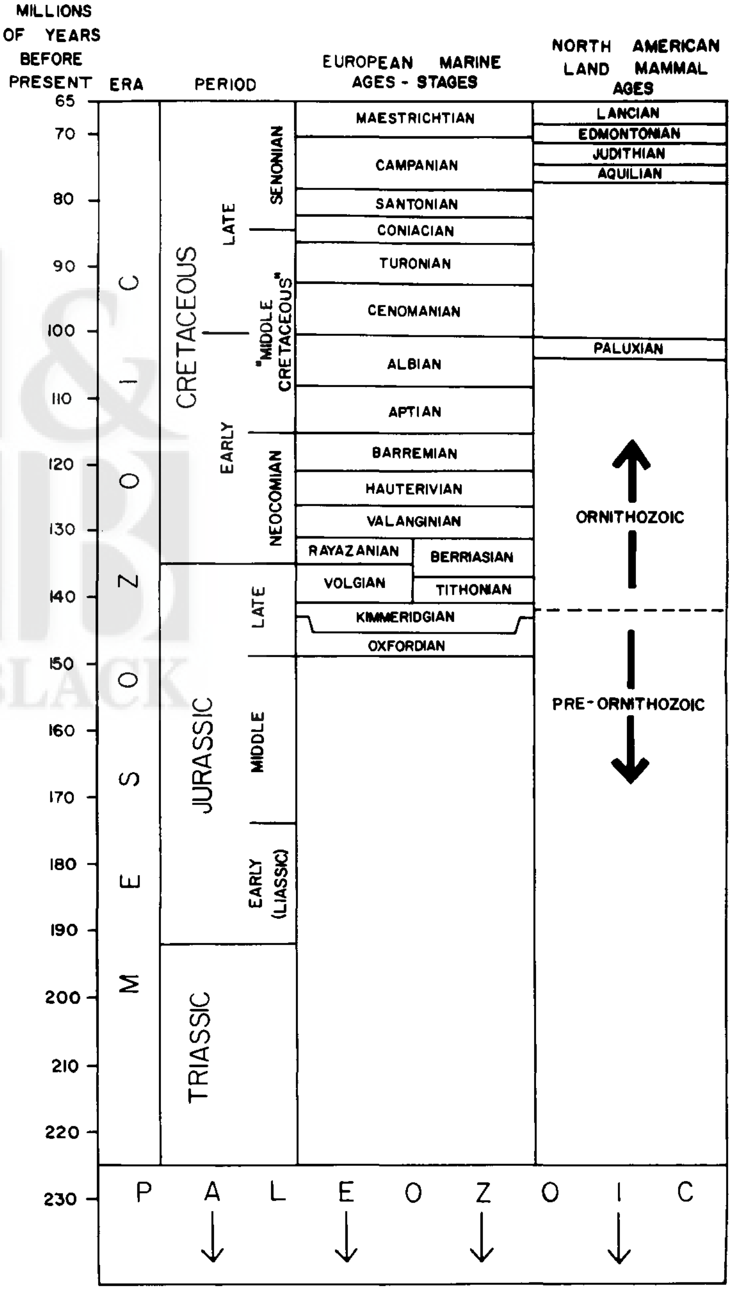

Fig. 1. Mesozoic time scale, as related to birds. (Largely derived from Clemens *et al* 1979. Acknowledgment to Dr E.H. Lindsay, University of Arizona).

