Fig. 3. Waves and arcs of echo which are caused by departures of birds on migration from known roosts have been recorded, both by day and by night. Fig. 3 is a plan-position photograph taken at 06.39 on 5 March 1958, within one minute of sunrise. Arcs of echo are spreading from three separate points on the display at the same time. In each case the sector of arc recorded is that moving eastward from its source, a standard direction of migration at this season. The most clearly-defined arcs are those to the northeast of the radar. Two are strongly evident, separated by a distance of 8 km, and a fainter third 6 km farther ahead. In all, 7 waves of echo spread out from this point, the first leaving the roost at 06.20, 20 minutes before sunrise, and the last at 06.46, 6 minutes after sunrise. (*Photo*: *W. G. Harper*)

(5) **Orientation of migrating birds.** Radar observations show that in some instances migrants compensate completely for wind drift over land and coastal areas, in other instances they are drifted to some degree by wind, and over the open sea they fail to compensate completely for wind drift. Explanations of these results are as yet only speculative. Experiments with small migrants, carried aloft in a box beneath a balloon, released and tracked by radar, demonstrate that the birds are well-oriented in clear nights and when horizon glow from the setting sun is visible, but not so in overcast nights. Radar tracks of individual White-throated Sparrows *Zonotrichia albicollis*, experimentally released

under clear spring nights, with the birds most often flying off in their normal migratory direction, are shown in Figure 2B. T.A.

RADIALE: one of the proximal carpal bones (see SKELETON, POSTCRANIAL; WING).

RADIATION (1): in the evolutionary sense, divergence of forms of common ancestry, with increasing dissimilarity as a result of differences in adaptation—the antithesis of convergence (see ADAPTATION; CONVERGENCE; see also EVOLUTION; NATURAL SELECTION; SPECIATION).

RADIATION (2): in the distributional sense, geographical spread of a species or group of related species from the area in which the particular species or the ancestral species of the group (e.g. family) was originally evolved as a separate entity (see DISTRIBUTION, GEOGRAPHICAL; RANGE CHANGES; see also SPECIATION).

RADIATION (3): in the physical sense, with only incidental application in ornithology, emission of ionizing rays—to which birds or other organisms may become exposed.

RADIO TELEMETRY: see RADIO TRACKING AND BIOTELEMETRY.

RADIO TRACKING AND BIOTELEMETRY: the remote monitoring of an animal's location by wireless is called radio tracking and remote monitoring of its physiology (e.g. heart rate) is termed biotelemetry. Radio telemetry involves a battery powered transmitter which emits low-powered signals via a transmitting antenna. These signals are received by another, directionally sensitive antenna which connects to a receiver. Ideally, the directional properties of the receiving antenna allow bearings to be taken on the animal's position from two places and the point at which these bearings intersect marks the animal's location. Biotelemetry and radio tracking should not be undertaken lightly; they are expensive, time-consuming and often, frustrating; but can lead to answers to biological questions which are otherwise unobtainable (e.g., location of sleep sites used by elusive nocturnal birds). Described here are practical aspects of selecting, building and using telemetry equipment.

The history of radio telemetry effectively began in the early 1960s. Early circuits were simple, robust, adaptable to both loop and whip antennae and could be packaged to fit most birds and mammals. A similar circuit (Fig. 1) was developed to capitalize on the more useful features of these circuits. Using this transmitter design, the writer has successfully tracked many species of birds. If a resistive device is incorporated in the circuit at R_T (150–400 K) physiological and environmental parameters can be measured by pulse interval modulation. For instance, a 200-K thermistor (at 25°C) may be substituted to measure linear temperatures between 31° and 45°C, accurate to 0.1°C. This temperature transmitter has been used to measure 24 h egg and body temperatures of incubating gulls (*Larus argentatus* and *L. fuscus*). Other environmental parameters such as light level (R_T = photoresistor), presence of moisture, and pressure (if a strain gauge is substituted for R_T) can also be measured.

If the circuit of Fig. 1 is built with subminiature components, it weighs as little as 1.0 g and operates for 7–10 days using a 0.3 g mercury hearing aid battery. This transmitter has been field-tested on birds as small as Great Tits *Parus major* weighing approximately 20 g and effective tracking ranges are up to 100 m in thick forest and 500 m line of sight.

Powerful multistage transmitters are required for long-range tracking (3–10 km). By pulsing the transmitter 2 or 3 times every few seconds, individual animals can be recognized, much as the alphabet and numbers are recognized through Morse Code transmission.

Pulse interval modulation allows activity and mortality sensing. An easily built two-stage activity-sensitive radio-tracking transmitter is shown in Fig. 2. The values given result in a pulse rate of 60 min^{-1} when the mercury switch is shorted. Opening the contacts of the mercury switch results in a doubling of the rate. Changes in pulse rate caused by opening and closing the switch allow movement to be detected. The sensitivity of the device to particular movements usually depends on where the transmitter is fitted to the animal and hence how it moves relative to the plane of animal movement. Unambiguous distinction can be made between inactive resting, sporadic and continuous activity.

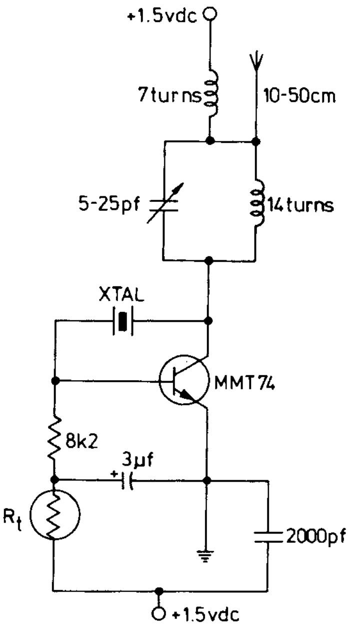

Fig. 1. A miniature, crystal controlled transmitter.

Batteries. A compromise between battery weight, increased transmitter life and range limits the use of many transmitters. Battery failures either through self-deterioration or penetration by moisture have been the commonest causes of transmitter failure (followed by poor-quality transmitter crystals). Recently, advances have been made using solar cells, where benefits were obviously only to studies of diurnal birds unless rechargeable batteries were incorporated into the solar transmitter.

Encapsulation and attachment. Transmitter components should be encapsulated in light-weight, durable and waterproof materials. Components should be coated in beeswax which increases waterproofing and facilitates the removal and replacement of batteries. As a general rule, the total package (transmitter, battery, antenna, harness and encapsulation), should weigh less than 3–5% of the animal's body weight.

Radio harnesses for birds include chest packs attached by a loop antenna that circles the bird's body, backpacks attached by harness loops under the wings with a whip antenna trailing down the bird's back and tail-mounted either on imped or natural feathers (see Amlaner and Macdonald 1980, for review). Swanson and Keuchle (1976) mounted a transmitter above a duck's bill using a nasal pin. Their transmitter included a switch so positioned that it changed the pulse rate depending on whether the duck's head was up, or down as when feeding.

Welfare. It is imperative for both humanitarian and scientific reasons that the transmitter does not hamper or damage the animal in any way. Boag (1972) found that Red Grouse *Lagopus lagopus scoticus* wearing transmitters fed less than those without. Sargeant, Swanson and Doty (1973) suggested that fitting a radio pack to a Blue-winged Teal *Anas discors* contributed to its being preyed on by Mink *Mustela vison* (see Siegfried *et al* 1977). Comparisons can be made between observations on the same animal before and after radio tagging, but some effects may be very subtle, e.g., on long-term reproductive potential. Kenward (1977) found no difference in weight loss or dispersion tendency of Goshawks *Accipiter gentilis* wearing transmitters from those wearing leg rings and noted that the hourly rate of bringing prey to the nest was the same for a Sparrowhawk *Accipiter nisus* before and after being fitted with a transmitter. Amlaner, Sibly and McCleery (1970) conducted a detailed study of the survival and hatching success of Herring Gulls carrying

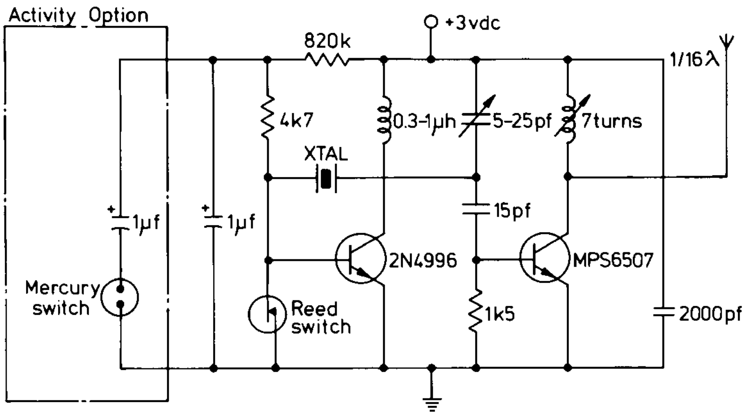

Fig. 2. A two stage transmitter for use in long range radio tracking studies. It includes a mercury switch whose movement enables the animal's activity to be monitored through changes in 'bleep' rate.

dummy transmitters weighing between 10–50 g and found that wearing heavier transmitters decreased survival of the offspring.

Basic radio tracking. Tester (1971) suggested three categories of error all of which could act together to frustrate the tracker's ability accurately to locate his quarry: error inherent in the receiving equipment and its operation, error resulting from the animal moving while bearings are being taken, errors resulting from anomalies such as reflection and refraction of the signal creating false bearings.

Although not commonly stressed in the literature, the radio tracker's subjective 'feel' for the radio landscape of his study area is widely acknowledged as an important facet of accurate radio tracking. The following suggestions help to minimize the risks of both movement and topographical error. Take consecutive bearings with as little delay as possible. For direction finding it is easier to detect the difference between signal and silence (i.e., null) than between signal and louder signal. Know the individual features of the landscape well, and how they affect radio signals. If errors are suspected, take several alternative bearings; at least three are necessary to detect movement errors. When radio tracking from a car it is helpful to continue listening to the signal while travelling between reception sites so that fluctuations in signal strength along the route can be noted in the context of the landscape. Bearings and the derived radio locations should be ranked in terms of their accuracy, depending on both the width of the null points and the variation of successive bearings that do not intersect at the same spot.

Conclusion. Radio tracking is an invaluable addition to the biologist's skills and fieldcraft, and has contributed to diverse studies (reviewed by Macdonald 1978). Just as this technique has revolutionized studies of elusive species during the past decade or so, now people look to the possibility of transmitting and receiving additional information, through biotelemetry, as the next methodological advance (Amlaner 1978; Amlaner and Macdonald 1980). RADIUS: a bone of the forelimb (see SKELETON, POST-CRANIAL; WING); also a barbule in the vane of a feather (see FEATHER).

RAFT: a closely-packed flock of birds on water.

RAIL: substantive name of many species of Rallidae (Gruiformes, suborder Grues); in the plural, general term for the family. The rails constitute a homogeneous and cosmopolitan family.

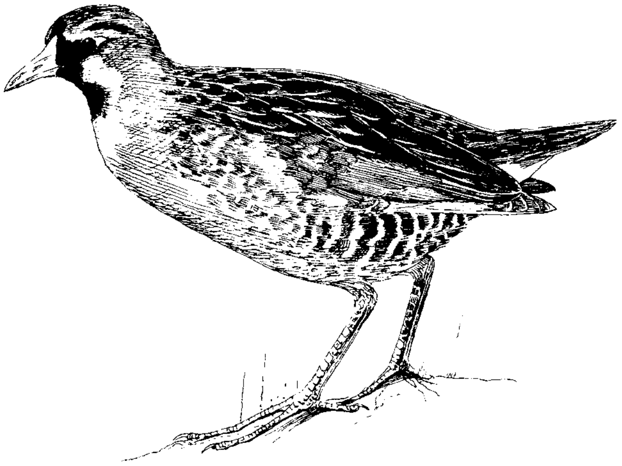
Characteristics. Rails are small- to medium-sized birds (20–65 cm long) with the body laterally compressed, with moderate to long legs and toes, short rounded wings of 10 or 11, rarely 8 or 9 primaries, and a short and soft tail usually of 12 rectrices (rarely as few as 6 feathers, sometimes almost non-existent). The bill varies from long and curved to short and conical. The plumage is of loose texture and the flight feathers are moulted simultaneously. The sexes often differ in size, the males being larger, but rarely differ in coloration. The plumage varies from nearly black or greenish-blue (but even deep purple) to olive-brown, buffish, or chestnut, sometimes with dark streaks and with white bars or spots.

Habitat. Although some forms prefer dry plains, Rails are mainly ground-dwelling water and swamp birds (see SWIMMING AND DIVING), well adapted to living in dense vegetation.

Distribution. Rails are found in all continents north to the Arctic Circle and south to the islands of the sub-Antarctic Convergence. Some 129 species are or were known, contained in 18 genera. Five genera are monotypic. The typical genus includes the Water Rail *Rallus aquaticus*, the only member of this genus with a Palearctic distribution; it is distinguished by a long red bill. It occurs from Great Britain and Iceland, discontinuously, to eastern Asia; migrants often fall victims to striking against lighthouses and powerlines. North American representatives are the larger Clapper Rail *R. longirostris* and King Rail *R. elegans*, inhabiting salt and freshwater marshes. The smaller and warmly brown-tinged Virginia Rail *R. limicola* is found in marshes of the Western Hemisphere. Widely spread over the southern part of Africa is the Cape Rail *R. caerulescens*, very similar to the Water Rail but with uniform dark brown upper parts. In south-eastern Asia, from southern China and India to the Philippines and Sulawesi, the Blue-breasted Banded Rail *R. striatus* is found; in India this species, with its rufous crown and hind neck and its dark brown upperparts barred with white, is one of the most familiar water birds. Rather similar, but smaller and with the back black-streaked olive-brown, is the Slate-breasted or Lewin's Water Rail *R. pectoralis*, occurring in Australia, Flores, and the mountains of New Guinea. In the same area and distributed also over the lesser Sunda Islands, Sulawesi, and the Philippines, is the beautiful Banded Rail *R. philippensis*, characterized by a rufous pectoral band and a grey eye-stripe. More restricted in distribution is the Barred Rail *R. torquatus*, inhabiting the Philippines, Sulawesi, and New Guinea. The head is blackish with a broad white line under the eye. Of the 13 other species included in this genus, there are 3 in South America and 1 in Madagascar, while the other 6 are or were inhabitants of small islands; of these last, one species still survives on Guam, but the others, known from Tahiti, Wake Island, and the Chatham Islands, are extinct.

Of the 2 known species of island woodrails the one formerly occurring on New Caledonia, *Rallus lafresnayanus*, is extremely rare, but a tiny population (18 birds in 1972) of the other, *R. sylvestris*, is still found on Lord Howe Island; these forms are more forest than swamp birds. Another peculiar form is the still common Inaccessible Island Rail *Atlantisia rogersi*, a very small, flightless, dark rail with degenerate hairlike plumage; it lives in the tussock grass which covers the island. Representatives of the banded crakes *Rallina* spp. are distributed from India to northern Australia. All have warm rufous heads and breasts, the abdomen more or less clearly banded black and white; they are shy and retiring birds, living in marshes or along streams in dense undergrowth.

Of the woodrails *Aramides* spp. of Middle and South America, eastern Indonesia and northern Australia 11 subspecies are known. They are large rails with stout bills, generally olive-brown upperparts, grey breast, and black hind parts; when flushed they take wing reluctantly. The wekas *Gallirallus* are restricted to New Zealand. They occur from sea level to well up in the mountains in different habitats. They are brownish in colour and the wings are rudimentary. Not unlike in general appearance, but with a more conical bill and red legs, is the Nkulengu Rail *Himantornis haematopus*, living in the forests of West and Central Africa. Here also occurs the Grey-throated Rail *Canirallus oculeus*, with chestnut neck and breast, olive upper parts and white spots on the almost black



Sora Rail *Porzana carolina*. (*C.J.F.C.*).

wing feathers.

The Corncrake or Landrail *Crex crex* is distributed over most of Europe and well into central Asia; its favourite habitat is grassland. In winter it migrates into Africa and may erupt occasionally into other southern latitudes.

One of the larger genera is *Porzana*, with a world-wide distribution and comprising some 21 species, one extinct (*palmeri*). Of these the Spotted Crake *P. porzana*, the Little Crake *P. parva*, and Baillon's Crake *P. pusilla*, are European birds which also range over part of middle Asia. Baillon's Crake has a peculiar discontinuous distribution, being also known from the southern part of Africa and from Australia and New Zealand. A widespread North American species is the Sora *P. carolina*, in winter reaching northern South America and accidentally occurring in Great Britain. Ranging from the Philippines to Australia, New Zealand, and many Pacific islands is the Spotless Crake *P. tabuensis*, a dark leaden-grey species with dark brown upper parts. Other species occur in South and Central America (3), in eastern and south-eastern Asia (3), in Australia and Oceania (2), and in Madagascar (1). In some species there is a slight difference in plumage between the sexes. In Africa the Black Rail *Porzana flavirostra*, with a yellow bill, is one of the commonest species.

Restricted to America are 11 species of *Laterallus*; of these the only one known in North America is the American Black Rail *L. jamaicensis*, a small bird with white spots and streaks on the upper parts, frequenting grassy inland swamps and brackish coastal marshes. Diminutive in size are the pygmy rails *Coturnicops* spp. (here taken to include *Sarothura*); the 13 species occur from Africa to the Western Hemisphere and Japan. They show a well-marked sexual dimorphism, and are exceedingly secretive in habits. Six species of *Amaurornis* are distributed from India to the Solomon Islands; except for the White-breasted Waterhen *A. phoenicurus*, they are dull grey and olive-brown.

The large Watercock *Gallicrex cinerea* has a reddish frontal shield projecting backwards in a horn; it is found over a wide area from southern to eastern Asia, and migrants reach the Greater Sunda Islands. The Moorhen or Waterhen or in America Common Gallinule *Gallinula chloropus* is distributed over much of the world, being found in all continents except Australia and having colonized many oceanic islands. In Australia, New Guinea, and eastern Indonesia it is replaced by the closely related Dusky Moorhen *G. tenebrosa*. In Africa occurs the small Lesser Moorhen *G. angulata*. The moorhen of Tristan da Cunha, *Gallinula* ('*Porphyriornis*') *nesiotis nesiotis*, was hardly able to fly and is now extinct; but another subspecies, *G. n. comeri*, is still not uncommon on Gough Island. The widespread (American) Purple Gallinule *Porphyrula martinica* has relatives in Africa and South America, *alleni* and *flavirostris*.

A large species is the (Old World) Purple Gallinule or Swamphen *Porphyrio porphyrio*, with a discontinuous distribution from southern Europe through southern Asia to Australia, New Zealand, and islands in the Pacific, and also occurring in Africa and Madagascar. It is azure or greenish-blue below, brown or almost black above, and has a stout and conical bill; all populations are now generally considered as belonging to 3 species, including the flightless Takahe *Porphyrio* ('*Notornis*') *mantelli* from New Zealand, thought to have become extinct but rediscovered in recent years in some inaccessible valleys in the mountains on South Island.

The Coot *Fulica atra* has lobed toes and a white frontal shield and is found over the greater part of Europe, Asia, and Australia, as is the American representative *F. americana* over the greater part of the Americas. Of the remaining 7 species, one is African and all others are Central and South American in distribution. Of these the Giant Coot *F. gigantea* and the Horned Coot *F. cornuta* breed in the high mountain lakes of the Andes; the latter species has the remarkable habit of using stones for building its nest.

Food. The diet is varied—mainly animal, but some species prefer vegetable food. The robbing of eggs and young of other birds is known.

Behaviour. Rails walk with bobbing heads and flirting tails possibly correlated with acuity of vision, as in other walking birds such as pigeons. Some of them are good flyers, covering long distances during migration; but in others, living on oceanic islands, the power of flight has been reduced, and in these cases the introduction of rats or other predators can at once endanger the existence of the species. The majority of the species have secretive habits and many are nocturnal, so that our knowledge of the life of many forms is still scanty.

Voice. At dusk and during the night rails may make themselves conspicuous by their specific loud calls and harsh repetitive squeals or monotonous notes like knocking pebbles together.

Breeding. Nests are well concealed; the clutch-size ranges from 1–14 eggs, sometimes due to more than one female laying *in situ*. The ground colour varies from near white to ochreous or brownish buff, often with reddish, greyish-brown, or black specks, spots, or blotches. The eggs may be incubated by both sexes for from 2½ to nearly 4 weeks. The nestlings are covered with black or dark brown down; they leave the nest soon after hatching and are cared for by both parents, sometimes also by young of an earlier brood. They become independent in up to 8 weeks.

RAIL-BABBLER: substantive name of some species of the subfamily Orthonychinae (Cinclosomatinae) of the family Timaliidae (Passeriformes, suborder Oscines); in the plural, general term for the subfamily. Within it are placed provisionally a small number of insectivorous species which all occur, except one, in the Australian–Papuan region and are all essentially terrestrial in their habits. They have thickset bodies and short bills, generally with small heads and thin necks. Their legs are fairly long, their tails broad and their plumage soft and fluffy. There are many uncertainties about their taxonomic relationship; they do not seem to be closely related to one another, and they may even belong to entirely different groups. These uncertainties are reflected in current Australian field-guides. Thus the logrunners or chowchillas (*Orthonyx*, 2 species), the quail-thrushes (*Cinclosoma*, 5 species) and the whipbirds and wedgebills (*Psophodes*, 4 species, although wedgebills were formerly in *Sphenostoma*) are either placed in a family of their own (Orthonychidae) or else, as here, absorbed into the babblers (Timaliidae); so are the scrub-robins (*Drymodes*, 2 species) which in the field-guides are placed in the thrushes (Turdidae). Also in this grouping are here included the genera *Eupetes* (4 species), *Melampitta* (2 species) and the monotypic genera *Androphobus* and *Ifrita*.

The provisional nature of the classification adopted here for these groups must be stressed. Recent evidence from DNA hybridization indicates that these and other Australian passerine birds of uncertain affinities are all the result of evolutionary radiation of ancestral Australian endemic stocks, and that the resemblance of some of them to babblers, thrushes and other passerine groups is attributable to convergence (Sibley and Ahlquist 1982).

Characteristics. The logrunners have robust legs and feet and a specialized tail in which the shafts of the feathers are modified at the tip into stiff spines, used to help prop up the birds while they feed. The sexes in both species may be distinguished through the colour of the throat, white in the male and chestnut in the female. The Northern Logrunner *Orthonyx spaldingi* (length *c.* 25 cm) is much larger and is more cleanly marked black and white than the Southern Logrunner *O. temminckii* (length *c.* 18 cm) which is mottled brown above. The 2 *Melampitta* species are black all over and also differ in size (18 cm and 29 cm respectively). They are active birds which cock their short tails and nervously flutter their wings as they move through the vegetation. The whipbirds and wedgebills (length 20–27 cm) are noted for their erectile crests. They are, in general, dull drab birds in which the sexes are the same, although the whipbirds do have a prominent white patch or streak on the throat.

The quail-thrushes (length 20–30 cm) are distinctively and boldly marked, particularly the males which are larger than the females. Males have two patterns of black and white on the underparts and these are used to determine the limits of the various species. The colour of the upperparts is variable in species living in dry habitats and matches the colours of the local soils. The white tips of the dark tail feathers are conspicuous in flight, which occurs in short bursts, is low and fast, and terminates with the bird running at the flying speed. The young of all species are spotted.

The sexes are alike in the scrub-robins (length 19–20 cm). One notable distinction between the 2 species is the colour of the mantle; this is grey in the Southern Scrub-robin *Drymodes brunneopygia* and reddish-brown in the Northern Scrub-robin *D. superciliaris*. They habitually cock their tails at about 45°, and raise and lower them, and flick their wings nervously whilst moving through the undergrowth.

In marked contrast to the rest of the group, the *Eupetes* species (length 20–30 cm) are brightly coloured blue, chestnut, or reddish, have rather long necks and their young are unspotted. The Green-backed Babbler *Androphobus viridis* is unique in having a dark olive-green mantle and so is the Blue-capped Babbler *Ifrita kowaldi* in having a shiny blue crown with a black patch in the centre.

Habitats, distribution and movements. The logrunners are mainly confined to rain-forests along the eastern coastal belt of Australia, but the Southern Logrunner surprisingly turns up again in New Guinea. The 4 species of Australian quail-thrushes are found on stony ground, particularly on ridges where there is plenty of cover, and live in open forests. The Ajax Quail-Thrush *Cinclosoma ajax* is found throughout the lowlands of south-east and south New Guinea but only locally in the west.

Whipbirds and wedgebills are confined to Australia. Three are dry country species whilst the Eastern Whipbird *Psophodes olivaceus* is found in dense thicket in or near the wet forests along the east coast. The 2 scrub-robins also occupy quite different habitats, the Northern Scrub-robin in forests in New Guinea and north-eastern Australia and the Southern Scrub-robin in dry country outside the forests in a number of localities in southern Australia.

All the *Eupetes* species are forest birds; 3 are found in New Guinea and the other, the Malaysian Rail-babbler *E. macrocercus*, occurs on the Malaysian Peninsula, Sumatra, Borneo and the Natuna islands. The remaining genera, *Melampitta*, *Ifrita* and *Androphobus* are found in mountain forests in New Guinea, the majority are rare and *Androphobus* is only found on the Snow and Weyland Mountains.

Food. Insects of one kind or other are the main diet of the majority of the rail-babblers but fruit has been found in the stomachs of some *Melampitta* and *Eupetes* species. The logrunners clear leaves from the soil by rapid scratching, throwing debris aside, and use both feet to excavate for food. The distinctive bare patches that remain on the forest floor give the birds' presence away. The Blue-capped Babbler is unique in the group, feeding at all levels of the forest, often reaching the tree-tops as it searches the moss-covered trees in a treecreeper-like manner.

Behaviour. Little or no information is available for the majority in this grouping. The logrunners, whipbirds and wedgebills and quail-thrushes move in pairs or small parties, but are sometimes solitary. The quail-thrushes are particularly shy and secretive, and freeze when disturbed or burst up from cover like quails.

Voice. Quail-thrushes and logrunners announce their presence by their loud, penetrating contact calls, especially at dawn and dusk. The quail-thrushes also have territorial songs and use song posts that may be as high as 6 m. The Northern Logrunner is an accomplished mimic and is said to drown the song of other birds with its oft-repeated *chow chowchilla*. The remarkable whipcrack call of the Eastern Whipbird is an antiphonal duet. The other whipbird and 2 wedgebills also duet but not the Chiming Wedgebill *Psophodes occidentalis*. The song patterns of scrub-robins have similarities to those of the quail-thrushes.

Breeding. Most members of the group nest near or on the ground. Logrunners build globular nests made from sticks, ferns, fibrous leaves, mosses, etc., and these may be placed on a bank, against a stone or log. Whipbirds and wedgebills use similar materials but the nest is cup-shaped and placed 1–2 m high in bracken, shrub or sapling. The quail-thrushes and some, possibly all, *Eupetes* species line a depression in the ground with grass, leaves and rootlets, often sheltered by an overhanging rock. In contrast, the Green-backed Babbler places its nest as high as 4 m above the ground.

Known clutch-sizes are 2–3 (whipbirds and quail-thrushes), 1–2 (*Eupetes* and logrunners) and one egg (Blue-capped Babbler). The eggs vary from white to pinkish buff, blue-white or blue-green and are, in the majority of species, marked with brown, black, reddish or purplish-grey spots or blotches. Pure white eggs are laid by logrunners and the Blue-capped Babbler. Incubation and fledging periods appear to be unknown.

RAIL, BENSCH'S: misnomer for the Monias *Monias benschi* (see MESITE).

RAIN BATHING: see COMFORT BEHAVIOUR.

RAIN-BIRD: name variously applied in different parts of the world (usually because the birds, when particularly noisy, are supposed to predict rain), e.g., to the Green Woodpecker *Picus viridis* in Britain (see WOODPECKER), the Grey Currawong *Strepera versicolor* in Australia (see CURRAWONG), the White-browed Coucal *Centropus superciliosus* in parts of Africa and other members of the Cuculidae in the New World and Australia (see CUCKOO), and Peale's Petrel *Pterodroma inexpectata* in New Zealand (see PETREL); also 'rain-goose' to the Red-throated Diver *Gavia stellata* in Orkney (see DIVER), and 'rain-quail' (because abundant in some parts in the rainy season) to *Coturnix coromandelica* in India (see under PHEASANT).

RAINBOW-BIRD: Australian name, alternatively Rainbow Bee-eater, of *Merops ornatus* (see BEE-EATER).

RAIN-FOREST: a tropical environment characteristic of areas where there are both high temperatures and heavy rainfall, the latter spread throughout the year; seasonal heavy rains (monsoon) produce a different result. In most parts of the world the true rain-forest has little undergrowth and consists mainly of trees rising unbranched for 30–50 m and then spreading to form part of a 'canopy' that is continuous for great distances, broken only—except temporarily for accidental reasons—by vertical rock faces and the courses of large streams. The avifauna is richer in species than that of any other habitat.

During the second half of the 20th century the rain-forests of the world began to suffer massive destruction with the prospect that only vestiges would be left by the end of the century. Campaigns to 'save the rain-forest' have figured largely in the programmes of the World Wildlife Fund and other conservation organizations.

RAIN-POSTURE: special anti-rain attitude adopted by birds of many families (both passerine and non-passerine), especially those frequenting open habitats and tropical areas subject to seasonal downpours, typically while perching with little or no shelter in heavy rain; the near-vertical stance with head retracted and feathers tightly sleeked against the contours of the body helps to drain the water off and minimize its wetting effects.

RALLIDAE: see under GRUIFORMES; RAIL.

RAMI, MANDIBULAR: (plural of 'ramus'), the two halves of the lower mandible, separated by soft tissue near the base but uniting distally in the gonys (see BILL).

RAMPHASTIDAE: see under PICIFORMES; TOUCAN.

RAMUS: a barb of a feather (see FEATHER); also in the sense shown under RAMI, MANDIBULAR.

RANGE CHANGES: the enlargement or contraction of, in particular, the breeding area of a species. It is clear from the fossil record that fundamental changes in bird distribution patterns have followed major planetary climatic cycles: hence in the warm Tertiary Period (20–40 million years ago) such tropical families as the turacos (Musophagidae), barbets (Capitonidae) and trogons (Trogonidae) extended into what is now Europe; while at the other extreme large parts of Eurasia must have had very impoverished avifaunas at the height of each Pleistocene glaciation. Recent changes have been less profound, but a good many have been detected in the short period (about 300 years) that ornithologists have been documenting bird distributions (see DISTRIBUTION, GEOGRAPHICAL).

Range expansions. The common occurrence of range expansion (geographical radiation) in the past can be inferred from the present extensive distributions of many species, on the presumption that each of these has spread from a more limited area in which speciation took place; the point has all the more validity when a species has begun to fragment into morphologically distinguishable populations (becoming SUBSPECIES), showing that some factor or factors have interrupted the even gene flow that kept the original population homogeneous. Past geographical radiation has led to such anomalies as the Old World larks (Alaudidae) having a Nearctic representative (*Eremophila alpestris*), and the New World family of wrens (Troglodytidae) sharing one species (*T. troglodytes*) with Eurasia. Such theoretical considerations apart, range expansion has visibly occurred, in various species and to a substantial extent, within the period of detailed ornithological recording.

Within the historical period gradual range expansions have been more common than abrupt ones, even after excluding cases where expansion has been a consequence of recovery from an earlier catastrophic decline. Doubtless a variety of reasons have caused this gradual spread. Thus the northward expansions shown by a variety of temperate zone species in northern Europe (including Iceland) in the 1920s and 1930s were clearly correlated with simultaneous climatic amelioration, and few of these gains were lost when this phase ended in the 1940s/1950s (with a subsequent lowering of mean spring temperatures in northern Europe). Since 1950 there has been an increased tendency for boreal species to nest further south in Scandinavia and especially in Scotland. Two (perhaps interacting) mechanisms have been suggested: the evolution of blocking anticyclones over Scandinavia in spring which induce some migrants to settle and breed further south than normal, and the adoption of new breeding areas following the acquisition of wintering grounds closer to the area to be colonized (exemplified in Scotland by Shore Lark *Eremophila alpestris* and Lapland Bunting *Calcarius lapponicus*).

The range expansion of a species over a continental area may (on occasion) be quite rapid, and a particularly remarkable instance has been the spread of the Collared Dove *Streptopelia decaocto* from the Balkans to the Atlantic within 30 years. In this case, and in those of the marked northward spread in western Europe of Cetti's Warbler *Cettia cetti* and Serin *Serinus serinus*, it is tempting to postulate genetic changes that conferred wider habitat and/or climatic tolerances. No range expansion can succeed unless the new territory invaded provides suitable conditions, whether through environmental improvements within the area, or through the colonizing species adapting to new conditions—as when the typically alpine Dotterel *Eudromias morinellus* nests below sea level in Dutch polders, and the cliff-nesting Kittiwake *Rissa tridactyla* breeds on sand dunes (regularly in Denmark).

Another important circumstance leading to range expansion is that of long-distance migrants breeding in their wintering areas; it may be relevant that most such cases involve species having delayed maturity, and therefore not infrequently oversummering within their respective winter ranges. An analysis of elements in the Afrotropical avifauna of European origin showed a continuum from long-established and well-differentiated taxa, through established breeders little or not at all morphologically distinguishable from European populations, to northern migrants nesting only irregularly in Africa. (In contrast, there have been only a few, marginal, cases of Afrotropical species extending into North Africa or southern Europe.) This phenomenon of 'migration suspension' can also be inferred to have occurred in the New World, where a number of migratory species have given rise to resident insular races in the Caribbean, on Galapagos, and elsewhere.

An abrupt range expansion occurs when a species colonizes an island (more rarely a continent) where it does not normally occur even as a migrant; and there are few, even oceanic, islands which do not have their own endemic land-birds as consequences of invasions in the past. Perhaps because the number of ecological niches on islands is restricted, and liable to be filled through speciation by the ancestral colonizer, there are few modern examples of successful abrupt range expansion. One conspicuous exception concerns the invasion-type movements across the Tasman Sea from Australia, whereby New Zealand has gained breeding populations of Silvereye *Zosterops lateralis* (since 1856), Grey Teal *Anas gibberifrons* (probably since the late 19th century), Spur-winged Plover *Vanellus miles* (since about 1932), White-faced Heron *Ardea novaehollandiae* (since 1941), Royal Spoonbill *Platalea regia* (since 1950, still rare), Coot *Fulica atra* (since 1954), Black-fronted Dotterel *Charadrius melanops* and Welcome Swallow *Hirundo neoxena* (both from 1958). Moreover, during the 1970s there were New Zealand breeding records for Masked Wood Swallow *Artamus personatus* (1972 only), and for Australian Dabchick *Tachybaptus novaehollandiae* and Hoary-headed Grebe *Podiceps poliocephalus* (both of which seem to be in process of establishing themselves). There are also now frequent records of the Cattle Egret *Bubulcus ibis* and even reports of breeding. Cases elsewhere include two high-latitude colonizations: of Greenland by the Fieldfare *Turdus pilaris* (in 1937, following an invasion during a period of climatic amelioration), and of South Georgia by the Speckled Teal *Anas flavirostris* (population discovered in 1971).

Certain irregular irruptions, especially those occurring in spring, may lead to breeding in new areas, although not usually to permanent establishment therein (see IRRUPTION). On the other hand, some overseas invasions—possibly accidental in origin—may result in successful colonization simply because suitable conditions were already present in the new area, inaccessible until the ocean barrier was passed. Moreover, artificially introduced species may be able to spread rapidly for the same reason, especially if the newcomer happens to be more versatile than potential native competitors; such secondary range expansion has been seen with the Starling *Sturnus vulgaris* in America, and in a variety of European passerines liberated in man-modified habitats in Australia and New Zealand. Among natural but accidental colonizations, the classic example is the spectacular spread by the Cattle Egret *Bubulcus ibis* in the New World, where since about 1930 it has extended its range explosively both northwards and southwards; it is presumed that the colonizers reached South America from Africa via St Helena and St Paul's Rocks, where there have been recent sightings to show that transatlantic vagrancy by the species is continuing. In the opposite direction it spread via New Guinea to Western Australia, with frequent sightings in the 1950s. The first record from New Zealand was in 1963.

The circumstances of range expansion among sea birds are obviously somewhat different, in that their often wide non-breeding ranges may include many potential new breeding sites. It seems likely that, in these birds, range expansion stems from population pressure within established colonies; in the cases of gulls, at least, new food sources from man's waste products and new safe roosts on artificial reservoirs appear to have been important factors. The expansion potential of seabirds is demonstrated in Britain and Ireland by the remarkable spread of the Fulmar *Fulmarus glacialis* (confined to St Kilda until 1878) and Kittiwake, by the establishment of new Gannet *Sula bassana* colonies, and by the adoption of nest sites on roof tops and other buildings in towns and cities by several species of gull.

Despite a variety of Nearctic vagrants reaching Europe annually, there has been only one known instance of nesting—of Spotted Sandpiper *Actitis macularia* in Scotland—excluding two instances of Black Duck *Anas rubripes* hybridizing with Mallard *A. platyrhynchos* in England.

Range contractions. With the exception of populations endemic to small islands, for which unchecked decline will result in extinction (see EXTINCT BIRDS), declines most often manifest themselves in reduced densities that are not necessarily reflected (at least initially) in contractions of gross distributions. Where declines and contractions of range occur, the ultimate factors may be natural (often climatic) or unnatural (usually through human impact). In either category, species with restricted habitat requirements are the most vulnerable.

Climatic amelioration in North Atlantic regions in the 1920s and 1930s enabled various temperate species to expand northwards (see above), but also resulted in contractions for some arctic species at the southern periphery of their range; instances include Brünnich's Guillemot *Uria* *lomvia* and Little Auk *Alle alle* in Iceland, and Ivory Gull *Pagophila eburnea* in Svalbard. When this warming phase ended by the 1950s, expansion by temperate birds slowed down and some early gains were lost, for example by Starlings in northern Fenno–Scandia. In Britain, modern contractions by certain insectivorous summer migrants, such as Wryneck *Jynx torquilla* and Red-backed Shrike *Lanius collurio*, may have been exacerbated by change towards cooler and wetter spring weather. At the other climatic extreme, increased aridity has resulted in an enlargement of southern deserts to the detriment of some resident species: Ostriches *Struthio camelus* formerly occurred much further north in Africa (also in the Middle East); while reduced Sahelian rainfall has also affected the survival of various European-breeding trans-Saharan migrants crossing or wintering in this zone. Short-term, traumatic weather factors (such as an unusually severe winter) generally have only a temporary effect, but can be serious in island situations: it may have been a hurricane which exterminated the remnant population of Grand Cayman Thrush *Turdus ravidus*. Special cases include contraction following hybridization with a more successful (dominant) congener—Mexican Duck *Anas (platyrhynchos) diazi* and Black Duck with Mallard in North America—or through BROOD-PARASITISM affecting breeding success in a small population—as in Kirtland's Warbler *Dendroica kirtlandii* in Michigan; such instances are generally preceded by declines through (especially) habitat loss, leaving small populations more vulnerable to other pressures.

The more worrying cases of range contraction observed this century are those attributed, directly or indirectly, to man's interventions. By far the more important factor has been habitat loss, especially through wetland drainage and deforestation, and it has affected tropical and temperate species alike. Changed agricultural practices have also made their impact in various ways. Thus more intensive land use has caused contractions affecting bustards (Otididae) and Demoiselle Cranes *Anthropoides virgo* on the steppes of the USSR and Prairie Chickens *Tympanuchus cupido* on the North American equivalent; changed hay-cropping regimes (following mechanization) have reduced the European population of Corncrakes *Crex crex*; pesticide usage has hit raptors especially; while greater care of livestock has been one cause for declines of vultures in southern Europe. When habitat loss is coupled with overhunting, the total impact is serious; classic cases include Eskimo Curlew *Numenius borealis*, Wild Turkey *Meleagris gallopavo*, the extinct Passenger Pigeon *Ectopistes migratorius* and various Asian cranes (Gruidae). Trapping for AVICULTURE is thought to have contributed to reductions among certain Australian parakeets (Psittacidae) and Asian pheasants (Phasianidae). Restricted populations have also proved vulnerable to the impact of alien species, especially mammals, introduced by man, whether through habitat destruction, e.g., by pigs and goats, or through direct predation on ground-nesting birds. Introduced disease has been suggested as a factor in a Hawaiian study, though it has not been established that this applies to larger land masses. R.W.H.

RANK: see BIOSTATISTICS.

RAPHIDAE: see under COLUMBIFORMES; DODO.

RAPTOR: term used in much the same senses as BIRD-OF-PREY.

RATIO-CLINE: a geographically continuous change in the ratio in which different morphs are present within a species that is dimorphic or polymorphic in appearance or behaviour (see POLYMORPHISM).

RATITAE: see below.

RATITE: having a flat, raft-like sternum, i.e., without a keel; the converse of 'carinate' (see SKELETON, POST-CRANIAL). The structure is especially characteristic of the orders of flightless running birds, mainly of large size, formerly grouped together as the 'Ratitae' and still loosely referred to collectively as the 'ratites' (see EARLY EVOLUTION OF BIRDS). A more or less ratite condition of the sternum is also found in some flightless species in other orders (see FLIGHTLESSNESS).

A family based on the fossil genus *Eleutherornis* is referred to the Struthioniformes, and one based on *Dromornis* to the Casuariiformes (see FOSSIL BIRDS). Further, the Tinamiformes (Tinamidae) of the Neotropical Region, although flying and carinate, are considered to be closely related to the 'ratites' (see TINAMOU).

The living or geologically recent ratites are all comprised in the order STRUTHIONIFORMES.

RAVEN: substantive name of some large species of Corvidae; used without qualification, in Britain, for *Corvus corax* (see CROW (1)).