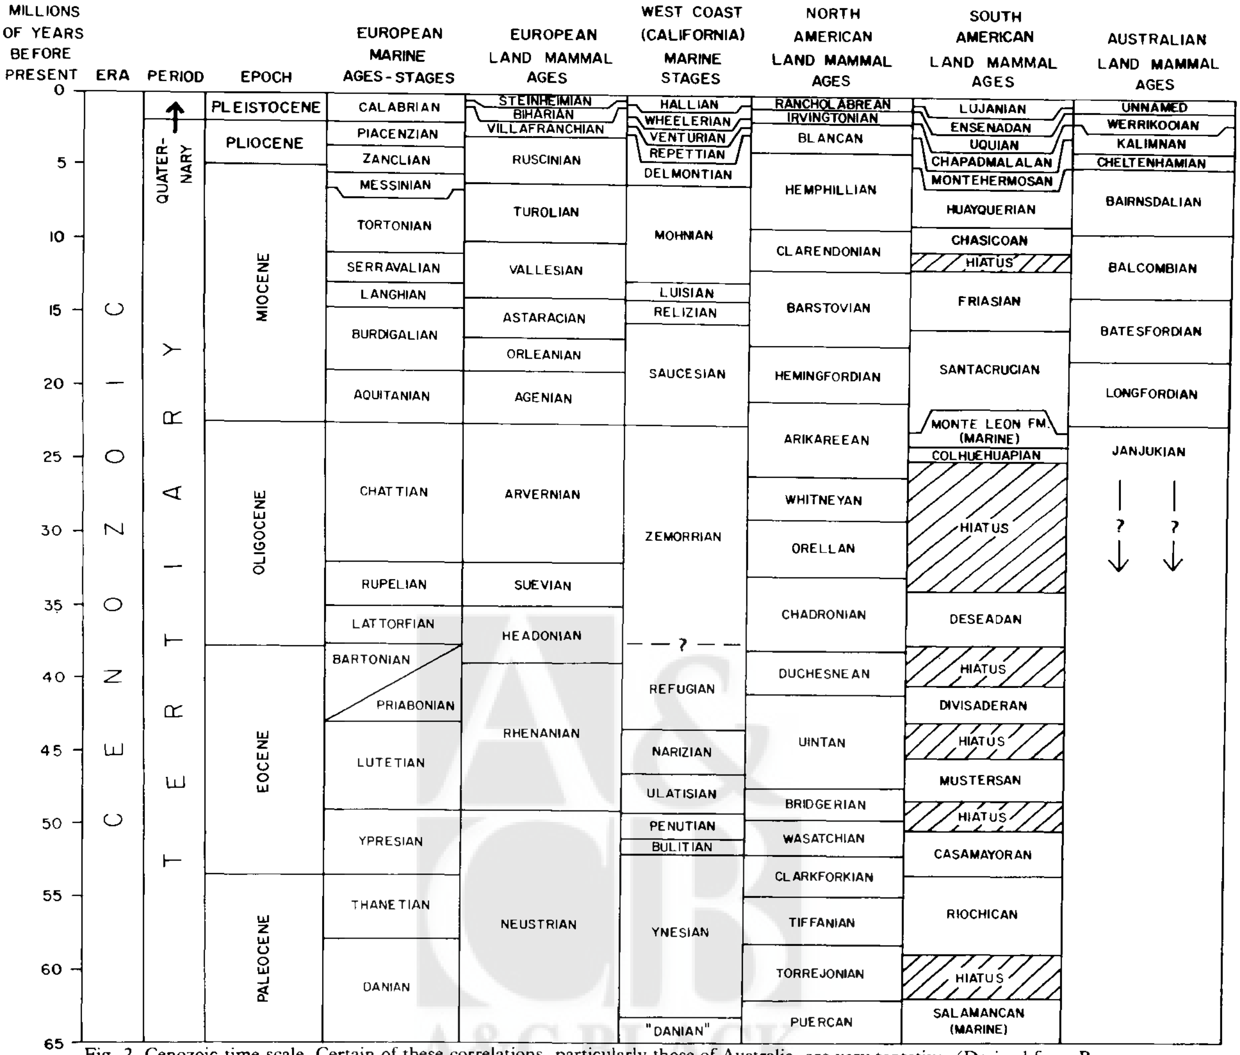

Fig. 2. Cenozoic time scale. Certain of these correlations, particularly those of Australia, are very tentative. (Derived from Berggren 1972, Berggren *et al* 1978, Berggren & van Couvering 1974, Lindsay & Tessman 1974, Marshall *et al* 1977, Stirton *et al* 1968).

geological time as it relates to fossil vertebrates. It is fortunate that essentially all terrestrial deposits of the Cenozoic Era that contain fossil birds have also yielded mammalian fossils, thus permitting biochronological correlation with other fossil sites in a sequence of land mammal ages. Likewise, most marine deposits with avian fossils have been temporally correlated on the basis of various invertebrate fossils or planktonic assemblages. In Africa and Asia, the fossil record of Cenozoic vertebrates has not yet been resolved into a system of land mammal ages.

The discovery and detailed study of new Mesozoic and Cenozoic vertebrate localities is proceeding rapidly on a world-wide basis, resulting in continuing significant changes and improvements in the temporal resolution of the fossil record. But much of the literature on fossil birds either ignores or deals inadequately with geochronology.

Archaeopteryx and the origin of birds. Birds evolved from archosaurian reptiles, as evidenced by the diapsid condition of the skull, the foraminate lower jaw, the shape and placement of the teeth, and the pelvic structure (see EARLY EVOLUTION OF BIRDS). The subclass Archosauria includes the following orders: Thecodontia (thecodonts), Crocodilia (crocodiles), Pterosauria (flying reptiles), Saurischia ('reptile-hipped' dinosaurs), and Ornithischia ('bird-hipped' dinosaurs). Crocodilians are the only surviving archosaurs, the other 4 orders being known only from Mesozoic fossils.

The ancestry of birds is a problem not yet resolved. A meaningful assessment of relationships of birds to various reptilian groups is very difficult in our present state of knowledge of avian osteology. For example, it has been shown that the names of certain palatal bones in the avian skull are probably not homologous with those of reptiles. Nevertheless, a close relationship to birds has been proposed at one time or another for each order of archosaurs. It appears, however, that all presently known archosaurs except thecodonts of the suborder Pseudosuchia are too specialized to qualify as possible ancestors. Evidence against a theory of avian origins from saurischians includes differences in their tarsal and dental morphology. Cranial and dental similarities have been used to suggest a rather close relationship between birds and crocodilians, but these similarities may be traced back to their thecodont ancestors, thus leaving no solid evidence to support an origin of birds via the crocodilians. The ornithischians differ from *Archaeopteryx* in the absence of sternal ribs, the presence of supraorbitals, and dental morphology, while the pterosaurs are different from birds in many ways, particularly in the tremendous elongation of the digits of the manus to form the main bony support for the wings.

A generalized pseudosuchian, perhaps similar to *Euparkeria* of the early Triassic of South Africa, has been suggested by various workers to be near the ancestry of birds. One must keep in mind, however, that nearly 100 million years separates *Euparkeria* from the earliest certain bird, ARCHAEOPTERYX of the late Jurassic (Tithonian) of Germany. It is in this long interval of time that we should search for reptiles with various sorts of avian characters that will provide new insights into the origin of birds.

The hypothesis of a pseudosuchian origin of birds has been strengthened recently by the discovery of 2 pseudosuchians that appear to have birdlike features. The first is *Cosesaurus aviceps* of the late Triassic of Spain, a very small reptile (skull length *c.* 18 mm) with a rather birdlike skull and indistinct linear structures near its long tail that may represent proto-feathers. The second new pseudosuchian is *Longisquama insignis* of the early Triassic of south-central USSR. The skull of *Longisquama* is 23 mm long and is less bird-like than that of *Cosesaurus*. The most interesting features of *Longisquama* are its fused clavicles that resemble an avian furcula and its greatly elongated mid-dorsal scales that roughly resemble feathers.

Stimulated by the discovery of several new specimens, there has been a strong renewal of interest in *Archaeopteryx* among palaeontologists of the past decade, especially in regard to its role in the origin and subsequent evolution of birds in general. The presence of highly developed feathers capable of sustaining flight leaves no doubt as to the avian nature of *Archaeopteryx*, in spite of the many reptilian characters in its skeleton. The toothed skull of *Archaeopteryx* is about 45 mm long and much more reptilian than avian in appearance. Other reptilian features of *Archaeopteryx* are the shape of the coracoid, the absence of an ossified sternum, the presence of gastralia, unfused carpals and metacarpals, clawed digits of the manus, and a long tail of many unfused caudal vertebrae. Avian characters of *Archaeopteryx* include the robust furcula, the elongated forelimb, and, most importantly, feathers that are very similar to those of modern birds.

Cretaceous birds. Most known birds of the Cretaceous are toothed, marine forms that are not clearly related to any birds recorded thus far from the Cenozoic Era. Large, flightless, diving birds inhabited the warm, shallow Cretaceous seas and include *Enaliornis* of the early Cretaceous (Albian) of England, and *Baptornis* and *Hesperornis* of the late Cretaceous (Coniacian) of North America. Another well known Cretaceous bird is the volant *Ichthyornis*, a sympatric contemporary of *Baptornis* and *Hesperornis*. The jaws of *Enaliornis* and *Baptornis* are not known, but *Hesperornis* and *Ichthyornis* had teeth that are basically similar to those of *Archaeopteryx*. All of the Cretaceous birds discussed thus far are probably specialized, dead-end groups. Many types of birds probably were toothless by the end of the Mesozoic, but *Gobipteryx* of the late Cretaceous of Mongolia is the only known avian skull of this period that lacks teeth.

Ambiortus, of the Neocomian of Mongolia, is very similar in overall structure to modern volant birds. Although it occurred only shortly after *Archaeopteryx*, *Ambiortus* possessed none of the reptilian features of *Archaeopteryx*. *Alexornis* (Campanian of Baja California) is the only other Cretaceous bird that may have any bearing on the evolution of modern land birds. *Alexornis* is a small bird that may be related to both the Momotidae (motmots) and the Bucconidae (puffbirds), but is different enough to warrant its own order.

Many named birds of the Cretaceous are of indeterminable systematic affinities because of the incomplete and undiagnostic nature of the fossils upon which they were based. Among such forms are *Gallornis* (Neocomian of France), *Parascaniornis* (Campanian of Sweden), *Torotix* (Lancian of Wyoming), and *Elopteryx* (Maestrichtian of Rumania), the first 3 of which have previously been regarded as early flamingos, and the last a pelecaniform. *Lonchodytes* and *Cimolopteryx* (both Lancian of Wyoming), as well as *Telmatornis* and *Palaeotringa* (both Maestrichtian of New Jersey) may be primitive charadriiforms. If so, they are among the few Cretaceous birds that seem referable to an existing order.

Tertiary birds. The fossil record of birds in the Tertiary Era is much more complete than that of the Cretaceous. Nearly all living orders of birds are first recorded in Paleogene (Paleocene to Oligocene) deposits, important exceptions being the passerines and the 'ratites', except possibly the Struthioniformes. Birds that are safely referable to living families appear from the early Eocene to the Oligocene. Thus the chronology of the first appearances of modern higher taxa of birds roughly parallels that of mammals, for which a more complete fossil record exists. Much caution should be used in stating the chronologies of various families and orders of birds because many fossils that have hitherto been thought to represent a modern family or order are actually too fragmentary to be diagnostic at even these levels.