RAYADITO: substantive name of the 2 species of *Aphrastura*, a South American furnariid genus (for family see OVENBIRD (1)).

RAZORBILL: *Alca torda* (see AUK).

RECENT BIRDS: those forms that either exist at the present day or at least survived into geologically recent times.

RECESSIVE: see GENETICS.

RECOGNITION: a term that was originally applied to human behaviour but requires a new definition when applied to animal behaviour. The prefix 're' implies a learning process which allows the subject to identify an object as something that it has met before, and to distinguish it from other things. It has nevertheless been shown (R.A. Hinde) that a Canary *Serinus canaria* will 'recognize' nest material as something to build a nest with (its behaviour shows that it identifies it and distinguishes it from other objects) when it has never before seen such material. Similarly, we speak of 'sex recognition', 'species recognition', and so on, when responses are confined to certain classes of objects, irrespective of the way in which this specificity of the response developed—whether it is 'innate' or has to be acquired. 'Recognition' is therefore usually taken to mean identification and distinction of an object or a class of objects among the multitude of external things that an animal is likely to encounter. It is not an absolute achievement; the range of objects identified and grouped together may vary from very wide (sex recognition) to very narrow (individual recognition); it never is so wide that it comprises all things; it probably never is so narrow as to be just one unique thing—even the best human observer may find it difficult to distinguish between identical twins. The width of the range is adapted in such a way as to make 'errors' in the natural situation sufficiently rare to avoid frequent miscarriages. 'Recognition', therefore, is an expression referring to what could be called the 'degree of specific releasability' of a response, and it has to be studied by an analysis of the stimulus situation evoking the response. This response is not (as often in human beings) a verbal one, but it has to be a recognizable movement.

In this sense, birds can be said to recognize a very great number of things. The range is usually wide in responses to food; a Song Thrush *Turdus philomelos* recognizes red berries as a class (and perhaps distinguishes between several kinds), and also snails and earthworms. The range is extremely narrow in all cases of individual recognition. There is a graded series between these two extremes.

Recognition is often achieved in a series of steps, viz., when the response is really a chain of separate reactions, each elicited by different stimuli provided by the same object. Thus the first response of a female Red-necked Phalarope *Phalaropus lobatus* to a prospective mate is often misdirected; she may approach birds of several other species (Purple Sandpiper *Calidris maritima*; Lapland Bunting *Calcarius lapponicus*; Ringed Plover *Charadrius hiaticula*). After this initial approach, however, the next response is shown only to Red-necked Phalaropes, while the other birds are ignored. Yet this second response is still the same to males and females and only the third step shows sex recognition, for it is then that females are chased and males are accepted. This seems to be a very general method of achieving specificity of response in spite of the relatively unspecific nature of each stimulus situation (see SIGN STIMULUS).

In many examples recognition is not dependent on previous conditioning; the female Canary's recognition of nest material has already been mentioned; similarly, a young Herring Gull *Larus argentatus* responds 'innately' to the adults' alarm calls. But song-birds refusing to eat wasps or their mimics have had to learn to recognize them as obnoxious, and a goose *Anser* sp. learns to recognize its fellow geese, first as representatives of a species, and later as individuals (see LEARNING; BEHAVIOUR, DEVELOPMENT OF). In symbiotic relationships in the widest sense (including intra-specific as well as inter-specific relationships), recognition has been enhanced by specializations both on the sensory side (responsiveness to special stimuli) and on the effector side (by the development of unambiguous releasers (see RELEASER)); a striking example of the latter is the specificity of song, and of signals that keep a flock of birds together. Highly specific releaser-response relationships seem to have been developed in connection with reproductive isolation between sympatric species (see SPECIATION; also ISOLATING MECHANISM; COLORATION, ADAPTIVE). N.T.

RECOGNITION, INDIVIDUAL: the ability of individual birds to recognize particular familiar individuals of the same species. To show that one bird recognizes another it is necessary to demonstrate that it behaves differently towards the familiar individual than towards other conspecifics, and that the response is not solely due to recognition of a particular site or context.

Individual recognition of offspring by parents has been demonstrated in many species of colonial seabirds, including penguins (Adélie *Pygoscelis adeliae*, Yellow-eyed *Megadyptes antipodes* and King Penguin *Aptenodytes patagonicus*), terns (Arctic *Sterna paradisaea*), gulls (Black-headed *Larus ridibundus* and Herring Gull *L. argentatus*) and Guillemots (*Uria aalge*), where parents bring food to their own chick in the midst of the colony even if it has strayed away from the nest site. Correspondingly, offspring of some seabirds, including guillemots, several species of gulls, and Wandering Albatross *Diomedea exulans* are able to recognize their parents and run towards them but not towards other adults that land nearby. In most species, recognition develops gradually during the early growth of the offspring (although auditory recognition may develop before hatching) resulting in the offspring becoming 'imprinted' on their parents. It is usually before adequate recognition has developed, when the chicks are very young, that in some species, parents may adopt strange chicks. Recognition may continue after the young have fledged in cases where parental care continues.

Species where individual recognition of offspring by parents has not been established during the nestling period include Black-browed *Diomedea melanophrys* and Grey-headed Albatross *D. chrysostoma*, Gannet *Sula bassana*, Kittiwake *Rissa tridactyla*, and Puffin *Fratercula arctica*; and many passerines, for example Robins *Erithacus rubecula* and Pied Flycatchers *Ficedula hypoleuca*. This could be due to the small chance that the young will stray from the nest site or that the parents will mistakenly feed strange chicks.

Mutual recognition between monogamous partners has been documented in a wide variety of species including Gannets, Bewick's Swans *Cygnus columbianus bewickii*, Herring Gulls, Flickers *Colaptes auratus*, Jackdaws *Corvus monedula* and American Goldfinches *Spinus tristis*, where individuals begin greeting displays when their partner appears at a distance. In some species recognition is observed even when partners have been separated for several months.

Recognition by territory owners of neighbouring territory holders occurs in several passerine species where individuals show a stronger aggressive response to strangers than to neighbours. Evidence that birds recognize unrelated flock members is less abundant, although experiments showing an increased aggressive response of domestic hens to strangers introduced into a small stable flock indicate recognition.

How individuals recognize each other is not always clear. In experiments showing recognition of neighbouring territory holders, individual birds were distinguishing differences in the songs (not the positions) of their neighbours from others. In particular, pitch and detailed phrase morphology have been found to be important in individual recognition in some species. However, among songbirds, it is not yet clear whether individual recognition can occur in species with large song repertoires. Auditory cues are also used by offspring guillemots, ducks (Wood Duck *Aix sponsa*), and domestic chicks even before hatching, and by partners of pairs in American Goldfinches. Recognition by visual cues has seldom been demonstrated directly. But Guillemots *Uria aalge*, whose eggs show great variation, and Ostriches *Struthio camelus* are able to recognize their own eggs (see AUK; OSTRICH).

Observations of birds recognizing their parents, mates and other flock members at a distance, in the absence of audible vocalizations, have been described for Gannets, Pintails *Anas acuta*, Herring Gulls, and Marsh Tits *Parus palustris*. Whether in these cases the birds are distinguishing particular physical characteristics or idiosyncratic behaviour is not clear. At closer range, experimental evidence suggests that the precise cues involved are mainly on the head: artificial changes in appearance of the head, neck and comb in chickens were most successful in preventing recognition by flockmates. In wild Bewick's Swans, individuals sometimes peck their mates when the latter are feeding with their heads below the water, but when the mate brings its head up a greeting immediately occurs, often with no audible vocalization. Despite the scarcity of evidence, the use of visual cues in individual recognition seems likely to be widespread in view of the exceptional visual acuity of birds and the extent to which they communicate visually. RECORDING: ultra-quiet song (see BEHAVIOUR, DEVELOPMENT OF (*Subsong*)); also, of course, the human activities of mechanically registering and reproducing bird or other sounds, and, more generally, the keeping of regular notes and observations.

RECOVERY: see MARKING.

RECTRIX (RECTRICES): a main tail feather (see TAIL).

RECTUM: the large intestine (see ALIMENTARY SYSTEM).

RECURVED-BILL: *Megaxenops parnaguae*; sometimes applied also to *Xenops* spp. (see OVENBIRD (1)).

RECURVIROSTRIDAE: see under CHARADRIIFORMES. The family comprises the avocets and stilts (see under AVOCET).

REDBILL: name in South Africa for *Anas erythrorhyncha*, otherwise Red-billed Pintail (see DUCK).

REDBREAST: alternative name of the Robin *Erithacus rubecula* (see THRUSH).

REDHEAD: *Aythya americana* (see DUCK).

REDIRECTION: the direction of a behaviour response at other than the normal object. As a rule, animal behaviour is directed at certain parts of, or objects in, the environment—food-pecking is directed at food, attack is directed at a rival, and so on—and this is made possible by steering (as distinct from merely releasing or inhibiting) mechanisms; but in certain circumstances a response is directed at an object other than that normally drawing the response. Such responses to abnormal objects can be classed in two categories. On the one hand, when an animal is very hungry it may peck at inedible or inadequate objects not normally aimed at; a sexually deprived animal may copulate with substitute partners sometimes very unlike the normal partner; and a broody bird may sit on objects very dissimilar to eggs. These responses have in common that they are directed at a substitute object in the absence of the adequate object, and that the adequate object is preferred as soon as it is present. On the other hand, when a man scolds his subordinate after he has himself been rebuked by his superior, or kicks a chair in anger although the fellow human who aroused his anger is there, we speak of a redirected attack; and such redirected attacks are common in birds. They occur when an individual is provoked to attack another individual, but cannot do so because it is either afraid of its attacker or is inhibited in some other way, for instance by personal 'love' for its sex partner. A redirected attack may be aimed at a third bird happening to be near, or it may be as extreme as table-banging by an angry human; thus a male Herring Gull *Larus argentatus* regularly pecks violently into the ground when facing a rival near the territory's boundary. It seems likely that such redirected attacks have also contributed to the 'raw material' from which signal movements have evolved (see DISPLACEMENT ACTIVITY; RELEASER). They are often followed by displacement activities, and can probably determine which particular displacement activity will be shown by providing stimuli that facilitate one particular movement. N.T.

REDPOLL: substantive name of 2 *Carduelis* spp.; used without qualification, in Britain, for *C. flammea* (see FINCH). See photo NEST BUILDING.

REDSHANK: substantive name of *Tringa totanus*, for which it is used in Britain without qualification, and one congener (see SANDPIPER). See photo COPULATION.

REDSTART (1): substantive name of *Phoenicurus* spp.; used without qualification, in Britain, for *P. phoenicurus* (see THRUSH).

REDSTART (2): substantive name, in North America, of species of *Setophaga* and *Myioborus* (see WARBLER (2)).

REDTHROAT: *Sericornis brunneus* (see WARBLER, AUSTRALIAN).

RED TIDE: the bloom of a single-celled organism in the sea, its large numbers often imparting a rusty-red coloration. In temperate waters the organism is usually *Gonyaulax tamarensis*, which, when at high densities, produces an extremely powerful nerve poison to which birds and mammals are very sensitive. Frequent red tides are recorded from the west coast of North America. The first major outbreak in Europe this century occurred in 1968, killing 80% of the breeding shags *Phalacrocorax aristotelis* on the Farne Islands (NE England) in a few days, and many other species being affected. Since then, blooms have been recorded from Norway to Spain. Red tides in tropical waters are caused by a different organism which does not produce a toxin but which de-oxygenates the water, killing large numbers of fish, but few seabirds. J.C.C.

REDUCTION-DIVISION: meiosis (see CELL; GENETICS).

REDWING: *Turdus iliacus* (see THRUSH); in North America sometimes applied to the Redwinged Blackbird *Agelaius phoeniceus* (see ORIOLE (2)); in Africa applied to *Francolinus levaillantii* (see PHEASANT).

REED-FINCH: substantive name of *Donacospiza albifrons*, a South American finch (for family see BUNTING).

REED-HAUNTER: substantive name of *Limnornis curvirostris* and *Limnoctites rectirostris* (for family see OVENBIRD (1)).

REEDHEN: substantive name sometimes applied to gallinules of the genus *Porphyrula* (for family see RAIL).

REEDLING: alternative name for the Bearded Tit *Panurus biarmicus* (see under PARROTBILL).

REELING: see CHURRING.

REEVE: see RUFF.

REFLEX: 'an innate relatively simple and stereotyped response involving the central nervous system and occurring very shortly after the stimulus which evokes it; it specifically involves a part only of the organism, though the whole may be affected, and is usually a response to localized sensory stimuli' (Thorpe 1951)—see FIXED ACTION PATTERN; also LEARNING.

REFRACTORY PERIOD: see penultimate paragraph of ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

REFUGE: see CONSERVATION.

REGENT-BIRD: Regent Bowerbird *Sericulus chrysocephalus* (see BOWERBIRD).

REGION, ZOOGEOGRAPHICAL: or faunal region, see DISTRIBUTION, GEOGRAPHICAL.

REGULIDAE: a family recognized by some authors, but here merged in the subfamily Sylviinae of the Muscicapidae (see WARBLER (1)).

REGURGITATION: ejection of partially digested food from the gizzard, as food for young; ejection of PELLETS; ejection of stomach oil by young birds, e.g., Fulmar *Fulmarus glacialis*, under threat from an intruder (see ODOUR). See photo PARENTAL CARE.

REINFORCEMENT: see LEARNING.

REJUNGENT SPECIES: see RING-SPECIES.

RELEASER: term originally given a precise and unambiguous definition by Lorenz in 1935 but since applied in two very different senses. In the original sense, a releaser is not a stimulus, but a type of effector device (in the widest sense—either a structure, or a movement, or a scent, or a call) with a very specific function, namely that of providing stimuli which release (or inhibit) a response or a set of responses in another animal of the same species. The concept became necessary when it was pointed out that there are structures, movements, sounds, and so on which can be shown to provide such stimuli, for which no other function can be found, and which are obviously well suited to the broadcasting of stimuli. Thus, the red colour of the breast feathers of a Robin *Erithacus rubecula*, the brightly coloured wing specula of ducks (Anatidae), the red patch on the lower mandible of a Herring Gull *Larus argentatus*, the nest-showing ceremonies of various male birds (Wren *Troglodytes troglodytes*; Kestrel *Falco tinnunculus*; Black-headed Gull *Larus ridibundus*; Redstart *Phoenicurus phoenicurus*; Pied Flycatcher *Ficedula hypoleuca*), the head-tossing movements of female gulls (Larinae), the song of male song-birds, alarm calls, and many more, all provide stimuli releasing or directing more or less specific responses in fellow members of the species, and are therefore called releasers. The 'rodent-run' and other distraction displays of waders (Charadrii) and other birds lure predators away from the brood (see DISTRACTION BEHAVIOUR); these activities, like the hissing of the Great Tit *Parus major* and Wryneck *Jynx torquilla*, aposematic coloration, and the luring flight of honeyguides (Indicatoridae), subserve interspecific communication; the term releaser can of course be applied to them as well.

While the word is not important, provided that it is used consistently, the distinction between the two concepts (releaser and stimulus) is essential. The difference between the concept of releaser and that of sign stimulus, to which the word 'releaser' is often applied, is to be found in the adaptedness of the releaser as a signalling device (see SIGN STIMULUS). A pike *Esox lucius*, snapping at a piece of shiny metal dragged through the water, is responding to a sign stimulus normally provided by its prey. Yet the silvery shine of, for example, a roach has certainly not developed as a means to enable the roach to be captured by a pike; if anything, the pike has helped to exert selection pressure against such conspicuousness. The red spot on the bill of the Herring Gull, on the contrary, must have been favoured by selection pressure, since it helps in eliciting the chick's begging, which in turn stimulates its parent to feed it; and song, by attracting females, facilitates pair formation and as such is favoured by selection. The argument is particularly convincing in those cases where releasers have developed in spite of the dangers to which they expose their bearers in other contexts, especially when they make them more vulnerable to attack by predators.

Thus the term 'releaser' is intended to characterize a category of effector by its exclusive or main function, just as the term 'wing' is used to name any organ which provides lift and propulsion in flight, even although a wing may also be used as, for instance, a weapon in fighting.

Many releasers, such as alarm calls, have been shown literally to release a response. Others, such as the head-flagging in gulls and other 'appeasement gestures', stop a response (see DISPLAY); others again, such as the song of male song-birds, release and also direct the movements of other birds (in this case, repulsion of males and attraction of females). For this reason, the term 'signalling device' is perhaps preferable. The latter example also shows that one feature may have more than one function. The second function need not be that of signalling, and its demands may even conflict with those of the releaser function; the most obvious examples of such conflicting demands are procryptic birds that have at the same time conspicuously coloured structures; such species have reached a compromize by concealing the bright colours so long as they are not actually needed.

Comparative studies sometimes enable one to make a guess at the origin of releasers, and it is probable that they are secondary specializations of organs and movements primarily adapted to other functions, selection pressure having favoured simplicity, conspicuousness, and unambiguity; and this seems in accord with the known properties of the sensory functions through which they exert their effect (see SIGN STIMULUS). Evolution being a slow and gradual process involving a very large number of extremely small steps, it is evident that the distinction between organs which are obvious, highly specialized releasers (such as the wings of a male Argus Pheasant *Argusianus argus*) and those that are not yet, or no longer, or not exclusively releasers cannot be sharp. This is of course true of every category of organ.

The function of an alleged releaser is often suggested by observations but can be experimentally tested in experiments with dummies. N.T.

Lorenz, K. 1935. Der Kumpan in der Umwelt des Vogels. J. Orn. 83: 137–213, 289–413.

RELICT (or RELIC): term applied to isolated (sometimes discontinuous) populations that appear to represent a former much wider distribution.

REMEX: a main flight feather; the remiges are classed as primary and secondary (see PLUMAGE; PRIMARY; WING).

REMICLE: term properly restricted to a small feather found on the wing in some species, attached to the second phalanx of digit II. Most authors have considered it to be a vestigial primary remex, but Stresemann believes it to have been a covert to the terminal claw possessed by ancestral forms (see under PRIMARY).

REMIGES: plural of REMEX.

REMIZIDAE: family of PASSERIFORMES suborder Oscines; PENDULINE TIT.

RENAL FUNCTION: see EXCRETION, EXTRARENAL.

REPELLENTS, CHEMICAL: man has probably tried to protect his crops with chemical repellents of some kind ever since he first tilled the soil. Concoctions of plants which, at least to humans, have pungent odours or an unpleasant taste feature in countless 'cottage' remedies for the prevention of bird damage and this folklore extends to the use of foul-smelling animal oils, faeces and urine, all of which may be used as ingredients in traditional repellent formulations. It is understandable that people should use such materials in an attempt to repel animals; we find them unpleasant, therefore other species having similar sensory systems will also find them unpleasant. This reasoning finds support in the fact that some animal species themselves employ chemical repellents in defence; skunks (*Mephitis*) are legendary in this respect but there are many less well-known examples including some birds. For example, Fulmars *Fulmarus glacialis* defend the nest site by squirting intruders with a foul-smelling liquid regurgitated from their crops and Eiders *Somateria mollissima* cover their eggs with faeces before leaving the nest unattended. However, these mechanisms have probably evolved for use against predatory mammals, rather than birds, and confirmation of the practical value of chemical repellents against birds is hard to find.

Since any repellent effect is first dependent on the bird perceiving the stimulus, it is pertinent to consider what we know about the chemical senses of birds. By far the most important of these are the senses of SMELL (olfaction) and TASTE (gustation) and, although normally regarded as separate functions, they are so closely related as to be, at times, indistinguishable. Consider a bird approaching a potential food source. The olfactory system will be the first of the chemical senses to receive stimulation; the question is 'Do birds have a functional sense of smell?' This has been a subject of controversy ever since Darwin and Audubon addressed themselves to the problem and is not fully resolved yet. On present evidence it seems fair to conclude that the olfactory mechanism is functional in most birds but only a few species exhibit odour-related behaviour in connection with food. If most birds disregard olfactory cues then in practice it will prove impossible to manipulate their behaviour via this channel of communication. Clearly this would not be true for those few species that do seek food by smell, e.g., the Kiwis *Apteryx* and honeyguides *Indicator*; their food-finding would be vulnerable to disruption by the introduction of false or masking odours. But these species are not pests and, unless future research reveals otherwise, we should regard the birds that eat our crops as unresponsive to odours. Hence the development of olfactory repellents seems unlikely.

If odours will not repel birds then perhaps flavours can be used to better effect. Nobody seriously doubts that birds can taste but nevertheless the role of gustation in food selection remains obscure. As in mammals, the sensory receptors for the perception of flavours are the 'taste buds', consisting of clusters of cells lying in cavities in the epithelium of the tongue, but whereas mammals typically have many thousands of taste buds few birds have more than a hundred. It is tempting to conclude that birds are correspondingly less sensitive to flavours than mammals but this is not necessarily so; for instance it has been shown (Duncan 1963) that pigeons can discriminate between substances that are tasteless to man. It is logical to assume that an animal possessing a functional sense of taste will utilize that sense in the selection of food, yet there is little evidence that birds do so. Englemann (1940) concluded that hens select grains on the basis of shape, and to a lesser extent colour; taste played little or no part. Much of the experimental work done since then, often in connection with the search for chemical repellents, points to the conclusion that taste *per se* is not very important to birds and suggests that a substance is unlikely to qualify as a bird repellent simply because it has an unpleasant flavour. However, taste stimuli rarely occur in isolation; certainly the ingestion of food represents a complex sensory experience, involving visceral, tactile, olfactory and thermal information in addition to that concerned with flavour. In consequence, behaviour that gives every appearance of being taste-orientated may be controlled by other factors.

Some authorities refer to a specific 'chemical sense' in birds and regard the many unspecialized nerve endings as receptor organs. If such a sense exists, it remains ill-defined and there is little to indicate how it functions. It is certainly true that in some cases chemical stimulation may result in pain, or other disturbing sensations, and animals quickly learn to avoid situations that give rise to such unpleasant experiences. This is known as 'conditioned aversion' and typically follows sub-lethal poisoning by a toxic food. The phenomenon often occurs in connection with poison baiting for rodent control when the condition is known as 'bait shyness'. In those circumstances it is a highly undesirable response, because it reduces the consumption of bait and hence the kill, but it is exactly the response we endeavour to achieve with repellents. Some chemicals, e.g., lithium chloride and certain carbamate compounds, seem to possess properties conducive to the establishment of aversive associations of this type and which can result in a dramatic avoidance of further contact with the chemical. One such compound, methiocarb, is now widely used in the USA and elsewhere as a bird repellent (Rogers 1980). Despite being highly poisonous few, if any, casualties occur because birds are repelled before they have time to ingest a lethal dose. Nevertheless, there are obvious risks associated with the use of such chemicals and it is open to question whether very toxic substances qualify to be called 'repellents'.

Chemical defence mechanisms evolved by insects against bird predators usually involve cardiac glycosides which have a specific action on the vertebrate heart. They also have side-effects, one of which is to stimulate vomiting, and since the emetic dose is about half the lethal dose this functions as a safety factor and normally prevents retention of a lethal dose. Brower (1969) has pointed out that in such a mechanism there are 3 levels at which repellency can occur; basic gastronomic rejection, brought about by the effect of the poison, and subsequently rejection by recognition of flavour or appearance as a conditioned response. It has been suggested that such aversive conditioning could be applied to predator–prey problems involving large raptors (Brett *et al* 1976). These experiments are a stimulating advance in repellent research although confirmation of success in practical application is still awaited.

Another mechanism of repellency is that of behaviour-modifying chemicals. There is no evidence for the existence in birds of any mechanism analogous to that of pheromones in insects, but chemicals have been used to modify behaviour in a different way. Birds display great panic following the ingestion of the compound, 2,4-animopyridine, possibly because they suffer pain and partial paralysis. Affected birds tend to utter distress calls and fly in spirals; conspecifics hearing the calls, and observing the strange behaviour, usually flee. Thus, for gregarious species, large flocks may be scared away by the aberrant behaviour induced in a few individuals. A bait containing 1% or 2% of treated particles is used and in this way sufficient can be laid to prove attractive whilst ensuring that relatively few birds are affected. It is sometimes argued that such a method is a useful conservation tool, since it avoids mass destruction, but many people consider the technique to be inhumane and its use is prohibited in many countries, including Britain.

Yet another approach to repellency is to consider feeding mechanisms and exploration of this is just beginning. It is obvious that any particular species of animal accepts as food only a narrow spectrum of potentially nutritious items. In other words, they are selective and this implies the existence of a mechanism of discrimination which results in acceptance or rejection. If these mechanisms can be elucidated they may mark a significant step toward the discovery of really effective repellents.

REPRODUCTIVE ISOLATION: a situation in which intrinsic factors wholly or largely prevent interbreeding between closely related species, or populations of a species (see ECOLOGICAL ISOLATION; ISOLATING MECHANISM; SPECIATION). It is to be distinguished from geographical or ecological isolation, where extrinsic circumstances prevent contact between populations that might otherwise be fully capable of interbreeding.

REPRODUCTIVE RATE: see CLUTCH-SIZE (Reproductive rates and other reproductive tactics); ECOLOGY.

REPRODUCTIVE SYSTEM: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

REPTILIAN ANCESTRY: see EARLY EVOLUTION OF BIRDS.

RESERVE, NATURE: see CONSERVATION.

RESIDENT: remaining throughout the year in the area under reference, the term being applied to a species, subspecies, population, or individual bird as the context requires; in another usage the term means breeding in the area, a distinction being then drawn between 'permanent resident' and 'summer resident' (='summer visitor')—see MIGRATION.

RESONANCE: setting up vibrations that increase the volume of a sound (see SYRINX; also MECHANICAL SOUNDS).

RESPIRATORY SYSTEM: in general, this system in birds is differentiated into the rigid lungs for gas exchange and into the air sacs, which act as bellows for their ventilation. This differentiation is based on the subdivision of the avian body cavity by septa (Duncker 1979). The unique avian respiratory system is characterized by the highest gas exchange capacity in vertebrates, and in its development it is necessarily based on the incubation in an egg.

Each of the two symmetrical lungs fills one of the cavities which are situated in the dorsal portion of the rigid thoracic cage. Each pleural cavity (Fig. 1) is lined medially by the vertebral column and its ventral processes, dorso-laterally by the flat transverse vertebral processes and by the ribs and their musculature. Dorsally, the ribs arch through the pleural cavity, making deep incisions into the lung. Ventrally, the pleural cavity is lined by the horizontal septum, which originates from the ventral margin of the vertebral column or its ventral processes, and is inserted, descending slightly ventrally, on to the ribs. At this lateral margin the horizontal septum contains the costoseptal muscles, which dilate during inspiration and contract during expiration (Fedde *et al* 1964). The actions of these muscles compensate for the slight volume changes of the pleural cavity, which are minimal due to their dorsal position in the rigid rib cage. Thus, the avian lung maintains a constant volume during the respiratory cycle, in contrast to reptilian and mammalian lungs which are inflated and deflated by the respiratory movements.

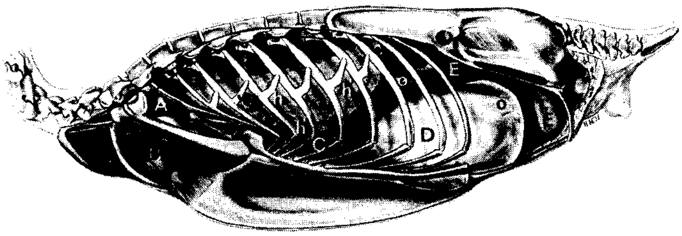

Fig. 1. Drawing of a preparation of a Mallard duck *Anas platyrhynchos*, left side from lateral. Thoracic and abdominal wall musculature has been removed and the lung is extirpated out of the pleural cavity. Horizontal septum (h) with Mm. costoseptales (h′), oblique septum (o). Cervical (A), clavicular (B), cranial (C) and caudal (D) thoracic, and abdominal (E) air sacs. (From Duncker 1971).

The volume changes of the respiratory movements act only on the air sacs, which ventilate the rigid bronchial system of the lung. The air sacs are situated in the subpulmonal cavity (Duncker 1979) beneath the lung and its horizontal septum. The symmetrical subpulmonal cavities are cranially united and together with the air sacs fill the thorax cranial to the heart, often protruding into the lower neck. Lateral and caudal to the heart, the subpulmonal cavity with the air sacs occupies the space on each side between the body wall and the intestines, separated medially from the intestines by the oblique septum. This septum originates from the vertebral column and cranially from the lateral pericardial wall; it is inserted ventrally near the lateral margin of the sternum. The subpulmonal cavity extends further caudally than the lung; and varies in extent among the different avian families. Only the most caudal air sac invades the peritoneal cavity and spreads dorsally around the intestines (Fig. 1).

The air sacs are thin-walled and in addition to filling the subpulmonal cavity and the dorsal peritoneal cavity, protrude in the form of diverticula between different organs: between the kidneys and the synsacrum, around the articulations of the bones of the trunk and the neck including the shoulder and hip joint; they also invade the bones of the trunk, the vertebral column and the proximal bones of the wing and leg. Additionally, they invade the vertebral canal between the vertebral bodies and the dura mater in the thoracic and lower neck region. This pneumatization is found in the majority of birds, independent of their body size, but varying in extent; it is generally reduced or lacking only in some birds which swim under water. It has no function in connection with respiration.

Upper air ways. The air enters through the external nares at the upper bill into the nasal cavities. The location, form and direction of the external nares are highly variable, e.g. near the tip of the bill in kiwis, at the base of the bill in most species. The air passes through the nasal cavities and/or the oral cavity, which function in warming and humidifying the air, and in olfactory control. This passage over the mucosal surfaces is important, especially in small species, as an aid to effective heat and water balance by re-utilization of the expired air (Schmidt-Nielsen *et al* 1970).

The slit-like opening of the glottis at the base of the tongue, which is controlled by muscles, regulates the in- and out-flow of air. There are no vocal chords as in mammals; the sound production in birds is restricted to the SYRINX. The glottis opens into the larynx, which leads into the trachea. The avian trachea is, in contrast to mammals, totally surrounded by tracheal rings, which ossify in many species. Externally, the trachea is accompanied over its length by the tracheal muscles.

The lower trachea enters the cranial thoracic aperture, where it is surrounded by the clavicular air sac, which incorporates also the bifurcation of the trachea. In some birds, especially in penguins, the trachea is double-tubed, starting more or less distant from the larynx. Starting at the bifurcation, the two extrapulmonary primary bronchi run

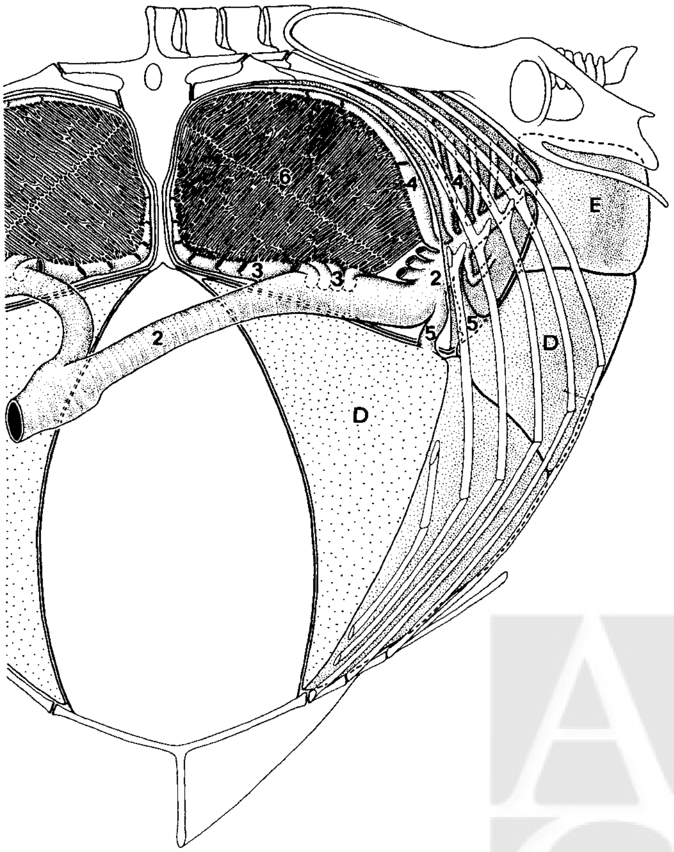

Fig. 2. Schematic cross section of the trunk of a White Stork *Ciconia ciconia*, view from cranial on to the caudal part of the trunk, out of which only the primary bronchus (2) projects. The lung with medioventrobronchi (3), mediodorsobronchi (4), lateroventrobronchi (5) and parabronchi (6) above the horizontal septum; beneath it, between body wall and oblique septum, the air sacs (D, E). Between both oblique septa space for the intestines. (From Duncker 1971).

toward the lung hilus. They are surrounded by C-shaped bronchial cartilages, which also protect the first short part of the intrapulmonary primary bronchus. Then the cartilages disappear completely; the further primary bronchus and all other bronchi of the avian lung are free of cartilage. The respiratory epithelium of the trachea and primary bronchi contain glands consisting of goblet cells, varying in number depending on the species and on the size of the bird. Goblet cells are responsible for the final humidification of the air (Menuam and Richards 1975).

Lungs. The lungs (Fig. 4) are not lobed and adhere to the walls of the pleural cavities. They are fixed and rigid in form and are constant in volume during all respiratory phases. The primary bronchus enters the lung hilus through the horizontal septum at the ventral lung surface together with the pulmonary vessels. The primary bronchus gives off immediately on its dorso-medial side the first set of secondary bronchi (the 4 medioventrobronchi) (Fig. 2), which spread over the ventral lung surface. The primary bronchus continues on its course to the dorsolateral lung surface, at or near which it bends caudally. It then runs in a dorsally curved course to the caudal lung margin, giving off the second set of secondary bronchi (the 7 to 10 mediodorsobronchi) which spread out at the laterodorsal surface of the lung. Opposite the mediodorsobronchi, the 4 or 5 lateroventrobronchi originate, spreading out between the primary bronchus and the horizontal septum. At the caudal lung margin the primary bronchus terminates in the abdominal air sac.

From the internal surfaces of these 3 sets of secondary bronchi the parabronchi originate (Figs. 2, 3). The parabronchi of the medioventrobronchi anastomose with those of the mediodorso- and lateroventrobronchi in the planum anastomoticum, situated medially in the lung. The cranial air sacs are connected to the medioventrobronchi, the caudal air sacs to the first lateroventrobronchus and to the terminal primary bronchus (Fig. 3). This system makes up the paleopulmo (Duncker 1971), which is present in all birds. Between the posterior primary bronchus and the air sac ostia of the caudal air sacs an additional connection is formed via a parabronchial network (Fig. 5), the neopulmo (Duncker 1971). The neopulmo is absent in penguins and emus; it is found in all other birds and is most highly developed in galliform and song birds.

The paleopulmo. The 4 medioventrobronchi (Figs. 2, 3, 4) originate dorsomedially from the entering primary bronchus, one directly behind the other. The first bends cranially, the others medially: they dilate and ramify, spreading over and occupying the ventral surface of the lung directly above the horizontal septum. The first medioventrobronchus, with its numerous branches lying side by side, occupies the cranial third of the ventral lung surface and terminates cranially, bending on to the dorsolateral lung surface, medially on to the lower medial surface. The second medioventrobronchus continues, with its branches, along the ventral covering of the lung surface, followed by the third medioventrobronchus which reaches the mediocaudal edge of the lung. The terminal branches of both medioventrobronchi curve onto the lower medial surface. The fourth medioventrobronchus joins the third on its lateral side, in most species with only a few branches or none at all. Only the lateral part of the ventral lung surface caudal to the lung hilus is not occupied by medioventrobronchial branches, but rather by paleopulmonic parabronchi. A branch of the first medioventrobronchus penetrates the horizontal septum cranial to the lung and opens into the cervical air sac. The third medioventrobronchus, directly after its origin, gives off a short, wide stem, which bifurcates through the horizontal septum directly medial to the lung hilus and opens into the clavicular and into the cranial thoracic air sacs. The region lateral to the hilus contains the lateral ostia into the clavicular and cranial thoracic air sacs. This region is supplied by a large lateral branch of both the first and second medioventrobronchus and in many species also by a lateral branch of the fourth medioventrobronchus (Fig. 3). However, in most species these ostia are not directly connected to the medioventrobronchus branches, but via the parabronchial net.

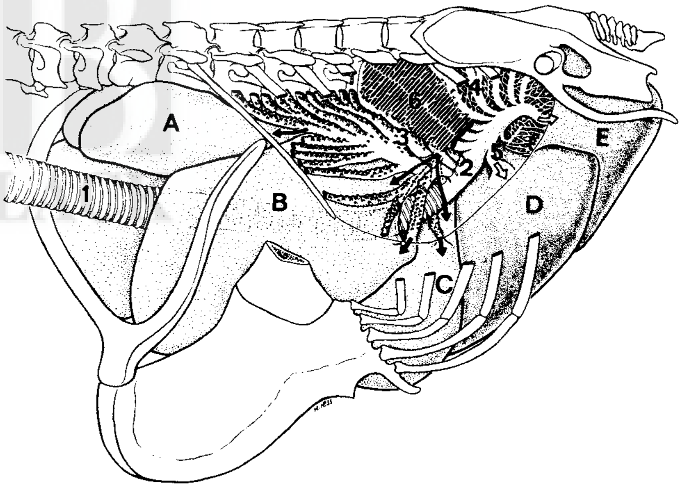

Fig. 3. Semi-schematic drawing of the lung and air sacs of the Stork. Trachea (1), primary bronchus (2), medioventrobronchi (3), mediodorsobronchi (4), lateroventrobronchi (5), parabronchi (6). Connections of the cranial air sac group indicated by black arrows: cervical (A) to the first medioventrobronchus, clavicular (B) and cranial thoracic (C) air sacs to the third medioventrobronchus and to the lateral ostia. Connections of the caudal air sac group are indicated by white arrows: caudal thoracic (D) and abdominal (E) air sacs to the lateroventrobronchus and caudal primary bronchus. (From Duncker 1972).

The 7 to 10 mediodorsobronchi (Figs. 2, 3, 4) originate dorsally from the primary bronchus, starting at that point where it bends caudally. The first 3 or 4 mediodorsobronchi originate directly one behind the other, their openings being separated from each other by only a thin membrane, whereas the distances between the openings of the succeeding mediodorsobronchi increase. All mediodorsobronchial openings are directed caudally, and the first 3 or 4 one above the other (Fig. 4). After their

Fig. 4. Drawing of the left lung of a Mute Swan *Cygnus olor*, from lateral. The lateral part of the lung has been removed to (1) expose primary bronchus (2), medioventro- (3), mediodorso- (4), lateroventrobronchi (5) and parabronchi (6). Ostia into the caudal thoracic (D′) and abdominal (E′) air sacs. The surface of the lung between the secondary bronchi is covered by thin-walled air bubbles (9). (From Duncker 1972).

initial cranial course, the mediodorsobronchi bend dorsomedially, except for the first and the last, which bend mediocaudally. They spread over the dorsolateral surface of the lung, directly beneath the thoracic wall. The first mediodorsobronchus ramifies into a large number of branches and supplies a broad area at the cranial lung surface, including the ventral part of the lung surface lateral to the lung hilus. The remaining mediodorsobronchi have a decreasing number of branches, and the last one, none at all. They supply areas of decreasing extent, which lie exclusively dorsal to the primary bronchus. In most species the neighbouring branches join each other directly, covering the entire dorsolateral surface. Their terminal branches end at a greater distance from the cranial margin of the lung, but mediodorsally they curve onto the medial surface. The mediodorsobronchi do not have any air sac connections.

The 2 to 5 lateroventrobronchi (Figs. 2, 3, 4) originate from the primary bronchus opposite the middle mediodorsobronchi. Their openings are directed caudally similarly to those of the mediodorsobronchi, and after their initial cranial course they bend ventrally and caudally. The first lateroventrobronchus is usually large, has no branches, and does not give off parabronchi into the paleopulmo. It connects to the caudal thoracic air sac via a funnel-shaped opening, penetrating the horizontal septum near the lateral lung margin between the lung hilus and the caudal lung margin. The next one to 4 smaller lateroventrobronchi regularly do not have ramifications. They occupy the space between the primary bronchus and the horizontal septum, giving off parabronchi medially. The lateroventrobronchi mark the lateral border of the paleopulmo, lying at the lateral lung surface in birds that lack a neopulmo.

The parabronchi of the paleopulmo (Figs. 2, 3) originate (1) from the entire internal surfaces of the medioventrobronchi and their terminal branches, and (2) from the entire internal surfaces of the mediodorso- and lateroventrobronchi and their terminal branches. Directly after their origin, they are interconnected with the neighbouring parabronchi by short ramifications. In most species they then run without further ramifications straight toward the medial planum anastomoticum. There, each parabronchus is connected with 2 or 3 parabronchi of the opposite side. Thus, the medioventrobronchi on one side are connected to the mediodorso- and lateroventrobronchi on the other side. The first and second medioventrobronchi and their lateral branches receive parabronchi from the first and second mediodorsobronchi and their lateral branches. The third and fourth medioventrobronchi receive parabronchi from all the succeeding mediodorsobronchi, the fourth medioventrobronchus also from the small lateroventrobronchi. These latter parabronchi lie directly at the ventral lung surface upon the horizontal septum, lateral to the fourth medioventrobronchus.

The neopulmo. Only in a few groups, such as penguins and emus, does the paleopulmo make up the entire lung. In cormorants and storks, there is a small additional network of parabronchi, the neopulmo (Fig. 5). It connects the caudal primary bronchus with the ostia of the caudal air sacs. The neopulmo becomes larger in more highly developed birds such as ducks, gulls and pigeons, and it achieves its highest development in plovers and sandpipers and in galliform birds (Fig. 5). The neopulmo never exceeds 20% of the total lung volume. The neopulmonal parabronchi possess the same species-specific structure as those of the paleopulmo, but they are richly interconnected over their entire length, lacking long unramified sections.