Avian fossils of the Paleocene are relatively rare and are dominated by large, flightless, cursorial birds of possible gruiform affinities. Among such forms are *Gastornis* of the late Paleocene in Europe, and *Diatryma* of the late Paleocene to middle Eocene in Europe and North America. A single bone of a primitive owl is known from the late Paleocene of Colorado. The fossil record of Eocene birds is much more complete than that of the Paleocene, and includes the first appearances of many modern orders and families, but no fossils that can be assigned to living genera. Late Eocene penguins have been found in several areas within their modern range. Well known birds of the North American early Eocene include *Limnofregata*, a frigatebird; *Gallinuloides*, a galliform; *Presbyornis*, a colonial shorebird with a charadriiform post-cranial skeleton and a duck-like skull; a variety of large gruiforms, most of which were, however, much smaller than *Diatryma*; and the primobucconids, small arboreal birds that were similar to modern puffbirds. Eocene birds of Europe include *Colymboides*, a late Eocene diver; the early Eocene pelecaniforms *Prophaethon* and *Odontopteryx*, the latter with many bony tooth-like projections on its bill; and various small, non-passerine land birds. There is no unequivocal evidence for the occurrence of cracids in the Tertiary of Europe, as has been suggested in the past. The extensive terrestrial avifauna of the phosphorites of Quercy, France, is composed of fossils that are both late Eocene and early Oligocene in age. Among the birds of this site are galliforms, gruiforms such as *Idiornis* and *Elaphrocnemus*, the caprimulgiform *Aegialornis*, and the trogon-like *Archaeotrogon*. The few Paleogene records of birds in South America predominantly comprise a variety of gruiforms. Except for penguins, there are no fossil birds known from the Paleogene of Australia. There is no published record of Paleocene birds from Africa and only a single specimen of a pelecaniform (*Gigantornis*) is known from the Eocene. All reports of elephant-birds (Aepyornithidae) from the Tertiary of Africa are unreliable.

The fossil record of Oligocene birds is less complete than that of the Eocene. No fossil passerines are known from Oligocene deposits, although primitive passerines may have existed at this time. Nearly all families of non-passerines were probably established before the close of the Oligocene, but substantiation by fossils is lacking for many of them, particularly certain charadriiforms. Although palaeobotanists rightly regard the Oligocene as a time of significant world-wide cooling, the occurrence of cracids in South Dakota (*Procrax*, Chadronian), todies in Wyoming (*Palaeotodus*, Orellan), and motmots in Switzerland (*Protornis*, early Oligocene) is evidence that Oligocene climates were not extremely harsh.

Giant penguins were well represented in both Oligocene and Miocene times. Their contemporaneous ecological counterparts in the North Pacific were the plotopterids, a family of huge, flightless pelecaniforms. Both the plotopterids and the giant penguins were wing-propelled diving birds whose extinction may have been caused by competition with seals and porpoises, two groups of marine mammals that diversified greatly in the Miocene. The bony-toothed pseudodontorns were a family of pelecaniforms that inhabited lower Eocene to upper Miocene seas.

Fossil birds of the Neogene (Miocene and Pliocene) are known much better than those of the Paleogene. Many living families of birds first occur in Miocene deposits, but this is almost certainly a bias due to the relative scarcity of bird-bearing Oligocene sediments, especially marine deposits. The birds of Neogene waters present a combination of ancient and modern groups. A number of Miocene birds can be assigned to living genera, and many additional modern genera are first recorded from Pliocene deposits. Living genera of aquatic birds recorded from the Miocene include *Gavia*, *Diomedea*, *Puffinus*, *Oceanodroma*, *Phalacrocorax*, *Sula*, *Morus*, *Pelecanus*, *Phoenicopterus*, *Mergus*, and *Larus*. Among the well known extinct Neogene genera are *Palaeolodus*, a possibly natatorial flamingo of the Aquitanian of Europe, and the alcids *Praemancalla* (Miocene) and *Mancalla* (Pliocene), wing-propelled divers of the eastern Pacific.

Many Neogene land birds have been found outside of the modern range of their family. For example, temperate North America supported accipitrid vultures (*Palaeoborus*, *Neophrontops*) and cracids (*Boreortalis*, *Ortalis*) in the Miocene and Pliocene, and a pratincole (*Paractiornis*) in the Miocene. The Miocene avifauna of Europe included parrots (*Archaeopsittacus*), turacos (*Apopempsis*), mousebirds (*Colius*), trogons (*Paratrogon*), hornbills (*Homalopus*), barbets (Capitonidae), and broadbills (Eurylaimidae).