The neopulmonal parabronchi (Fig. 5) originate from the lateral side of the primary bronchus, starting cranially at the origin of the first mediodorsobronchus, and also from the lateral sides of the large and the succeeding smaller lateroventrobronchi. In species with a more highly developed neopulmo, parabronchi originate also from the initial parts of the mediodorsobronchi and run toward the ostia of the caudal thoracic and the abdominal air sacs, entering the ostia laterally, often forming a separate funnel-shaped opening or a collecting saccobronchus. In a larger neopulmo, multiple layers of interconnected parabronchi occupy the lateral part of the lung and displace the primary bronchus, together with the origins of the mediodorso- and latero-ventrobronchi, medially into the lung.

In a large neopulmo, an increasing number of neopulmonal parabronchi connect with the abdominal air sac, whereas in the primary bronchus the diameter terminally decreases. Thus, in galliform and song birds the primary bronchus is functionally substituted by the neopulmonal network, its entrance into the abdominal air sac being reduced

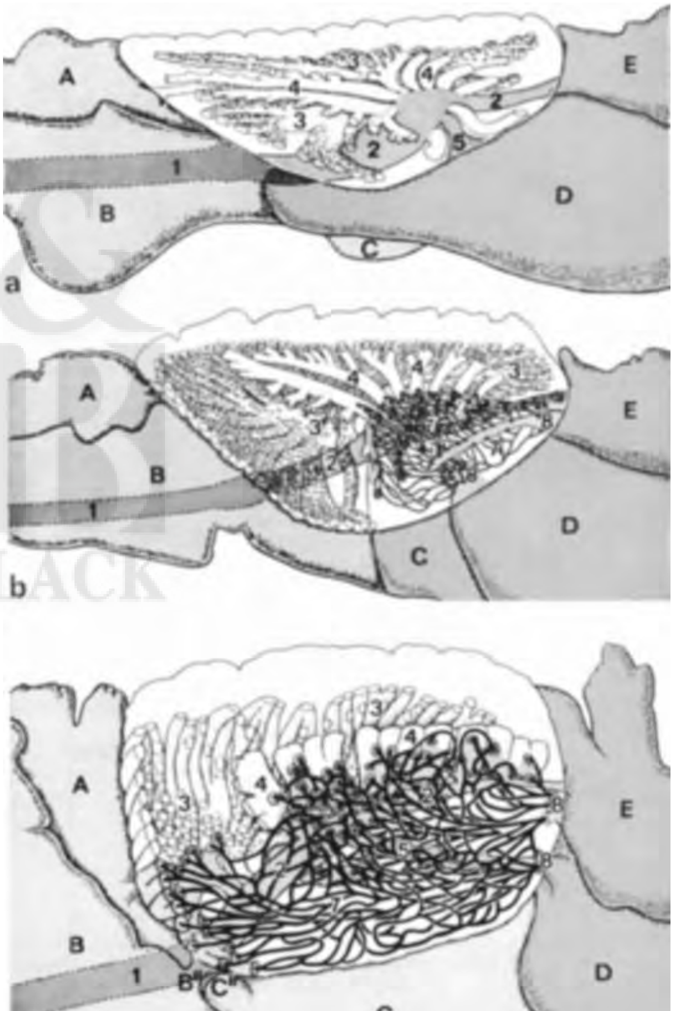

Fig. 5. Semi-schematic drawing of the paleopulmo and neopulmo. Trachea (1), primary bronchus (2), medioventro- (3), mediodorso- (4), lateroventrobronchi (5), neopulmonal parabronchi (7), saccobronchi (8), cervical (A), clavicular (B), cranial (C) and caudal thoracic (D), abdominal (E) air sacs with their ostia. (From Duncker 1971).

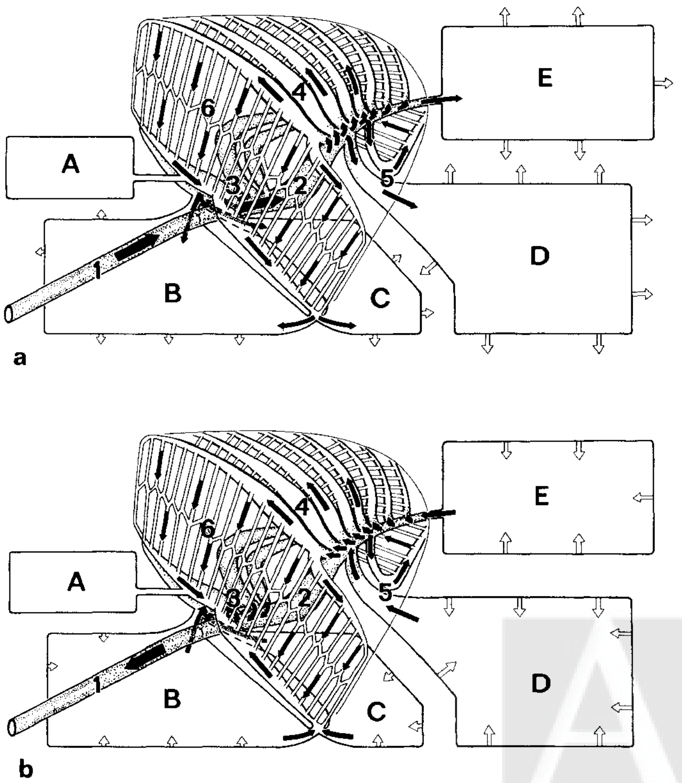

Fig. 6. Diagram of the paleopulmo and its air sac connections, (a) inspiratory phase, (b) expiratory phase. The black arrows indicate the direction of air flow during the respiratory phases; the white arrows express the air sac dilatation or compression. Trachea (1), primary bronchus (2), medioventro- (3), mediodorso- (4), lateroventrobronchi (5) and parabronchi (6). Cervical (A), clavicular (B), cranial (C), caudal thoracic (D), and abdominal (E) air sacs. (From Duncker 1974).

to a diameter smaller than a parabronchus. However, the large lateroventrobronchus, connecting with the caudal thoracic air sac, is never reduced in its diameter. Its ostium is laterally enlarged by the development of the neopulmonal ostium, or it is displaced toward the medial ventral lung surface, and a separate neopulmonal ostium occupies the lateral lung margin. A large neopulmo also expands into the lung region lateral to the hilus, replacing the lateral branch of the first mediodorsobronchus. Thus, the neopulmo receives direct connections to the lateral ostia of the clavicular and cranial thoracic air sacs.

The parabronchus (Fig. 8) is the functional unit of the avian lung, being unique among vertebrates. It consists of a long hollow tube, through the lumen of which the air flows. The parabronchial lumen is surrounded by a zone of hollow chambers, the atria, through which the air diffuses into the surrounding broad mantle of exchange tissue. The exchange tissue is made up of a blood–capillary/air–capillary meshwork, which is supplied by arterioles and venules running in the interparabronchial septa between the neighbouring parabronchi. The parabronchial lumen is surrounded by circular bundles of smooth muscle cells, which are interconnected by oblique strands, or by a more hexagonal arrangement of these bundles, varying in different species. Between the bundles, openings from the lumen into the atria are separated by thin membranes (Fig. 8), which carry only a few capillaries to supply the muscles. Around the muscle bundles and in these membranes a loose network of elastic fibres is found, whereas in the mantle of exchange tissue there are no elastic fibres. Thereby, the diameter of the parabronchial lumen can be changed by the interaction of smooth muscle bundles and elastic fibres without altering the volume of the exchange tissue.

From the outside of each atrium a few infundibula invade the parabronchial mantle, giving rise to a great number of air capillaries. These are air-filled tubes lined by a very thin epithelium and in their diameter (5 μm–14 μm, species-specific) similar to blood capillaries. The air capillaries intrude between the numerous blood capillaries and fuse around them to form a sponge-like three-dimensional net (Fig. 8). The blood capillaries, originating from interparabronchial arterioles, run slightly curved, but mostly without interconnections, from outside the parabronchi toward its lumen. Here, beneath the atria, they collect into small venules which bring the blood back into the interparabronchial venules. This intermingled meshwork of blood and air capillaries makes up the large surface at which the gas exchange between blood and air takes place (Fig. 9).

The basic structure of the parabronchus varies only to an astonishingly limited degree in different bird species, even with extreme differences in body size, taxonomic position and flying ability. The diameter of parabronchi varies from maximally 2 mm in ostriches, swans and turkeys to minimally 0.5 mm in some small song-birds and hummingbirds. In the latter and other advanced flyers, the atrial zone may be reduced or lacking, whereas the basic parabronchial form is found in poor flyers. The anatomical constancy is due to the fact that exchange of gas in the air capillaries takes place only by diffusion, so that a thickness in these capillaries of more than 0.5 mm is ineffective. Based on certain physical laws stating that the surface tension of the wet phase of the air capillary boundary against air strongly increases with the reduction of the diameter of the air-conducting structure, the volume constancy of the lung and the

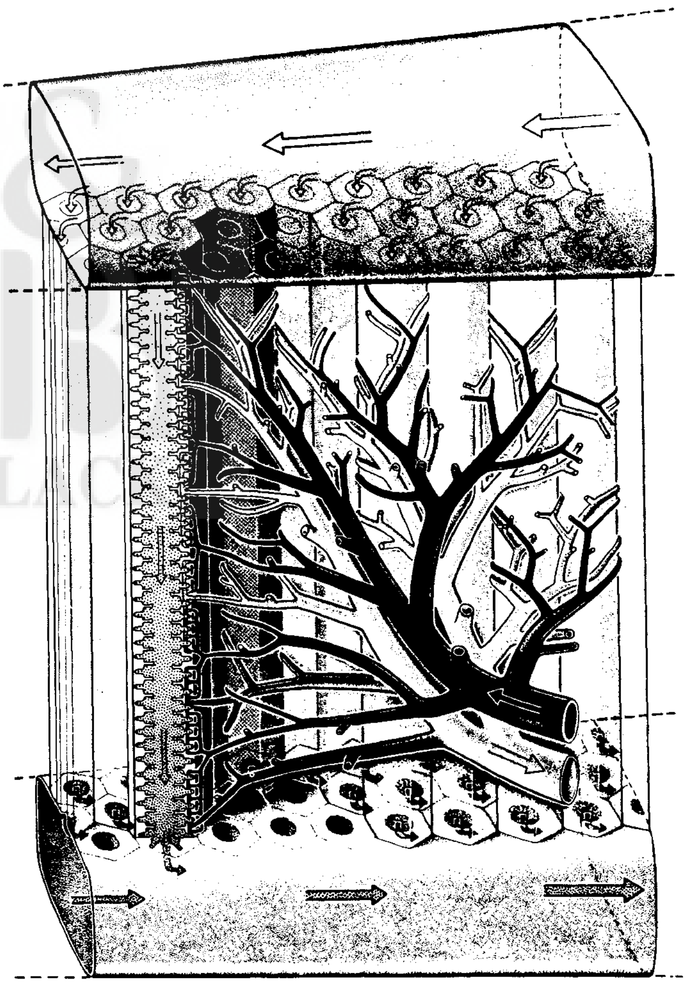

Fig. 7. Scheme of the vascular system of paleopulmonal parabronchi. The inspired air (white arrows) flows through a mediodorsobronchus (above) into the parabronchi, where the gas exchange takes place. The end expiratory air leaves the parabronchi (below) via a medioventrobronchus (densely stippled arrows). The venous blood flows through the pulmonary artery (dark) to all levels of the parabronchus, the arterial blood mixed from all parabronchial levels leaves the lung through the pulmonary vein (light). (From Duncker 1974).

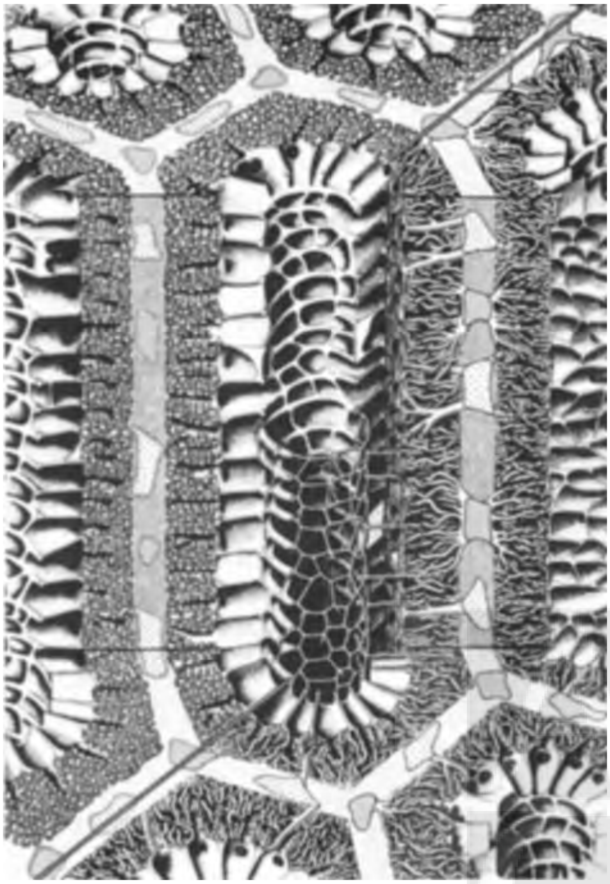

Fig. 8. Drawing of a parabronchus. On the left side: the atria with departing infundibula, which give off the air capillaries, making up a three-dimensional meshwork around the blood capillaries. On the right side: in the interparabronchial septa, arterioles (dense stippling) give off blood capillaries, which run toward the lumen where they collect to venules (light stippling); the latter penetrate the parabronchial mantle into the interparabronchial veins. The septa of the atria and their smooth muscle bundles are supplied by a loose capillary network. (From Duncker 1974).

rigid structure of the parabronchial mantle were a necessary precondition for the evolution of small tiny gas exchange structures, which have simultaneously allowed an enormous increase in the exchange surfaces.

The vascular system. The pulmonary artery enters the lung hilus cranial to the primary bronchus. It ramifies between medioventro- and mediodorsobronchi among the parabronchi so that its branches reach all parts of the parabronchi by the shortest distances (Fig. 7). A long parabronchus, connecting the medioventro- to the mediodorsobronchi, is equally supplied over its entire length with arterioles. The numerous venules of a parabronchus are collected into branches of the pulmonary vein, which run in the neighbourhood of the branches of the pulmonary artery. The pulmonary vein leaves the lung hilus caudal to the primary bronchus. The parabronchi of the neopulmo receive their vascular supply from caudal branches of the pulmonary artery and vein; a large neopulmo receives a separate, lateral branch of both vessels (see also VASCULAR SYSTEM).

Air sacs. Air sacs are large, extremely thin-walled extensions of bronchi, which expand beyond their penetration of the horizontal septum beneath the lung, filling the subpulmonal cavity or the dorsal peritoneal cavity. Their poor vascularization by the systemic circulation excludes participation in gas exchange and determines their function as bellows for ventilation. In the basic arrangement, a total of 9 air sacs exist, which can be separated into two functional groups: (1) the cranial air sacs, including the paired cervical, the unpaired clavicular and the paired cranial thoracic sacs (Figs. 1, 3, 5), are all connected to the medioventrobronchi; (2) the caudal group of air sacs consists of the paired caudal thoracic and the paired abdominal air sacs (Figs. 1, 2, 3, 5). The latter are directly connected to the primary bronchus, which terminates in the abdominal air sac ostium. The caudal thoracic sac is connected to the large lateroventrobronchus, and thus it is also connected to the caudal primary bronchus. The cranial group of air sacs occupies the space in the subpulmonal cavity in front of and lateral to the pericardium. The caudal thoracic air sac occupies the caudal part of the subpulmonal cavity, whereas the abdominal sac invades the dorsal peritoneal cavity. An abdominal air sac located in the peritoneal cavity is lacking only in kiwis. Their air sac, in which the primary bronchus terminates, lies in the subpulmonal cavity as the most caudal one.

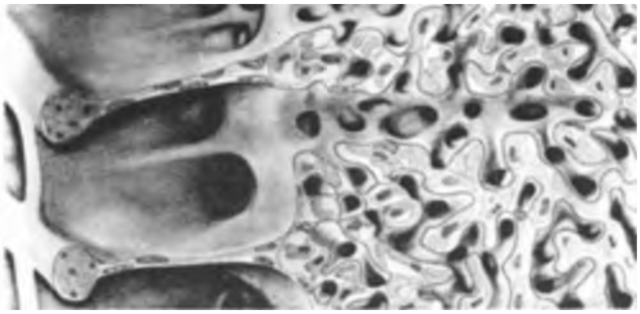

Fig. 9. Three-dimensional drawing of the wall of a parabronchus. At the left, atria are seen, separated by thin septa, from which a few infundibula originate. At the right, one infundibulum in longitudinal section is shown, giving origin to numerous air capillaries which cross-link and interlace, making up a three-dimensional meshwork around the blood capillaries. (From Duncker 1974).

The paired cervical air sac (Fig. 3) is connected by a branch to the first medioventrobronchus which penetrates the horizontal septum cranial to the lung hilus. The air sac extends cranially into the lower neck region, below the ventral neck musculature, adjacent and dorsal to the oesophagus. Lateral to the oesophagus the cervical air sac joins the dorsal part of the clavicular sac to form a separating membrane. By reduction of this membrane the cervical sac can fuse with the clavicular sac, as in turkeys or hummingbirds. The cervical air sac gives off pneumatic diverticula into the adjacent vertebral bodies, and a larger diverticulum between the rib cage and the cranial part of the scapula and the shoulder joint.

The clavicular air sac (Fig. 3), unpaired due to the early fusion of embryonic paired sacs during development, is connected to both lungs by a short stem of the third medioventrobronchus, medial to the lung hilus, and via the ostium at the lung margin lateral to the hilus. It fills the most cranial part of the thoracic cavity in front of the pericardium and beneath the lung and bulges through the cranial thoracic aperture under the skin and muscles cranial to the thorax. The clavicular air sac expands laterally to the pericardium where it joins the cranial thoracic air sac to form a separating membrane. In a large number of families the clavicular air sac extends ventrally and caudally between the pericardium and the sternum, most often as a narrow diverticulum up to the middle of the sternum. However, in hummingbirds and song-birds the clavicular air sac extends up to the caudal margin of the sternum. In contrast to all other air sacs, the clavicular sac surrounds several structures, which run through the cranial thoracic aperture: the oesophagus, the trachea with syrinx and extrapulmonary primary bronchi, the tracheal muscles, the subclavian artery and parts of the brachial plexus. The carotid artery, the jugular vein, the accompanying endocrine glands, and the vagus nerve run in the membrane separating the clavicular and cervical air sacs. In addition to numerous diverticula for the pneumatization of the adjacent bones, the clavicular air sac gives off large diverticula between the scapula and the rib cage, and also into the axilla and around the shoulder joint.

The paired cranial thoracic air sac (Fig. 3) is connected to the third medioventrobronchus medial to the lung hilus and to the ostium at the lung margin lateral to the hilus, very similar to the clavicular sac. This air sac is bordered dorsally by the horizontal septum and medially by the pericardial wall and the oblique septum, and laterally by the thoracic wall. Caudally, the air sac is separated from the caudal thoracic air sac by a membrane, which originates out of the joined walls of both air sacs. The cranial air sac in the majority of birds is smaller than the caudal thoracic sac, but in pigeons and galliform birds it is larger. An extreme situation arises in turkeys, in which the caudal thoracic air sac is lacking and the cranial thoracic air sac occupies the entire caudal subpulmonal cavity. In hummingbirds and song-birds the cranial thoracic air sac retains the original position, but is fused with the clavicular sac. In these species the cranial group of air sacs is represented by only one sac, which possesses all the ostia of the fused 5 sacs. The adjacent bones are supplied with pneumatic diverticula from this air sac, whether fused or not.

The paired caudal thoracic air sac (Figs. 2, 3, 5) is bordered dorsally by the caudal part of the horizontal septum, which contains the ostium of the lateroventrobronchus. Into this ostium the parabronchi of the neopulmo or its saccobronchus open laterally. Medially, the caudal thoracic sac is bordered by the oblique septum, laterally by the thoracic wall. The caudal extension of this air sac varies largely in different families and thereby also its volume. The caudal thoracic air sac is large in most birds, but relatively small in pigeons and galliform birds. In the turkey, the connections of the missing caudal thoracic air sac to the lateroventrobronchus and to the neopulmo are incorporated into the ostium of the abdominal air sac.

The abdominal air sac (Figs. 2, 3, 5) is connected to the caudal primary bronchus, which at the caudal lung margin penetrates the united, dorsal, perpendicular portion of the horizontal and oblique septa and opens into the funnel-shaped air sac ostium. The abdominal air sac is the only one (with the exception of the kiwi) which is not situated in the subpulmonal cavity, but spreads out in the dorsal peritoneal cavity lateral to the dorsal mesentery. The air sac wall adheres to the dorsal body wall over a varying wide oval area, so that the cranial parts of the kidney and the testes are covered, but not the left ovary. From the margins of this area of adhesion the very thin walls of the abdominal air sac hang freely movable into the peritoneal cavity. The dimensions of the air sac walls are limited in penguins, ostriches and rheas, but in most other birds are so wide that the thin walls are regularly folded up between intestinal loops. Air sac diverticula protrude from the dorsal area of adhesion between kidney and synsacrum, into the synsacrum and the femur, and around the hip joint.

The ostia of the air sacs and their connecting bronchi are to some extent structurally different. The ostia into the cranial air sacs are rigidly extended into the horizontal septum; the connecting medioventrobronchi are not able to vary their diameter. The ostia into the caudal thoracic and abdominal air sacs are also rigidly extended into the horizontal septum or in the septum at the caudal lung margin. However, the connecting lateroventrobronchus and the terminal primary bronchus possess a well-developed circular musculature. In contrast to the medioventrobronchi, which are poor in musculature and rigidly stretched, these connecting bronchi can vary their diameter, and thus they may contribute to the regulation of air flow into and out of these air sacs.

The ventilation of the lung is caused by the volume changes produced by the respiratory movements, which act only on the air sacs. The measured pressure changes are the same in all air sacs. During inspiration, fresh air flows directly through the primary bronchus and the large lateroventrobronchus into the caudal air sacs (Fig. 6a). In contrast, the cranial air sacs receive an inflow of air only via the richly interconnected medioventrobronchi. Thus, a pressure gradient to the mediodorsobronchi is developed, causing the air to flow from the primary bronchus through the mediodorsobronchi via the parabronchi and through the medioventrobronchi into the cranial air sacs. They therefore receive only expiratory air. During expiration, the air from the caudal air sacs is forced into the openings of the mediodorsobronchi, which are situated one above the other (Fig. 6b). This air flows through the parabronchi and through the medioventrobronchi, where it is joined by air from the cranial air sacs, leaving the lung through the primary bronchus. Thus, the air flows unidirectionally during inspiration and expiration through the paleopulmonal parabronchi (Scheid 1979, 1982) which is a consequence of the arrangement of the secondary bronchi and the orientation of their origins and their air sac connections.

In contrast to this unidirectional ventilation of the paleopulmo, the neopulmonal parabronchi are ventilated in directions altering with the respiratory phase, due to the fact that this parabronchial net lies in the direct connection between the primary bronchus and the caudal air sacs.

The gas exchange in the long parabronchi, whether ventilated unidirectionally or otherwise, is physiologically unique and much more efficient than in mammalian alveoli. The venous blood perfuses equally all capillaries over the entire length of the parabronchus (Fig. 7). In the proximal portion of the parabronchus the blood exchanges with fresh air, whereas in the more distal parts it exchanges with increasingly deoxygenated air, up to the terminal part of the parabronchus where the venous blood comes into equilibrium with the fully exchanged (end-expiratory) air. The gas content of the blood, varying in composition at the various parabronchial levels, has a lower CO_2 partial pressure than the end-expiratory air, and under hypoxic conditions, e.g. during flight at high altitudes (Scheid 1979, 1982), also has a higher O_2 partial pressure than the expired air. This so-called cross-current exchange system is responsible for the high physiological efficiency of the avian lung.

Contrary to earlier belief, the movements of birds due to flight are totally independent of respiratory movements, and they do not even support respiration. The two activities are anatomically independent of each other. The large flight muscles originate solely from the broad sternum, the coracoid, the clavicula and their membranes, but not from the rib cage (the respiratory apparatus), from which the movements of the flight apparatus are isolated by loose connective tissue and air sac diverticula. The respiratory movements are produced only by the muscles of the ribs and their uncinate processes, which give them a more effective leverage, and by the muscles of the abdominal wall (Duncker 1971). The separation of flight and respiratory movements has been proven by recording wing beats and breaths, which are found in different relationships to one another, varying from 3:2 to 5:1 in most species investigated. Only in the crow *Corvus* and the pigeon a 1:1 synchrony occurs (Berger and Hart 1974), which was the reason for the statement that flight and respiratory movements were coupled.

Ontogenetic development. Because of its structural peculiarities the avian lung/air sac system requires special developmental conditions. At the beginning of the second half of the incubation period, the lung fuses with the walls of the pleural cavity. Only the air sacs, which develop at the same time, can be inflated in the embryo. A few days before the end of the incubation period, the lung is fully developed together with all secondary bronchi and parabronchi. At this time air capillaries sprout from the atria into the parabronchial wall between the developing blood capillaries. The parabronchi and their developing air capillaries are full of pulmonary fluid. One to three days before hatching, the embryo ingests the amniotic fluid and the rest of the albumen, and breaks the membrane to the air space inside the egg. At this time regular respiratory movements start, and the embryo breathes air, thereby starting ventilation of the lungs and air sacs, and also of the parabronchi. During this time the gas exchange of the embryo is carried out by the chorio-allantoic membrane, but after ventilation has started the pulmonary fluid gets resorbed from the developing air capillaries. Thus, the gas exchange is increasingly taken over by the growing blood–capillary/air–capillary network, until at the end of this process, the embryo hatches. The air capillaries cannot be inflated because of their high surface tension and the rigid construction of the lung; moreover, they cannot suddenly be emptied of pulmonary fluid at the moment of birth. Therefore, birds require one to three days before hatching for their lungs to develop full functional status, during which time an overlap of the gas exchange process by the chorio-allantoic membrane and the air ventilation of the lungs occurs; this is only possible in a hard-shelled egg. Thus, the phylogenetic development of viviparity, which would have a number of biological benefits also for birds, was denied avian species by the structural peculiarities of their respiratory system (Duncker 1971, 1978) (see also DEVELOPMENT, EMBRYONIC). RESTLESSNESS, PRE-MIGRATORY: see PRE-MIGRATORY RESTLESSNESS.

RETICULATE: term applied to a podotheca consisting of small scales, the divisions between which form a fine network (see LEG).

RETINA: part of the eye (see VISION).

RETRAP: see MARKING; TRAPPING.

REVERSE MIGRATION: a phenomenon in which birds fly in a direction opposite to that which they would be expected to take during a particular migration (see WEATHER AND BIRDS (Reverse migration)).

RHABDORNITHIDAE: family of PASSERIFORMES, suborder Oscines; CREEPER, PHILIPPINE.

RHACHIS: see RACHIS.

RHAMPHOTHECA: the horny covering of the bill, the upper and lower parts of it being sometimes separately designated rhinotheca and gnathotheca (see BILL).

RHEA: substantive name of the 2 species of Rheidae (Struthioniformes, suborder Rheae); in the plural, general term for the family. The group is restricted to the campo region of South America, where the birds are called 'Ema' or 'Nhandu' (Nandu). They are large running ratites, showing a general resemblance to the Ostrich *Struthio camelus* of Africa. The Ostrich, Cassowaries *Casuarius*, Emu *Dromaius novaehollandiae* and rheas are considered to be of monophyletic origin.

Characteristics. The Greater Rhea (or Common Nandu) *Rhea americana*, to which the following account refers, stands about 1.5 m high and weighs 20–25 kg or more. The normal coloration is not conspicuous, but white individuals are not uncommon. The sexes are similar, but the males are slightly taller.

Each foot has 3 well-formed toes, and the birds are fine runners. When alarmed they run with their necks stretched almost horizontally, and they can double at right angles to their course. At the same time they lift one of their wings, with a sail-like or ballooning effect. When there is enough cover they crouch down to conceal themselves. Although the wings are bigger in proportion than those of other ratites, they are useless for flying; they cover the upper part of the rump like a cloak when they are at rest. Unlike those of the Ostrich, the feathers have little commercial value; they are used in South America as dusters. Rectrices are absent. Rheas love to bathe and they are able to swim.

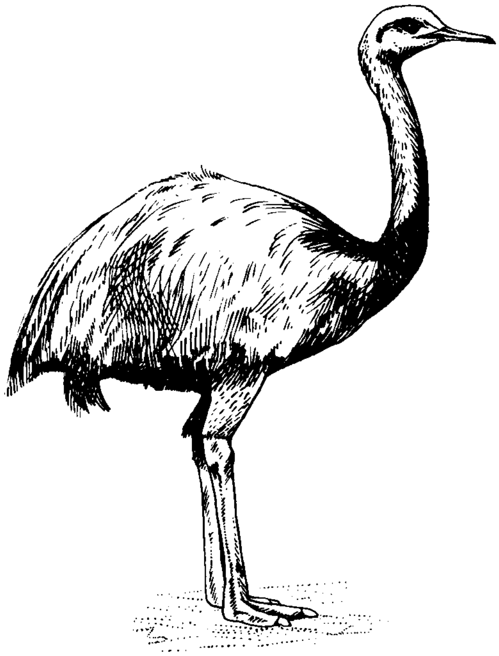
Habitat. Generally the species prefers country with taller vegetation to pure grasslands, with the breeding territory near a swamp or river if possible.

Distribution. *Rhea americana* is found from north-eastern Brazil to central Argentina. The other species, in a closely related genus, is Darwin's Rhea *Pterocnemia pennata*, occurring from Patagonia to the high plateaux of the Andes in southern Peru. It is somewhat smaller; the plumage shows white spots on a brownish background.

Food. Rheas feed on tender leaves, roots, seeds, and the like, also eating many insects, especially grasshoppers, and small vertebrates.

Behaviour and voice. The birds live in flocks; except in the breeding periods these groups consist of 20–30 individuals, at times considerably more. Occasionally they mix with herds of the Bush Deer *Dorcelaphus bezoarticus*, both species keeping a sharp look-out. In regions where they are not hunted they also mix with grazing cattle. Old male birds are solitary.

At the beginning of the breeding period the older males chase away the young ones and fight with their rivals by twisting their necks together, biting, and kicking. The male displays in front of 3–8 females: he runs to and fro, stands in front of them, pulls his neck in, jerks his wings and then spreads them away from his body so that the feathers flutter in the breeze. He frequently lets out a kind of low roar which sounds more like the voice of some wild beast than of a bird. At the same time he stretches his neck straight upwards, the inflated oesophagus serving as a sounding board. The Rhea also produces other sounds; the syrinx is better developed than in the Ostrich.



Greater Rhea *Rhea americana*. (*M.Y.*)

Breeding. At a dry spot protected by bushes, the victorious male prepares a shallow hollow in the ground by ripping away the grass with his bill; frequently he uses an already existing depression and often works at a number of spots. Finally, he lines the hollow with some dry vegetable matter. Some of the nests are surrounded by an open zone partly prepared by the birds themselves biting off the grass; this zone occasionally serves to protect the nest against campo fires.

The male then leads the females to the nest, showing his strikingly light-coloured rump. Frequently they have already started laying, dropping their eggs in various spots; but now they concentrate on the definite nest. It may happen that 6 females, one after another, each lay an egg in the nest and then leave together. Even females that belong to a different flock will join in and, consequently, the clutch may increase rapidly. Each female lays an egg every 2 or 3 days up to a total of 11–18. Otherwise they do not bother with the nest.

After there are a certain number of eggs in the nest the male begins to incubate. From then on he defends the nest by stretching out his neck and moving it in a snake-like fashion accompanied by hissing and snapping. Females who want to lay more eggs in the nest must behave submissively to reduce the male's aggression before they are allowed to do so. More eggs are also laid in the vicinity; the male rolls into the nest, with his bill, those eggs nearest it. Depending on circumstances, the clutch is complete with from 13 to 20–30 eggs; but clutches with more than twice that number of eggs have been found (e.g. 80). The number of eggs which go to waste is even larger. The measurements of the eggs vary considerably, the average is about 132 × 90 mm; the weight of an egg is about 600 g. Newly laid eggs of *Rhea americana* are golden yellow, but this quickly fades to an off-white colour. The eggs of *Pterocnemia pennata* are green.

After an incubation of 35–40 days by the male alone, the young hatch, one shortly after the other. They are grey with dark stripes. The young soon leave the nest, led by the male. They keep contact with each other by long-drawn plaintive whistles. Even so they get lost at times, especially when they lag too far behind after cowering low at the sign of danger. The strays will join another flock, if possible, and this results in considerable age variations within flocks. The development of the young is rapid; after 5 months they are already as big as the adult birds. Sexual maturity, however, is not reached for 2 years. H.S.

RHEAE; RHEIDAE: suborder and family of STRUTHIONIFORMES; RHEA.

RHINOCRYPTIDAE: family of PASSERIFORMES, suborder Deutero-Oscines; TAPACULO.

RHINOTHECA: term sometimes applied to the part of the rhamphotheca covering the upper jaw (see BILL).

RHIPIDURIDAE: a family of PASSERIFORMES, suborder Oscines; FANTAIL.

RHOMBOID SINUS: a structure in the avian spinal cord (see NERVOUS SYSTEM).

RHYNCHOKINESIS: a form of upper jaw mobility seen in some birds with schizorhinal nostrils, in which the flexible region has shifted rostrally, and bending occurs instead at various points along the length of the upper jaw (zonae elasticae maxillares) (see SKULL (Cranial kinesis)).

RHYNOCHETI; RHYNOCHETIDAE: see under GRUIFORMES; KAGU.

RHYTHMS AND TIME MEASUREMENT: processes which recur at regular intervals in organisms or groups of organisms are commonly referred to as rhythms or periodicities. Four groups of biological periodicities constitute a special category in that their periods match natural environmental periodicities: tidal, daily, lunar and annual rhythms with periods of 12.4 h, 24.0 h, 29.5 days and 365 days, respectively. The 4 corresponding kinds of biological rhythms represent special adaptations which have evolved in many organisms to cope with the conspicuous temporal changes in the environment associated with the tides, the succession of day and night, the phases of the moon, and the cycle of the seasons. Since these environmental periodicities are highly stable and predictable, organisms have been able to evolve innate endogenous temporal programmes in physiology and behaviour, with the result that particular biological activities are performed at specific appropriate phases of the environmental cycles. In that respect biological rhythms often serve as clocks, i.e. time measuring systems that both couple temporal programmes of performance with environmental cycles and guarantee the appropriate sequence in the successive events of the programme.

In birds, as in most other organisms, all physiological and behavioural processes are organized on the basis of a daily periodicity. Similarly, annual rhythms are common, at least in birds inhabiting the temperate and higher latitudes with their pronounced seasons. Overt tidal and lunar rhythms, on the other hand, are less widespread in birds, but in some species they serve a significant function; for some seabirds and waders that feed in the intertidal zone, a tidal rhythm is superimposed on the daily pattern of foraging activity. Lunar rhythms related to the variations in nocturnal light-intensity are sometimes found in the time of onset and end of activity in crepuscular birds such as the foraging flight of Nightjars *Caprimulgus europaeus*, the LEKS of Black Grouse *Tetrao tetrix*, and in the duration of nocturnal restlessness in migratory passerines. The breeding cycles of the Sooty Tern *Sterna fuscata* on Ascension Island and of 2 passerines on Borneo closely approximate 10 lunar cycles, suggesting that reproduction in these birds is somehow controlled by the phase of the moon. But, whereas endogenous tidal and lunar rhythms have been investigated in other organisms, nothing is known about the properties of such rhythms in birds. The following account is therefore restricted to daily and annual rhythms.

Daily rhythms

General features. Although daily rhythms in biological activities closely match the daily environmental cycles to which they are adapted, they are not usually caused by them. This is indicated by the persistence of daily biological rhythms in experimental conditions devoid of daily variations. The daily rhythm of perch-hopping in the Chaffinch *Fringilla coelebs* continues for many cycles even when the bird is maintained in continuous light and at constant temperature. During the first 12 days of the experiment shown in Fig. 1, the bird was exposed to a 24-h light–dark cycle, but when the light was kept on continuously, the times of onset of successive bouts of activity shifted progressively forward relative to local time, indicating a 'free-running' rhythm of activity and rest with a period shorter than 24 h. Such a deviation of the period from 24 h—usually not exceeding about ±20% of 24 h—is characteristic of daily biological rhythms in constant conditions. This observation excludes the possibility that uncontrolled daily environmental cues might cause the rhythmicity in the animal and thus justifies the designation of these periodicities as 'circadian rhythms' (from *circa* = about and *dies* = day).

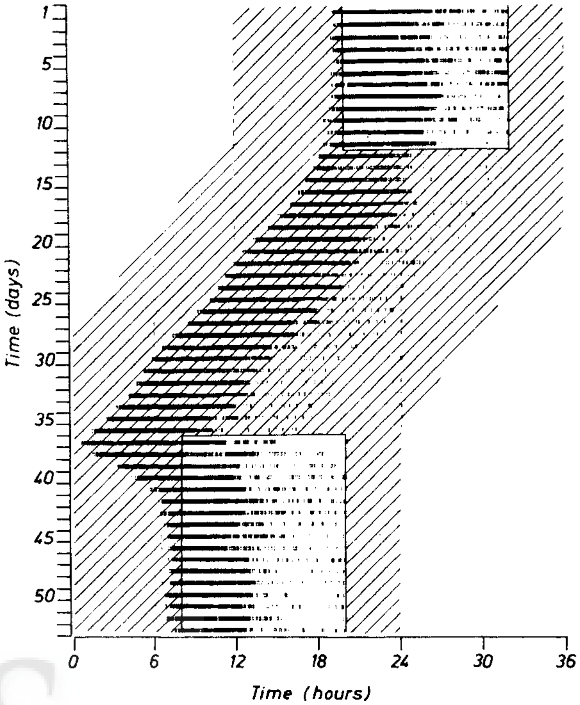

Fig. 1. Circadian rhythm in perch-hopping activity of a Chaffinch *Fringilla coelebs*. Each day's record is displayed below the record of the previous day. Black bars indicate intense activity. The bird was kept from day 1 through 12 (top box) in conditions of bright light from 2000 h to 0800 h (light area in the box) and dim light from 0800 h (shaded area outside the box) each day. From day 13 onwards it was kept in continuous dim light until day 37 (bottom box) when it was exposed once again to alternating bright and dim light on a 24 h light cycle. Note the persistence of the rhythm under constant conditions with a circadian period shorter than 24 h, and its entrainment by the light-dark cycle.

Whereas circadian rhythms have a period slightly different from 24 h under constant conditions, their period is exactly 24 h under natural conditions. There must, therefore, be daily rhythmic factors in the animal's normal environment which are capable of synchronizing circadian rhythms with the natural day. Such environmental cycles capable of synchronizing (entraining) biological rhythms are called Zeitgebers. For birds, as for essentially all other organisms, the most important Zeitgeber of circadian rhythms is the 24-h rhythm in light-intensity, i.e. the alternation between day and night. In Fig. 1 the free-running activity rhythm of the Chaffinch in constant darkness is 'caught' by the light–dark cycle; the bird's natural free-running period is altered to the period of the Zeitgeber. Other Zeitgebers of avian circadian rhythms are 24-h temperature cycles of an amplitude greater than 30°C, and acoustical signals consisting of regular daily alternations between noise and silence. However, the effectiveness of these supplementary Zeitgebers is small compared with that of light–dark cycles.

Since circadian rhythms persist without damping for many cycles in constant conditions they behave like self-sustaining oscillators in the technical sense. Therefore, the terminology of general oscillator theory is often used for describing them. They are innate: circadian locomotor activity rhythms develop even in chicks raised from the egg in constant darkness. Their period length τ is relatively unaffected by environmental influences. It is particularly significant for the use of these rhythms as clocks that τ shows little variation over a wide range of temperatures. This holds true for all sorts of organisms, including cold-blooded. A change in temperature of 10°C usually changes τ predictably, but by less than 5%. For birds, an increase in environmental temperature usually leads to a slight shortening of τ. Apart from temperature, light intensity has slight but consistent effects on τ. In diurnal birds τ usually shortens as light-intensity increases, whereas in nocturnal birds the reverse may be true, at least under high light intensities. In addition, physiological factors (e.g. reproductive state) may affect τ.

Within a single organism different biological functions are often controlled by different discrete circadian clocks. When, under constant environmental conditions, circadian rhythms are no longer synchronized, those of, e.g. body temperature and locomotor activity, may free-run with different τs. Even a single function may be under the control of more than one circadian oscillator. Thus, locomotor activity of birds kept in continuous dim light may, under certain conditions, 'split' into two components, the morning and evening peaks of activity, which separate and free-run with different periods. Under normal conditions of synchronization, however, the various circadian rhythms usually assume rather rigid phase-relationships to each other, ensuring that each circadian function occurs at the right phase of the environmental cycle and in the proper sequence relative to the other functions.

Whereas a Zeitgeber of circadian rhythms is by definition capable of changing τ so that it matches its own period T, the range of possible T-values to which circadian rhythms can entrain is limited: it extends from about 18 h to about 30 h. Between these limits, the range of T-values within which entrainment occurs depends on the nature of the Zeitgeber cycles, its amplitude, and the natural period τ_n of the animal's circadian rhythm. As the Zeitgeber period increases or the natural period of the circadian rhythm decreases, the phase of the biological rhythm shifts forward relative to the phase of the Zeitgeber rhythm. The phase relationship (ψ) between the two rhythms is given by $\psi \sim T/\tau_n$, as predicted if entrained circadian rhythms were to behave like self-sustaining oscillators under the influence of an external periodic driving force. Many aspects of circadian rhythms of animals under different Zeitgeber conditions are consistent with this relationship. For instance, it has been found that the circadian locomotor activity rhythm in many diurnal birds is relatively more phase-advanced in summer than in winter; the size of this seasonal difference increases with increasing latitude. Such changes are to be expected if the animal responds to the average light intensity it experiences in the course of a day, since this is higher in summer than in winter (and the extent of this seasonal difference is greater at higher latitudes). Since τ_n of a diurnal bird shortens with increasing light-intensity but T does not change, one should expect higher ψ values in the synchronized state in summer. Hence, some of the systematic seasonal and latitudinal changes in ψ can be interpreted as a consequence of the seasonal and latitudinal changes in day length. It must be emphasized, however, that other variables such as the duration of twilight affect the activity pattern as well.

Synchronization, in principle, is possible only if there is a periodically changing sensitivity of the circadian rhythm to stimuli from the Zeitgeber. This phenomenon has been explored in detail for the sensitivity of circadian rhythms to light. Light pulses and transitions from light to darkness or from darkness to light cause phase shifts of the circadian rhythm which are dependent in direction and amplitude on the phase of the rhythm hit by the light signal. This relationship is represented in so-called phase-response curves. On the assumption that light-pulses mimic the dark/light/dark transitions occurring during a natural day, phase-response curves can be used to predict the behaviour of circadian rhythms under various Zeitgeber conditions. This model of entrainment has proved successful in explaining the behaviour of avian circadian rhythms in, for instance, the Japanese Quail *Coturnix japonica* and the House Sparrow *Passer domesticus*. For these, the limits of the range of entrainment and the dependence of ψ on T or on photoperiod can be quantitatively derived from phase-response curves.

Localization of circadian pacemakers. Although it is clear that in higher vertebrates there is a multitude of circadian rhythms occurring at various levels from the organ down to the cell, there is now equally good evidence that this circadian system is integrated by central circadian pacemakers. In at least some passerine birds such a pacemaker seems to be localized in the pineal gland. If House Sparrows held in constant darkness are pinealectomized, their free-running rhythms of locomotor activity and body temperature are almost instantaneously abolished. Rhythmicity is restored, however, when the pineal of another sparrow is transplanted into the anterior chamber of an eye. The emerging rhythm has the phase of the rhythm of the donor bird. These results strongly suggest that the pineal is a circadian pacemaker, driving or integrating overt circadian rhythms, and that the information about circadian time is chemically transmitted to the subordinate system. Presumably melatonin, a hormone produced by the pineal, is the essential substance. In birds, as in other vertebrates, melatonin concentration shows a conspicuous daily rhythmicity with high values during the dark (inactive) and low values during the light (active) phase of each day. The synthesis of melatonin is controlled by the activity of the enzyme N-Acetyl-transferase which exhibits a strong daily (circadian) rhythm, persisting for at least two cycles in chickens kept in continuous darkness, and even in isolated chicken pineals cultured in vitro. Chronic melatonin treatment affects the free-running circadian activity rhythms in both sparrows and European Starlings *Sturnus vulgaris*. The highly disorganized circadian activity rhythms of pinealectomized Starlings kept in continuous dim light can be synchronized by daily injections of melatonin. All these facts, taken together, suggest that the pineal is the seat of a self-sustaining circadian oscillator, which controls overt circadian rhythms by its rhythmic output of melatonin.

Whereas pinealectomy results in arhythmic activity in the House Sparrow, the White-crowned Sparrow *Zonotrichia leucophrys* and the White-throated Sparrow *Z. albicollis*, pinealectomy of European Starlings leads to impairment and instability but not complete abolition of the circadian rhythm of locomotor activity. In Japanese Quail and the chicken *Gallus gallus*, in contrast, pinealectomy has no profound effect on circadian activity rhythms. These interspecific differences may reflect differences in the degree of self-sustainment, not of the circadian oscillator in the pineal itself, but of a subordinate oscillatory system which is affected by the pineal output. If this subordinate system is comprised of a population of circadian oscillators, the different effects of pinealectomy in the different species might be due to differences in the mutual coupling among these oscillators. In the gallinaceous birds, coupling may be strong, so that even in the absence of the pineal driver a normal circadian rhythm persists, whereas in sparrows coupling may be weak, so that the rhythm deteriorates in the absence of the pineal pacemaker, with the Starling intermediate. Even in pinealectomized sparrows a residual rhythmicity can be observed, as their locomotor activity rhythms can still be synchronized by light as for normal birds: it takes the rhythm about a week to disappear if such birds are subsequently transferred to constant darkness. This observation can be interpreted in terms of an internal uncoupling of circadian suboscillators controlling locomotor activity.

Another important part of the circadian system controlling locomotor activity is localized in the suprachiasmatic nuclei (SCN), in the anterior hypothalamus. In sparrows, their ablation has effects similar to pinealectomy. However, it is not clear yet how the pineal and the SCN interact, and how both of them eventually control the overt circadian functions.

Photoreceptors for the entrainment by light. In birds, the eyes are not the most important photoreceptors involved in the perception of the light-synchronizing circadian rhythms. Blinded House Sparrows can still entrain to 24-h light-dark cycles. However, the eyes are normally also involved, because after sparrows are blinded they require a greater minimum light intensity for synchronization to a 24-h light–dark cycle. The extraocular photoreceptors are located in the brain. This has been shown in experiments in which the entrainment response of normal sparrows to low-amplitude light–dark cycles was abolished by opaque material, placed on top of the bird's skull, which greatly reduces the light intensity reaching the brain. Conversely, the entrainment threshold can be lowered by plucking feathers from the head, thereby drastically increasing the light-intensity penetrating the skull. So far, the photoreceptors in the brain have not been identified.

Adaptive functions of circadian rhythms. The selective forces, which have led to the evolution of endogenous circadian rhythms in all eukaryotic organisms, are still obscure. It is possible that their primary function early in evolutionary time was the maintenance of internal temporal order among various metabolic functions. This, indeed, may still be a major function of some modern circadian systems. However, it is clear that many organisms now utilize circadian rhythms for a variety of other purposes as well. Many physiological and behavioural functions follow endogenous daily programmes that match periodically recurring and therefore predictable environmental demands. For instance, feeding activity of many diurnal birds shows a bimodal pattern, with morning and evening peaks. The evening peak may be adaptive in that it enables a bird to store a surplus of energy for the coming night, whereas the morning peak may be a mechanism to make up for the deficiencies built up during the previous night of starvation. However, this daily pattern does not depend on the availability of or demand for food, since it persists in constant conditions with a circadian period, even if food is available *ad libitum*. One of the possible advantages of such preprogramming is that the complex biochemical and behavioural events related to food uptake and digestion can be temporally organized relative to each other, early enough that the organism is ready for feeding at the appropriate times of day. Anticipation of future demands is also a major function of both physiological and behavioural circadian rhythms. For example, body temperature begins to increase long before the daily onset of activity, so that the animal's metabolic state is already elevated when it becomes active. In diurnal birds that migrate at night, both normal day-time activity and nocturnal migratory unrest are under circadian control. The alternation between these two types of activity is accompanied by circadian changes in preferred light intensities in a gradient. European Robins *Erithacus rubecula* select high intensities during their daytime activities (such as feeding) but low intensities during their nocturnal activities (such as migratory calling). Obviously the naturally occurring variations in light intensity have become incorporated as an 'expectation' in the endogenous circadian organization of these birds.

Circadian programmes are often highly flexible and subject to modification by individual experiences. In a sense, the circadian system provides a '24-h continuous loop tape recorder' on which the experiences of an individual animal at particular times of a day are stored. This ability is illustrated by the phenomenon of Zeitgedächtnis or time memory, first described for the honey bee but later also demonstrated for birds. Under experimental conditions bees can be trained to search for food at particular places at particular times of day; even if no longer rewarded, this temporal and spatial pattern persists for some days before it eventually becomes extinguished. Presumably, many of the daily habits that can be observed in free-living animals result from a similar circadian programming of learned behavioural functions based on some form of time memory.

Circadian rhythms also provide the basis for special adaptations. One of these is 'time-compensated sun-compass orientation', first discovered in birds and bees by G. Kramer and K. von Frisch respectively. Birds tending to fly in a particular direction during migratory unrest, or searching for food in a direction to which they had been trained, compensate for the sun's apparent movement by continuously changing their orientation angle relative to the sun in such a way that a constant compass direction is maintained. That a circadian clock is involved can be demonstrated by experiments in which birds are exposed to artificial light–dark-cycles shifted relative to the natural day; this procedure resets the animals' circadian rhythms within several days. If then tested under the sun again, they select the compass direction predicted by the hypothesis that the birds relate the sun's position to subjective circadian time. This can be shown even more convincingly in experiments in which the circadian clock of birds is allowed to free-run under constant conditions, and by testing birds under an artificial stationary sun: each bird behaves as though the sun was moving and changes its orientation angle relative to it in the expected counter-clockwise direction (see NAVIGATION).

Many seasonal events are controlled by the annual variations in photoperiod, the light fraction of the 24-h day. The stimulatory effect of long photoperiods on the development of avian reproductive systems has been extensively investigated. If temperate-zone birds are exposed in winter to a long photoperiod simulating spring or summer conditions, the pituitary begins to secrete gonadotrophins which in turn initiate gonadal recrudescence. Neither the duration of light time nor the duration of dark time is important; the release of this response depends only on the phase of the animal's circadian rhythm which is exposed to light. If birds are exposed to a short non-stimulatory light period, followed by an extended (more than 24 h) dark period, which is then interrupted by another short light period (given at different times in different experimental groups of birds), their responses are usually a function of the circadian phase hit by the second light period, as shown in Fig. 2. Light periods with maximal effects and those with minimal effects on release of luteinizing hormone from the pituitary of White-crowned Sparrows are spaced approximately 24 h apart; the pattern of response is a circadian rhythm itself. These results are consistent with the hypothesis proposed in 1936 by E. Bünning, according to which organisms are equipped with a circadian rhythm in photosensitivity which measures day-length by determining whether or not light falls on a particular photo-inductive phase of that rhythm. Details of this circadian time-measuring process are still unknown but there is now compelling evidence that a circadian rhythmicity is involved somehow, not only in mediating the gonadal growth response to long days, but also in other seasonal activities such as migratory behaviour, moult and gonadal recrudescence (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; MIGRATION; MOULT).

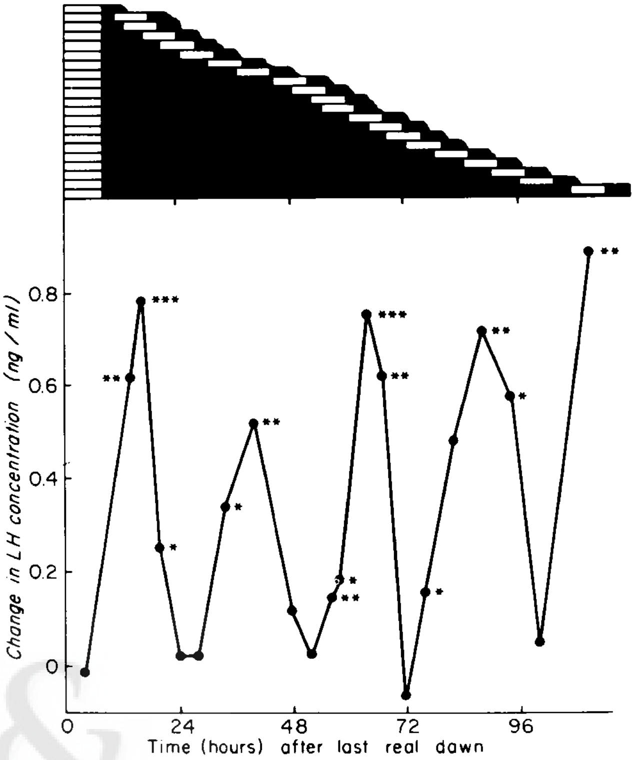

Fig. 2. The effect of an 8 h light period given at various intervals after beginning of darkness on plasma luteinizing hormone concentration in White-crowned Sparrows *Zonotrichia leucophrys*. The white and black bars at the top illustrate the various treatments. (White = period of light, black = period of darkness). Birds were previously maintained on 8 h of light per day and a pre-experimental blood sample was taken for all birds early in the last 8 h light period. The post-experimental sample was taken 7–16 h after the end of the test photoperiod. The ordinate shows the change in hormone concentration between these two samples that resulted from a particular treatment. (From Follett *et al* 1974).

Annual rhythms

General features. Like daily rhythms some annual biological periodicities are endogenously pre-programmed as circannual rhythms. Figure 3 demonstrates that annual variations in testicular width persisted in European Starlings maintained for 3½ years under constant photoperiodic conditions. Periods of increased testicular size alternated regularly with periods of moult. The interval between successive corresponding events deviated from one year, indicating that these rhythms are not driven by uncontrolled annual environmental cues.

Circannual rhythms persisting for at least two cycles, with periods deviating from 12 months, have been demonstrated for at least 15 avian species. Functions shown to be under circannual control are gonadal activity, migratory disposition, moult, feeding and body weight. In Garden Warblers *Sylvia borin* and Blackcaps *S. atricapilla* up to 9 successive circannual moult cycles have been measured under constant photoperiodic conditions, suggesting that in these species a circannual clock keeps running throughout the entire lifetime. In some species, however, circannual rhythms tend to damp out with time; and yet others show no annual rhythmicity at all if kept under seasonally constant conditions. This suggests that circannual rhythms are not as ubiquitous as circadian rhythms, and represent special mechanisms that have evolved in only a few species, for special purposes.

Circannual rhythms behave in many respects like circadian rhythms. There is evidence that they are innate. Their period in constant conditions seems to be relatively insensitive to environmental variables such as the actual duration of the constant photoperiod. And some results suggest that different functions may be controlled by different circannual clocks. Like circadian rhythms, they can be synchronized by cyclic variations in environmental conditions. In birds, the annual cycle in photoperiod constitutes such a circannual Zeitgeber; the period of the circannual rhythm can be altered by compressing the period of the normal annual change in photoperiod into less than 12 months. Using this technique in the European Starling, up to 8 cycles in testicular size and moult can be squeezed into one calendar year, indicating that the range of entrainment of these circannual rhythms is large compared to that of circadian rhythms.

Adaptive functions of circannual rhythms. Since circannual rhythms, in contrast to circadian rhythms, appear to be restricted to certain species, it appears likely that they have evolved independently several times to serve specific biological functions. In migratory birds, one such function may be the timing of seasonal events at those times of year when reliable seasonal timing cues are not available. Circannual rhythms appear to be most strongly involved in the control of migratory disposition and moult in equatorial migrants that live for about 6 months each year in a tropical environment where seasonal environmental changes are absent or highly variable. However, they also occur in some short-distance migrants and even in entirely resident species such as the Crested Tit *Parus cristatus*. In migrants, timing of seasonal activities is not the only function of circannual rhythms. Nocturnal migratory restlessness of caged first-year warblers shows a seasonal pattern similar to the changes in average migratory speed of free-living conspecifics during their actual migration. Moreover, when warblers of various species, which normally migrate over different distances, are maintained in cages, corresponding differences are found in the duration and amount of migratory restlessness. These differences are related to the distance normally covered by the birds on their actual migration: the longer the distance between breeding grounds and winter quarters, the greater the intensity of autumnal migratory restlessness observed in the caged birds. These results suggest that the time course and distance normally covered by these warblers during their first autumn migration may be controlled, at least in part, by a circannual programme determining the seasonal time course and total intensity of migratory unrest and, hence, that a circannual clock may be part of these birds' navigational system.

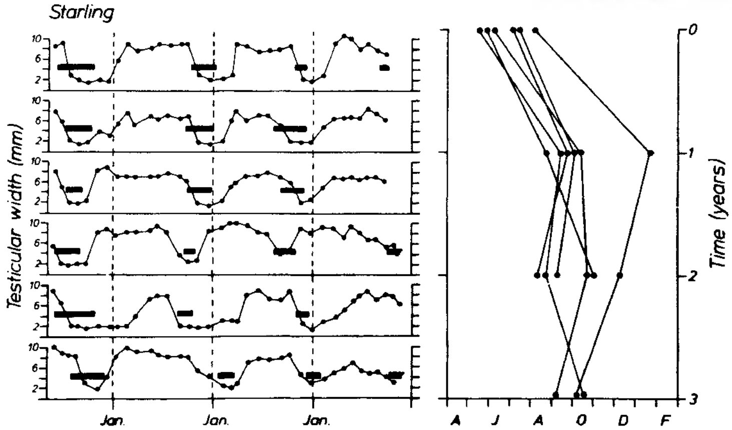

Fig. 3. *Left*: Variations in testicular width (curves) and occurrence of moult (black bars) of 6 European Starlings *Sturnus vulgaris* kept for 43 months under an 11:11 (upper three) or a 12:12 (lower three) hour light-dark cycle.

Right: Symbols connected by lines indicate dates at which the same birds began to moult in the successive years of the experiment. Note the persistence of the rhythms under these seasonally constant conditions and the deviation of the period of the rhythms from year to year. (After Gwinner 1981).

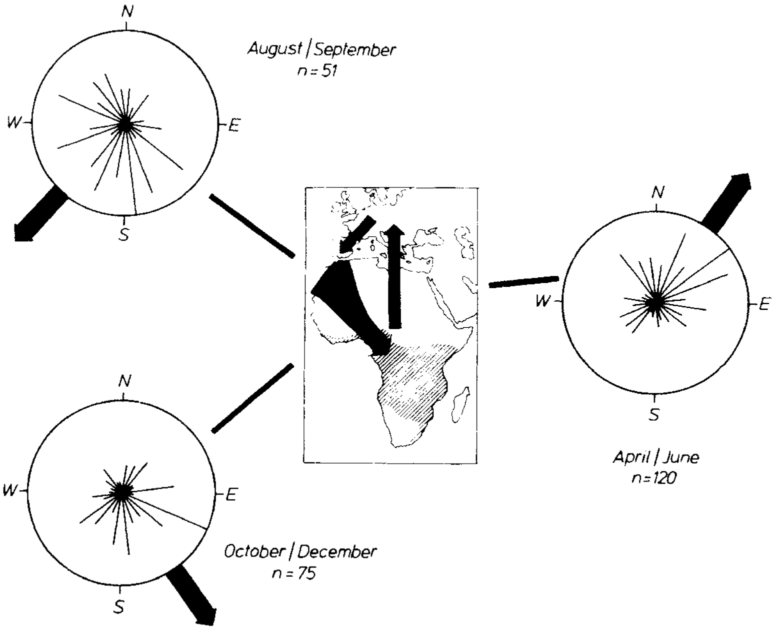

Fig. 4. Spontaneous seasonal changes of directional preferences in Garden Warblers *Sylvia borin* during nocturnal migratory restlessness. Garden Warblers were kept throughout the experiment under a constant 12:12 hour light-dark cycle and tested repeatedly in circular orientation cages. The birds had no view of the sky but were exposed to the natural earth's magnetic field. The three circular diagrams summarize the results obtained in August and September (*upper left*), in October through December (*lower left*) and in April through June (*right diagram*) of the following year. The data are plotted on a relative scale such that the radius equals the greatest amount of activity in any one 15° sector. The large arrows at the periphery of the diagrams show the direction of the mean vector calculated for each test series. Numbers in the diagrams refer to the number of tests. The map in the centre shows schematically the changes in migratory direction known to occur in Garden Warblers in the wild in the course of the year (After Gwinner & Wiltschko 1978, 1980).

Even the directional component of migration appears to be affected by a circannual rhythm. If Garden Warblers are maintained under a constant 12-h-photoperiod and tested repeatedly in orientation cages for directional tendencies of their nocturnal migratory unrest, they show changes in their directional preferences corresponding to the changes in migratory direction of free-living conspecifics (Fig. 4). This suggests that the shifts in migratory direction occurring in these birds along their way to and from their winter quarters may not be controlled primarily by exogenous cues but rather be the result of spontaneous circannual changes in the birds' internal physiological state. E.G.

RICE BIRD: alternative name for the Bobolink *Dolichonyx oryzivorus* (see ORIOLE (2)).

RICHMONDENINAE: see EMBERIZIDAE; CARDINAL-GROSBEAK.

RICTAL: pertaining to the gape; often applied to bristles in that area.

RIDING: young on parents' backs, see CARRYING.

RIFLE-BIRD: substantive name of species of *Ptiloris* (see BIRD-OF-PARADISE).

RIFLEMAN: *Acanthisitta chloris* (see under WREN (3)).

RINGDOVE (or RINGED DOVE): name (also 'Ring-dove', 'Ring Dove') applied to the so-called *Streptopelia 'risoria'*, a domesticated variety of one of the subspecies of *S. decaocto*; liable to confusion with 'Ring Dove' (etc.) used as an alternative name for the Wood-pigeon *Columba palumbus* (see PIGEON).

RINGING: see MARKING.

RINGNECK: substantive name sometimes used for the 2 Australian parrots of the genus *Barnardius*; not to be confused with Ringneck(ed) Parakeet, sometimes used for Rose-ringed Parakeet *Psittacula krameri* (see PARROT).

RING OUZEL: *Turdus torquatus*, a western Palearctic THRUSH of mainly montane distribution.

RING-SPECIES: term (for which R. Meinertzhagen has alternatively suggested 'rejungent species') expressing the concept that a species may differentiate into a graded series of geographical forms and that extreme members of the series may later come into direct contact, through range expansion, and then prove to be so different from each other as to behave as separate species; this occurs in that fraction of the total range in which both forms are found, whereas elsewhere (the long way round the ring, so to speak) they remain connected by intermediate forms. In such a case, when the extreme forms are recognized as separate species, the allocation of intermediates as subspecies of one or the other becomes somewhat arbitrary. Examples are to be found in *Parus major/minor*, *Lanius schach/tephronotus*, *Pycnonotus barbatus/tricolor/capensis*, *Acrocephalus arundinaceus/stentoreus*, *Apus apus/pallidus*, *Merops superciliosus/philippinus* and *Larus argentatus/fuscus*. See also ISOLATING MECHANISM; SPECIATION; SPECIES; SUBSPECIES.

RITUALIZATION: the evolutionary process responsible for the origin of displays and for the changes which occur in these to make them more effective in evoking the appropriate behaviour in the partner (see DISPLAY). For example, displacement preening movements have been incorporated into the male courtship display of ducks (see DISPLACEMENT ACTIVITY): in some species they have been reduced so that they can no longer make any contribution to feather care, and instead simply draw attention to features such as the 'sail' of the Mandarin drake *Aix galericulata*. The formal pointing movement, made more conspicuous by this enlarged feather ('morphological enhancement' of the display) serves purely to influence the behaviour of others. Ritualization also plays a role in the evolution of inter-specific signals, such as the 'broken wing' display of certain waders, which serves to draw predators away from the nest or chicks (see DISTRACTION BEHAVIOUR).

This article concentrates on the ritualization of visual displays; similar principles apply to the evolution of auditory signals. Explanation of this process requires description of the various types of change which are found to occur during the evolution of displays, and the analysis of the reasons for them and of the mechanisms involved. The functional analysis of the changes involves two distinct problems. Where a display modifies the behaviour of a member of a different species (as in anti-predator displays) so that the interests of the partners in the interaction are opposed, the evolutionary changes must make the display better able to tap a pre-existing responsiveness in the partner. For instance, the eyespot displays of certain moths tap an avoidance response in small birds which must be of benefit to these birds in interactions with predators. Here, selection must fit the display to a feature-detecting mechanism which is maintained by independent selective forces. In contrast, when displays operate within a species, or between species that compete for resources, it is not always obvious what selective forces determine the pattern of responsiveness of the reacting individuals. One possibility is illustrated by aggressive displays. These operate in some instances to allow opponents to assess their chances of success in combat with the rival, and in this case the reactor should respond to cues which provide reliable information about the rival's fighting ability. The selection acting on the display, enhancing the apparent potential of the displaying animal, will be opposed by selection on the reactor, making it unresponsive to bluff. An alternative possibility is illustrated by parent–offspring interactions where the interests of parent and offspring are in harmony. Here, the responsiveness of the reactor to signals may be constrained by general features of its perceptual system, and the fact that signals must be detected against a particular background. Within these general constraints, any appropriate changes in the responsiveness alone, or the signal alone, or changes in both together (providing they were compatible) might benefit the partners. In this situation we have no idea what factors determine which change, or combination of changes, will occur.

Black-headed Heron *Ardea melanocephala* greeting display at nest. (*Photo: J. Taylor*).

The types of change that have occurred in displays over the course of evolution are well known as a result of 'comparative ethology'. Comparison of the behaviour of many species from a family or smaller taxonomic group allows us to infer the origin of many of the components of their displays, and the way in which they have evolved. For example, in the Estrildid finches, males of many species carry a grass-stem in their bill during courtship. This originated as an element of nest-building behaviour, and in the Red-browed Finch *Aegintha temporalis* the stem is carried throughout courtship and copulation, and may subsequently be built into the nest. In other species, which drop it before copulation, it becomes symbolic rather than functional behaviour, and in the Crimson Finch *Neochmia phaeton* it is entirely symbolic in nature, since the type of stem chosen for the courtship dance is different from the material chosen for nest building. Among the other groups which have received particularly intensive comparative study are the gulls, gannets and boobies, weavers, ducks, finches and buntings.

Comparative work has shown that displays arise from a variety of sources: intention movements of locomotion, attack or escape and nest building; displacement activities such as preening or feeding; and autonomic responses such as feather raising. Ritualization has produced changes in the speed of performance of motor patterns, the omission or differential exaggeration of components or other changes in their detailed co-ordination, and the development of rhythmic repetition of elements. Displays may also evolve a 'typical intensity' rather than vary in intensity with the underlying motivation. Associated with these changes may be the development of morphological structures which emphasize the displays. Since the changes are all of the sort which make the display conspicuous to the human observer, it seems likely that they increase its conspicuousness to the reactor, but there is little direct information on this point. Hailman's (1977) demonstration, that the winter plumage colours of bay and sea ducks (Aythyinae) fit the particular requirements for signals visible against the background of the water surface, shows what can be done for the static colour-badges which enhance displays, but there is no equivalent work on the properties required for conspicuousness in the actions themselves.

Often, ritualization increases the appearance of formality in an action (leading ultimately to such elaborate behaviour as the courtship dance of the Great Crested Grebe *Podiceps cristatus*). In some cases (for example, the 'strut display' of the Sage Grouse *Centrocercus urophasianus*) the display has become highly stereotyped, but not all displays are as stereotyped as was once believed. Detailed film analysis of a few displays has revealed unsuspected variation in the presence or intensity of elements, so that earlier descriptions of these as unitary displays involved oversimplification: this fine variation was related to the stimulus situation and the motivation of the displaying animal. While the displays in question came from the lower vertebrates, analogous examples in birds may include the 'song spread' display of the Carib Grackle *Quiscalus lugubris* (in which independent variation of beak and wing elevation is related to the sex of the partner), and also the 'upright facing away' display of the Laughing Gull *Larus atricilla* (in which two forms of the display, differing in whether the brown hood is hidden from the partner, are used differentially in sexual and aggressive contexts). Use of film and videotape should make possible a more thorough analysis of ritualized displays than was possible with the eye alone, but the underlying problem is one of pattern-recognition, and cannot be solved by simple measurement. However, it is clear that the appearance of formality in many ritualized displays need not be synonymous with their stereotypy.

A more dramatic change which has sometimes occurred as a result of ritualization is the transfer of signal function from one structure to another. The Greater Bowerbird *Chlamydera nuchalis* presents a conspicuous patch on the back of its head to the female as it manipulates the objects in its bower, and the objects themselves play little part in its display. But in the Fawn-breasted Bowerbird *C. cerviniventris*, the head-patch has been lost (although the movements for its presentation remain) and presentation to the female of the objects in the bower plays a much more important role in the display. With the transfer of display function to the bower, this species has been able to respond to predation pressure by losing the conspicuous male plumage, so that male and female are alike.

This example illustrates the point that even when used for communication within a species, ritualization must involve response to several selection pressures: predation pressure will limit the evolution of conspicuous displays and unwieldy ornaments; selection for interspecific divergence may occur where closely-related species occupy the same habitat and, within the species, there may be selection for contrast between two displays (for example, aggressive and appeasement displays are often antitheses of one another). The habitat will influence the types of action available as a starting point for ritualization (for example, the importance of bathing and cleaning movements in duck displays can be understood in the context of their aquatic display), and constraints arising from existing displays will also influence the direction of future evolution. For example, the symbolic carriage of nest material in estrildid courtship displays is a modification of earlier displays in which the material was functional.

Blue-footed Booby *Sula nebouxii* greeting display. (*Photo: F. Pölking*).

It has been argued that the further evolution of a display is also constrained by its underlying motivation: for example, that selection will act by changing the strength of aggressive or fearful tendencies underlying a threat or courtship display rather than modify the display as a unit. (This interpretation is based on the 'conflict hypothesis' of display; see AMBIVALENCE.) But we know much less about the evolutionary changes in the motivation of displays than about changes in their form, and the possibility that phylogeny constrains displays in this way should not lead to the neglect of current selective forces which might be responsible for the constraints. The conflict hypothesis makes sense of the phylogeny of many displays, but it is not yet certain that, in its present form, it provides the best interpretation of their causation; and the possibility that during the course of evolution the elements of displays have become divorced from their original motivation (the process of 'emancipation') must also be considered. There is little direct evidence on these points, and statements about the motivational changes underlying ritualization must still be considered tentative. P.G.C.

ROA: former Maori name for a bird that may have been *Apteryx haasti*,

Black-headed Gulls *Larus ridibundus* greeting display. (*Photo: H. Schouten*).

as some authorities have concluded, or possibly a late surviving species of Dinornithiformes (see MOA).

ROADRUNNER: substantive name of *Geococcyx* spp. (see CUCKOO).

ROATELO: in the plural ('roatelos'), alternative general term for the Mesitornithidae (see MESITE).

ROBIN: commonest name in Britain today for *Erithacus rubecula*, the more formal alternative 'Red-breast' having become an almost pedantic usage. From this original source, the name has been transplanted to other parts of the English-speaking world and attached to local species actually or supposedly resembling the prototype, in being red-breasted or in other ways. Thus, in North America it is applied to the familiar *Turdus migratorius*, a larger but also red-breasted bird; and the Indian Robin *Saxicoloides fulicata* is a chat with chestnut underparts. It has also been used by ornithologists in fabricating English names for foreign species of Turdinae, either as a simple substantive name or in compounds such as 'magpie-robin', 'scrub-robin', 'bush-robin', and 'robin-chat' (see under THRUSH; also CHAT; SCRUB-ROBIN).

Outside the Turdinae, 'robin' is the substantive name used in the Australasian Region for various Muscicapinae, some of them with red breasts, e.g. *Petroica* spp. in Australia and New Zealand; and in Australia for certain Pachycephalinae, e.g. *Eopsaltria* spp. (see THICKHEAD). And it is an avicultural name ('Pekin Robin') for *Leiothrix lutea* (see BABBLER).

Further, 'robin' is misapplied in some quite unrelated groups, e.g. as a popular misnomer for the Jamaican Tody *Todus todus*, a small, dumpy, red-breasted bird (see TODY).

See photos BILL ABNORMALITIES; COMFORT BEHAVIOUR; VOCALIZATION.

ROC: see FABULOUS BIRDS.

ROCKET NET: see TRAPPING.

ROCKFOWL: substantive name of *Picathartes* spp. (see BABBLER).

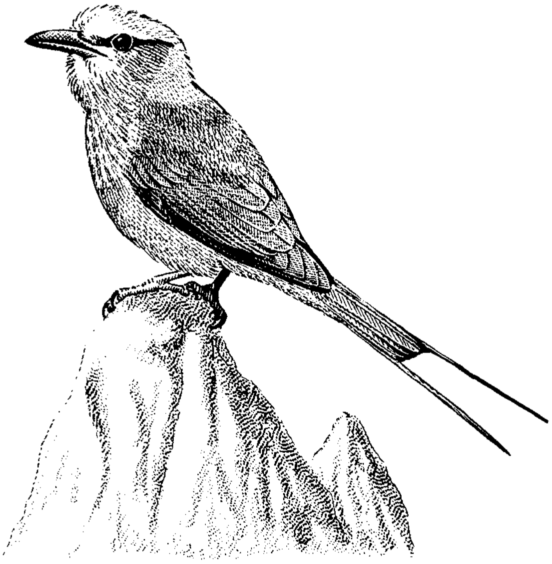
ROCKJUMPER: substantive name of *Sphenoeacus pycnopygius*, a warbler confined to arid rocky areas in south-western Africa (for family see WARBLER (1)).

RODENT RUN: see DISTRACTION BEHAVIOUR.

RODING: the territorial or patrolling flight of male birds (from the Anglo-Saxon 'rode', meaning to raid). The term is usually applied only to the characteristic twilight display flights performed by male Eurasian Woodcock *Scolopax rusticola* during the period February–July (in Britain). When roding, woodcock fly above the woodland canopy with a distinctive, deliberate wing action, uttering every few seconds a series of croaks followed immediately by a far-carrying squeak. Research with radio-tagged birds suggests that roding woodcock are not defending exclusive territories but are searching for females with which to mate. Males are successively polygynous and differ significantly in their success at locating and mating with females, but unlike other waders with polygynous mating behaviour, they do not defend either an exclusive or specific area to which females are attracted and in which mating and/or nesting takes place. Instead the male displays solitarily over an extensive area (sometimes more than 100 ha in extent) until called down by a receptive female. Then, probably to ensure that he alone copulates with her, he remains with the female constantly, close to the nest site, until the eggs are laid, before resuming display flights. G.J.M.H.

ROLLER: substantive name of the 11 species of the family Coraciidae (Coraciiformes, suborder Coracii); see also GROUND-ROLLER and CUCKOO-ROLLER. Rollers comprise 2 genera of Old World, essentially paleotropical, insectivores; species of *Coracias* are sit-and-wait predators searching from tree perches for large arthropods on the ground, and species of *Eurystomus* hawk insects in flight and are markedly crepuscular.

Characteristics. The head is large, the neck short, the legs rather short and syndactylous feet small but robust. In *Coracias* the beak is crow-like—strong, arched and hook-tipped, and in *Eurystomus* (the broad-billed rollers) it is short and wide. Flight is strong and the wings quite large. The tail is narrow and of medium length, and several species have elongated outer rectrices. Rollers are handsome birds with strong but muted colours, mainly dark blue and azure, with olive, chestnut and pink in *Coracias* and lilac and cinnamon in *Eurystomus*. The sexes are alike and juveniles resemble adults.



Lilac-breasted Roller *Coracias caudata*. (*N.A.*).

Rollers get their name from their impressive courtship flight, a fast, shallow dive from considerable elevation with a rolling or fast rocking motion, accompanied by loud raucous calls. Whether they actually somersault as has been claimed needs confirmation. Most are aggressive and readily fly at people and raptors, using the same rolling action. All are arboreal, and when *Coracias* species land on the ground in pursuit of their prey they may use a clumsy hop.

Systematics and distribution. Relationships among the coraciiform families remain controversial. There is good evidence that rollers have close affinity with the ground-roller (Brachypteraciidae) and less close affinity with the cuckoo-roller (Leptosomatidae) (both of Madagascar). Studies of anatomy, behaviour, ectoparasites, pterylosis and egg proteins suggest some affinity of rollers with bee-eaters and, decreasingly, with motmots, kingfishers and todies, hoopoes and hornbills.

Within the Coraciidae relationships are easier to discern (Fry 1978). *Coracias* comprises 8 species and systematically they fall into two groups and an isolated species. The first group are 3 large (length 33–38 cm, excluding long tail-streamers), olive-backed, full-tailed rollers: *C. benghalensis* of southern Asia, and *C. naevia* of African savannas and *C. temminckii* of Sulawesi, both of which seem to be derivatives of *C. benghalensis*. The second group are 4 lightly-built species (length range *c.* 28–30 cm) with brown backs and narrow tails: *C. garrulus* of the western Palearctic, its allospecies *C. abyssinica* of the northern tropical woodlands of Africa, the east and southern African *C. caudata* whose range borders with *C. abyssinica* along the Rift Valley, and *C. spatulata*, which is restricted to mopane and *Brachystegia* woodlands of south–central Africa and is broadly sympatric with *C. caudata*. All 3 African birds in this group have long outer tail feathers, racqueted in *C. spatulata*. The isolated roller is *C. cyanogaster*, a small azure and dark blue bird of the *Isoberlinia* woodlands north of the African equatorial rainforests, with whitish hood, black back, and short tail streamers. In the genus *Eurystomus* (length 27–30 cm) there are 3 species, and they resemble *Coracias* rollers in their raucous voices, rolling display flights, aggressiveness, and also somewhat in plumage. They hawk insects from elevated perches and have a strong, buoyant flight on rather long wings—feeding at dusk they resemble hawks or nightjars. Beaks are short, strong and very wide, and the tail is narrow and short, without streamers. *E. glaucurus* is widespread in sub-Saharan Africa and in Madagascar, a migratory woodland bird having rich brown plumage, violaceous below, with purple primaries and light blue in the tail. *E. gularis* of the African rainforest zone is very similar, and both have bright yellow beaks. *E. orientalis* is larger, dusky blue with scarlet beak and legs, and is distributed in 11 races from New South Wales to Nepal and through China north to 50°N on the lower Amur R.; a white patch showing conspicuously in flight gives it the name Dollar-bird.

Distribution, habitat and movements. The habitat is varied tropical woodlands and all types of open country from thornveld in South Africa to parks, cultivated fields and suburban gardens in the tropics, grassy hillsides with scattered trees, plains, scrubland and forests in Europe, Asia and Australia. Rollers breed from about 60°N in the west Palearctic and 50°N in the east, south to about 30°S in Africa and 35°S in Australia, being absent only from desert regions and from central and north-west Europe. Most species are migratory, and move by day. From Europe and south-west Asia *C. garrulus* migrates to winter, exclusively, in open country from tropical Africa to the Cape. Madagascan *E. glaucurus* winter in south-east Africa. High-latitude populations of *E. orientalis* migrate towards the Equator and the species winters in India, south-east Asia and Indonesia between the Tropic of Cancer and Java and New Guinea.

Food. *Coracias:* large arthropods taken on the ground—mainly beetles (93%) in Asia, and grasshoppers and crickets (27%) and ants and termites (40%) in Africa; also mantises, bugs, cockroaches, centipedes and scorpions. Rarely slugs, frogs, small lizards and birds; also grapes, figs and other small fruits. *Eurystomus:* insects taken in flight, mainly beetles in Asia and ants and termites (80–95%) in Africa. Occasionally they take prey from trees or the ground—molluscs, centipedes, spiders, small frogs and fruits (Thiollay 1971).

Behaviour and voice. In monogamous pairs for most of year and family parties after breeding; but *C. naevia* is reportedly more gregarious. Some rollers form small loose flocks during migration; *Eurystomus* also congregates to feed at a hatch of flying termites. Otherwise, rollers are strongly territorial when breeding, and probably also on their wintering grounds. The voice is a harsh, guttural *aaa–aaaaa*, repeated in a frenzied staccato during courtship flights. Birds call periodically several times an hour, perched or flying, often in response to each other. Intense calls are accompanied by a lively bowing.

Breeding. Rollers nest in holes in trees and bamboos, in hollow stumps, old walls, cliffs and mud-banks; feathers or a few chips of rotting wood may be added as nest-lining. Eggs are glossy white, subspherical; 4 is the commonest clutch at both low and high latitudes. Both sexes incubate and feed the young. The incubation period is 17–19 days (data for 3 species only); the nestling period is not known but is not less than 20 days.

ROLLER CANARY: see CAGE BIRD.

ROOK: *Corvus frugilegus* (see CROW (1)).

ROOKERY: primarily a nesting colony of Rooks *Corvus frugilegus*; but applied to colonies of some other birds, including penguins (Spheniscidae).

ROOKOOING: the production of a bubbling sound by the male Black Grouse *Tetrao tetrix* at the LEK.

ROOSTING: derived from an old German word meaning 'a sleeping house for fowls', the term has often been used synonymously with SLEEPING, but while roosting birds usually sleep, at other times they simply rest. Roosting also includes the act of going to or taking up a roost, i.e. travelling, gathering and establishment of site.

Roosting has also been confused with 'loafing' (Amlaner and Ball 1983), a term stemming from a German word for tramp or vagabond, and meaning 'to spend time idly'. In contrast to loafing, the main purpose of roosting is for sleep. Loafing also includes activities involved in COMFORT BEHAVIOUR and digestion. Although loafing flocks almost inevitably include sleeping birds, they do not always form for sleeping, and hence are not always roosting flocks. Birds may loaf at any time of day or night, singly or communally, between periods of any sort of activity, notably feeding. As in roosting, birds may use habitual loafing sites, and resort to them from some distance. Some categories of birds, e.g. immatures, non-breeders and off-duty breeders, may loaf at times when other birds are occupied with parental duties (see CLUB). The off-duty bird may also loaf at the nest-site, while its mate may loaf whilst sitting on the nest itself. In general, the use of the term loafing should be encouraged wherever quiescent behaviour does not have a strictly roosting function (N.J. Ball).

Several recent papers discuss the functions of communal roosts, and observations on particular species are scattered throughout the literature; for reviews see Ydenberg and Priss (1981), Amlaner and Ball (1983). Roosting habits of Western Palearctic species are summarized in Cramp and Simmons (1977 *et seq.*). Most recent papers dealing especially with roosting refer to timing, thermal benefits and shelter, censusing, and pest control.