The Neogene record of birds in Australia comprises many families of non-passerines, of which only the endemic Dromornithidae are extinct. The dromornithids were huge, flightless birds that are known from the middle Miocene to the Pleistocene. Five genera and 8 species of dromornithids are currently recognized, but their relationships to other families of birds are not resolved. The Neogene avifaunas of South America and Africa are poorly known at present. That of Africa is particularly incomplete and contains only forms that are closely related to modern African species. That of South America includes penguins, tinamous, rheas, large cursorial gruiforms such as *Brontornis* and *Phor-*

orhacos, a variety of seriema-like gruiforms, and the spectacular teratorn *Argentavis*, which is the largest known flying bird. *Argentavis*, from the Huayquerian of Argentina, had a wing-span of *c.* 7.0–7.6 m and an estimated weight of 120 kg.

The first certain passerine fossils occur in Miocene deposits, but no rich fauna of passerines is known before the Pleistocene. The only Miocene passerines are an indeterminate broadbill from Germany, 2 corvids (*Miocitta* from Colorado and *Corvus* from France), a possible shrike from France, a sparrow from Kansas, and *Palaeoscinis* from California, which is thought to represent an extinct family perhaps related to bulbuls, waxwings, corvids, or dippers. The Pliocene record of passerines is somewhat better than that of the Miocene, but still is extremely incomplete and includes no species of major evolutionary or zoogeographic consequence.

Pleistocene birds. Although Pleistocene avifaunas are dominated by living species, they also contain a significant number of extinct ones. The record of late Pleistocene birds is much more complete than that of the early Pleistocene. Probably the single most important late Pleistocene site is Rancho La Brea, California, where past avian life is recorded in thousands of beautifully preserved, tar-impregnated bones. The teratorns were perhaps the most spectacular birds of the North American Pleistocene. *Teratornis incredibilis* had an estimated wing-span of about 5 m, greater than in any living bird. Although somewhat vulture-like in their post-cranial skeleton, the teratorns had a large, sharply hooked bill unlike that of any cathartid vulture. Other noteworthy extinct birds of the late Pleistocene in North America include 2 species of storks (*Ciconia maltha*, *Mycteria wetmorei*), a cathartid vulture (*Breagyps*), 2 accipitrid vultures (*Neogyps*, *Neophrontops*), a variety of large eagles of uncertain taxonomic position, 2 small turkeys (*Meleagris californica*, *M. crassipes*), a shelduck *Anabernicula*, and a flightless eider *Chendytes*.

The advance and retreat of continental ice sheets in the Holarctic Region had a profound effect upon the distributions of temperate and arctic birds. Fossil localities of glacial age have recorded northern birds such as ptarmigan *Lagopus* and jays *Perisoreus* hundreds of km south of their modern southern limits. It appears that many areas in tropical latitudes were more arid during glacial advances than during interglacial intervals, such as exists today. These changes in tropical climates and habitats had a great influence on avian evolution and distribution during the Quaternary. This subject has been analyzed in detail for tropical South America, based on the systematics and distributions of modern species. A useful fossil record of Pleistocene birds in South America is emerging; two recently studied late Pleistocene sites from Ecuador and Peru have yielded extinct species of cathartid vultures, hawks, a caracara, a heron, plovers, scolopacids, a seedsnipe, a phalarope, ducks, and a nightjar. The Pleistocene avifauna of Africa is still very poorly known, pending completion of study of a large number of avian fossils from Olduvai Gorge. Pleistocene birds from Australia consist mainly of living species of non-passerines, but extinct species include megapodes, a flamingo, and the dromornithids.

Quaternary fossil birds from oceanic islands. Fossil birds are known from many oceanic islands throughout the world. These ancient insular avifaunas are usually characterized by a high percentage of extinct forms, particularly flightless species (see FLIGHTLESSNESS). The age of many insular sites cannot be refined beyond 'Quaternary' because absolute age determinations are seldom available for sites that contain fossil birds but no cultural remains. Archaeological sites on islands often do contain extinct birds, however, and many of these sites have now been dated by radiocarbon. Past changes in climate (wind patterns, moisture regimes, oceanic currents) have affected avian extinctions on oceanic islands, but man has been the principal agent of extinction in island birds during the Holocene, through the combined forces of habitat destruction, hunting, and introduced mammalian predators. The numerous archaeological associations of man and extinct birds in New Zealand are particularly convincing evidence of man's ability to disrupt an island's avifauna (see EXTINCT BIRDS).

Flightless RAILS are especially characteristic of islands, although flightless species of many other families are also known. For example, flightless or nearly flightless fossil birds of the West Indies include an ibis from Jamaica (*Xenicibis*), and *Ornimegalonyx* from Cuba, the largest known owl. In addition, several volant extinct species of West Indian barn owls *Tyto* are larger than any living tytonids. Flightless geese *Thambetochen* and a flightless ibis *Apteribis* are known from Hawaii. Among New Zealand's endemic ancient birds are the huge MOAS, various anseriforms and rails, and *Megaegotheles*, a large owlet-nightjar. The fossil birds of Madagascar are dominated by the elephant-birds *Aepyornis*, a group of massive, ground-dwelling birds that are unknown outside Madagascar (see ELEPHANT-BIRD).

Prospects. Avian fossils have provided a wealth of data bearing on the evolution, systematics, and zoogeography of birds. Through careful work by modern avian palaeontologists, our knowledge in these subjects can only improve with time. An important duty in current avian palaeontology is to re-examine many fossils that have been mistreated taxonomically, either because they were described in the absence of adequate comparative skeletons, or because the fossil itself was simply too fragmentary to permit an accurate assessment of its taxonomic position. The relative scarcity of avian fossils as compared to mammalian fossils has promoted the philosophy that every avian fossil, no matter how badly damaged or incomplete, can and should be identified and named. As a result, there is an abundance of generic and specific names of fossil birds that are based on specimens that cannot be safely assigned even to a family or order.

FOSSORIAL: term applied to the habit of digging (not just scratching or probing) or burrowing in the soil, exhibited by various birds in preparing nesting holes (see NEST).

FOSTER PARENTS: see BROOD-PARASITISM.

FOUNDER PRINCIPLE: the thesis that the founders of a new population (e.g. breeding colony) contain only a small fraction of the total genetic variation of the parental population.

FOVEA: part of the retina of the eye (see VISION).

FOWL, DOMESTIC: see DOMESTICATION.

FOWLING: see TRAPPING; WILDFOWL.

FOWL PLAGUE: see DISEASE.

FRANCOLIN: substantive name of *Francolinus* and *Pternistis* spp. (see under PHEASANT).

FRATERCULINI: see AUK.

FREGATAE; FREGATIDAE: see under PELECANIFORMES; FRIGATEBIRD.

FREQUENCY-DEPENDENT SELECTION: a process which causes a character to be advantageous to an individual when it is rare in the population and disadvantageous when it is common. Differences between individuals in their ability to survive and reproduce may be due to genetic differences between them (see NATURAL SELECTION). When the superiority of a particular genotype depends upon the genetic composition of the population and the genotype is at a selective advantage when rare, then the rarer forms will increase in frequency until they reach an equilibrium level at which they no longer gain an advantage. Such selection can occur if a predator or parasite attacks a disproportionately large number of the commonest individuals, or where individuals preferentially mate with those which possess a rare allele (disassortative mating). Frequency-dependent selection, also known as apostatic selection, may be an important factor in maintaining genetic diversity (Clarke 1979).

Most avian studies of frequency-dependent selection have concentrated on the feeding behaviour of predators and its effect on the visual polymorphisms of prey. Imagine a bird feeding on a prey species which can be one of two colours, pink or brown. When the pink morphs are common and brown ones rare, predators consume pink prey in a greater proportion than expected from their frequency in the population. As a result, the overlooked brown ones gain a reproductive advantage and begin to increase in relative frequency. At some stage they may become so common that the predator switches its attention to the brown individuals, ignoring the pink which will now have the advantage. This process will continue until eventually a balanced mixture of the two morphs will arise which is maintained by frequency-dependent predation.

A tendency to take disproportionately more of the common varieties of prey and overlook rare ones has been shown experimentally with studies of chicks and quail feeding on coloured mixtures of artificial baits. Frequency-dependent predation has been invoked to explain the maintenance of colour polymorphisms in prey species e.g. snails, mimetic butterflies. This mode of predation may be advantageous to the predator. By switching to the commoner prey types the predator may maximize its rate of food intake (see OPTIMAL FORAGING). One proximate means of producing this preference is through the formation of a searching image for particular forms of prey.

Frequency-dependent factors may also select for colour polymorphism in predators. Diurnal birds of prey which feed on relatively intelligent prey with good visual acuity (e.g. birds and mammals) are more polymorphic for colour than other predators (see POLYMORPHISM). One possible explanation is that it may be advantageous for the predator to differ from the visual norm. The success of the character in deceiving the prey will depend on its relative frequency in the population (Paulson 1973). P.J.G.

FREQUENCY DISTRIBUTION: see BIOSTATISTICS.

FRIARBIRD: substantive name, alternatively 'leatherhead', of the HONEYEATERS of the genus *Philemon* (see also MIMICRY).

FRIGATEBIRD: substantive name of the species of Freigatidae (Pelecaniformes, suborder Fregatae); in the plural, general term for the family. Five species and some 14 subspecies are listed, but the taxonomy of the group requires revision. There is a single genus *Fregata*.

Characteristics. Frigatebirds range in length from 70–80 cm (*F. ariel*) to over 110 cm (*F. minor* and *F. magnificens*); females tend to be larger than males, and there is marked sexual dimorphism in all species. The enormous black wings (spanning over 2 m in the larger species), long hooked bill and forked tail provide an unmistakeable flight silhouette. Frigatebirds have a low wing-loading and soar effortlessly, taking advantage of updraughts to gain height and remaining semi-motionless on the wing for hours at a time (see also FLIGHT). In pursuit of prey they are speedy and highly manoeuvrable; the large tail twists and turns for steering and braking. On the ground the wings are an encumbrance, and in strong winds the birds have difficulty in landing. The legs are small and the feet, with reduced webbing, and sharp claws, are appropriate more for perching than for swimming.