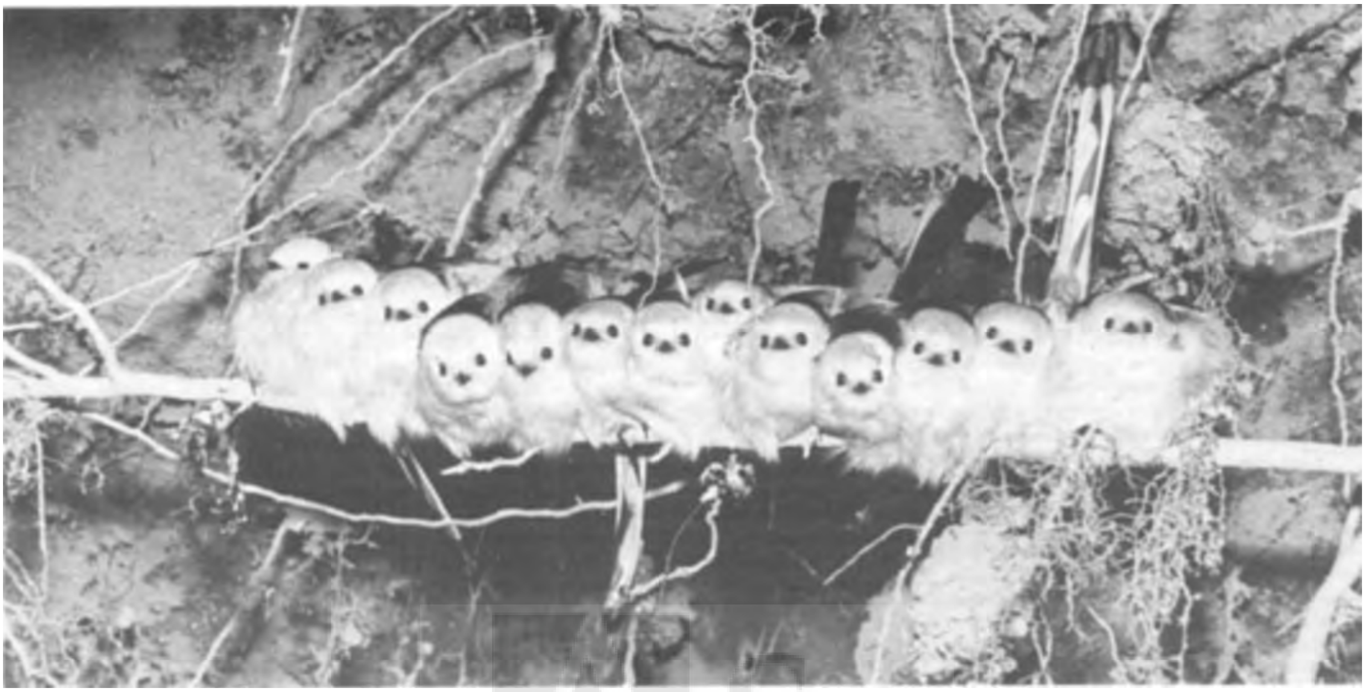
Times of roosting. The times of day when birds roost are adapted to their other activities, especially feeding. Unless sick, birds generally roost only when there is nothing more important to do, such as feeding or defending a territory, or when temporary (weather) conditions preclude their normal activity. Most species accordingly roost at night, although night feeding species roost during the day. Waders (Charadrii) and wildfowl feeding in the inter-tidal zones may, depending on the state of the tide, roost either during the day or at night, as they feed largely by touch and can find food in the dark. Other species are known to feed nocturnally, for example, swans (on submerged vegetation), some diving ducks (e.g. Pochard *Aythya ferina*) and Sooty Terns *Sterna fuscata*. Tits (*Parus* spp.), have been observed feeding by the light of street lamps.

Birds roost for a shorter time in summer than in winter, but even in the continuous daylight of high latitude summers they spend periods asleep, some species sleeping sporadically throughout the 24 hours, but others at a particular time, usually around midnight (see SLEEP).

Precise timing. As times of sunrise and sunset change throughout the year, so do the times at which birds roost. Some authors claim a characteristic light intensity for awakening ('Weckhelligkeit') for each species but this term does not seem very useful for, although there may be thresholds below which activity normally ceases, prolonged studies show that these threshold intensities change gradually with the season. Moreover, experiments in which birds were kept under constant conditions showed that they retain a sleeping rhythm similar to their natural one, at least for a few days. Seasonal changes in timing of roosting are most obvious at high latitudes, e.g. northern Scandinavia, where in the middle of winter passerines awaken and retire at far lower light intensities than in summer. This is presumably due to the amount of time they require to find sufficient food relative to day length, as food reserves of many passerines may only just exceed their requirements for a single night in extreme conditions (extreme conditions may also pertain during long tropical nights). For example, in temperate latitudes Murton *et al* (1963) have shown that Woodpigeons *Columba palumbus* need to spend 95% of available winter daylight feeding.

Superimposed on these general seasonal changes are day to day variations, due in part to weather, particularly if this affects light intensity. Several brief studies have referred to this aspect, but none of them adequately. The researchers have tended to concentrate on the effects of minor factors, such as temperature, even though the influence of major factors, such as light intensity, are as yet little understood. Moreover, they often overlook the fact that cloudy days are, on average, both darker and warmer than clear days. Unpublished evidence suggests that birds use both their knowledge of the time of day at which it generally 'gets dark' (from their 'internal clock', see RHYTHMS AND TIME MEASUREMENT) and the prevailing light intensity to predict when it will 'get dark' on a particular day, and therefore by what time they need to be at the roost. It is then reasonable to suppose that other factors would determine their response to this prediction, so that individuals which had, early on, found sufficient food would be likely to play safe, and arrive earlier at their roost than those that were still hungry. Similarly, it is known that birds flying long distances to a roost will leave their feeding ground earlier on darker days and on days when they must fly into the wind.

Dawn chorus. A number of papers refer to dawn awakening, particularly the relative times at which different species start to sing in the (spring) dawn chorus. The times, and light intensities, for these onsets of song also vary seasonally and daily. In a series of experiments Kacelnik (1979) has investigated the reasons for the dawn chorus and its timing in the Great Tit *Parus major*. He considers the dawn chorus to be a special case of a 'trade-off' between the competing demands of feeding and territorial defence. Thus the dawn chorus of Great Tits occurs at a time of



Long-tailed Tits *Aegithalos caudatus* in winter roost in December, southern Primorskiy, USSR. (*Photo: Y. Shibnev*).

day when low light intensity and low temperature (affecting prey mobility) reduce feeding efficiency, while territorial intrusions are at their peak and vocal defence of territory, by song, is more effective due to enhanced sound transmission (poor visibility militates against visual display). Kacelnik concludes that no single factor hypothesis can explain the timing of the dawn chorus.

Roost site. Birds have two basic requirements of a roost site, namely, protection from predators and shelter from the elements. Holes are presumably both safe and warm. City centres are warmer than surrounding land (1.4°C warmer, and drier, in London), while street lights may permit birds to find roosting perches later (if they can see adequately by street lighting), or even serve as warm roost sites themselves, while the better lighting should aid detection of predators. Wildfowl and many seabirds tend to roost on islands, on the water or in open sites where predators can approach them less readily. Many ground-feeding birds roost either in the open or perch on low branches, out of the reach of foxes *Vulpes* spp. and other predators. Many species roost as solitary individuals. The nest site may be an important roost both prior to, as well as during, nesting (incubating birds are often asleep). In communal roosts the alarm calls of the more alert individuals may often function to warn their companions of danger, as with quails *Coturnix* spp. which roost in grouped circles, each individual facing outwards. The fine structure of roosts, for group or communal roosting species, may be important, as birds at the centre of a line or group are presumably less vulnerable to predation. Swifts *Apus apus* may pass the night on the wing, although they also use more conventional sites, such as the nest.

Shelter is needed to help the bird maintain its body temperature, as it must burn food reserves during the night which it cannot replenish until morning. Small birds, with a large surface to volume ratio, lose heat more rapidly, and particularly in cold climates. Those that roost in holes have the advantage that the heat they lose warms the air around them, but even roosting under cover, such as in a conifer wood, can appreciably reduce heat loss by radiation. Several species of grouse tunnel out roosts under snow. More important, however, is shelter from rain and wind, which reduce the insulative benefits of fluffing up the feathers and thereby lead to more rapid chilling. Swingland (1977) has shown that communally roosting Rooks *Corvus frugilegus* apparently compete for sheltered sites: the more dominant older birds force younger individuals, which also have lower food reserves, from the higher, more sheltered sites to lower, more exposed ones; those lower sites may also incur greater risk from predators. Yom-Tov (1979) has shown that birds low down in a communal roost may have the water-repellent properties of their feathers seriously impaired by droppings from those roosting above them. Small waders may roost among larger species, using them as 'windbreaks'. In extreme cold weather some species may huddle closely together, e.g. Long-tailed Tits *Aegithalos caudatus*, treecreepers, wrens, swifts, Australian wood-swallows (Artamidae), Emperor Penguins *Aptenodytes forsteri*, Bobwhite Quails *Colinus virginianus* and many others. Hummingbirds may also roost in enclosed spaces, but have a remarkable ability, rare among birds, of becoming nocturnally torpid, their body temperature dropping to as low as 4°C. Reducing the temperature difference between their body and the environment also reduces their energy loss, thus helping them to survive long cool nights and live in areas they could not otherwise inhabit (see TORPIDITY).

Communal roosting. Many territorial species roost within their territory boundary during the summer, and some during winter too. Outside the breeding season birds that feed in flocks generally roost communally, e.g. Rooks, Starlings *Sturnus vulgaris*, finches, hirundines (Hirundinidae), pigeons and many waders. Some relatively unsociable feeders may also congregate to roost, e.g. the Pied or White Wagtail *Motacilla alba*. Terns form communal roosts just prior to the breeding season, where courtship and copulation may take place. Large mixed roosts of several species are not uncommon, e.g. Starlings, Common Grackles *Quiscalus quiscula*, Brown-headed Cowbirds *Molothrus ater* and Red-winged Blackbirds *Agelaius phoeniceus* in North America. Waders for example, roosting communally on a tide-island in an estuary, may simply resort to the safest site available from their dispersed feeding areas. In other instances, however, the reasons for communal roosting are much less obvious. Starlings, for example, often roost near their feeding sites in autumn, but desert these in winter in favour of larger roosts that may be 50 km or more away. These sites may be used year after year. It is difficult to assess the numbers of birds using them, but some Starling roosts contain several hundreds of thousands, while the Quelea *Quelea quelea*, a serious pest of grain crops in large parts of Africa, collects at night into roosts of millions (see QUELEA CONTROL). Many species that roost communally perform spectacular aerobatic displays around the roost, and often have conspicuous staging posts ('pre-roost gatherings') where groups congregate before a mass entry into the roost. Such displays may act as visual markers, locating the present roost site for birds unfamiliar with it; this could be particularly useful if unpredictable disturbance, e.g. predators, should alter the precise location of a roost from one day to the next. Similarly, there are typical sequences of behaviour for dawn emergence, and the mass dawn exits of Starlings, at 3- or 4-minute intervals, even produce spectacular patterns of radially dispersing 'rings' on RADAR screens. The larger communal roosts may contain so many birds that vegetation is damaged, even destroyed, either by physical damage or by the toxic effects of accumulated droppings; in exceptional circumstances this may cause serious local problems to man, e.g. in city centres, or to forestry and agriculture.

It seems unlikely that predator avoidance is responsible for the enormous total numbers in the larger roosts, and there has been much speculation as to their likely function. An attractive hypothesis, proposed by Ward and Zahavi (1973), suggests that these roosts serve as 'INFORMATION CENTRES' as to where to find food locally. They point out that communal roosts are normally composed of species whose food is patchily distributed, locally super-abundant and ephemeral, so there is accordingly no advantage to be gained from trying to 'defend' such a food source, nor in 'keeping its location quiet'. Conversely, birds not knowing of such food sources would gain from following others to feeding sites. In these circumstances (patches of super-abundant, ephemeral food) all individuals could benefit from the pooled information. Cheating (trying to keep a patch quiet, but still knowing about those of others) would be difficult and, if the patches are ephemeral, risky. Accordingly, a system of mutual benefit might persist due to advantages accruing to individuals. (For Posture see SLEEP.) P.J.B.

ROSEFINCH: substantive name of most species of *Carpodacus*, a Holarctic and mainly montane genus of finches (for family see FINCH).

ROSELLA: substantive name of the Australian *Platycercus* spp. (Psittacinae, Platycercini) (see PARROT).

ROSTRATULIDAE: see CHARADRIIFORMES; PAINTED SNIPE.

ROSTRUM: the bill or beak (see BILL); adjective, 'rostral'.

ROSY-BILL: *Netta peposaca* (see DUCK).

ROULROUL: *Rollulus roulroul* (see under PHEASANT).

r-SELECTION: see K-SELECTION.

RUBY: *Clytolaema rubricauda* (for family see HUMMINGBIRD).

RUBY-CHEEK: name, alternatively 'Ruby-cheeked Sunbird', of *Anthreptes singalensis* (see SUNBIRD).

RUBYTHROAT: substantive name of some *Luscinia* spp. (for subfamily see THRUSH).

RUFF: name of *Philomachus pugnax* as a species; also a term particularly for the male, the female then being termed 'reeve' (see SANDPIPER). See photo LEK.

RUKH: see FABULOUS BIRDS.

RULES: statements formulating what appear to be regularities in natural phenomena, e.g. in the correlation of morphological variation with geographical, climatic, or other factors—e.g. ALLEN'S RULE; BERGMANN'S RULE; GLOGER'S RULE.

RUMP: see TOPOGRAPHY.

RUNNING: see LOCOMOTION, TERRESTRIAL; LEG.

RUSH: a fall of birds on migration (see FALL).

RUSHBIRD: substantive name of *Phleocryptes melanops*, a South American furnariid (see OVENBIRD (1)).

RYNCHOPIDAE: see under CHARADRIIFORMES; SKIMMER.

S

SABREWING: substantive name of *Campylopterus* (including '*Pampa*') spp. (for family see HUMMINGBIRD).

SACRUM (adj. **SACRAL**): the part of the vertebral column between the lumbar and caudal portions (see SKELETON, POST-CRANIAL).

SADDLE: term used where the colour of the upper surface of the wings continues across the mantle without a break. See TOPOGRAPHY.

SADDLEBACK: *Creadion* ('*Philesturnus*') *carunculatus* (see WATTLEBIRD (2)).

SADDLEBILL: sometimes used alone as the name of the Saddle-billed Stork *Ephippiorhynchus senegalensis* (see STORK).

SAGITTAL: in the median longitudinal plane of the body, e.g. a section from head to tail in the mid-line; the 'sagittal suture' is the junction of the parietal bones of the skull.

SAGITTARII; SAGITTARIIDAE: see under ACCIPITRIFORMES; SECRETARY-BIRD.

SAHEL ZONE: the belt of grassland with trees (savanna) and thorny scrub which lies immediately south of the Sahara, and which is subject to drought.

SAKABULA: *Euplectes progne* (see WEAVER).

SAKER: *Falco cherrug* (see FALCON).

SALIVARY GLANDS: see ALIMENTARY SYSTEM; TONGUE.

SALPORNITHIDAE: family of PASSERIFORMES, suborder Oscines; CREEPER, SPOTTED.

SALTATOR: generic name used as substantive name of *Saltator* spp. (see CARDINAL-GROSBEAK).

SALT GLAND: alternatively 'lateral nasal gland' (see EXCRETION, EXTRARENAL; NARIS).

SALTING or SALTMARSH: an area of intertidal mud which has been colonized by salt-adapted plants.

SAMPLING: see BIOSTATISTICS.

SANCTUARY: see CONSERVATION.

SANDERLING: *Calidris* (formerly *Crocethia*) *alba* (see SANDPIPER). See photo LOCOMOTION, TERRESTRIAL.

SANDGROUSE: substantive name of the species of Pteroclididae (Pteroclidiformes); in the plural (unchanged), general term for the family. This mainly Afro-Asian group has affinities with the waders (Charadriiformes, suborder Charadrii) and the pigeons (Columbidae), but is best regarded as having separate ordinal rank; resemblance to true grouse (Tetraoninae) is purely superficial.

Characteristics. Sandgrouse are terrestrial birds, much like pigeons in size and shape. They vary in length from 25–48 cm, including the elongated tail feathers in the larger species; weights range from 170 g to 650 g; most are between 230 and 300 g. They are coloured in soft shades of grey, red, yellow, brown and buff, often marked with white and black. The males of most species have breast bands and all show sexual differences in coloration. Species inhabiting semi-desert tend to be paler than those of savanna habitats. The plumage is close and thick with a dense underdown, even on the apteria (see APTERIUM; PLUMAGE), which insulates the birds against extremes of heat and cold. The central tail feathers of 6 species are elongated and pointed. The wing is aquintocubital (lacks the fifth secondary remex: see PLUMAGE; WING) and has 11 primaries which are long and adapted to strong sustained flights undertaken daily to water.

Despite their short legs, sandgrouse walk and run well. Their toes are also short, sometimes partially webbed. The family includes 2 genera, *Syrrhaptes* (tarsus and toes completely feathered, hind toe absent) and *Pterocles* (tarsus feathered in front only, toes naked, hind toe rudimentary and raised above ground level). Other generic divisions based on plumage characters or drinking times are generally considered unacceptable except perhaps as subgenera which from time to time have included *Eremialector*, *Namapterocles*, *Parapterocles*, *Macleanornis*, *Nyctiperdix*, *Dilophilus* and *Calopterocles*.

Habitat. Most sandgrouse inhabit arid to semi-arid regions, including the major deserts of Africa and Asia. They prefer areas covered with stones or low shrubby growth. A few species live in rather dry savanna. The Tibetan Sandgrouse *Syrrhaptes tibetanus* is montane.

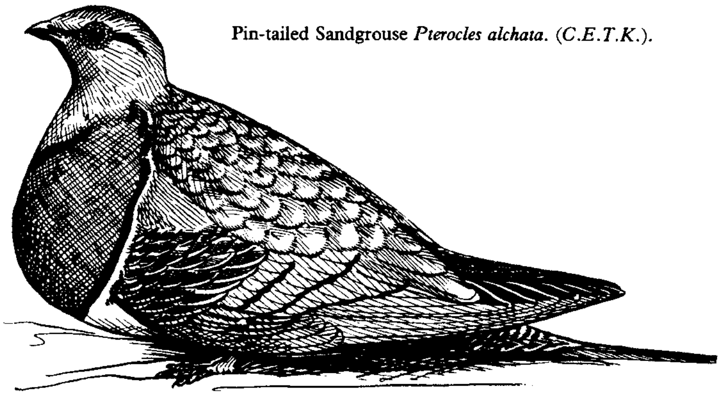
Distribution. The 14 species of the genus *Pterocles* occur in Africa, southern Europe and southern Asia, including the Indian subcontinent. *P. personatus* is confined to Madagascar. The 2 species of *Syrrhaptes* inhabit the steppes and mountains of central Asia. The main centres of sandgrouse distribution are the Sahara, the Kalahari and the deserts of the Middle East.

Movements. Most sandgrouse are resident or locally nomadic, but the most southerly populations of the Namaqua Sandgrouse *Pterocles namaqua*, the Zambian populations of the Yellow-throated Sandgrouse *P. gutturalis* and the Indian populations of the Black-bellied Sandgrouse *P. orientalis* are truly migratory. Pallas's Sandgrouse *Syrrhaptes paradoxus* of the central Asian steppes has undergone eruptive 'migrations' in certain years as far west as Britain and nearly as far east as Peking (see IRRUPTION). British immigrants remained and bred, although they are unlikely ever to have become established.

Food. All sandgrouse feed mainly on small hard seeds picked up from the ground. They may sometimes take small bulbs, green leaves, shoots, berries and even insects (termites and ants) especially during the breeding season. Grit is eaten for grinding food in the gizzard. The largely dry food necessitates daily drinking, particularly in hot weather. Drinking times are regular and species-specific (either in the morning or at dusk). Ten species are morning drinkers, 4 drink at dusk, and 2 are said to drink both morning and evening, but this needs confirmation. A few individuals of both kinds of sandgrouse may drink twice a day—probably mainly birds that have been incubating in the hot sun during the day, since most evening drinkers of morning-drinking species appear to be females.

Sandgrouse drink by taking a draught of water into the mouth by sucking once or twice and then raising the head to swallow (see DRINKING); this process is repeated up to 10 times but takes just a few seconds. When the crop is full the bird flies directly away from the water unless it is a member of a mated pair whose mate is still drinking: then it waits until the two can fly away together.

Behaviour. Although sandgrouse pair off monogamously when breeding, they are all highly gregarious, especially when gathering to drink.



Pin-tailed Sandgrouse *Pterocles alchata*. (*C.E.T.K.*).

The birds call in flight as they travel to the waterholes, thereby attracting others of the same species (and sometimes other species) along the way, until drinking flocks may number thousands of birds. Sandgrouse may fly up to 80 km to water each day (a round trip of 160 km) at a cruising speed of about 70 km/h. Depending on the species, the birds may land right at the water's edge (or even in the water), drink quickly and depart at once, or they may assemble some distance from the water and then fly or run down to it once the coast is clear. Both these methods reduce the possibility of attack by predators.

Voice. Sandgrouse calls are characteristic whistles or clucks, usually in phrases of two, three or more syllables. These calls are most often heard in flight, but other quieter calls are also heard from birds on the ground.

Breeding. Sandgrouse pair off during the breeding season which is largely determined by rainfall and the resulting adequate food supply. The nest is a shallow scrape on the ground, usually out in the open, but sometimes against a stone, shrub or grass tuft. The scrape is sparsely lined with small stones or bits of dry vegetable matter gathered by the parents during incubation. The clutch is almost invariably 3 eggs, rounded at both ends, coloured dull pinkish or greenish and more or less heavily marked with grey, brown and olive. The female incubates by day and the male by night; both sexes have a brood patch.

The eggs hatch after 21–31 days. The downy chicks leave the nest as soon as the last to hatch is dry, following the parents to forage for seeds. They are not fed at all by either parent, but are shown food by the parents pecking at suitable items. They are provided with water by a unique mechanism. The male soaks his belly feathers during his daily drink and the chicks take the water from his wet plumage on his return. He adopts an upright 'watering posture' which exposes the wet belly and attracts the chicks from their hiding places under shrubs.

Female sandgrouse seldom soak their belly feathers, probably doing so only if the male has been killed by a predator, or perhaps when the brood has reached the age at which the male's water-carrying capacity needs to be augmented by the female. The belly feathers of both sexes are specially adapted to taking up water in a bed of microscopic filaments on the inside surface of the feathers against the body, where evaporation is reduced to a minimum while the birds are in flight. Nevertheless the distance over which enough water can be carried in this way is limited to about 30 km. Young sandgrouse are watered thus until after their first moult when they fly to water like the adults. Only *Syrrhaptes tibetanus* appears not to water its young from its belly feathers, but lets them drink at open water which is freely available in streams resulting from snow-melt in their high mountain habitat; this species also lacks the specialized feather structure.

When the chicks are very young, the parents fly to water separately so that the chicks are not left unattended; from the age of about 3 weeks, they are left alone as the parents fly together to drink. The young can fly at the age of 4–5 weeks.

BELLY-SOAKING behaviour and a similar, though less well developed microscopic feather structure occurs in the closely related waders (Charadriiformes), but waders that transport water in their belly feathers do so only for cooling eggs and chicks, not for providing drinking water.

SANDPIPER: a term often restricted to the members of 2 genera (*Tringa* and *Calidris*) of long-billed wading birds (waders = shorebirds) in the family Scolopacidae (Charadriiformes, sub-order Charadrii); more broadly used to include the whole of the family of sandpipers and snipe, many of which are referred to normally by other substantive names which encompass only single species or small groups of species (as outlined below). (For reference to related families see under CHARADRIIFORMES.)

Characteristics. Members of the Scolopacidae vary in length from 12–60 cm but frequently a large proportion of this is the slender, long and often decurved bill (recurved in a few species). The bill is flexible and can be opened at the tip only (see RHYNCHOKINESIS). It is often assumed that long bills have evolved for probing but this delicate mechanism is also well suited for collecting seeds and berries. Usually sandpipers have long legs, the tibia is partially bare and the toes are long; the hallux is short, and absent in one species (Sanderling *Calidris alba*). The wings are normally long and pointed, the tail short and the neck long. In summer plumage the upper-parts of most species are a mixture of rich browns and greys and, in some species chestnut reds, the underparts being often well spotted and streaked. In winter these markings are usually lost and the upper parts are also more uniform. It is generally assumed that the plumage is cryptic and this is certainly the case in summer in the nesting habitat. However, at communal roosts flocks of Knot *Calidris canutus* can be seen for several km from the air, and clearly the plumage draws particular attention to them at this time (Ward and Zahavi 1973). Other species of flocking waders have similar plumage characteristics, though perhaps do not stand out as much as Knot.

Habitat. In the breeding season sandpipers are birds of open habitats, moorland and tundra. In the non-breeding season they are mainly gregarious and to be found in coastal areas, particularly in the intertidal regions of estuaries.

Distribution. Most sandpipers inhabit the Northern Hemisphere during the breeding season and occur into the high Arctic; the majority breed at high latitudes and several species have a circumpolar distribution. Most are highly migratory and in winter many species occur well into the Southern Hemisphere. Generally speaking, the more northerly breeding populations undertake the longest migrations and the temperate breeders the shortest migrations; these latter often winter within the breeding range whilst the former perform transequatorial migrations.

Due to their extensive distribution, it is not surprising that several species show variation in both size (often clinal) and colour (more than one morph). These have probably evolved in some cases through isolation and it is possible that some previously recognized sub-species, e.g. Southern Dunlin *Calidris alpina schinzii*, British Redshank *Tringa totanus britannica*, are hybrids derived from previously separated breeding populations. Usually there is a large degree of overlap of populations in winter quarters but some, e.g. Knot, seem to be almost totally separated, Greenland/N. Canada and Siberian populations wintering in western Europe and N. Africa respectively.

Food. During winter, invertebrates form the major part of the diet, most food being collected from, or not far below, the surface of the intertidal zone, or from shallow water. Occasionally insects are taken on the wing, and form a high percentage of the diet during the breeding season; at this time berries are also important to some species at higher latitudes. In winter a large part of the food is taken at night.

Behaviour. During feeding and roosting sandpipers mainly form single species parties or flocks, but species often intermingle, particularly when leaving the estuary roosts. All species are strong flyers and those which flock often perform complex aerial movements, which, like their winter plumage, are clearly evolved to attract attention. These flights are very spectacular and the precision with which they are performed is remarkable, particularly in tightly packed flocks of Knot.

Many species are territorial during the breeding season but others, e.g. Redshank, lack specific territorial boundaries and are semi-colonial. The pair bond is usually monogamous and, at least in some species, for life. It is established in smaller sandpipers in the first or second year of life, and perhaps as late as the third year in some species. Female Redshanks have been recorded incubating a full clutch within 10 months of hatching. Polygamy has been suggested as occasional in some species, e.g. Greenshank *Tringa nebularia*, but it is difficult to be certain of this. There is often an elaborate courtship display, beginning with a song flight (often later used in distraction display) associated with pair formation; in some species at least there are ground chases and complex pre-copulatory ceremonies. Distraction displays vary from repetition of display flight (e.g. Oystercatcher *Haematopus ostralegus*, Redshank) to 'rodent-runs' (Purple Sandpiper *Calidris maritima*) and injury feigning (Reeve *Philomachus pugnax*).

There is a great variety of call notes, from raucous squeaks to extended songs. Some species, especially snipe, also produce non-vocal sounds (see MECHANICAL SOUNDS).

Breeding. The nest is usually on the ground, often concealed in herbage, though a few species use disused nests of arboreal birds e.g. Fieldfares *Turdus pilaris*. The scrape, often made during a 'scraping ceremony' by the male in the presence of the female, is lined usually after laying the first egg and more lining is added during incubation. Eggs usually number 4, but in some cases 2 or 3. Most species have pyriform eggs, with dark brown and black markings, on a paler ground; all are cryptically coloured. Incubation normally begins with the last egg and chicks hatch almost simultaneously. Both sexes usually share incubation, though one bird often takes the greater share. Downy young leave the nest within a day of hatching and may make extensive journeys (often 1–2 km) to suitable feeding areas. The chicks crouch when alarmed and may be carried over obstacles by parent birds. The parental role varies with species. In some populations of Sanderling (Arctic Canada but not Greenland) and in Temminck's Stint *Calidris temminckii*, the female lays 2 clutches and each bird of a pair incubates a clutch; in other species e.g. Pectoral Sandpiper *C. melanotus*, only the female incubates, while only male phalaropes incubate (see PHALAROPE). Normally both parents tend chicks for at least part of the fledging period but in Pectoral and Curlew Sandpipers *C. ferruginea* only the female remains; in these cases the bird leaving the brood migrates south first, which may relieve pressure on the food supply.

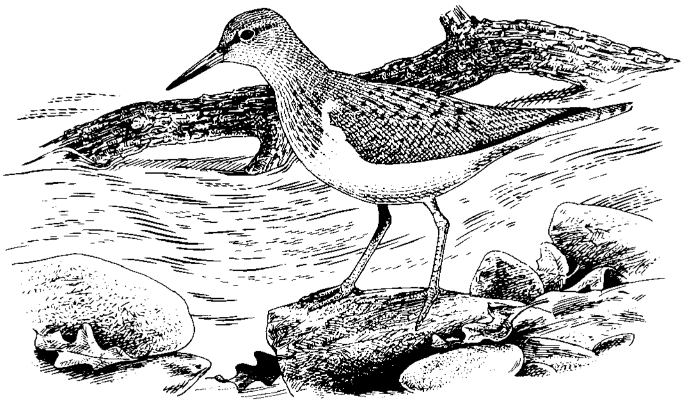
Taxonomic sub-divisions. The taxonomic sub-division of the group is based largely on skeletal structure and external morphology but has been improved by recent work on the colour pattern of downy young and studies of electrophoretic protein patterns. The sub-families recognized are: Tringinae (curlews, godwits and tringine sandpipers); Arenariinae (turnstones); Scolopacinae (woodcock); Capellinae (dowitchers and snipe); Calidriinae ('calidritine' sandpipers, the Eroliinae of some authors); Aphrizinae (Surfbird). Within the Scolopacidae there are 85 species in 27 genera.

Curlews, Godwits and Tringine Sandpipers. The curlews are the largest members of the family and are characterized by their long decurved bills. The Eskimo Curlew *Numenius borealis* is now extremely rare; however, its close relative the Little Curlew *N. minutus* is not in immediate danger in eastern Siberia where it nests in an interesting association with the Golden Eagle *Aquila chrysaetos* from which it apparently derives a degree of protection through other predators being excluded from the eagles' territories. The Eurasian Curlew *N. arquata* is the largest Palearctic species and is replaced in the Nearctic by the Long-billed Curlew *N. americanus*. The Whimbrel *N. phaeopus*, which has a circumpolar distribution, occupies a more northerly range and in North America is referred to as the 'Hudsonian Curlew'. The Slender-billed Curlew *N. tenuirostris* is now quite rare and restricted to a small area of Western Siberia. Curlews make extensive migrations, the Little Curlew, which nests in Siberia, reaching Australia.

Like the curlews, the godwits are large waders but they have long, slightly recurved bills. There are 4 species in a single genus *Limosa*, the Marbled and Hudsonian Godwits (*L. fedoa* and *L. haemastica*) being Nearctic forms whilst the Bar-tailed and Black-tailed Godwits (*L. lapponica* and *L. limosa*) are Palearctic breeders.

The Upland Sandpiper (Bartram's Sandpiper or Upland Plover) *Bartramia longicauda* is a North American species in a monotypic genus and is possibly more closely related to the curlews and godwits than to the tringine sandpipers. There are 9 species in the genus *Tringa*, the largest of which are the Greater Yellowlegs *T. melanoleuca* of North America and the Greenshank *T. nebularia* of Eurasia, both a little smaller than godwits. The Greenshank occupies a range in Eurasia intermediate between that of the more northerly Spotted Redshank *T. erythropus* and the more southerly Common Redshank *T. totanus*, though there is overlap of ranges in western Europe. In North America the Lesser Yellowlegs *T. flavipes* replaces the Redshank ecologically. Two species, the Solitary Sandpiper *T. solitaria* and the Green Sandpiper *T. ochropus*, nest in trees, in the abandoned nests of other birds, as may the Wood Sandpiper *T. glareola*.

Two species closely related to the genus *Tringa* are placed in the genus *Actitis*. These are the Common Sandpiper *A. hypoleucos* and its North American replacement the Spotted Sandpiper *A. macularia*; both occur in temperate latitudes. The Terek Sandpiper *Xenus cinereus* breeds from Finland to eastern Asia; the latter is the only area from which the Spotted Greenshank (Armstrong's Sandpiper) *Pseudototanus guttifer* has been recorded breeding. The Grey-rumped Sandpiper *Heteroscelus brevipes* and the Wandering Tattler *H. incanus* are thought by some authorities to be conspecific but their ranges overlap in Anadyrland (N.E. Siberia), and there are morphological differences of an order justifying their being regarded as specifically distinct.



Common Sandpiper *Actitis hypoleucos*. (*A.H.*).

The Willet *Catoptrophorus semipalmatus* is a large (for tringine sandpipers) species with no obvious relatives; it is an inhabitant of middle North American latitudes.

The rare Tuatamu Sandpiper (Peale's Sandpiper) *Aechmorhynchus parvirostris* is another species with no obvious present day close relatives, though 2 closely related species (one of them possibly conspecific) are now extinct, the White-winged Sandpiper *Prosobonia leucoptera* of Tahiti and the Sharpbilled Sandpiper *Aechmorhynchus cancellatus* known only from a single specimen. Like the Tuatamu Sandpiper both these latter species had a limited distribution in Polynesia.

Turnstones. From both electrophoretic studies and downy chick patterns it appears that turnstones *Arenaria* are a tringine off-shoot, rather than relatives of the plovers. There are 2 species, the Ruddy Turnstone *A. interpres*, which has a circumpolar breeding distribution mainly within the Arctic but south to the Baltic Sea, and the Black Turnstone *A. melanocephala* which is restricted to Alaska. Turnstones usually occur in small flocks on rocky shores where they often feed in the company of Purple Sandpipers. Flocks seldom exceed 100 birds and they feed mainly on invertebrates found under stones which they push over with their short, blunt bills. The bill is also used for excavation but never for true probing. Turnstones will also feed on carrion and eggs of their own and other species.

Turnstones are the most littoral of all waders and only rarely are they found far from the coast. On such occasions they remain on moss and lichen tundra in short vegetation and do not close their toes in walking as do some waders which are adapted to deeper vegetation.

Turnstones make extensive migrations and the Ruddy Turnstone can be found wintering in South America, South Africa, Australia and New Zealand.

Woodcock. Five species of woodcock are generally recognized, the European Woodcock *Scolopax rusticola*, 3 oriental species of the same genus, and the American Woodcock *Scolopax minor*, which is smaller than the European species. All have a relatively long, straight bill and the eyes are set well back on the head. The legs are relatively shorter than in most other waders, the neck is short, the body compact and the head relatively large, the external opening of the ear being below, instead of behind the orbit.

Woodcock are the only group of waders to frequent woodland; woods with damp floors on fertile mull soils with a high earthworm content are preferred. The spring display flight of the European Woodcock is known as RODING. It occurs at dusk and is an owl-like flight, much more frequently seen than the ground display of courtship which leads to coition. This display involves the male strutting round the female with drooping wings and fanned tail, but very little is known of the courtship of woodcock.

As in the snipe, normally only the female incubates, in contrast to most waders where the sexes share incubation. The eggs of woodcock tend to be more rounded than other wader species and paler in colour than most sandpipers'. The European Woodcock has been recorded on several occasions carrying the young between the legs, against the belly.

Snipe. Like woodcock, snipe have long, straight bills and relatively short legs. They often remain undisturbed until almost trodden on, even when feeding, and then flush in a characteristic zig-zag flight. They are birds of open marsh land throughout the year and seldom occur on the shore. Some species are solitary though others occur in small groups ('wisps'), but seldom in large flocks. Several species produce loud non-vocal sounds ('drumming' or 'bleating') with the outer tail feathers in flight and a similar habit has been recorded in the Little Curlew.

Snipe are birds of lower latitudes and generally do not perform extensive migrations. They are found in most temperate regions of the world; members of the genus *Gallinago* (*Capella*) of which there are 13 species occur also as visitors to southern Asia and Australia. The Common Snipe *G. gallinago* is a cosmopolitan species and is known as the Fantail Snipe in India. Like the Jack Snipe *Lymnocryptes minimus*, the Great Snipe *G. media* has a more restricted range in the Palearctic and is unique in being, apart from the Ruff *Philomachus pugnax*, the only wader with a lekking system (LEK) of courtship. Perhaps of particular interest in this group is the sub-antarctic Snipe *Coenocorypha aucklandica*, races of which occur in subsidiary islands around New Zealand; uniquely in the group, this species nests in burrows excavated by other birds; it appears to fly little and to be largely nocturnal.

Recent work has shown that dowitchers are probably more closely related to snipe than to godwits. The Asian Dowitcher *Limnodromus semipalmatus* is the only Old World species, nesting in Siberia. Most authorities now treat the American dowitchers as 2 species, the Long-billed Dowitcher *L. scolopaceus* and the Short-billed Dowitcher *L. griseus*. These nest in the Arctic and sub-arctic and perform long migrations, unlike most snipe.

Calidritine sandpipers. These are, perhaps, the true sandpipers and most are placed in the genus *Calidris*, which contains the smallest waders, the stints. The 23 species are birds of high latitudes with a circumpolar breeding distribution and because of this many perform extensive migrations; out of the breeding season they are birds of the shore and generally highly gregarious. They are known as 'peeps' in North America. Their twittering calls are not as loud as those of tringine sandpipers. The Knot *C. canutus* is the largest species, 25 cm in length, whereas the Least Sandpiper *C. minutilla* is only half this size. The most southerly breeder is the Dunlin which nests as far south as south-western England and the southern Baltic.

Most calidritine sandpipers have medium sized pointed bills, used for picking and probing. The Spoon-billed Sandpiper *C. pygmeus* of North-east Asia is exceptional in having flattened and broadened tips to both mandibles. This species feeds differently from most sandpipers, not running from place to place, but running forward often up to its belly in water, moving its bill in semi-circles in front of it. Its feeding mechanism is not clearly understood. A second exception is the Sanderling, often placed in the monotypic genus *Crocethia*; it is the only sandpiper lacking a hind toe. Whilst most calidritine sandpipers feed outside the breeding season on sandy and muddy shores, the Purple Sandpiper and Rock Sandpiper *C. ptilocnemis* feed on rocky shores often in the company of turnstones.

The most aberrant member of this group is the Ruff, so named because the male sports an erectile collar of feathers and ear tufts during the breeding season; the female (reeve) lacks these adornments and is much smaller. The male's breeding plumage is associated with communal displays on a 'hill' or LEK, to which females are attracted. The female incubates and tends the young alone and there is no permanent pair bond. In this it is unique in the Scolopacidae. The Ruff breeds right across northern Eurasia and migrates south as far as Ceylon or Cape Province.

Surfbird. Some authorities have included the Surfbird *Aphriza virgata* with the turnstones but recent work has shown that, whereas turnstones have affinities with the tringine sandpipers, the Surfbird has calidritine origins. Like turnstones, the Surfbird lives on rocky shores and its short bill suggests a convergence with the plovers. It breeds in Alaska, in mountainous regions above the tree line.

SAND-PLOVER: substantive name of some species of *Charadrius* (for family see PLOVER (1)). See photo ENERGETICS.

SANITATION, NEST: see PARENTAL CARE.

SAPPHIRE: substantive name of *Chlorestes notatus* and many *Hylocharis* spp. (for family see HUMMINGBIRD).

SAPPHIREWING: *Pterophanes cyanopterus* (for family see HUMMINGBIRD).

SAPPHIRONIA: substantive name (some authors) of *Lepidopyga* spp. (for family see HUMMINGBIRD).

SAPSUCKER: substantive name of *Sphyrapicus* spp. (see WOODPECKER).

SARMATIC: derived from the coastal fauna of the brackish or salt inland 'Sarmatic Sea' of late Tertiary and Pleistocene times, an extension of the eastern Mediterranean.

SAUROGNATHOUS: see PALATE.

SAUROPSIDA: term embracing reptiles and birds.

SAURORNITHES: name formerly used for a sub-class equivalent to the Archaeornithes (see under CLASS).

SAVANNA: also written 'savannah', a type of open country found in semi-arid regions or in those with a long dry season; term originally applied in South America but now used widely as a habitat description. For example, in Africa immediately south of the Saharan desert there is a belt of 'thorn-scrub savanna', characterized by a sparse vegetation of spiny bushes and tufted grass; south of that, where there is a substantial rainfall during part of the year, is a belt of 'grass-woodland savanna', park-like country characterized by patches of woodland and isolated trees in a general area of abundant long grass withering in the dry season.

SAWBILL: general term for the mergansers *Mergus* spp. (see DUCK).

SAW-WHET: *Aegolius acadica*, a very small North American OWL.

SAW-WING: substantive name used in East Africa for rough-winged swallows of the genus *Psalidoprocne* (see SWALLOW).

SCALY-WEAVER: name of 2 species of weavers of uncertain systematic position. For family see SPARROW-WEAVER AND SCALY-WEAVER.

SCANSORIAL: pertaining to the act of climbing, especially on tree-trunks (see LEG; LOCOMOTION, TERRESTRIAL).

SCAPULA: a paired bone ('shoulder blade') of the pectoral girdle (see SKELETON, POST-CRANIAL).

SCAPULARS: (plural) the feathers above the shoulder (see TOPOGRAPHY).

SCAPUS: term sometimes applied to the whole stem of a feather, i.e. calamus and rachis combined (see FEATHER).

SCARING: a scaring stimulus is one that produces stress within birds so that they will try to avoid it. In this article bird scaring refers to the use of such stimuli to deter birds from areas where they cause damage. There is a great diversity in the sorts of bird damage that can occur, whether to agricultural or horticultural crops, fisheries or property. Traditionally the term bird-scarer has been applied to devices that deter birds without physical contact; such scarers therefore involve visual and/or auditory stimuli. Deterrents using tactile or gustatory stimuli, which clearly require physical contact, have been called 'bird repellents' (see REPELLENTS, CHEMICAL).

Traditional scaring techniques have involved the use of sudden loud sounds and/or bright novel objects which startle birds and cause them to flee (see Frings and Frings 1967). Purely visual devices range from the classic scarecrow to brightly coloured material suspended from poles, tethered balloons and various 'windmill-like' devices with vanes of different colours. A folklore has grown up that some colours, in particular red and orange, are 'naturally' repugnant to birds; there is however, no scientific evidence to support this belief.

By far the most common acoustic scarer is the propane gas gun. Gas from a cylinder is periodically released into a firing chamber where it is ignited, the interval between explosions being adjustable. The sound level of these explosions can measure as much as 130 decibels at a distance of 1 m from the mouth of the gun. In order to minimize noise nuisance it has been suggested that ultrasonic scarers, emitting sound frequencies above the normal human hearing range, should be used. Unfortunately the upper frequency limits of the bird species so far investigated are very similar to man's. Even in those species that can detect frequencies as high as 25,000 cycles/sec in laboratory tests (e.g. the Bullfinch *Pyrrhula pyrrhula*), the frequency range over which the birds' hearing is most sensitive is much lower, between 2,000 and 4,000 cycles/sec.

Just as people living next to a main road may slowly adapt to the traffic noise, so birds gradually lose their fear of loud and/or novel scarers. This process is called habituation. To slow the rate of habituation, one should, where possible, use periodic rather than continuous presentation, frequently vary the site and type of scarer, and occasionally reinforce the response by providing a real source of danger, such as shooting at birds around the scarers (for a recent review see Slater 1980).

More recently, scarers have been developed that employ natural frightening stimuli encountered by birds. Most avian pests are prey to mammals and other birds at some stage of their life cycle and thus scarers that seek to mimic aspects of encounters with predators will to some degree be reinforced naturally outside the scaring context. The birds' fear response to devices of this kind should therefore persist longer than to scarers that rely upon the startle response produced by novelty, for a bird that does not quickly and repeatedly respond to predators is unlikely to survive. Indeed many species have a genetically inbuilt tendency to respond to various cues associated with the presence of predators.

Trained raptors have been used with some success on airfields where birds pose serious dangers to aircraft (Blokpoel 1976). Models of birds of prey suspended from balloons or mounted on poles are generally ineffective, probably because raptor recognition can involve quite complex visual cues, such as plumage details, as well as features based upon flight characteristics. Much more successful have been attempts to deter birds using the calls they emit when they sight a predator (alarm calls) or are actually caught by one (distress calls). Broadcasts of these calls are now commonly used on airfields to clear the runways of birds before aeroplanes land or take off (Busnel and Giban 1965, Blokpoel 1976). Such calls are at present less widely employed in agriculture; perhaps their most common use is in the dispersal of Starling *Sturnus vulgaris* roosts. Responses to broadcast calls vary between species, some (e.g. Starlings) disperse immediately whilst others (e.g. Rooks *Corvus frugilegus*) approach and mob the loudspeaker before dispersing.

Several species (e.g. Woodpigeon *Columba palumbus*) seem not to have alarm or distress calls, but apparently use visual means to communicate fear. For example, geese, when disturbed, frequently adopt a pre-flight posture which involves the vertical straightening of the neck and a rapid side-to-side shaking of the head. By using models that mimic this posture, Inglis and Isaacson (1978) successfully deterred skeins of Dark-bellied Brent Geese *Branta bernicla bernicla* from landing in fields containing the models. Similarly work by Murton and his colleagues (Murton *et al* 1974) suggested that the white wing bars of Woodpigeons were used as a visual alarm signal eliciting flight, and prototype devices that mimic these characteristics can deter Woodpigeons from landing in their vicinity (see Inglis 1980).

The development of devices that employ the pest species' own acoustic and/or visual alarm signals seem to offer the best prospect for the production of an efficient scarer, although this is something that it is very difficult to quantify; firstly because within any given area there will be variation over time in the numbers of birds attempting to feed, and secondly because at any given time, areas will differ in their attractiveness to birds. An obvious general 'rule-of-thumb' is that scarers are most effective at those times of the year when alternative food sources are available nearby. The provision of cheap decoy crops together with the erection of scarers on the more valuable areas is likely, therefore, to be the most satisfactory method of protection. A problem could arise, however, if the decoy crops were provided throughout those periods of the year when starvation has a powerful influence on the population size of the pest, in that more birds may survive to return the following year.

SCAUP: substantive name of some *Aythya* spp.; used without qualification in Britain for *A. marila* (see DUCK).

SCHIZOGNATHOUS: see PALATE (Neognathous).

SCHIZORHINAL: see NARIS.

SCIMITAR-BABBLER: see BABBLER.

SCIMITAR-BILL: substantive name of *Rhinopomastus* spp. (see WOOD-HOOPOE).

SCISSOR-BILL: alternative substantive name of species of Rynchopidae (see SKIMMER).

SCLEROPHYLL FOREST: evergreen forest in which the dominant tree species have hard leathery leaves normally less than *c.* 10 cm long, resistant to water loss. Very variable in species composition, occurring throughout the world in areas with periodic (usually seasonal) water shortage.

SCLEROTIC: see SKULL; VISION.

SCLERURINAE: see OVENBIRD (1).

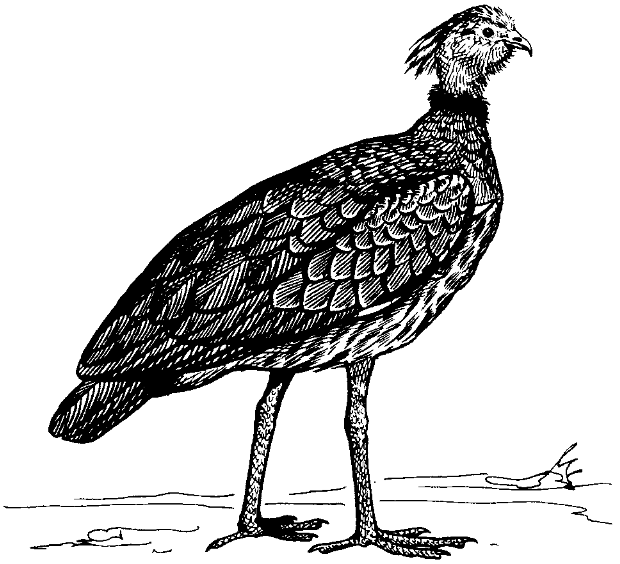
SCOLOPACIDAE: see under CHARADRIIFORMES. The family includes species known as 'woodcock', 'snipe', 'sandpipers', 'curlews', and 'godwits', and by various special names (see under SANDPIPER).

SCOPI; SCOPIDAE: suborder and family of CICONIIFORMES; HAMERKOP.

SCOTER: substantive name of *Melanitta* spp. (see DUCK).

SCRAPE: a shallow water-filled hollow excavated to attract water birds. See also NEST SCRAPE.

SCRATCHING: for head scratching see COMFORT BEHAVIOUR; for scratching the ground see FEEDING HABITS. See photo COMFORT BEHAVIOUR.



Crested Screamer *Chauna torquata*. (*C.E.T.K.*).

SCREAMER: substantive name of the 3 species of Anhimidae (Anseriformes, suborder Anhimae).

Characteristics. Screamers are goose-like birds (length 69–90 cm) with heavy bodies and small heads, but longer, fleshy legs, and semi-palmate feet with the hind toe long and not elevated. The bill is more like that of gallinaceous birds. On the leading edge of wing are 2 spurs 2–5 cm long which shed their outer layers periodically. Such shells found imbedded in breasts of other screamers suggest that the spurs are used in aggressive encounters. One species has a long (up to 15 cm) cartilaginous horn attached to the crown, but its delicate structure suggests decoration rather than armament. Screamers are unique in lacking uncinate processes on the ribs that provide support for the delicate body cage of other living birds. Unlike other waterfowl, they lack well-defined feather tracts, simultaneous wing moult and copulatory organ. Small air cells between the skin and muscle are more widespread than even in Pelecaniformes and create rumbling or crackling noises on take-off. The sexes differ little in size. They swim well but high on the water and somewhat belaboured; diving has not been recorded. They are strong flyers and at least one species soars regularly.

Habitat and distribution. The Crested Screamer *Chauna torquata* is grey with white and black rings on the neck. It is well known because of its extensive distribution in the pampas of Argentina, Uruguay and southern Brazil and in the subtropics in Bolivia and Paraguay. Crested Screamers are most numerous near marshes where they may graze with livestock. Pairs and flocks roost in shallow water at night. The Black-necked Screamer *Chauna chavaria* occurs in a small area in Colombia and Venezuela, and differs from the Crested Screamer in its more extensive black neck, chin and face. The largest of the 3 is the Horned Screamer *Anhima cornuta* of the tropical savannas of the Guianas, northern Venezuela, Colombia, western Ecuador, Peru, Brazil and Bolivia. Whereas the other 2 screamers are predominantly grey, this species is a glossy greenish-black. Horned Screamers perch in trees regularly, where they probably roost overnight, and like other screamers, feed on grasses and sedges near water.

Food. Screamers are herbivores that graze near lakes and marshes or feed on aquatic plants. Insects are thought to be taken by or for young.

Behaviour. Information is based mostly on studies of Crested Screamers. Pairs are obvious year-round, but they seek isolation in marshy areas in late winter or early spring where they trumpet (duet) and mutual-preen. Mating occurs on land. Large flocks of non-breeding birds suggest that maturation is delayed for several years.

Voice. They are highly vocal birds with piercing trumpet-like alarm calls, also uttered while soaring.

Breeding. The nest is constructed of aquatic plants or sticks, usually over water. Both sexes build the nest and probably incubate. Down is rare or lacking in nests. Four to 7 eggs are laid at intervals of 35–40 h, and incubation requires 43–45 days. The young remain in or near the nest for several days and stay in wet areas until they are old enough to run to safety. Black-necked Screamer adults feed chicks in captivity.

SCRUB-BIRD: substantive name of the 2 species of the Atrichornithidae (Passeriformes, suborder Oscines); in the plural the general term for the family.

Characteristics. The Noisy Scrub-bird *Atrichornis clamosus* (21 cm) and the Rufous Scrub-bird *A. rufescens* (16 cm) are small terrestrial birds with strong pointed bills; long powerful legs; short rounded wings and long graduated tails. The dorsal plumage is brown (more rufous in *A. rufescens*) with fine black cross bars; the ventral plumage grades from white on the chin to rufous at the vent. Males are larger and also have a black bar across the upper chest which in *A. rufescens* extends down the flanks.

Systematics. Traditionally, this small endemic Australian family has been grouped with the lyrebirds in the suboscine suborder Menurae. This arrangement is based mainly on the facts that both families have only 3 pairs of intrinsic syringeal muscles compared to 4 in other Passeres, and that the lower tracheal rings are not fused into a 'drum'. In addition, certain skeletal features such as the rudimentary clavicles in the scrub-birds and the number of flight and tail feathers in the lyrebirds were used to support this arrangement. Both families are ancient and relict members of the Australian avifauna.

Habitat. Both species are primarily birds of wet forest, and occupy the ecotone between forest and swamp or where the canopy is broken. Such areas have a dense zone of shrubs and rushes, which provides essential nest sites, nest material and cover. The feeding habitat is on the forest side of this zone where the decreased density of shrubs and rushes allows the development of a litter layer which is the main food source. The only known population of the Noisy Scrub-bird is confined to the narrow gullies and soakage lines on an elevated headland of about 2,000 ha. The Rufous Scrub-bird is found in scattered areas of suitable habitat.

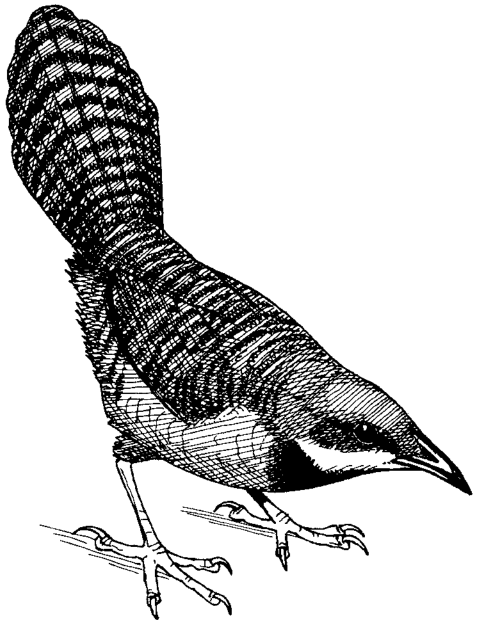
Distribution. The scrub-birds have an interrupted distribution. *A. clamosus* is only known from an isolated headland on the south coast of Western Australia, while *A. rufescens* is found in a small number of isolated montane locations from southern Queensland to northern New South Wales.

Though formerly more widespread, the reduced distribution and population of scrub-birds since the mid 1800s has been caused by the destruction of habitat for agricultural pursuits and forestry and by the increased frequency with which their habitat has been burnt. Drought and introduced predators may also have played a minor role.

Populations. Because of the dense habitat and their secretive habits no census of scrub-birds is possible, but counts of singing males provide an index of the number of breeding pairs. During the 1960s the number of *A. clamosus* breeding pairs was of the order of 40–50; since 1970 the number has increased from 45 to 138 in 1983. It is unlikely that there are more than a few hundred breeding pairs of *A. rufescens*.

Food. Both species are generalized insectivores, who may also prey occasionally on small lizards or frogs. Most of their prey is obtained from the litter layer which they poke into or turn over with a sideways flick of the bill. Occasionally they flush insects by a rapid drumming on one foot on the litter, or more rarely by vibrating the erected breast feathers on the litter. Less frequently, they hunt insects at the base of lower levels of the rushes and shrubs that form the understorey of their habitat.

Behaviour. Scrub-birds are fast, alert ground-dwelling birds, who



Noisy Scrub-bird *Atrichornis clamosus*. (*N.W.C.*).

rarely fly and then only a few metres. They are seldom seen, and usually only the song of the male indicates their presence. *A. clamosus* male territories are well dispersed and adjacent males rarely make contact except by song. Their territories range from 5–10 ha, within which the males may spend up to 80% of their time in an area of 1–2 ha centred on the best feeding places. Males have a number of roosting sites in trees or taller shrubs away from their feeding area to which they move after sunset and leave before sunrise. Males are generally monogamous, although they may mate with females on adjacent territories who have lost their mates. Polygamy was observed in the captive colony. Females occupy areas with suitable breeding habitat and good feeding on the periphery or away from the males' preferred station. They nest in the same area year after year and only move their site after losing the egg or chick. The little contact between males and females is probably confined to the breeding season. At its beginning, young males may occupy territories in sub-optimal habitat for 1–15 weeks. They do not develop their territorial song until the second, and may not be sexually mature until their third year. Females may breed in their first year and, if they cannot acquire a territory, may nest adjacent to an established pair. What little is known of *A. rufescens* suggests that it is similar to *A. clamosus* except that the males only defend their territories during the breeding season.

Voice. The male *A. clamosus* has a loud and far reaching territorial song of 10–20 notes. Individual males may have 4 or 5 song patterns, all of which may be given in the same bout of singing. Males within hearing distance of each other have similar patterns of song. These continually change and the songs of any group may be quite different from year to year. The plasticity of the song pattern is in marked contrast to that of *A. rufescens* which has a very stereotyped and simple song not varying significantly throughout its range. *A. clamosus* males have another song, briefer than territorial song, more variable and of lower intensity, and which incorporates modified segments of the song of other species; it is used in interactions with other scrub-birds. In similar situations *A. rufescens* uses pure mimicry. *A. clamosus* also has a three-note call and two alarm notes. These alarm notes are the only vocalizations of the females of both species.

Breeding. Both species breed during the wet season, winter for *A. clamosus* and spring/summer for *A. rufescens*. The male *A. clamosus* plays no role in nest building, incubation, feeding the chick or nest sanitation. The female builds a domed nest with a side entrance, lining the bottom with decayed rushes or wood which dries hard. Nests are built close to the ground, usually near a stream, and take about 3 weeks to build; the single egg is laid 1–2 weeks after the nest is completed. Incubation takes 36–38 days in the wild, but only 30–33 days in captivity. The difference may be attributed to the increased time needed to feed in the wild. For about 7 days after hatching the female broods after each feed, but subsequently only at night. The chick fledges at about 25 days, after which it stays with the female, probably until the start of the next breeding season. Chicks are fed a wide variety of invertebrates and occasionally a small lizard or frog. The female removes the faecal sacs which she deposits in a stream or under a bush. If the egg is lost, the female will build another nest and relay. Little is known of the breeding of *A. rufescens*, but it is probably similar to *A. clamosus* except that 2 eggs are laid and the nest is completely lined.

Conservation. Following the rediscovery of *A. clamosus* in 1961, a reserve was established with a resident ranger. Constant policing and the development of a fire-break system have prevented any fires in this area since 1970. The consequent regeneration of habitat has contributed to the increase in population since 1970. In the short term the population appears reasonably secure. In 1975/76 a captive colony of 1 male and 3 females was established and in 1979 the first chick was successfully reared. Knowledge of how to breed the species in captivity should assist in the long term survival of the species. *A. rufescens*, although rare, is not endangered because all the known localities are within National Parks and are of sufficient number that its long term survival seems as assured.

SCRUB-FOWL: name sometimes applied to *Megapodius* spp. (see MEGAPODE).

SCRUB-ROBIN: substantive name of *Drymodes* spp. (see RAIL-BABBLER; THRUSH); also used for *Erythropygia* (or '*Cercotrichas*') spp., alternatively 'bush-robins' or (in one case) 'Rufous Warbler' (for families see WARBLER (1); THRUSH).

SCRUB-WREN: substantive name of *Sericornis* spp. (see WARBLER, AUSTRALIAN).

SCUTELLATE: term applied to a podotheca consisting of rather large and often overlapping scales (see LEG).

SCYTHEBILL: substantive name (formerly 'sicklebill') of *Campylorhynchus* spp. (see WOODCREEPER).

SEA EAGLE: see HAWK (True kites and fish eagles).

SEARCH IMAGE: a predator can be said to 'adopt a Search Image' when it can be shown that it has learnt to see prey which it at first overlooked. Many of the insects and other animals which are preyed upon by birds are highly camouflaged in that their colour and patterning blend in very closely with their background. Birds have, nevertheless, been shown to be able to 'break' the camouflage when they have had experience of finding a particular type of prey.

As an example of this, de Ruiter (1952) found that, when Jays *Garrulus glandarius* and Chaffinches *Fringilla coelebs* were first shown the stick-like caterpillars of geometrid moths resting among twigs, they apparently failed to see them. But although the birds took a long time to find their first caterpillar, some birds which had eventually found an insect were then able to pick out the other insects without difficulty. They were thus 'taken in' by the camouflage at first, but were able to detect the difference between sticks and caterpillars after they had sampled the first insects. The birds could then be described as having adopted a Search Image for stick insects. Similar phenomena have been observed in crows, domestic chicks and other birds.

It should be pointed out, however, that not everyone uses the term Search Image in the same way. Some people use the term to cover cases where a predator simply develops a taste for a type of food even when it is not camouflaged, and there is no suggestion of a change in how easily the predator can see it. (The predator might just be learning, for example, which of several conspicuous foods are best to eat.) These different uses have led to confusion and, in some quarters, a feeling that the term should be dropped altogether. But without it, we would have no name to give the process of a predator learning to see through its prey's camouflage. So, used in this restricted sense, the term Search Image does serve a useful function. It is a graphic way of describing an important behavioural phenomenon. M.D.

de Ruiter, L. 1952. Some experiments on the camouflage of stick caterpillars. Behaviour 4: 222–232.

SEASONAL CHANGE: occurring in birds in respect of physiological condition and behaviour, and very often also of external appearance and location (either or both). The cycle of a bird's life is usually an annual one, linked with the recurring seasons—whether these be summer or winter, or wet season and dry (see RHYTHMS AND TIME MEASUREMENT; WEATHER AND BIRDS). The alternation in physiology and habits is, in adults, between reproductive and non-reproductive periods (see BREEDING SEASON). It may involve a greater or lesser degree of geographical displacement (see MIGRATION; and IRRUPTION). The physiological changes include the seasonal replacement of feathers and other integumentary structures (see MOULT). This may or may not involve marked change in external appearance, as when there is a distinctive breeding plumage in one or both sexes (see PLUMAGE).

SEA-SWALLOW: popular name for TERN.

SEA-WATCHING: a form of BIRDWATCHING from a single observation point, usually a prominent headland, whence passing birds are counted and identified over a period of hours or days. Sometimes sea-watches are co-ordinated over a number of stations to yield comparative data. The term is not usually applied to watches from on board ship, which have been carried out all over the world, notably by the Royal Naval Birdwatching Society.

SECONDARY: or 'secondary feather', any one of the flight feathers borne on the forearm (ulna), as contrasted with the 'primaries' borne on the manus (see PRIMARY; also PLUMAGE; WING); they are sometimes called 'cubitals'. The secondaries are customarily numbered inwards from the carpal joint.

SECONDARY COVERTS: see TOPOGRAPHY.

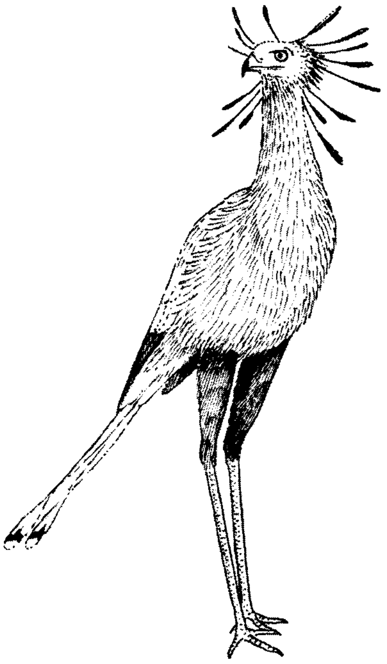
SECONDARY SEXUAL CHARACTERS: see SEXUAL DIMORPHISM.

SECRETARY-BIRD: *Sagittarius serpentarius*, sole extant species in the Sagittariidae, a family currently placed in the Accipitriformes, suborder Sagittarii.

Characteristics. A large bird with a wing span of just over 2 m, weighing about 4 kg, and standing over 1 m tall, characterized by long legs that are feathered to the inter-tarsal joints, a well-developed basal web which joins the 3 front toes, elongate central tail feathers and a loose crest of spatulate feathers on the nape. The hooked bill, display flights and carnivorous diet suggest affinities with large eagles. The long legs and nesting habits are stork-like, but there are also many similarities with the seriemas (Gruiformes) of South America. Bustards and cranes have also been suggested as relatives, but until the species is properly studied and homologous and convergent characters are separated, the true relationships will remain obscure.

Habitat and distribution. The Secretary-bird is found in open savanna, grassland and steppe, shunning areas that are heavily wooded or densely vegetated or of broken terrain. It is found in Africa south of the Sahara desert, although fossils are known from France.

Populations and movements. No regular movements are known, but in many areas and at certain seasons it is locally nomadic as food supplies fluctuate. Densities of a breeding pair per 45 km^2 (grassland in South Africa) to one per 20 km^2 (tropical savanna in South Africa) are known, but higher densities in richer environments or lower in more arid areas are likely.



Secretary-bird *Sagittarius serpentarius*. (*K.J.W.*).

Food. Largely rodents, reptiles, large beetles and grasshoppers, but any small animal up to the size of a hare may be eaten if caught. Eggs and nestlings of ground-nesting birds (e.g. plovers) are also taken. All hunting is done while walking with long, measured strides over the ground, prey being immobilized by kicking with the short, stout toes and their nail-like claws. The reach attained with the long legs and agility obtained by using wing movements allow active prey to be killed, such as birds and mice, or dangerous prey avoided such as venomous snakes. If snakes cannot be subdued on the ground, they are taken aloft and dropped from a height. Small animals burnt in fires may be scavenged.

Behaviour. Adults are usually in pairs, holding and residing in a territory as long as conditions permit. Numbers may congregate at water-holes to drink or bathe, or at temporarily abundant food sources such as grassland fires, but often these appear to be non-breeding birds. Territorial advertisement consists of soaring flights made almost daily and during the heat of the day, sometimes with calling, and defence may involve aerial chasing or running and kicking fights on the ground.

Voice. The Secretary-bird is mostly silent, but has a variety of deep croaking calls. Loud croaking precedes breeding and is uttered perched or during display flights. A single high pitched croak signifies alarm, a deep croak indicates threat. Small chicks make a loud chucking noise, later croaking and sometimes they throw back their heads as they call. Mewing calls are made at roosts.

Breeding. Displays consist of undulating diving flights by either sex, with croaking calls. The nest, which is used year after year, is built of sticks, weeds and grass and forms an extensive platform on top of a tree or bush, often rather low (3–7.5 m above ground) and usually in a thorny species. The basin is lined with dry material, mainly grass tufts. Up to 3 white eggs, rather pointed, and small for the size of the bird, are laid at intervals of several days. Incubation proceeds for 45 days, almost entirely by the female, the male delivering food carried in the crop and regurgitated on the nest rim. The chicks hatch in white or grey down, the second down being darker, and the feathers appear on the crest when they are 3 weeks old. The female gives most attention to them at first, although either parent may brood and feed them. Within a month of hatching the female leaves the nestlings for much of the time to help the male search for food. At first a liquid diet, probably of partly digested food, is fed to the chicks, but later whole items are given and latterly the food is left on the nest for the chicks to feed themselves. They leave the nest 65–80 days after hatching, being barely able to fly, and spend about a month in the nest area learning to hunt before moving off to join the parents on their foraging expeditions. Breeding may occur at any time of the year, usually in spring or summer, and is probably linked to food availability. The immature bird resembles the adult but has a pale grey eye (which is hazel in the adult) with black barring on the underwing and undertail coverts (both white in the adult). A.C.K.

SECRETION, INTERNAL: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

SEDENTARY: commonly used in the special sense of 'non-migratory' (compare RESIDENT).

SEED-CRACKER: substantive name of *Pyrenestes* spp. (see ESTRILDID FINCH).

SEED DISPERSAL: in this context, the dispersal of seeds, and hence of the plants producing them, by birds.

Many seed-eating birds act as distributors; they do so, however, more or less accidentally, by failing to digest a proportion of the seeds or by dying with a full crop or stomach. Nevertheless, by such means plants are on occasion dispersed over great distances (Ridley 1930). A primary distinction should be made between such birds, which are essentially seed-predators (although some, such as the parrots and many pigeons, are commonly referred to as frugivores), and the true or 'legitimate' frugivores, which digest the fleshy parts of fruits and void the seeds intact. Avian frugivores of the latter sort are the main distributors of many trees, shrubs and epiphytic plants, and of a smaller number of herbaceous plants. They are especially numerous in tropical forest, and the interaction between them and their food plants has led to mutual adaptations (see COEVOLUTION). There is reason to think that fleshy fruits of the kind eaten by birds evolved early in the history of the flowering plants in equable, tropical conditions; and that other kinds of fruits, such as those dispersed by wind, evolved later, perhaps in association with the climatic deterioration that took place during the Pliocene.

The interaction between a frugivorous bird and its food plant is in the nature of a bargain: the bird obtains nourishment from the fleshy part of the fruit, and in exchange disperses the seed or seeds. To understand the details of the bargain, in particular the benefits obtained by each party, it is necessary to know the relative mass of flesh and seed, the number of seeds per fruit, the nutritive content of the flesh, the proportion of the crop harvested by the frugivore, the distances and sites at which the seeds are dropped, and many other things. In spite of much recent research on frugivory in birds, few studies have been thorough enough to give quantitative data on all of the important factors, and generalizations remain tentative. A broad distinction can be drawn between unspecialized and specialized frugivores, and between the kinds of fruit on which they feed. An unspecialized frugivore is one that regularly takes other foods besides fruit, and cannot subsist indefinitely on fruit alone. It is typically an opportunist, taking fruits as and when they become available. In order to attract unspecialized frugivores, it will be advantageous for a plant to have conspicuous fruits and a well-synchronized fruit crop. The fruits are usually borne in profusion, and linked with this, the nutritive content of individual fruits is not very high; they tend to be watery (succulent) and to contain mainly sugars and little fat or protein. Typically they are small, and contain small seeds. Many small trees and shrubs that colonize clearings, edge habitats and other transient areas of secondary vegetation have fruits of this unspecialized sort. As colonizers of temporary open ground, they tend to be in competition with one another, not only for ground space but also for dispersal agents.

Thrushes, tanagers in tropical America, and bulbuls in the Old World tropics are typical unspecialized frugivores. It is characteristic especially of the tropics that temporarily superabundant supplies of unspecialized fruit are exploited by birds of many families that are not usually thought of as frugivorous, e.g. woodpeckers and tyrant-flycatchers. Many plant families produce unspecialized fruits, among the most important in the tropics being the Rubiaceae and Melastomataceae, and in North Temperate regions the Rosaceae and Caprifoliaceae.

Specialized frugivores are typically larger birds than unspecialized frugivores, and the fruits that they eat are correspondingly large. Plants producing such fruits are mainly trees of primary tropical and subtropical forest. A common type of fruit consists of a single seed surrounded by a dense and nutritious, and often surprisingly thin, layer of flesh. Specialized frugivores process such fruits remarkably quickly, stripping off the flesh and regurgitating the large seed, which represents so much useless ballast, intact. In another common type of nutritious fruit the seed is partly or entirely covered by an aril, which is an edible outgrowth of the seed itself. A number of fruits of both these types have been analysed and have been found to contain high percentages of fat and protein. Fruits of these kinds are often not very conspicuous, probably because they need to attract only a small number of regular frugivores which are likely to be resident and to know intimately the fruit resources available in their area. They also tend to be available over a longer period than the fruits that are produced in a mass to attract opportunist unspecialized frugivores.

Specialized fruit-eating birds belong to fewer families than the unspecialized fruit-eaters, and are mainly tropical. The most important families are the toucans and cotingas in the American tropics, the turacos in Africa, the hornbills in Africa and south-east Asia, the birds-of-paradise in Australasia, and the true fruit-pigeons (Columbidae, genera *Ducula*, *Alectroenas* and *Ptilinopus* only, other pigeons being seed-predators) in south-east Asia and Australasia. Trees producing fruits adapted for specialized frugivores belong to a variety of families, the Palmae, Lauraceae and Burseraceae being of outstanding importance.

A limited number of birds in all the main tropical and subtropical areas are specialized feeders on the fruits of mistletoes (Loranthaceae) and the chief dispersers of these plants. Some epiphytic plants may also be dispersed by these birds (bromeliads, aroids, and the epiphytic cactus *Rhipsalis*). The coevolutionary relationship between bird and plant is close, and there are some special features that set it apart from the typical bird-fruit relationship discussed above. The birds are mostly small (as are the fruits), with short and rather stout bills, and may have highly modified digestive systems. Effective dispersal depends on the seeds being lodged in a crack on a tree branch, and the fruits are adapted for this by having the seed embedded in a sticky coating which resists digestion in a bird's gut. The bird either swallows the fruits whole and passes them very rapidly through the alimentary canal, voiding them with their sticky coating intact so that they adhere to the branch on which they land, or squeezes the fruit in the bill, swallows the skin and pulp, and wipes the seeds off onto the branch on which it is perched. The most important mistletoe-berry eaters are the mistletoe-birds (Dicaeidae) of south-east Asia and Australasia, the small neotropical tanagers of the genera *Euphonia* and *Chlorophonia*, and the small African barbets of the genus *Pogoniulus*. A few species of other families are also more or less specialized eaters of mistletoe berries, for instance the Phainopepla *Phainopepla nitens* and the small neotropical flycatcher *Tyranniscus vilissimus*.

Among the seed-predators there is one group of birds that have apparently co-evolved with the plants that they exploit and act as their main dispersal agents. They are seed-hoarders or 'scatter-hoarders', birds of temperate or boreal regions that bury large numbers of seeds in late summer and autumn and dig them up and eat them, or feed them to their young, in the following winter and spring. All those that are known are nutcrackers and jays (Corvidae). Storing food for later consumption is a widespread habit in the Corvidae and some other families, especially the tits and nuthatches, and all these birds must occasionally act as dispersal agents for the plants whose seeds they store, but in most cases there is no evidence that they are the main dispersal agents or that any coevolutionary adaptations are involved. One species at least of pine, however, in the mountains of western North America, *Pinus edulis*, has co-evolved with Clark's Nutcracker *Nucifraga columbiana* and perhaps other corvids, producing seeds that are especially suitable for being harvested by the nutcracker. Similarly, the European Jay *Garrulus glandarius* is the main disperser of oak trees (*Quercus* spp.), and jays have probably been the main selective agent determining acorn size (Bossema 1979). (See also FOOD STORING.)

Seeds, and other parts of plants, furnished with hooks or barbs are occasionally distributed by birds, but probably are adapted primarily for dispersal by other kinds of animals. Birds may, however, be significant agents of dispersal of plants that they use for nest material. The melastomataceous herb *Nepsera aquatica*, whose fruiting panicles are used as nest lining by many small neotropical birds, may be mainly distributed in this way. Ridley (1930) gives other examples. No thorough study has, however, been made of the importance of birds as distributors of plants other than by ingesting or storing their seeds.

SEEDEATER: substantive name of species of *Sporophila* and allied genera in the New World, and of *Serinus* spp. in southern Africa (for family see FINCH).

SEED-FINCH: substantive name of certain small seed-eating species, particularly in the Neotropical genus *Oryzoborus*, also called 'rice grosbeaks' (for family see FINCH).

SEEDSNIPE: substantive name of the 4 species of Thinocoridae (Charadriiformes, suborder Charadrii, superfamily Thinocoroidea); in the plural (usually unchanged), general term for the family. The name derives from the birds' diet of seeds and other vegetable matter, and their snipe-like flight, including the *bzeep* take-off call, although they have no near relationship to snipe (*Gallinago* species, family Scolopacidae) on present evidence. Seedsnipe are undoubtedly charadriiform, but it has not yet been possible to establish which are their closest relatives.

Characteristics. Seedsnipe are entirely South American and range in size from that of a quail *Coturnix* to that of a small partridge *Perdix*. The genus *Thinocorus* contains the 2 smaller species, the Least Seedsnipe *T. rumicivorus* (measuring about 18 cm and weighing 50–60 g) and the Grey-breasted Seedsnipe *T. orbignyianus* (measuring about 20 cm and weighing 110–140 g). The genus *Attagis* comprises the 2 larger species, the Rufous-bellied Seedsnipe *A. gayi* (about 30 cm long and weighing 300–400 g) and the similar-sized White-bellied Seedsnipe *A. malouinus*. They resemble doves (Columbidae) or sandgrouse (Pteroclididae) with plump bodies, small heads and short legs, but they have relatively long toes; the middle toe is as long as or longer than the tarsometatarsus. The bill is shaped rather like that of a partridge and the nostrils are protected by shield-like coverings. The plumage is cryptically coloured in grey, black, brown, white and rufous. The belly is white in the 2 *Thinocorus* species and in the White-bellied Seedsnipe, but rufous in the Rufous-bellied Seedsnipe.

Males of the 2 *Thinocorus* species have dove-grey breasts bordered ventrally by a black collar. The Least Seedsnipe also has a vertical black line joining a black-bordered white throat to the chest band to give an anchor-shaped effect. The 2 *Attagis* species have the breast finely marked with black. Sexual dimorphism is well developed in *Thinocorus*, but almost absent in *Attagis*. Seedsnipe all have long wings and are excellent fliers.

Habitat and distribution. The White-bellied Seedsnipe lives on windswept hilltops above the treeline on Tierra del Fuego and the islands south to Cape Horn; it also extends northward into the southernmost parts of the Andes in Chile and Argentina. The Rufous-bellied Seedsnipe, the largest and most strictly montane member of the family, lives just below the snowline in the puna or páramo zone of the Andes of Ecuador, Perú, Bolivia, Argentina and Chile up to about 5,500 m. The Grey-breasted Seedsnipe is also an Andean bird, but of rather lower elevations, especially in the southern parts of its range in Patagonia and Tierra del Fuego where it inhabits open grasslands. The Least Seedsnipe is not montane, occurring in arid country down to sea level, from Ecuador in the north to northern Tierra del Fuego in the south. It is common in Argentine Patagonia.

Movements. Southern populations of the Least Seedsnipe migrate northward in winter as far as the province of Buenos Aires; more northerly populations are sedentary or nomadic, especially in the more arid areas. The other species of seedsnipe may merely move to lower elevations in winter, but do not appear to undergo long migrations.

Food. Seedsnipe spend most of their time on the ground feeding on seeds and green leaves. The arid-zone Least Seedsnipe feeds on succulent leaves as a source of water. None of the 4 species of seedsnipe appears to drink under natural conditions, although they will do so in captivity.

Behaviour. During the breeding season seedsnipe are monogamous and move about in pairs or family groups. In winter when they are not breeding, the birds gather in large flocks which are migratory or nomadic. They roost at night on the ground, often in groups, making shallow scrapes in which to lie. The males have characteristic territorial flight displays in the breeding season, accompanied by a mellow song which may also be given from a perch on top of a rock or, in the case of the Least Seedsnipe, a bush or tall weed. Territorial males frequently fight vigorously at their territory boundaries.

Voice. The songs of seedsnipe are mostly mellow-toned, incorporating hooting notes like *puku puku puku* and may be uttered for many minutes at a time without a break. When taking off they give a short *bzeep* call like that of a snipe.

Breeding. Seedsnipe nest on the ground, either in the open or next to a grass tuft or low shrub. They lay 4 eggs in a scrape filled with dry plant material. The eggs are usually creamy to pinkish in ground colour, spotted with shades of brown, grey and mauve. The White-bellied Seedsnipe and some females of southern populations of the Least Seedsnipe lay eggs of a greenish ground colour; this seems to be an adaptation to the greener habitats in the higher-rainfall regions inhabited by these birds. Incubation is by the female only in the *Thinocorus* species and possibly in the others too. Both *Thinocorus* species invariably cover their eggs completely with nest material when they leave the nest (whether to feed or when disturbed). The White-bellied Seedsnipe may also do so (although only one nest has ever been recorded), but the Rufous-bellied seems not to line its nest scrape thickly enough to allow of egg-covering. Where it occurs, egg-covering is done rapidly with sideways movements of the feet. An incubating female leaves the nest to feed for about an hour in the morning and again in the late afternoon.

During the incubation period the male seedsnipe spends much time on a perch near the nest, where he acts as a lookout, giving a warning call and running away with the female as soon as danger is sighted. If disturbed suddenly at the nest, especially if she has not had time to cover the eggs, the female performs an elaborate injury-feigning distraction display as she flutters away low over the ground.

The incubation period of the Least Seedsnipe is about 26 days. The young are led away from the nest by both parents as soon as they are dry, but only the female broods them. From the start they feed by themselves on seeds and green leaves and do not need to be shown food by their parents. Like the adults they do not normally drink water. The young fly at about 7 weeks of age. If disturbed with young, both parents will perform distraction displays, but those of the male are less elaborate, usually consisting only of the 'rodent-run' typical of waders (see DISTRACTION BEHAVIOUR). See photo COLORATION, ADAPTIVE. G.L.M.

Sibley, C.G., Corbin, K.W. & Ahlquist, J.E. 1968. The relationships of the seed-snipe (Thinocoridae) as indicated by their egg white proteins and hemoglobins. Bonn. zool. Beitr. 19: 235–248.

SELECTION: see NATURAL SELECTION; and under SPECIATION.

SEMATIC: serving as a signal, e.g. of warning or attraction. This adjective is the base of such terms—applied particularly to coloration—as 'aposematic' (protective) and 'episematic' (aiding recognition), and of compounds thereof (see under APOSEMATIC; EPISEMATIC); also GAMOSEMATIC. 'Allosematic' (adventitiously derived from association with other organisms—see NESTING ASSOCIATION), and 'parasematic' (deflecting attention from one part of the body to another, e.g. from more to less vulnerable parts). Not all such terms as these have application in ornithology. See, in general, COLORATION, ADAPTIVE.

SEMICIRCULAR CANALS: in the ear (see HEARING AND BALANCE).

SEMIPALMATE: half webbed.

SEMIPLUME: a feather type intermediate between contour feather and down (see FEATHER; PLUMAGE).

SEMI-PRECOCIAL: newly hatched young which have eyes open, are down covered, stay at the nest until able to walk and are fed by parents (see YOUNG BIRD).

SEMI-SPECIES: a term of convenience for geographically isolated forms, with obviously near relatives elsewhere, that may be either species (members of a superspecies) or subspecies, there being no way of applying the objective test.

SENESCENCE: see under AGE.

SENMURV: see FABULOUS BIRDS.

SEQUENCE: see ARRANGEMENT.