Lesser Frigatebird *Fregata ariel*. (*J.B.*).

Habitat and distribution. Frigatebirds (or Man-of-war birds) occur in tropical and subtropical oceanic areas, particularly where flying fish are abundant. Breeding birds tend to stay close to their breeding grounds throughout the year; non-breeding young disperse widely and may appear over 800 km from the nearest land. The presence of several frigatebirds together is often an indication that their breeding ground is not far away.

The sedentary habit of frigatebirds and their isolation on islands has led to the formation of many small, isolated populations. The Ascension I. Frigatebird *Fregata aquila* is peculiar to Ascension, where a population of 2,000 to 3,000 adults breed on nearby Boatswainbird Island. The total population has been estimated at 8,000 to 10,000 birds. *F. andrewsi* the Christmas I. Frigatebird breeds on Christmas I. and other islands in the eastern Indian Ocean. The Magnificent Frigatebird *F. magnificens*, largest of the genus, ranges from the Galapagos Is. and eastern Pacific Ocean to the Caribbean, Cape Verde Is. and the coast of West Africa. The Lesser Frigatebird *F. ariel* and Great Frigatebird *F. minor* breed on islands of the Indian and Pacific Oceans and also at South Trinidad in the southern Atlantic Ocean.

Food. The skill of frigatebirds in chasing home-coming boobies, forcing them to disgorge fish and then catching the food in mid-air, has been described by many observers. Frigatebirds are, however, fully capable of fishing for themselves. They seldom settle on the sea; their oil glands are small and the plumage seems inadequately coated, readily becoming saturated. Instead they fly above shoals of hunting tuna or dolphins and catch on the wing the flying fish that leap out of the water ahead of their pursuers. They also snap up refuse from the surface of the sea, and may swoop low over open breeding colonies of terns and other small birds, taking unwary chicks; chicks of their own species may be taken if left unattended.

Behaviour. In the courtship season males develop an inflatable crimson gular sac, which they display prominently. In splendid iridescent black plumage they take up nest sites on the colony; with wings spread and sac inflated like a balloon, they posture to females flying overhead, shivering violently and rattling bills and quills as potential partners approach.

Resting adults and juveniles seek shade from strong tropical sun, but in exposed places they take up a 'sunning' posture with wings extended and turned so that the concave under-surface lies uppermost, possibly as a means of shedding heat.

Breeding. Frigatebirds nest typically in trees or low shrubs, but in the absence of vegetation they breed successfully on the ground. There is strong competition for sites or for nesting material on the colonies, which are often crowded, with special areas of concentration. Nest material, including sticks, feathers and bones, accumulated by both parents during courtship and incubation, is often lost to neighbours. A single large white egg is laid, and both parents incubate. The chick is hatched after some 55 days' incubation, and closely brooded for a further 2 or more weeks until covered with pale grey down. The chicks defend themselves from intrusions of neighbours while both parents search for food; nest losses at this stage may be very high when competition for sites is keen. Fully feathered after 4–5 months, the juveniles (in all species distinguished by a white head) remain dependent on their parents for a further 2–6 months, sometimes augmenting food brought to them by scavenging on the colony. They fly together in small bands, picking up feathers and seaweed from the surface of the sea, snatching small unattended chicks of their own species, occasionally attacking boobies and other flying birds, and gradually acquiring the skills necessary for catching food on the wing. FRIGATE-PETREL: substantive name of *Pelagodroma* ('*Fregetta*') spp. (see PETREL).

FRINGILLIDAE; FRINGILLINAE: a family and subfamily of PASSERIFORMES, suborder Oscines; FINCH.

FROGMOUTH: substantive name of the species of Podargidae (Caprimulgiformes, suborder Caprimulgi); in the plural, general term for the family.

Systematics and distribution. This is a group of large 'nightjars' (in the ordinal sense) confined to the Oriental and Australasian Regions (not New Zealand); it comprises 2 genera: *Podargus* (3 species, 33–58 cm long), restricted to Australia, New Guinea and the Solomon Islands, and *Batrachostomus* (9 species, 23–40 cm long), occurring from India to Malaya.

Characteristics. Frogmouths have the same marbled grey-brown and rufous cryptic colouring and soft plumage as true nightjars, but differ considerably in some of their habits and structural characters. Anatomical peculiarities, as compared with the true nightjars, include a desmognathous instead of an aegithognathous palate, no functional basipterygoid processes, 13 instead of 14 cervical vertebrae, sternum double-notched on each side, outer toe with 5 phalanges, a single carotid, and a bronchial syrinx. The tongue is large and paper-like. In both genera there is a pair of remarkably well-developed powder-down tufts arranged on either side of the rump. *Podargus* lacks an oil gland, while *Batrachostomus* possesses a very small one. The bills are wide and boat-like, so that earlier naturalists surmised that they were superbly adapted for hawking after nocturnal flying insects. However, it has been demonstrated that frogmouths capture most of their prey on the ground or from branches. Frogmouths are comparatively fast fliers for short distances, but they are inferior to the Nightjar *Caprimulgus europeaus* for sustained FLIGHT owing to their lower aspect-ratio. Manoeuvring ability, as judged by relative tail area, has been lost by *Podargus* in greater degree than by *Batrachostomus*.

Podargus has a characteristic alarm posture in daylight; the bird stretches out, with its bill pointed obliquely upward, and the resemblance to a broken branch is remarkable. It freezes into this rigid 'broken branch' stance only if flushed unawares by day and does not adopt the attitude at night. The birds are active after dusk and before dawn.

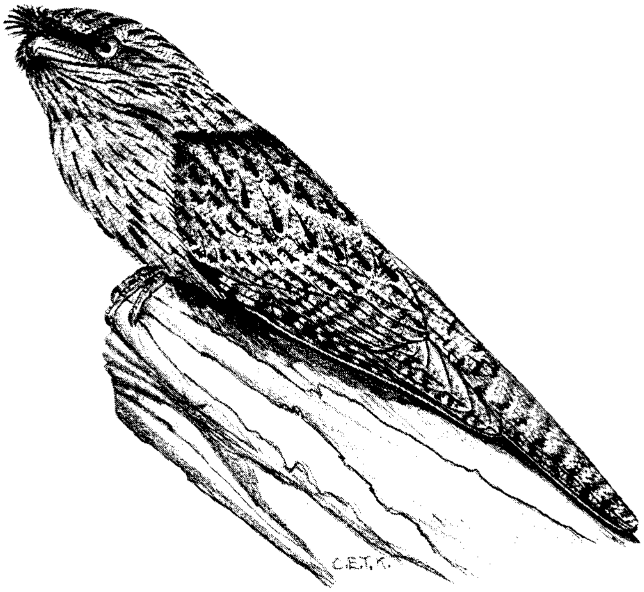
Habitat. Frogmouths are arboreal, occurring in forested country.

Population. Frogmouths occur in pairs, but they are nowhere particularly numerous, and, in the Australasian Region, are never seen in the great densities reported of nightjars in Africa and tropical America.

Food. Frogmouths make short flights from a sally point to take a resting beetle, scorpion, centipede, snail, or frog from the ground or a branch. Mice and small birds, and occasionally fruits, are also eaten. They have to a large extent lost the aerial feeding habit.

Voice. Calls include repeated low-pitched hoots, also hissing and screeching notes.

Breeding. *Podargus* builds a flimsy stick nest on the horizontal bough of a tree, *Batrachostomus* a pad-like structure made up of its own down and with an external covering of spider-web and lichens. The eggs are white, *Batrachostomus* lays one, and *Podargus* 2, occasionally 3. Both incubation and fledging periods are about 30 days. The young are covered with long white down. Probably only the female incubates, but both parents share in the feeding of the young.



Tawny Frogmouth *Podargus strigoides*. (*C.E.T.K.*).

FROGMOUTH, OWLET: see OWLET-FROGMOUTH.

FRONTAL: pertaining to the forehead (for the frontal bones see SKELETON, POST-CRANIAL); also used on occasion (e.g. aerodynamically) in its ordinary more general sense of entire forward-facing aspect.

FRONTED: refers to the forehead (in such combinations as 'white-fronted').

FRUGIVOROUS: fruit eating.

FRUITCROW: substantive name of *Querula purpurata* and *Pyroderus scutatus*, also applied as a general term to other large COTINGAS.

FRUITEATER: substantive name of COTINGAS of the genera *Pipreola* and *Ampelioides*.

FULICINAE: see under RAIL.

FULL-WINGED: having the power of flight.

FULMAR: substantive name of *Fulmarus* spp. and *Macronectes giganteus*, and often applied without qualification to *F. glacialis*; in the plural, a general term for these and allied genera of the Procellariidae (see PETREL). See photos DISPLAY; FEEDING HABITS.

FULMAR-OIL: see PETREL.

FURCULA: bony structure ('wishbone' or 'merrythought') formed by fusion, in birds, of the right and left clavicles (see SKELETON, POST-CRANIAL).

FURNARII: infraorder of PASSERIFORMES, suborder Deutero-Oscines.

FURNARIIDAE: see under PASSERIFORMES, suborder Deutero-Oscines; OVENBIRD (1).

G

GADWALL: *Anas strepera* (see DUCK).

GAGGLE: see ASSEMBLY, NOUN OF.

GAIT: see LOCOMOTION, TERRESTRIAL.

GALAH: name now generally used (formerly Roseate Cockatoo) for the small Australian cockatoo *Cacatua roseicapilla* (see PARROT).

GALAPAGOS FINCHES: see DARWIN'S FINCHES.

GALBULAE; GALBULIDAE: see under PICIFORMES; JACAMAR.

GALBULOIDEA: see under PICIFORMES.

GALL-BLADDER: not always present in birds (see LIVER).

GALLERY FOREST: a type of riverine forest consisting of trees whose roots need wet conditions and are adapted to resist flooding. The tree canopy may extend over the water, hiding the bank from view.

GALLI: see below.