SERAL COMMUNITY: a community of plants and animals associated with a stage of a SERE. For example, in Britain bare ground will develop through the seral stages of grassland, scrub and low woodland to deciduous forest. Each stage will have its characteristic seral community of birds. Grassland will support a bird community of Skylarks *Alauda arvensis* and Meadow Pipits *Anthus pratensis*, the low scrub stage species such as Dunnock *Prunella modularis* and Whitethroat *Sylvia communis*. A more advanced scrub seral stage will contain several warblers and Nightingales *Luscinia megarhynchos*, and the climax forest, with its components of mature and dead trees, a more varied community including tits *Parus*, Nuthatches *Sitta europaea*, treecreepers *Certhia* and woodpeckers.

SERE: a series of plant communities leading to climax vegetation.

SERICORNIS: substantive name of some Australasian warblers of the genus *Sericornis* (for family see WARBLER, AUSTRALIAN).

SERIEMA: substantive name of the 2 species of Cariamidae (Gruiformes, suborder Cariamae); in the plural, general term for the family. The birds are to be found in the drier areas in south-central South America. The common name is derived from the Tupi word 'çariama', rendered in Latin as *Cariama* by Marcgrave in his account published in 1648, copied by Willughby in his *Ornithologia* of 1676, and so given in many subsequent accounts. Seriema, a modification of the original American Indian word used in Brazil, is preferred and is now replacing the other form in current ornithological writings.

Numerous fossil species related to the modern Cariamidae have been described from middle Tertiary beds of Argentina, and a closely related fossil family, the Bathornithidae, with 4 species described in the genus *Bathornis*, was common during Oligocene time in the Great Plains area of North America.

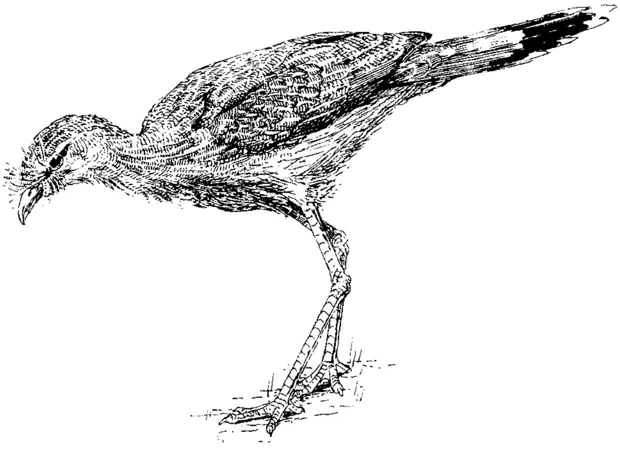
Characteristics, habitat and distribution. Seriemas are allied to cranes (Gruidae) and rails (Rallidae), and are placed in the same order. They show resemblance in form to small cranes (lengths 66–86 cm) as they have long necks, long slender legs, and elongated muscular bodies. The head is heavily feathered, with a frontal crest, the tail is long, and the wings are rounded.

The Crested Seriema *Cariama cristata*, which ranges from central and eastern Brazil south through Paraguay to northern Argentina and Uruguay, is the best known, from its wide distribution and from the fact that the young are readily domesticated and are often taken and reared among fowls, where they serve efficiently as guardians to give warning of predators. The Crested Seriema, which stands about 76 cm tall, is greyish-brown in colour with fine darker vermiculations throughout; the wings and tail are broadly banded with black and white, and the feathers of the underparts have pale longitudinal streaks. The frontal crest is conspicuous, and the bill and legs are red. It lives in areas of open scrub mixed with grasslands, where it moves about on foot and runs rapidly to escape any enemy.

Burmeister's Seriema *Chunga burmeisteri*, found only in Argentina and the western Chaco of Paraguay, is somewhat smaller, with a much less conspicuous frontal crest. It is greyer in plumage, unstreaked below and with a creamy white belly, and the bill and legs are black. It lives in areas of rather open, thorny woodland, where it ranges the ground like the other species. As they are hunted for game, they are wary, so that except for occasional distant glimpses of birds running swiftly through cover their presence is known mainly through their high-pitched yelping calls.

Food. Both species of the family are omnivorous in feeding, and are among those birds that regularly eat smaller snakes of any kind. The common supposition that seriemas have an immunity to the venom of the poisonous species is not true, since it has been found experimentally that birds of both species were killed by injections of attenuated amounts of a crotaline snake poison.

Voice. The loud calls of both seriemas often indicate their presence when the birds themselves are not seen.



Crested Seriema *Cariama cristata*. (*C.J.F.C.*).

Breeding. The nest of the Crested Seriema, rather compactly made of sticks, is recorded up to 3 m above the ground. The eggs, which regularly number 2, are faintly pink when fresh but fade to dull white, sparingly marked with lines or small blotches of brown that appear dark grey or dull purple where overlaid by deposits of shell. The young, covered with dark down when hatched, remain in the nest under the care of the parents until well grown.

The nest of Burmeister's Seriema is located low in trees, and the 2 eggs are similar to those of the other species but with heavier markings.

A.W. (D.W.S. (1)).

SERIN: substantive name of most *Serinus* spp.; used without qualification, in Britain, for *S. serinus* (see FINCH).

SEROLOGICAL CHARACTERS: those expressing differences between species in respect of the chemical nature of the proteins in, particularly, the blood serum—as shown by precipitation reactions and other tests. These proteins (also referred to as 'antigens' or 'serum globulins') represent an important part of the animal constitution and are conservative hereditary traits; they are thus of potential value as supplementary taxonomic criteria; and the same applies to the albumens of egg-white (see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA; TAXONOMY).

SERPENT EAGLE: same as HARRIER EAGLE (and see HAWK (Snake eagles)).

SERTOLI CELLS: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM (Reproduction).

SERUM: see BLOOD; SEROLOGICAL CHARACTERS.

SESAMOID: term applied to small, isolated pieces of bone or cartilage formed in tendons or ligaments.

SET: in respect of eggs, has the same meaning as CLUTCH (see also EGG).

SETOSE: carrying bristle-like feathers.

SEVEN SISTERS: name applied collectively to parties of the Jungle Babbler *Turdoides striatus* in India, from the habit of associating in small bands, often of about 7 birds, at all times of year (see BABBLER). Whistler points out that there is a vernacular (but masculine) equivalent, 'sath-bhai', in which the numeral is used in an approximate sense. Related species have similar habits and may sometimes have the term applied to them.

SEX, CHANGE OF: see OVOTESTIS.

SEX, DETERMINATION OF: see GENETICS.

SEXUAL CHARACTERS: those differentiating male and female. Primary sexual characters are the testis and ovary; accessory sexual characters are other parts of the reproductive system (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM); secondary sexual characters are those, apart from the foregoing, in which the sexes differ—in birds, notably in plumage and voice, sometimes also in size (see below).

SEXUAL DIMORPHISM: the existence of differences in appearance between male and female members of a species. (For dimorphism not related to sex, see POLYMORPHISM.) There are differences of size, structure, shape, plumage and coloration. Although sexual differences in behaviour (for example, singing by males but not by females) should not strictly be referred to as sexual 'dimorphism', because morphology means the study of physical form, in fact most of the theories of sexual dimorphism apply both to sexual differences in form and in behaviour.

Kinds of sexual dimorphism. Most sexual dimorphism in birds is of size and shape, and of coloration. There are a few examples of structural dimorphism. The bill of the extinct Huia *Heteralocha acutirostris* is one (see WATTLEBIRD (2)). The male's bill was relatively short, straight, and stout; the female's was longer, more slender, and more curved. Sexual differences in size are found in many species. The Capercaillie *Tetrao urogallus* is an extreme example, in which the male is more than twice the weight of the female. In the American Jacana *Jacana spinosa*, by contrast, the female is 75% heavier than the male. In most species there is smaller (less than about 10% of body weight) sexual dimorphism in weight, and males tend to be the heavier sex.

Plumage dimorphism is the main source of sexual differences of colour, although in some species the bills or the legs are of different colours. The sexual dimorphism of the Peafowl *Pavo cristatus* is largely due to the greater development in the male of the upper tail-coverts, to form the beautiful metallic green train with its array of eye-spots. Similarly bizarre plumage differences are found in the birds-of-paradise (Paradisaeidae). For instance, in the King of Saxony Bird-of-Paradise *Pteridophora alberti*, the male has two plumes, one growing out of each side of his head. The plumes are about 45 cm long, which is twice the length of the rest of the bird.

In most sexually dimorphic species the sexes show the same constant sex difference throughout the year. But this rule is not universal. In the phalaropes, for example, the males and female both moult into a very similar winter plumage, but in the summer they moult into differing plumages, the female being more brightly coloured.

Theories of sexual dimorphism. The general reason for the evolution of sexual dimorphism is that natural selection can favour different characters in males and in females. There are three particular theories, variously invoking sex differences in reproduction ('sexual selection'), in feeding, and in risk of predation.

Sexual selection. The theory of SEXUAL SELECTION was invented by Charles Darwin, who used it in his book *The Descent of Man, and Selection in relation to Sex* (1871) to explain sexual dimorphism in birds. Sexual dimorphism, he argued, evolves when males (substitute 'females' in role-reversed species) with certain characteristics mate more than do males with other characteristics. The mating advantage might be due either to success in competition with other males, or because females preferentially mate with males that possess some particular characteristic. Preferential mating by females with the most extravagantly adorned males is the most likely explanation of the extreme sexual dimorphism such as that found in the Peafowl. Sexual selection is the only known theory which can explain the evolution of deleterious sexually-dimorphic characters, characters that reduce survival. The Peacock would probably survive better without his long train, but the train might still be a net benefit if it conferred a sufficient advantage in mating. Males, then, in these sexually dimorphic species may have a higher mortality rate than females. There are few observations testing this supposition. In one study of the Great-tailed Grackle *Quiscalus mexicanus* the sex ratio among nestlings was found to be 1:1. Two samples of adults revealed female biased sex ratios (43% and 29% males in the two samples of 939 and 1,349 individuals). The male Great-tailed Grackle is more brightly coloured and has a longer tail than the female. The bright colour might attract predators, and the long tail was observed to inhibit flight, especially in strong wind.

Feeding. Some differences between the sexes may have evolved to reduce competition for food between the male and female of a pair. If the male and female have a different bill size, they may eat different food. Thus when the pair forage they will not compete for the same food. For example, Selander (1972) studied the feeding habits of male and female melanerpine woodpeckers *Melanerpes* spp., which live on Caribbean Islands, and in central America. The species inhabiting the islands of Hispaniola and Puerto Rico have bills which are strongly sexually dimorphic. When Selander watched the feeding habits of the two sexes he found differences. The male and the female therefore probably take different food.

Stonechat *Saxicola torquata* male (above) and female (below) showing sexual dimorphism. (*Photo: J.B. & S. Bottomley*).

To prove that sexual dimorphism serves to reduce competition for food between males and females it is not enough to show that males and females take different food. It must also be shown that food is in so short a supply that the pair catch more food than if they were not dimorphic. That food is in sufficiently short supply in the melanerpine woodpeckers has not been proved, but it is a reasonable assumption.

Predation. The colours of birds may act as signals of various kinds to predators. The most important kind in the evolution of sexual dimorphism is probably the signal to the predator that the signalling bird is an 'unprofitable prey'. Some kinds of prey are easy to catch, and so 'profitable' to the predator. Others ('unprofitable') are less easy to catch. The predator would, if it could distinguish the easy from the difficult prey, concentrate on the easy catches. Thus if a bird is a difficult catch it may evolve bright coloration so that the predator, after a few failed attempts, will learn not to try to catch that kind of prey. The theory is very similar to the evolution of warning coloration in which predators learn to avoid sickening or distasteful prey by virtue of its bright coloration. That predators learn not to eat sickening prey has been proved in experiments.

The two sexes may differ in how easy they are for a predator to catch. If one sex is bigger, it may be better able to fight back. If one sex has to sit on the eggs, it will not be able to run away from predators so easily as the other sex which is not tied to the eggs. The sex which sits on the eggs will then evolve camouflage—it will become cryptically coloured. The other sex will evolve to be conspicuous.

The 'predation' theory predicts that the brightly coloured sex will be eaten less than the cryptic sex. This is the exact opposite of the prediction of the 'sexual selection' theory. As was noted above, few facts have been collected on sexual differences in mortality due to predation.

Explaining trends in sexual dimorphism. The three theories are not completely exclusive of one another. Sexual dimorphism could be favoured at the same time both by sexual selection and by the reduction of competition for food. In other cases the theories are exclusive: the theories of sexual selection and of predation lead to exactly opposite predictions of the relative mortality of the two sexes. The different theories also explain different kinds of dimorphism. The feeding theory explains sexual dimorphism of the feeding organ such as the bill; the predation theory explains sexual dimorphism of coloration; the sexual selection theory is more versatile: it can in principle explain sexual dimorphism of coloration, or of the size of any parts of the bird.

The main force in the evolution of sexual dimorphism would ideally be discovered by testing the three theories on many individual species. In the absence of such detailed studies, some idea of the main forces can be obtained by deriving different predictions from the three theories about which kinds of species should show sexual dimorphism and which should not. In all three theories there is a connection between the mating system and sexual dimorphism; but the connection is not the same in each case.

If sexual dimorphism evolves to reduce competition for food between the sexes, sexual dimorphism should be commoner in monogamous than in polygamous species. If, for example, the breeding group is of one male and three females, all the females would compete for the same food, and sexual dimorphism would be ineffective in reducing competition. However, the general trend is the opposite. Sexual dimorphism tends to be greater in polygamous than in monogamous species. If sexual dimorphism does reduce competition for food, therefore, it is probably a secondary consequence. The theory of sexual selection predicts a greater degree of dimorphism in polygamous than in monogamous species because there is greater competition for mates in polygamous species. Species with the most extreme differences between the males in the number of matings should evolve the most extreme dimorphism. This prediction is borne out: the extremely polygamous LEK species tend to be the most dimorphic. Sexual selection also predicts 'reversed' sex dimorphism in role-reversed species such as jacanas and phalaropes. In these species only the males care for the young, so sexual selection is reversed and females compete for males.

The predation theory makes similar predictions to the theory of sexual selection. If one sex cares for the young while the other is active, the more active sex will be more brightly coloured. So both theories predict the same patterns of sexual dimorphism in polygynous and polyandrous species.

Sexual selection, feeding, and predation are the main (but not the only) factors affecting sexual dimorphism. We do not yet know their relative importance. See photos HEAT REGULATION; LEK. M.R.

Baker, R.R. & Parker, G.A. 1979. The evolution of bird coloration. Philosophical Transactions of the Royal Society of London B287: 63–130.
Selander, R.K. 1972. Sexual selection and dimorphism in birds. *In* Campbell, B. (ed.). Sexual Selection and the Descent of Man. London.

SEXUAL SELECTION: a form of natural selection resulting from competition between members of one sex for opportunities to mate with members of the opposite sex. Darwin pointed out that sexual selection could arise either by direct competition for access to members of the opposite sex, e.g. by fighting ('intrasexual selection') or by differences in ability to court members of the opposite sex ('epigamic' or 'intersexual selection'). The distinction is not absolute: males may compete with each other for high quality territories and females may choose to mate with males that possess such territories. Sexual selection often results in the production of characteristics, such as the bizarre plumage and exhausting courtship behaviour of the Ruff *Philomachus pugnax*, that benefits the individual but is wasteful in terms of the species as a whole. The realization that this is also true of other forms of natural selection has led evolutionists to consider sexual selection as part of natural selection, rather than as a distinct phenomenon (see NATURAL SELECTION).

In general, the number of offspring a female produces does not depend on the number of males she mates with but on her capacity to produce eggs. Selection will generally favour females that only allow themselves to be inseminated by males that are likely to have genetically fit offspring, since those offspring will bear the genetic output of the females. Males, however, can inseminate many females with little physiological effort, so selection generally favours males that inseminate any willing females, even females that are unlikely to produce many offspring. This is why females generally require to be courted whereas males are less discriminating. It is also why sexual selection is most intensive in males.

In birds, parental care is important in determining the survival of offspring and a male may increase his reproductive output more by caring for the offspring of one mate than by striving to obtain many mates but not helping to raise his offspring. This is why birds are typically monogamous, in contrast to the majority of animals. In those species where paternal care is less important, polygyny prevails and there is more intensive sexual selection. Many polygynous species show marked SEXUAL DIMORPHISM, with elaborate male plumages and much effort put into competition between males. In species where males, not females, are mainly responsible for parental care, the males are a resource for which females compete, so that sexual selection is more intensive on the females than on the males, leading to 'sex-role reversal' (e.g. PHALAROPE).

Though of reduced intensity, sexual selection still occurs in monogamous species. The members of each sex compete to mate with those members of the opposite sex that are likely to produce most surviving offspring, because they are ready to breed at the optimum season, are in possession of high quality territories, and are likely to be good parents.

While the processes of intrasexual selection are easy to understand, those involved in epigamic selection are less clear. Such selection arises because females (usually) choose males with certain characters. If some females show a preference for a particular type of male, and the rest of the females show no preference, then the preferred type of male will be selectively favoured, other things being equal. Furthermore, as first noted by R.A. Fisher, the preference itself is selectively advantageous. Males of the preferred type, and thus the females that prefer them, will tend to produce sons of the preferred type; these will be selectively favoured because they are of the preferred type; thus their mothers, females showing the preference, will tend to produce more grandchildren than females that do not show the preference. Thus there is a runaway process in the joint establishment of the preference and the preferred characteristics. The female choice may originate in various ways. Its origin may be 'accidental', a by-product of other selective forces operating on the behavioural repertoire of the female. Alternatively females may choose mates that are likely to be good fathers, either because they are able to care for their offspring well or because they are likely to pass on to their offspring genes that will result in the offspring being genetically fit. Courtship feeding by terns, for example, may be a way in which a male demonstrates his fish-catching abilities, on which his success as a father partly depends, to a potential mate.

Sexual selection may be important in the development of breeding barriers between species. Suppose that the hybrids between two populations are less fit than individuals of pure parentage, as may happen when the genetic constitutions of two populations originally of the same species come to diverge markedly. In each population, selection will favour those individuals that choose to mate only with members of their own population. The result will be the evolution of discriminatory behaviour and of species-specific recognition characters (see SPECIATION). J.J.D.G.

Halliday, T. 1980. Sexual Strategy. Oxford.
O'Donald, P. 1980. Genetic Models of Sexual Selection. Cambridge.

SHAFT: see FEATHER.

SHAG: substantive name almost interchangeable with 'cormorant' for *Phalacrocorax* spp.; but in the British Isles, each name standing alone, Shag means *P. aristotelis* and Cormorant means *P. carbo* (see CORMORANT).

SHAKESPEARE'S BIRDS: see POETRY, BIRDS IN (References).

SHAKETAIL: substantive name sometimes used for *Cinclodes* spp. (see OVENBIRD (1)).

SHAMA: substantive name of some *Copsychus* spp. (for subfamily see THRUSH).

SHANK: a popular term for the whole or some part of the leg, lacking definition (see LEG). In such bird names as 'redshank' it clearly refers to the visible part of the leg, and especially to the so-called tarsus (which is in fact the foot, and thus not equivalent to any part of the human leg that would be thus termed).

SHAPE AND POSTURE: see SIZE.

SHARMING: grunts and squeals of a Water Rail *Rallus aquaticus*.

SHARPBILL: substantive name of *Oxyruncus cristatus*, sole member of the family Oxyruncidae (Passeriformes, infraorder Tyranni). A Neotropical species with a rather discontinuous distribution in upper tropical and lower subtropical humid forests in Costa Rica, Panama, south-eastern Venezuela, Guyana, Surinam, south-eastern Brazil and Paraguay. It is about 16 cm long with a stout, short-legged, small-headed appearance. The bill tapers from a broad base to a sharply pointed tip. The plumage is olive green above and pale yellow below, profusely spotted with black. A flattened crest with elongated scarlet feathers is present but usually concealed. The sexes are similar in appearance but males have a serrated outermost (10th) primary of unknown function.

Sharpbills are occasionally encountered among canopy-feeding flocks of barbets, honeycreepers and tanagers. Birds watched in the Serra dos Orgãos, Brazil, in December were feeding largely on invertebrates, 'caught with great agility from among the leaves in the very outermost twigs of the canopy. A common technique involved hanging upside down and feeding tit-like with rapid pecks into the bases of leaf-clusters' (Brooke *et al* 1983), to which the bird's sharp bill is well adapted. Stomach contents and other field observations suggest a diet mainly of berries.

Males apparently call from expanded leks of 4 to 6 individuals. The advertisement call varies geographically but is basically a buzzy, high-pitched, long-drawn-out whistle, which gradually descends in pitch.

The first Sharpbill's nest was found in October 1980 in montane forest some 50 km north of Rio de Janeiro. It was situated just below the higher leaves in the canopy of a 30 m tall tree. Only one bird, assumed from its drab plumage to be the female, was ever seen. The nest was a shallow cup made of leguminous petioles and a few dry leaves, coated with mosses, liverworts and spiders' webs, and was saddled, like a hummingbird's nest, on a slender horizontal branch. There were probably 2 eggs, which hatched after between 14 and 24 days' incubation; the fledging period was probably 25–30 days. N.G.S.

Brooke, M. de L., Scott, D.A. & Teixeira, D.M. 1983. Some observations made at the first recorded nest of the Sharpbill *Oxyruncus cristatus*. Ibis 125: 259–261. (Contains useful list of references.)

Mees, G. 1974. Additions to the avifauna of Suriname. Zool. Mededelingen 48: 55–67.

Ridgely, R.S. 1976. A Guide to the Birds of Panama. Princeton.

Wetmore, A. 1972. The Birds of the Republic of Panama, Part 3. Smithsonian Institution.

SHARPTAIL: abbreviated name of the Sharp-tailed Grouse *Tympanuchus phasianellus* (see GROUSE).

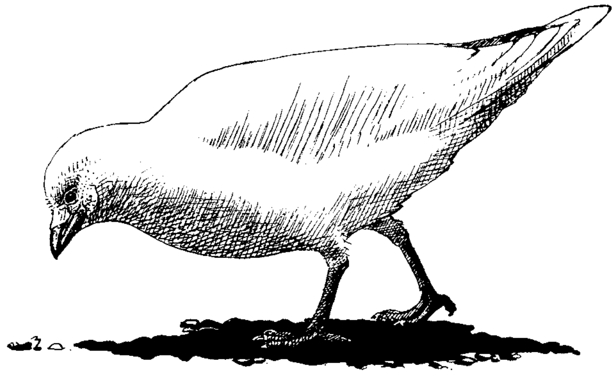
SHEARTAIL: substantive name of *Doricha* spp. and *Thaumastura cora* (for family see HUMMINGBIRD).

SHEARWATER: substantive name of certain species of Procellariidae, in the genera *Puffinus*, *Procellaria*, etc.; in the plural, a general term for these (see PETREL). The name is sometimes locally misapplied to other sea birds, e.g. *Rynchops* spp. (see SKIMMER). See photo NOCTURNAL HABITS.

SHEATHBILL: substantive name of the 2 species of Chionidae (Charadriiformes, usually placed in the suborder Charadrii); in the plural, general term for the family.

Characteristics. Sheathbills are small white pigeon-like shorebirds 36–42 cm long; biochemical indicators suggest slightly closer affinities with Lari than with Charadrii.

'Sheathbill' derives from the horny yellow-green sheath that covers the base of the short, stout bill. In American Sheathbills *Chionis alba* the bill is yellow and black, in the Lesser Sheathbill *Chionis minor* (which is slightly smaller) it is almost entirely black. The eyes are pink-rimmed and the cheeks bear wattles and patches which are small in juveniles, bigger in mature birds. The plumage is entirely white with grey underdown. The legs, blue-grey or pink, are short and stout, and the toes have only vestigial webs. Although sheathbills have been seen in flight several hundred km from land and are capable of long migratory flights, they spend much of their time on the ground, trotting busily about the shore in search of food and showing reluctance to fly even when pursued. The wings are small, with sharp carpal spurs that the birds use in fighting. Males are slightly larger and heavier than females.



Sheathbill *Chionis alba*. (*B.P.*).

Habitat and distribution. Sheathbills live on or close to the shore of islands in the sub-antarctic sectors of the Atlantic and Indian Oceans, often but not exclusively in association with penguin colonies. Sheathbills (or American Sheathbills) breed on South Georgia, the South Orkney and South Shetland Islands, possibly the South Sandwich Islands, and the Antarctic Peninsula to about 65°S; some winter in Patagonia, the Falkland Islands and Tierra del Fuego, others are resident through the year. Lesser sheathbills breed on Marion, Prince Edward and Heard Islands and Iles Crozet and Kerguelen; island races are postulated.

Food. Sheathbills feed on shore animals of the intertidal zone; they eat large quantities of *Ulva* and other algae, perhaps for the animals that live among them, and dig with their bills in crevices between rocks. Stranded plankton, faeces of seals and penguins, carcasses and offal of every kind are taken. On penguin colonies they scavenge for eggs and fallen chicks, darting between the brooding parents to pick up scraps of spilled food; some learn to flutter or peck at parents engaged in feeding their chicks, causing both to spill food. Though constantly in danger from darting beaks, they are usually quick enough to escape without harm.

Behaviour. Between breeding seasons they live in small flocks, quarrelling frequently among themselves and feeding communally. They are inquisitive and enterprising in searching for food, quickly learning to associate with men at expedition bases and campsites.

Voice. Sheathbills are usually silent; chicks have cheeping alarm and food calls, adults croaking or growling threat calls.

Breeding. The nests are built in crevices and under boulders, often on a rocky headland overlooking a penguin colony. Sheathbills continue to feed gregariously but nest in isolation; nests are well hidden and approached indirectly. Two to 4 brown eggs, flecked with grey or black, are laid in December/January; incubation (both parents) takes 29 days. Chicks hatch asynchronously in brown down, changing to grey mesoptile down at 7 days and fledging in 7 to 9 weeks. Most pairs rear one or 2 chicks only. B.S.

Jones, N.V. 1963. The Sheathbill, *Chionis alba* (Gmelin), at Signy Island, South Orkney Islands. Bull. British Antarctic Survey 2: 53–71.

SHELDGEESE: general term for some larger species of Tadornini (Anatidae) (see under DUCK).

SHELDUCK: substantive name of *Tadorna* spp.; used without qualification in Britain for *T. tadorna*, and sometimes written 'sheld-duck' or 'sheldrake' (see DUCK).

SHELL-GLAND: or 'uterus', part of the oviduct (see LAYING; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

SHIELD, FRONTAL: a hard, featherless plate extending from the base of the upper mandible backwards over the forehead, as in coots *Fulica* spp. and others (compare CASQUE).

SHIKRA: *Accipiter badius* (see HAWK).

SHOEBILL: name, alternatively 'Shoe-billed Stork' or 'Whale-headed Stork', of *Balaeniceps rex*, sole member of the Balaenicipitidae, a family of disputed affinities. It has usually been placed in the order Ciconiiformes, sometimes in the suborder Ardeae, sometimes, as here in the suborder Ciconiae—even in the Ciconiidae (see STORK) instead of in a separate family—and sometimes in a suborder of its own. Wetmore (1960) holds that it has affinities both with Ciconiae and Ardeae, and that the resemblance of the skull to that of Pelecaniformes is due to convergence. More recent behavioural and morphological studies have not altered this assessment (Guillet 1979).

Characteristics, habitat and behaviour. The Shoebill is a large bird, standing 120 cm high or more, with slaty plumage, long dark grey legs with very long toes. The most obvious character is the large head on a not very long neck, with a slight untidy crest on the nape and an enormous bulging bill, particoloured and carrying a hook on the upper mandible. It is a bird of swamps and water margins, often standing on 'islands' of floating vegetation. In such situations it remains motionless, bill on breast, waiting for fish or other aquatic prey to come within reach. The highly modified bill is adapted for catching and extracting prey among dense aquatic vegetation; and it is not used, as has been claimed, for digging lung-fish out of the mud. It is partly nocturnal in its habits and it is considered to be of a rather sluggish disposition; but it can fly strongly—and soar—on its broad wings, with neck drawn in and bill resting on the breast (as in the Pelecanidae). It is not a gregarious bird; and it is rather silent, apart from a laughing note and a stork-like clattering of the bill which is mainly performed during territorial and courtship displays.

Distribution. The species has a limited range in eastern tropical Africa, mainly in the southern Sudan, northern Uganda, and some eastern parts of Zaire. The semipermanently flooded White Nile valley and the swampy borders of Uganda lakes are typical habitats.

Breeding. The nest is a truncated cone of grass placed on floating vegetation, occasionally on an islet; in this, 2, sometimes only 1 or 3 bluish white chalky eggs are laid. The young are downy and nidicolous.

SHOVELER: substantive name of some *Anas* spp.; used without qualification in Britain for *A. clypeata* (see DUCK).

SHRIKE: substantive name (or part of compound name) of most species of Laniidae (Passeriformes, suborder Oscines); in the plural, general term for the family. Formerly considered by Rand (1960) to include 4 subfamilies: Prionopinae, the helmet-shrikes; Malaconotinae, the bush-shrikes; Laniinae, the true shrikes; and the monotypic Pityriasinae containing the Bornean Bristlehead *Pityriasis gymnocephala*. In this volume Voous, following others, places the helmet-shrikes in their own family Prionopidae and, in addition, places the Bristlehead in its own family Pityriasididae. Recently the bush-shrikes have been placed in their own family Malaconotidae (see Benson and Benson (1977) for reasons and references) but Voous retains them as a subfamily of Laniidae. Sibley (1970) has emphasized, however, that relationships between shrikes are complicated by the frequency of convergence of the shrikelike bill, and similarities of egg white protein patterns of some bush-shrikes and true shrikes are not sufficient proof of a relationship between them.

Of the 68 species of true shrikes and bush-shrikes recognized by Hall and Moreau (1970), the only ones not endemic to the Afrotropical Region are an isolated population of the Black-headed Tchagra *Tchagra senegala* in North Africa, and 13 species of *Lanius* which inhabit the Holarctic region, apart from a race of the Black-headed Shrike *L. schach* found in New Guinea. Six of the 8 *Lanius* species endemic to Africa are closely related to Eurasian species and a number of superspecies have been proposed (Hall and Moreau 1970, Mayr and Short 1970). Similarly Hall and Moreau have grouped 37 of the other 47 African shrikes into 9 superspecies. Their approach emphasizes the high degree of specialization and subsequent speciation that has occurred in African shrikes, and their groupings and nomenclature are followed here. They retain the genus *Rhodophoneus*, which Rand (1960) absorbs into *Tchagra*, and place the members of the genus *Telophorus* in *Malaconotus*. In the past these have been separated on the grounds of size but this ignores the remarkable evolutionary parallelism that exist in the 2 genera (White 1962).

Systematic characteristics. All shrikes have a sharply hooked bill with a tooth in the upper bill and a corresponding notch in the lower mandible. Their legs and feet are strong and the claws sharp for catching prey. The wing has 10 primaries and the tail 12 rectrices.

Malaconotinae. These are a mixed group. In some (*Malaconotus*) the bill is large and strong, in others (e.g. *Tchagra*) moderately so, and in others (*Dryoscopus*) relatively weak. The feathers on the rump are soft and elongated, particularly so in *Laniarius* and *Dryoscopus*. Seven genera are recognized: *Lanioturdus*, *Nilaus*, and *Rhodophoneus* (all monotypic), *Dryoscopus* (6 species), *Tchagra* (5 species), *Laniarius* (15 species) and *Malaconotus* (16 species). In many species, but not all, the sexes are dimorphic. Their lengths range from medium (14.5–19.5 cm) in *Dryoscopus* to large (18.5–27.0 cm) in *Malaconotus*.

Laniinae. These are the most typical of the shrike family. The bill is particularly strong and heavily notched, the external nostrils are oval and partly covered with small hairs, the rictal bristles are well developed, the tarsus scutellated only in front and lamellated behind. Two genera are recognized: *Lanius* (21 species) and *Corvinella* (2 species) which is occasionally split into a third genus *Urolestes*. The majority are sexually dimorphic. In *Lanius* lengths are in the range 15–31 cm and in *Corvinella* 30–35 cm.

Field characteristics, habitat and distribution

Malaconotinae. Of the 3 species in monotypic genera, the most widely distributed is the Brubru *Nilaus afer*. It inhabits moist and dry savanna woodlands north and south of the Equator and several races are recognized. Males are black above, females brown, and both are mottled with white and buff; the underparts are white with some chestnut.

Four of the 6 puff-backs *Dryoscopus* spp. are placed in a superspecies. They are similarly patterned black, white and grey above and white below. Differences between males mainly lie in bill size; the females have distinctive colours. Usually they are allopatric but when sympatry occurs the species are always ecologically separated. The Black-backed Puff-back *Dryoscopus cubla* occupies the mainly deciduous woodland in southern Africa and the Puff-back *D. gambensis* similar habitat in West Africa. The Black-shouldered Puff-back *D. senegalensis* occurs in secondary forest in Zaire and Nigeria, and Pringle's Puff-back *D. pringlii* in dry acacia steppe in north-east Africa. In contrast, the other puff-backs are forest birds.

The tchagras have rufous wings, brown backs, paler underparts, black and white graduated tails and patterned heads. Three of them have mainly brown heads and each may be distinguished from the others by the size of the bill and amount of black on the head; in addition, all 3 are allopatric. The Brown-headed Tchagra *Tchagra australis* is widespread in savanna woodland throughout Africa; it is replaced by the Three-streaked Bush-shrike *T. jamesi* in acacia steppe in Somalia and Kenya and by Levaillant's Bush-shrike *T. tchagra* in the coastal strip from Natal to Cape Town. In contrast, the Black-headed Tchagra *T. senegala* has a black crown and, although it has a similar distribution to *australis*, it, in general, prefers a drier habitat. The Blackcap Tchagra *T. minuta* is restricted to wetter areas than are the other tchagras and is the only one which is sexually dimorphic.

The *Laniarius* species divide into 3 colour groups in each of which the species are largely allopatric. In the crimson group, 3 out of the 4 species with crimson underparts inhabit acacia steppe and sometimes are considered conspecific; the Gonolek *L. barbarus* in West Africa, the Black-headed Gonolek *L. erythrogaster* in central Africa and Burchell's Gonolek *L. atrococcineus* in southern Africa. The fourth, *L. mufumbiri*, is smaller, has a distinctive orange tinge to the crimson, and is confined to papyrus swamps in central Africa. In other parts of Africa they are replaced by other members of the group which are coloured differently. The most divergent of the group is the Red-naped Bush-shrike *L. ruficeps* found in the arid acacia steppe of north-east Africa. The black of the back is mixed with grey and white and it has a prominent white eye-stripe not present in the others. The female is more olive grey on the mantle. In the other species of this group the sexes are alike.

The black and white group has 4 species often considered conspecific. The best known is the Bell Shrike or Tropical Boubou *L. aethiopicus*, which is glossy blue black above and pinkish white below. It inhabits thickets in savanna woodland throughout Africa, both lowland and montane. In southern Africa, coastal Gabon and Angola, and in the forests of Sierra Leone and Guinea, it is replaced by 3 other species of the group.

The black group, some of which show sexual dimorphism, range in colour from deep black to dark slate grey. The Sooty Boubou *L. leucorhynchus* occurs in West African and Zaire lowland forest blocks and, in contrast, the Slate-coloured Boubou *L. funebris* in acacia steppe in north-east Africa. The distribution of the other 2 species is restricted to separate montane forest blocks some 2,200 km apart.

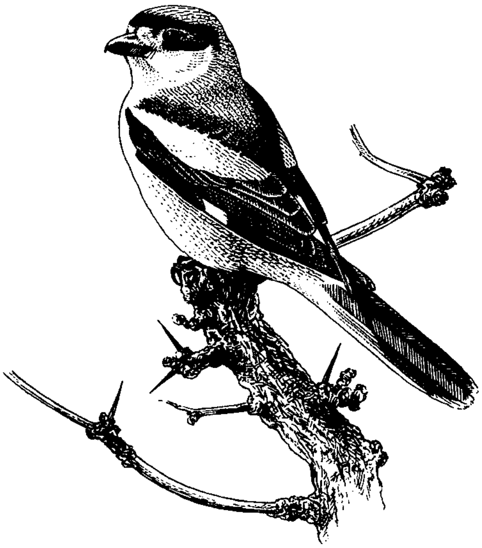
Of the *Malaconotus* species 10 are grouped into 2 superspecies. Both contain savanna and forest species, those in the lowland forest being polymorphic. The remarkable feature about them is that wherever a savanna or forest form of one superspecies meets a corresponding form of the second superspecies there is almost perfect colour match between them. Thus the savanna dwelling Sulphur-breasted Bush-shrike *M. sulfureopectus*, with green back, grey head and mainly yellow underparts, is simply a small replica of the much larger savanna species, the Grey-headed Shrike *M. blanchoti*. Similarly the small Many-coloured Bush-shrike *M. multicolor*, found in the forests of West Africa and Zaire, is matched in colour by the Fiery-breasted Bush-shrike *M. cruentus*, a larger forest species in the other superspecies (further details are given in Hall, Moreau and Galbraith 1966).

Of the remaining 6 species, 3 are grouped to form a third superspecies. They are all bright green above, their tails are black and breasts red with a black pectoral band. Two are birds of thicket and forest edge, Perrin's Bush-shrike *M. viridis* in Angola, and the Four-coloured Bush-shrike *M. quadricolor* in Kenya, Mozambique and South Africa. The other, Doherty's Bush-shrike *M. dohertyi*, is confined to mountains of eastern Zaire.

Laniinae. The true shrikes are birds of open woodland, rarely forest edge. They have the habit of dropping off a perch when alarmed and flying off close to the ground before swooping up to the next perch. When perched they frequently swing their tails from side to side, and up and down.

Two of the red-backed group occur in Africa. Emin's Shrike *Lanius gubernator* inhabits the savannas north of the Equator, and Souza's Shrike *L. souzae* the brachystegia woodlands south of the Equator. Both are similar but not identical to the Red-backed Shrike *L. cristatus* (*collurio* considered a race of *L. cristatus*) the male of which has a grey head, a black eye streak, and a grey rump. The races of *cristatus* in Asia are a uniform mouse brown on the upperparts and these have sometimes been treated as a separate species. Other red-backed shrikes replace it in south-east Asia and India and overlap its distribution in eastern Asia.

Five black and white shrikes, all with long graduated tails, are found in Africa. All are essentially allopatric, but when sympatry occurs there is ecological segregation between species. The most widely distributed is the Fiscal Shrike *L. collaris* which occurs throughout Africa in savanna woodland, forest clearings and cultivations. The Great Grey Shrike *L. excubitor*, a paler bird than *collaris*, is only found along the southern edge of the Sahara but is widespread in the Palearctic and is the only shrike found in North America (the Loggerhead Shrike being considered a race); numerous races have been described. Two other African black and white shrikes with very long tails, the Grey-backed Fiscal *L. excubitorius* and the Long-tailed Fiscal *L. cabanisi*, are noted for their sociability. They are allopatric and occur in wooded savannas of central and east Africa. Two other sociable shrikes in Africa have unusual coloration; the Yellow-billed Shrike *Corvinella corvina* of west and central Africa is a heavily streaked brown shrike with yellow bill, the Magpie Shrike *C. melanoleuca*, confined to the southern half of Africa, is black with some white on the flanks and in the tail.



Woodchat Shrike *Lanius senator*. (*A.H.*).

The Strong-billed Shrike *L. validirostris* is of interest as it is confined to the Philippines and found in oak and pine forest between about 1,300 m and 2,600 m. Its upperparts are grey, wings and tail brown-black, and underparts grey-white with rufous flanks; a black streak extends from the lores to the ear coverts.

Movements. Although there are no ringing data to show that shrikes endemic to Africa migrate within it, there are visual records which suggest that local movements occur in some populations of the Sulphur-breasted Bush-Shrike, and are likely in the Brubru and Magpie Shrike.

Africa is the wintering area for all populations of the Lesser Grey Shrike *L. minor*, Woodchat *L. senator* and Nubian Shrike *L. nubicus*, and for some populations of the Red-backed Shrike and the Red-tailed Shrike *L. isabellinus* (Moreau 1972); their other populations winter in south-east Asia. Of the other Laniinae found outside Africa only 4 migrate southwards after breeding further north; the Chinese Great Grey Shrike *L. sphenocercus* winters from Korea southwards; the Tiger Shrike *L. tigrinus* winters in the Malay peninsula, some stragglers reaching the Philippines and Sulawesi; some populations of the Bull-headed Shrike *L. bucephalus* winter in central Korea and south China; and some populations of the Black-headed Shrike migrate into northern India. Only the most northern populations of the Great Grey Shrike migrate southwards after breeding.

Food

Malaconotinae. These are predominantly insectivorous. All tchagras, *Rhodophoneus* and most, if not all, *Laniarius* species feed near or on the ground in or under thicket, but in more open areas *Rhodophoneus* is more arboreal. The Flycatcher-shrike *Lanioturdus torquatus* feeds both on the ground and in trees. All other members of the subfamily are arboreal feeders, the puff-backs feeding much like warblers. Occasionally the Grey-headed Shrike takes other food items (various vertebrates and bird's eggs), and so do the Southern Boubou *L. ferrugineus*, the Brown-headed Tchagra and the Black-headed Tchagra (van Someren 1956).

Laniinae. These characteristically search the ground for prey from a vantage point, from which they drop to the ground to catch it. Although a great variety of insects are taken, many depend on small vertebrates for an important part of their diet. They may catch insects on the wing, search for prey on the wing, hovering before pouncing on it, and some search leaf litter. Most Palearctic species use larders but only 2 shrikes in Africa are known to do so, Mackinnon's Shrike *L. mackinnoni* and some races of the Fiscal Shrike. None of the shrikes that winter in Africa are known to use larders while there.

Behaviour

Malaconotinae. In general, bush-shrikes are found singly or in pairs but small groups (5 or 6 birds), apparently not family groups, of Brown-headed Tchagras, Grey-headed Shrikes and Fiery-breasted Shrikes have been reported. They breed in pairs and some remain paired throughout the year (observed in *Laniarius*, *Dryoscopus*, *Tchagra* and *Malaconotus* species) (Kunkel 1974). What little data we have on this group suggest that both sexes build nests, incubate and feed young, and that territories are maintained outside the breeding season by some savanna species. The puff-backs and the Brubru form mixed feeding parties with other species in the non-breeding season.

Courtship display in *Dryoscopus* involves the raising of the rump feathers by the male to produce the puff from which the genus obtains its name; this also occurs in some *Laniarius* species (details in van Someren 1956). In the tchagras it involves a display flight with duetting, and some wing flapping, although less developed in the Blackcap Tchagra.

Little is known of the monotypic genera *Lanioturdus* and *Rhodophoneus*. Both are found in parties, particularly the latter which forms noisy display groups on the ground at dusk, the significance of which is not known.

Laniinae. The majority of true shrikes breed in pairs, are highly territorial even when on migration, and some are known to hold territories in their winter quarters (Red-backed Shrike, Lesser Grey Shrike and probably the Great Grey Shrike). The migratory species are usually solitary in winter quarters and usually migrate singly, but the Woodchat and some races of the Red-backed Shrike are paired on arrival at their breeding grounds. The Fiscal Shrike may remain paired for several years and Souza's Shrike remains paired outside the breeding season. In several species both sexes help in nest building, incubation and feeding young; in others the male has only been reported feeding young.

In contrast, the 2 *Corvinella* species, the Grey-backed Fiscal and the Long-tailed Fiscal, are all highly social. Although the first 3 breed in groups of 5 or more birds (Grimes 1980), some populations, at least, of the Long-tailed Fiscal breed in pairs with individual territories (van Someren 1956). Nothing is known about the permanency of the pair bond; in the Yellow-billed Shrike a female may remain the breeding female of a group for more than one breeding season and then become the breeding female of a subsequent group.

Voice

Malaconotinae. The bush-shrikes have a diverse range of calls rather than a recognized song, although the Olive Bush-shrike *M. olivaceus* is noted for its warbling song. The Brubru, an onomatopoeic name, utters a drawn out *brruuu*, reminiscent of a pea whistle, which often is answered by the female with a similar note of lower pitch. The calls of *Dryoscopus* species are variously described as loud, oft repeated or prolonged whistles; the Puff-back has a melodious song and the Black-backed Puff-back is known to duet. The tchagras are noted for their melodious, almost human whistles, given during a display flight, occasionally from a perch, while the female responds antiphonally with a call characteristic of the species. Duet song, usually antiphonal, is characteristic of all the *Laniarius* species. Each *Malaconotus* species has loud, distinctive and repetitive calls, that of the Bokmakierie *M. zeylonus* is onomatopoeic, and duetting is frequent.

Laniinae. Although the true shrikes have harsh and discordant contact and alarm calls, the majority of them have notable songs and many are good mimics.

Breeding. The nests of the Brubru, puff-backs, tchagras, gonoleks and boubous are inconspicuous but neatly formed shallow cups, either secured to a horizontal branch as in the Brubru, or placed in a fork of a tree from 2–7 m above ground. Occasionally nests of puff-backs are found as high as 18 m. Materials used include tendrils, spider webs, lichen, rootlets, grass and bark fibre.

In *Malaconotus* the nests of the majority of species are usually shallow cups of twigs, tendrils and root fibres, lined with finer materials, and placed 3–8 m above ground; some species build as high as 18 m. The nest of Lagden's Bush-shrike *M. lagdeni* is described as a bulky bowl of dry leaves and bracken.

The nests of the Laniinae also vary a great deal. Those constructed at high latitudes have wool, hair and feathers as lining, whereas those at lower latitudes are usually lined only with tendrils and fibres or grass. Nests are built from twigs, tendrils and other materials and usually placed 3–9 m high in a tree, although the Red-backed Shrike prefers thickets and brambles.

Shrike eggs have a range of ground colours, variously listed as white, greyish-white, pale-blue grey, blue, greenish blue, and pale pinkish. The eggs are either streaked, speckled or blotched with various shades of brown, purple-brown and chestnut-brown, the markings being concentrated usually at the large end. The clutch size of bush-shrikes is either 2 or 3, not 4 or more. By contrast, a clutch of 4 or more has been recorded in the following African *Lanius* species: Fiscal Shrike, Somali Shrike *L. somalicus*, Taita Fiscal *L. dorsalis*, Grey-backed Fiscal, Long-tailed Fiscal and the 2 *Corvinella* species; in others for which data are known the clutch is 2 or 3 (Mackinnon's Shrike, Souza's Shrike, Great Grey Shrike). The resident shrikes in India and south-east Asia have clutches between 3 and 6, although it is 2 for the New Guinea race of the Black-headed Shrike. The clutch size of shrikes breeding in higher latitudes is in the range 5–7, but larger clutches are not uncommon.

Incubation periods are most frequently in the range 12–14 days, occasionally 15–18 days for some *Lanius* species. The most frequently reported range for the nestling period is 16–20 days, but 12–15 days are recorded for the Red-backed Shrike and the Lesser Grey Shrike. The breeding seasons of shrikes in Africa, India, and south-east Asia are prolonged and overlap both dry and wet seasons. The migratory shrikes breed during the northern summer, some as early as April but mainly in late May, June and early July. L.G.G.

SHRIKE, ANT-: see ANTSHRIKE; ANTBIRD.

SHRIKE-BABBLER: substantive name of *Pteruthius* spp. (see BABBLER).

SHRIKE, BUSH-: see BUSH-SHRIKE; SHRIKE. Also used as substantive name in some genera of Formicariidae (see ANTBIRD).

SHRIKE, CATERPILLAR-: see CUCKOO-SHRIKE.

SHRIKE, CROW-: name sometimes applied to *Strepera* spp. See CURRAWONG.

SHRIKE, CUCKOO-: see CUCKOO-SHRIKE.

SHRIKE, FLYCATCHER-: see CUCKOO-SHRIKE.

SHRIKE, HELMET-: see HELMET-SHRIKE.

SHRIKE, PEPPER-: see PEPPER-SHRIKE.

SHRIKE, SONG-: name sometimes used for CRACTICIDAE.

SHRIKE, SWALLOW-: see WOOD-SWALLOW.

SHRIKE-THRUSH: substantive name of *Colluricincla* spp. (see THICKHEAD).

SHRIKE-TIT: substantive name, in Australia, of *Falcunculus* spp. (see THICKHEAD).

SHRIKE-TYRANT: substantive name of the species of *Agriornis*, a genus of South American tyrant-flycatchers (see FLYCATCHER (2)).

SHRIKE, VANGA: see VANGA.

SHRIKE-VIREO: substantive name of species of the subfamily Vireolaniinae (Passeriformes, suborder Oscines); in the plural, general term for the subfamily. The shrike-vireos are a small group of arboreal song-birds confined to the forested regions of continental tropical America. The 2 genera and 3 species are sometimes placed in a separate family, the Vireolaniidae, but are now often included, as here, in the Vireonidae. The shrike-vireos differ from typical vireos in having a heavier bill, which is hooked at the tip (see VIREO; also PEPPER-SHRIKE). They feed mainly upon caterpillars and mature insects which they glean from the foliage of trees but vary their diet with berries. Like typical vireos and pepper-shrikes, they hold large objects beneath a foot while they tear them apart with the bill.

Characteristics, habitat, distribution and behaviour. The Chestnut-sided Shrike-Vireo *Vireolanius melitophrys*—the only member of its genus—is a stout, long-tailed bird about 17 cm long. The largest member of the subfamily, it is also the northernmost and the only one of which the sexes, although similar in plumage, are readily distinguished in the field. Its upper plumage in plain olive-green, with the top and back of the head slate-grey, bordered on each side by a yellow superciliary stripe, below which a black band stretches from the lores to the ear coverts. The ventral plumage is white, with black malar streaks and a chestnut band that crosses the breast and continues along the sides and flanks. This little-known bird is found, chiefly in forests of pine, oak, and other broad-leaved trees, from central Mexico to the volcanic highlands of Guatemala and from 1,200 to 3,000 m. It forages, often in pairs, amid the foliage of trees and shrubs at all heights, where it moves slowly and deliberately, peering from side to side, sometimes hanging inverted to pluck an insect from a leaf. Among its notes are a low, nasal rattle and a peculiar, long-drawn, high-pitched, far-carrying, whistled screech. The two known nests, built by both sexes, were hemispheric cups, attached by their rims to the arms of horizontal forks, in the usual manner of vireos. Situated amid foliage at heights of 7–8 m, they were composed largely of filamentous lichens and vegetable fibres. Eggs, incubation and care of young remain undescribed.

The 2 species of *Smaragdolanius* inhabit heavier, more humid forests at low and middle altitudes. The Green Shrike-Vireo *S. pulchellus* is about 14 cm long. Its upper plumage is bright parrot-green with more or less blue on the crown. The throat is yellow, and the remaining under parts light greenish yellow. From south-eastern Mexico to Colombia and north-western Venezuela, this bird lives in the upper levels of the forest, from which it sometimes ventures into neighbouring clearings with scattered trees. Although its loud, clear, tirelessly repeated whistles, grouped in trios or more rarely quadruplets, are often heard, its nest has apparently never been found. Equally unknown are the breeding habits of the Slaty-capped Shrike-Vireo *S. leucotis*, widespread in tropical South America. Both sexes are olive-green above, mostly bright yellow below, with the head boldly marked with a yellow superciliary band, a black streak through the eye to the hindhead, and below this a white streak.

Barlow, J.C. & James, R.D. 1975. Aspects of the biology of the Chestnut-sided Shrike-Vireo. Wilson Bull. 87: 320–334.

SIBIA: substantive name of the species of BABBLERS of the genera *Heterophasia* and *Crocias*.

SIBLING SPECIES: 2 or more closely related species that are morphologically very similar but are reproductively isolated (i.e. able to inhabit the same area without interbreeding); sometimes called 'cryptic species'.

SICK BIRDS, CARE OF: see CARE OF INJURED, SICK AND ORPHANED BIRDS.

SICKLEBILL: sole or substantive name used for various species possessing the form of bill suggesting it; these belong to several widely separated families. Thus, it is the name of *Falculea palliata* (see VANGA) and of *Hemignathus procerus* (see HAWAIIAN HONEYCREEPER), the latter alternatively called 'Akialoa'. Again, it is the substantive name of *Drepanornis* spp. and *Epimachus* spp. (see BIRD-OF-PARADISE), and also of *Eutoxeres* spp. (see HUMMINGBIRD). Further, it has been used (but 'scythebill' is now preferred) as the substantive name of *Campylorhynchus* spp. (see WOODCREEPER); and it is sometimes applied, in Australia, to the White Ibis *Threskiornis molucca* (see IBIS).

SICKLES: term (plural) sometimes applied to elongated central tail feathers, found in certain species.

SIEGE: see ASSEMBLY, NOUN OF.

SIERRA-FINCH: substantive name of the species of *Phrygilus*, a genus of finches found in the Andes and the temperate southern extremity of South America (for family see FINCH).

SIGHT: see VISION.

SIGNAL: see DISPLAY; RELEASER.

SIGNIFICANCE: see BIOSTATISTICS; STATISTICAL SIGNIFICANCE.

SIGN STIMULUS: term coined by E.S. Russell to indicate those parts of the available environmental information to which an animal responds at any given moment, particularly when these are strikingly limited. One sees the first indications of this restriction to a few stimuli in observations of astonishing errors such as a Herring Gull *Larus argentatus* chick pecking at a cherry in the way in which it does at its parent's red bill-tip; or waders panicking when another wader descends in a wildly swooping flight, thus showing roughly the same type of movement as a striking Peregrine *Falco peregrinus*; or aggressive or sexual responses to animals only remotely similar to the adequate objects. Such 'errors' are in curious contrast to other evidence demonstrating the wonderful acuteness of a bird's perceptive abilities, and this apparent paradox has led to experiments in which the potentialities of the sense organs were compared with the actual stimulus situations releasing particular responses. In birds, the majority of papers on this subject deal with visible stimuli. The potentialities of the eyes are studied with as great a variety of methods as possible: by studying conditioned responses of the intact animal, by observing pupillary reactions, by electrophysiological recordings in or behind the retina, and so on. There is now much evidence to show that the visual acuity of birds is high, that they can recognize forms well, and that their discrimination of intensity and colour is of the highest order (see VISION). Observations on geese (*Anser* spp.), gulls, crows and other birds have shown that they can distinguish between individuals of their own species much better than even a highly trained human observer.

Actual stimulus situations releasing a particular response have been studied by means of tests with dummies. In these, precise imitation of the natural object normally releasing the response (the standard dummy) is offered in alternation with dummies lacking one or more characteristics, and the intensity or frequency of the response to these various dummies is compared. If there is no or little difference of effect between the standard dummy and one of the incomplete dummies, the character lacking in the latter can be of no or little importance as a stimulus; if the difference is striking, this is indicative of a sign stimulus. There are indications that the difference between a sign stimulus and a non-effective aspect of the environment is often one of degree only. In this way it was found, for instance, that the red patch on an adult Herring Gull's lower mandible is effective in releasing the chick's begging response, whereas the yellow of the rest of the bill is no more effective than any other colour, and this is expressed by saying that the red patch provides a sign stimulus. Further tests showed that it acts by its colour as well as by its contrast with the rest of the bill. Similarly, dummy tests with Song Thrush *Turdus philomelos* nestlings revealed that one of the sign stimuli is provided by the parent's head, which acts through being a protuberance of the outline of the body—above the body and with a certain size in relation to that of the body.

Precise investigations of this type, in which the potentialities of the sense organs involved and the actual stimulus situations are systematically explored and compared, are still very much needed, but there seems to be little doubt that many responses are released (and others inhibited) by very simple stimulus situations.

The fact that not all available information is 'used' or admitted for eliciting the response is posing an interesting physiological problem: where and how is the information refused passage? Lorenz (1935) pointed out that the restriction of a response to very few aspects of the total situation seems to be typical of 'innate' (i.e. non-conditioned) behaviour, and that conditioning usually leads to a fuller use of all details of the situation (unless special manipulations of the experimenter subsequently reduce the numbers of details used). Thus the conditioned responses to individual birds, or fear responses to (often amazingly slight) changes in the usual environment, are strikingly different from responses that occur prior to conditioning. This suggestion has not been followed up experimentally to any extent.

Sign stimuli often have to be described in 'configurational' terms, which means that they evoke complicated processes of reception that cannot, at the present stage of analysis, be measured on one linear scale. Thus, many responses can be elicited only by a special type of movement, or by a special shape, or by a certain degree of contrast between two colours. In such cases it has been possible to design 'supernormal' stimuli, exaggerating the quality of the natural object to which the animal responds. For instance, the speckling of eggs can be exaggerated in models until they are preferred to normal eggs. N.T.

SILKTAIL: substantive name for the taxonomically perplexing, monotypic and sexually monomorphic *Lamprolia victoriae* (Passeriformes, suborder Oscines) of Vanua Levu (= *L. v. kleinschmidti*) and Taveuni (= *L. v. victoriae*) Islands, Fiji; locally called Satin Flycatcher (Watling 1982).

In general appearance it is extremely suggestive of a diminutive bird-of-paradise, to which family it has often been tentatively allied; but it has also been considered possibly part of the thrush-flycatcher-warbler complex Muscicapidae and of the Australasian Malurinae (Harrison and Parker 1965), within the babblers Timaliidae (Cottrell 1967). Olson (1980) reviews the evidence against a paradisaeid relationship, and on the basis of plumage, external morphology and zoogeography suggests a placement in the MONARCH FLYCATCHERS (Monarchidae) closest to the genera *Clytorhynchus*, *Metabolus* and *Monarcha*. Certainly the nest of *Lamprolia* is unlike those of Paradisaeidae but like those of Monarchidae. The present view of K.H. Voous is to place it close to the genera *Eremiornis* and *Cinclorhamphus* of the Sylviidae.

Characteristics. A small (13 cm long) fine-billed insectivorous passerine of velvet black plumage with a silky-white rump, upper tail coverts and upper tail, and with iridescent tipped scale-like feathers about the head, neck, throat and breast which may appear blue, green or violet. Juveniles are like adults but duller, less glossy and spangled; the white tail develops clearly in the first juvenile plumage, whereas other decorative plumage appears only gradually with age. An adult just completing moult, and others in fresh post-moult plumage, have been recorded in mid-July.

Habitat and food. The Silktail is a bird of mature forests, found from over 1,000 m to the coast where forest remains, but mostly above 400 m where it actively forages for insects in the lower understorey and on the leaf litter.

Behaviour. It is most frequently encountered singly, in pairs, or a pair with fledged young, but groups of up to 6 join mixed feeding flocks.

Voice. Adult song is an unimpressive series of slurred trilled whistles, three initial notes slightly descending in pitch, followed by two or three elaborations of the same note; the entire song lasting 5 seconds.

Breeding. Breeding takes place throughout the year, with a possible peak in June–September. Two aggressive display postures have been seen but no courtship display is recorded. The nest is a deep thick-walled, loosely built cup slung beneath a horizontal twig fork 1–3 m above ground, usually below large leaves. The clutch is only one egg, and observations suggest that only one parent incubates as no change-over was seen at the nests. C.B.F.

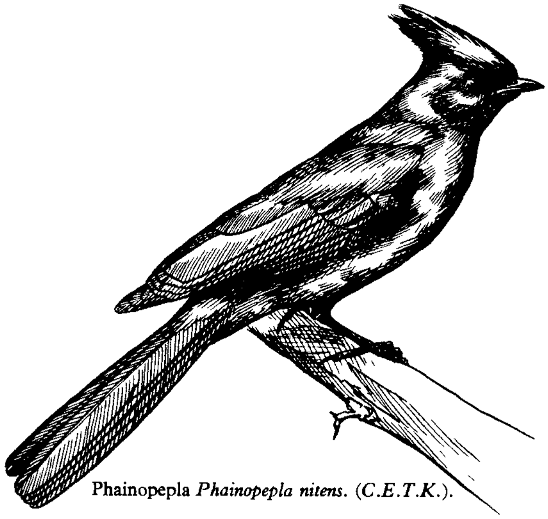
SILKY-FLYCATCHER: substantive name of certain species of the family Ptilogonatidae (Passeriformes, suborder Oscines); in the plural, general term for the family. The relationship of the 3 genera and 4 species, ranging from south-western United States to western Panama, has long been disputed; often they have been classified as a subfamily of the Bombycillidae; but evidence from egg-white proteins, as well as other features, fails to uphold this treatment. Their closest relatives may be the solitaires *Myadestes* (family Turdidae).

Characteristics, habitat and distribution. Silky-flycatchers range from about 17–23 cm in length. They have short, rather broad bills, relatively short wings, and short tarsi. The Phainopepla *Phainopepla nitens*, which ranges from deserts and arid woodlands of south-western United States to the highlands of Mexico, is a slender, long-tailed, crested bird with silky plumage, shining black with white wing patches on the male, grey on the female. The 2 species of *Ptilogonys* are also slender, long-tailed, and prominently crested. The males are grey or blue-grey with yellow flanks and crissum, black wings, and black-and-white tails; the females are similar but more olivaceous. The Grey Silky-flycatcher *P. cinereus* inhabits pine-oak woodlands in the highlands of Mexico and Guatemala. The Long-tailed Silky-flycatcher *P. caudatus*, which has elongated central tail feathers, is confined to the high mountains of Costa Rica and western Panama. The Black-and-yellow Silky-flycatcher *Phainoptila melanoxantha*, with the same range as the Long-tailed, is crestless and more thrushlike in aspect. The male is mostly glossy black, with bright yellow rump, sides, and crissum; the female is more olive.

Food, voice and behaviour. *Phainopepla* and the 2 species of *Ptilogonys* associate in loose, wandering flocks. They perch on high, exposed treetops, from which they make long, spectacular sallies to catch insects. *Phainoptila* lives in pairs amid lower, denser montane vegetation and seizes insects on less spectacular darts. All members of this family eat many berries. *Ptilogonys* and *Phainopepla* use their voices freely but sing sparingly and not brilliantly.

Breeding. The only species that have been carefully studied, the Phainopepla and the Long-tailed Silky-flycatcher, breed in monogamous pairs. Nuptial feeding is frequent. All 4 species build compact open cups in shrubs and trees, often high. Those of the Long-tailed Silky-flycatcher are composed almost wholly of grey beard-lichen *Usnea*; those of the Black-and-yellow largely of green moss; those of the other 2 species of more varied materials. Building is done chiefly or exclusively by the male Phainopepla, but by both sexes of the Long-tailed Silky-flycatcher. *Phainopepla* lays 2–3 (rarely 4) eggs; *Ptilogonys*, 2; and *Phainoptila*, 2 (1 record). The eggs of all 4 species are grey or greyish white, heavily marked with brown or lilac. Both sexes of *Phainopepla* incubate, but only the female *Ptilogonys*. The incubation period of the former is 14–15 days;



Phainopepla *Phainopepla nitens*. (*C.E.T.K.*).

of the latter, 16–17 days. Nestlings have abundant white down, long in *Phainopepla*, in short, compact tufts in *Ptilogonys*. Both sexes feed the young, which remain in the nest for 18–19 days in *Phainopepla*, 24–25 days in *Ptilogonys*. A.F.S.

SILVERBILL: substantive name of some *Lonchura* spp. (see ESTRILDID FINCH).

SILVER-BIRD: *Empidornis semipartitus* (for subfamily see FLYCATCHER (1)).

SILVER-EYE: name used for some species of Zosteropidae (see WHITE-EYE).

SIMURG: see FABULOUS BIRDS.

SINGING: see VOCALIZATION.

SINGLE-BROODED: laying a single clutch during a breeding season, although a replacement may be laid if the first clutch fails. See CLUTCH-SIZE.

SINUATED: term applied to a feather of which one edge appears as if cut away along a wavy line—not abruptly as when the vane is emarginated.

SINUS VENOSUS: see HEART.

SIRKEER: *Taccocua leschenaultii* (for family see CUCKOO).

SIRYSTES: generic name used as common name of *Sirystes sibilator* (for family see FLYCATCHER (2)).

SISKIN: substantive name of some *Carduelis* (or '*Spinus*') spp.; used without qualification, in Britain, for *C. spinus* (see FINCH).

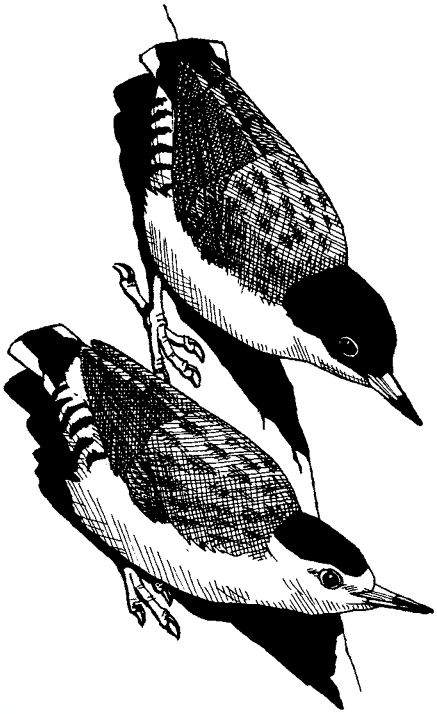
SITE-ATTACHMENT; see TERRITORY.

SITTELLA: alternatively 'treerunner'; in the plural, substantive name for the 3 species of Neosittidae or Daphoenosittidae; (Passeriformes, suborder Oscines). Formerly included in the Sittidae (see NUTHATCH), sittellas differ in leg musculature, bill morphology, plumage, nest type and social structure (Rand 1936; R. Orenstein). They may be most closely related to other Australian Oscine groups such as whistlers and monarch flycatchers (Sibley and Ahlquist 1982).

Characteristics, habitat and distribution. The Varied Sittella *Daphoenositta* (= *Neositta*) *chrysoptera* is a common resident of open *Eucalyptus* or *Acacia* woodland in Australia. It resembles a small nuthatch (10–12 cm) with a laterally compressed, upturned bill and a conspicuous white or orange-buff band across the flight feathers. The possibly conspecific Papuan or Mountain Sittella *D. papuensis*, which lacks the wing-band, is an uncommon New Guinea species of moist mountain forests between 1,075 and 2,450 m. The Black Sittella or Pink-faced Nuthatch *D. miranda*, locally common in Papuan mountain forests between 2,000 and 3,500 m, is a straight-billed, blackish bird with a rose-red face and white wing-band. Sittellas show limited sexual dimorphism, varying among races. Juveniles have whitish spots.

Varied and Papuan Sittellas vary geographically in head colour and, in *D. chrysoptera*, in bill colour, streaking in the plumage, and wing-band colour. The 5 recognized races of Varied Sittella were long considered separate species, but all except, possibly, 2 hybridize extensively where they meet (Ford 1980).

Food. Foraging Varied Sittellas explore branches in a series of rapid, tight spirals, working from their tips towards or on to the trunk, climbing head downwards or on the undersides of limbs. They pry up bark flakes for invertebrates or, rarely, use twigs to probe deeper crevices (Green 1972). Birds may fly long distances between trees; their flight is undulating. The Papuan species behave similarly, although *D. miranda* may be less acrobatic (Diamond 1972).



Varied Sittella *Daphoenositta chrysoptera*, female and male (below). (*N.W.C.*).

Behaviour and voice. Sittellas associate in groups of 3 to 12 or more, males outnumbering females. Members maintain contact with thin, high-pitched calls, louder in flight, and with rapid wing-flicks which expose the wing-band when it is present. The song has a series of 'zitting' notes.

Breeding. *Daphoenositta chrysoptera* breeds between July and March. All group members build the nest, a cup of spider-webs and cocoons, camouflaged with bark and lichen, placed up to 20 m high in a vertical fork. Normally only one female lays and incubates. There are usually 2 or 3 eggs, pale blue or greyish-white with dark spots and blotches. Incubation takes 12 or 13 days. Young birds remain in the nest for 13 or 14 days, fed by all group members, including juveniles from previous broods (Noske 1980). R.O.

SITTIDAE: a family of the PASSERIFORMES, suborder Oscines (see NUTHATCH).

SIVA: substantive name of some *Minla* spp. (for family see BABBLER).

SIZE: discussions of the evolution of birds are usually concerned exclusively with the radiation of different kinds, emphasizing body shape and posture, plumage colour, bill shape and feeding behaviour or taxonomic affinity. However, it is not so much the kind of bird as the size that has the most dramatic effect on the bird's requirements and ecological opportunities.

There are several measurements for describing the size of a bird. The most satisfactory of these is body weight or mass, primarily because it overcomes the complex variability of linear measurements due to differences in shapes of birds. However, there are considerable seasonal changes in body mass of migratory birds, and of birds such as penguins (Sphenisciformes) which fast during incubation, as well as weight changes due to egg formation and laying. Clark (1979) has provided an excellent review of these problems and bibliography on bird weights.

Range of sizes. The first known bird, *Archaeopteryx lithographica*, was somewhat lighter than a pigeon; its body mass has been estimated at about 270 g. Apparently from a start in this size-range, there evolved a range in sizes from the Bee Hummingbird *Calypte* (*Mellisuga*) *helenae* to the Giant Moa *Dinornis giganteus* and the Elephant Bird *Aepyornis*. The mass of the Bee Hummingbird is variously given as from 1.6 g to less than 3 g, while Amadon (1947) estimated 236 kg for the Giant Moa and 457 kg for the Elephant Bird. The largest living bird, the Ostrich *Struthio camelus*, may weigh 100–136 kg as an adult, 67,500 times as much as the smallest. Including the extinct forms, the class Aves has spanned a 228,500-fold range in body mass. The range in sizes of living land mammals is considerably greater (see Table 1), but in the case of elephants or mammoths, the huge mass is supported by four limbs instead of two. If we limit consideration of the largest mammal representatives to bipedal forms the range is 350,000 to 680,000, about the same order of magnitude as birds.

The avian extremes, hummingbirds and ratites, differ not only in size, but in form, locomotion, habits, and ecological niches. The smallest birds are able to extract a net energy profit from minute droplets of nectar in flowers, taken during an energy-expensive hovering manoeuvre. Energy-balance considerations have made the hummingbird plan seemingly unsuitable at sizes greater than 21 g. The lower size limit for hummingbirds may be related to problems of overnight survival on body energy reserves or the mechanics of the avian method of oviparous reproduction (see Brown *et al* 1978). At the other extreme, the Ostrich's large body size must have conferred benefits such as an opportunity to exploit a grazing niche or reduced vulnerability to attack.

It is more instructive to consider size ranges within some phylogenetic and locomotive subgroupings (Table 1). Within several orders, the range in body mass exceeds 2 orders of magnitude, although there are exceptions to this in the more specialized groups such as penguins, ducks and swifts.

There is an upper limit to flying size (see below and FLIGHT), but the range in body mass for fliers is 10 times that for diving birds. Heat loss to the highly conductive water may limit the smallest size practical for diving, but some warm-blooded mammals dive successfully despite very small sizes: the watershrews *Sorex palustris* or *Neomys fodiens* have one-fifth the mass of the dipper or water ouzel (*Cinclus*).

An important characteristic of flying birds is the wing-loading, or ratio of body mass to the surface area of the wings which provides lift. Analyses by Hartman (1961), Greenewalt (1962) and others have shown that wing-loading increases with body mass; that is, the surface area of the wings was not increased in proportion to body mass increase as larger birds evolved. At any given body size for comparison, gliding and soaring birds have very light wing-loading. Heavy wing-loading is the rule for diving birds that use the wings to swim underwater. They have been limited in wing size because of the greater resistance to movement in water, which has considerably greater viscosity and density than air. Pennycuick (1969, 1972) derived an equation relating characteristic velocities (such as stalling speed, speeds for minimum power consumption or maximum range) to the square-root of wing-loading. Thus to remain airborne a diving bird with relatively smaller wings must fly at a greater speed than a non-diving bird of similar mass.

Allometry. There are no birds weighing more than 13 kg, and still capable of horizontal flapping flight, although it is speculated that some large fossil carinates may have been capable of flight. Pennycuick (1969) provided a theoretical basis for the upper limit to body mass for flight. If a basic body-plan for a bird is scaled up such that its linear dimensions (height, length, width) are each multiplied by a factor of 10, then its volume will be increased to 10 × 10 × 10, or 1,000 times as great. Built of the same materials, the mass to be lifted in flight will be 1,000 times that of the prototype bird. The power required to lift this mass will actually be proportionately greater, about 3,200 times as great as the bird that weighed 1/1,000 as much. The force generated to flap the wings by the pectoralis and supracoracoid muscles is proportional to the cross-sectional area of these muscles. Thus the power available has increased by a factor of only 10 × 10 while power requirements for sustained flight have increased by 32 × 10 × 10. A disproportionate increase in muscle mass to offset the power requirements would require greater oxygen and energy supply. Thus the heart, lungs, and the digestive tract, kidneys, and liver would have to be increased to meet the metabolic requirements for the larger muscles, making the bird still larger and more difficult to lift.

Failure to appreciate the subtleties of scaling has led biologists to a number of erroneous conclusions. It is often stated that birds have faster heart beats and lighter skeletons than do mammals, but compared on an equal-mass basis, this generalization is untrue (Prange *et al* 1979). It is also untrue that larger birds lose less heat than small birds (Calder 1974).

The study of scaling is *allometry* (allos = other; metryon = a measure), first applied to birds in a study of egg size by J.S. Huxley. Contributions of Max Kleiber, Samuel Brody and others have led to a rapidly increasing use of allometric analysis of avian biology. This, in turn, has yielded fundamental understanding of the dimensions of eggs and incubation, the similarity in basal metabolic rates of mammals and birds (except Passeriformes, which are characteristically higher in this regard), the insulative equivalence of feathers and fur, and the longer life spans of birds as compared with mammals. From body mass, we can predict practically any feature of a bird's natural history, its flight speed, territory size, energy requirements and the size of body organs. Note in Fig. 1 that the size-dependent changes are not scaled in the same proportion. Skeletal mass must increase more than heart mass, and the brain mass increases less than either.

Allometric analysis is simple, mathematically. The best fit for the relationship of many biological variables (Y) to body size is an exponential or power function of body mass (M):

$$Y = aM^b$$

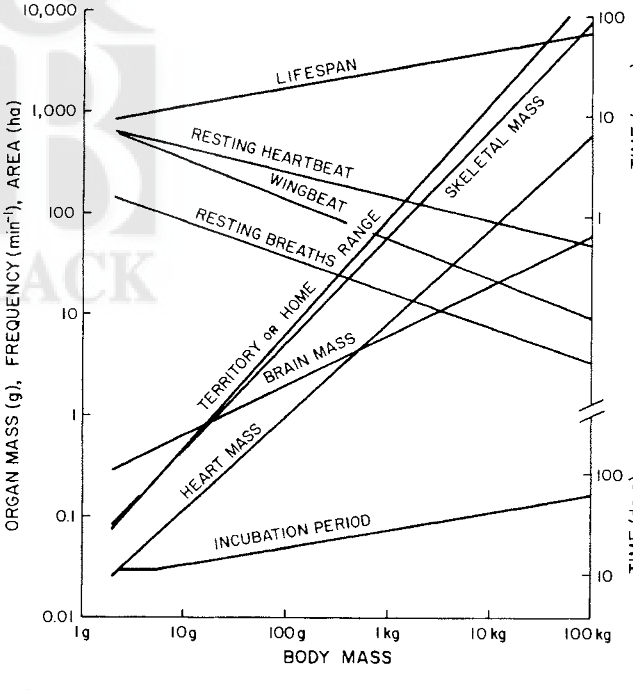

Fig. 1. A sample of avian life history and body construction features which scale as various exponential functions of body mass ($Y = aM^b$; see text). Note that the scales (vertical and horizontal) are logarithmic, which results in straight-line plots, the slopes of which are the exponents b. These lines represent mathematical generalizations; values for actual birds vary above and below the line of statistical best-fit. This shows that, in the evolutionary scale-up, the heart size increases in approximately direct proportion to body size increase while the heart beat, wing beat, and breathing frequency (min^{-1} means per minute) are fast in small birds and slow in large birds. The skeletal mass and territory size increase in greater proportion, while the brain increase does not keep pace with body size increase. Size increase has proportionately the same effect on incubation period and lifespan. (By permission of Harvard University Press).

Table 1: Size ranges in bird groups compared with mammals.

Type of animal	*Smallest species*	*Body M (g)*	*Largest species*	*Body M (kg)*	*Ratio of largest/smallest*
All birds	Bee Hummingbird *Calypte helenae*	2	Ostrich, *Struthio camelus* *Elephant Bird *Aepyornis maximus*	135 457	67,500 228,500
All land mammals	Pygmy Shrew *Microsorex hoyi*	2	African Elephant *Loxodonta africana*	7,000	3,043,478
Bipedal mammals	Little Pocket Mouse *Perognathus longimembris*	8	Gorilla, *Gorilla gorilla*† Man *Homo sapiens*	290 70	35,366 8,537
Ratites	Little Spotted Kiwi *Apteryx oweni*	666	Ostrich *Struthio camelus* *Elephant Bird *Aepyornis maximus*	135 457	203 686

‡ Olson and Hasegawa (1979, Sci. 206: 688) report that the largest fossil plotopterid (Pelecaniformes) may have been larger than any of the giant fossil penguins.

If *b* is 1.0, there is a straight-linear proportionality (i.e. doubling of body mass has involved a doubling of Y, such as a doubling of heart or respiratory system size). If *b* exceeds 1.0 the curve becomes increasingly steep. For example, as bird size increases, the skeleton must be progressively a larger percentage of body mass, and the power requirement for flight grows disproportionately as well. When *b* is a fraction less than 1.0, a doubling of body mass requires less than twice as much of Y, and the graph of the relationship is shallower. Thus a 100 g bird requires less than twice as much (about 1.7 times) food or metabolic heat production as does a 50 g bird. A *b* value of zero indicates that the variable is independent of size of the bird or egg. For example, body temperatures of resting birds are independent of body mass, although the temperature of a hand-held or struggling bird may rise more rapidly the smaller the bird. Birds' eggs, large and small, all lose about 15% of their fresh mass by evaporation during the incubation period. Finally, if *b* has a negative value, the allometric correlate decreases as the body size increases; the heart of a goose beats more slowly than a hummingbird heart, and the wing beat is also much slower.

Plotted on logarithmic scales, these relationships all take the form of straight lines, the exponents becoming slopes of the straight lines, which are fitted by the method of least squares regressions (see BIOSTATISTICS). The plots or equations then provide a basis for comparing birds with mammals in general or for comparing unusual birds with more 'typical' ones (such as the differences in insulation between a ptarmigan *Lagopus* and a bird of more moderate climate). From allometric analysis we can appreciate the complexities of natural selection for larger or smaller birds, and we can predict approximately the requirements or dimensions of the yet unstudied birds. When consistent patterns emerge from the analysis there is strong suggestion of underlying physical constraints which have had a major influence upon the evolution of birds. With this background, one can begin to analyse the structure, physiology, and life history of birds from a fresh perspective.

Birds and mammals compared. We can then make fair comparison of birds and mammals if they are of the same sizes. From Table 2, it may be observed that the basal rates of energy demand by birds and mammals are indistinguishable, as are their skeletal weights. Compared at 1 kg size,

Table 2: A Cpmparison of Birds and Mammals Based Upon Body Size

	1 kg bird	*1 kg mammal*	*Effect of size increase (exponents)*	
			Bird	*Mammal*
Basal metabolic rate (ml O_2/hr)	679	676	0.72	0.75
Energy cost of travel (kJ/km)[a]	49	118	0.77	0.60
Speed of travel (km/hr)[b]	47	6	0.17	0.24
Skeleton mass (g)	65	61	1.07	1.09
Brain mass[c] (g)	7	11	0.51	0.66
Heart mass (g)	9	6	0.94	0.98
Respiratory system volume	161	54	0.91	1.06
Lung mass (g)	13	11	0.95	0.99
Incubation/gestation (da)	28	70	0.17	0.23
Lifespan (yr), in captivity	28	12	0.19	0.20
Heartbeat/min	156	241	−0.23	−0.25
Breaths/min[d]	17	54	−0.31	−0.26

a. Compares flying of birds with running of mammals. 1 kJ = 0.239 kcal or energy in 25 mg fat.

b. Pennycuick, C.J. (1969) Ibis 111: 525, theoretical calculation for minimum power requirements for birds; Heglund, N. *et al* (1974) Science 186: 1112, empirical regression for trot-gallop transition of mammals.

c. Note difference in proportionate effects of size upon brain mass. These relationships predict that birds with body mass under 34 g would have larger brains than mammals of the same sizes, while above 34 g size mammals have progressively larger brains than do birds.

d. Excluding Passeriformes.

birds have smaller brains than mammals, but the smaller scaling exponent translates to the fact that very small birds (<34 g) have larger brains than mice of the same size. Except for small birds and mammals (<34 g) birds have smaller brains. Birds' hearts and respiratory systems are larger, and heart beats and breathing are slower. Time required for incubation of eggs is less than one half of that required for mammalian gestation, but birds' lifespans are more than twice those of mammals of equal size. Birds not only fly faster than mammals can run, but the energy cost for a bird of 1 kg or less to fly a km is less than half the cost for the equivalent mammal to run that distance. The difference in exponents means that size has a greater proportionate influence on birds (0.77) than on mammals (0.60). The relative advantage is reduced to 63% of mammalian running cost at the maximum body size for flying birds. From this energy comparison it is obvious why migration is more common in birds than in mammals. Amongst the mammals, long distance migration is limited to the larger terrestrial mammals, to bats and to marine mammals.

Having compared these two classes of 'warm-blooded' vertebrates, consider the details of scaling within the class Aves. As noted above, with the evolution of larger birds, the margin between power available and power required for flight decreased until flight was no longer feasible. Similarly the 'dead weight' of the skeleton must increase out of proportion to body size increase. This is slightly offset by the fact that the brain need not increase in linear fashion to coordinate the bird's physiology. Organs basic to life support, such as heart, lungs, respiratory system, gut mass, and blood volume are increased in an approximately direct linear proportion to body mass increases (Calder 1974; 1984). The exponent 0.94 for heat mass as a function of body mass may reflect more than statistical scatter in its departure from strict linearity (1.0). This may be attributed to the fact that the largest birds are not fliers and do not experience as intense demands for oxygen, hence can manage with hearts that are proportionally somewhat smaller than those of smaller birds.

Heart rate bears an inverse relationship to heart mass, the smaller heart beating more rapidly. This is seen not only within Class Aves, but in the comparison with Mammalia, noted above. A 1 kg bird has a heart 1.48 times as heavy as that of a 1 kg mammal, while the mammal's resting heart rate is 1.55 times as fast as the heart of a 1 kg bird. From more limited data, there appears to be no significant difference in ratios of active to resting heart rate between birds (2.6 ± 0.75 s.d.), eutherian mammals (2.13 ± 0.945 s.d.), and marsupial mammals (2.24 ± 0.35 s.d.), nor is there any size-related trend to the variability within these groups. Similarly, breathing rates decrease as respiratory system volume increases with body mass in both birds and mammals. At a comparable 1 kg body mass, the breathing rate of the mammal is 3.1 times that of the bird, while the RESPIRATORY SYSTEM of the bird has 3 times the volume of that of the mammal.

Body size and environment. Within many species or genera, body size increases with increasing latitude or altitude, increases which are associated inversely with temperature. These empirical trends are established beyond argument, but their interpretation has been controversial (James 1970).

The smaller the bird, the greater the ratio of surface area ($\propto M^{2/3}$) to volume ($\propto M^1$). Since heat is produced by the volume or mass of tissues but lost by the surface, the higher surface:volume ratio is taken to indicate a greater liability for heat conservation. While it is true that the metabolic cost per gram is higher in smaller birds, the total heat loss from a large bird is greater than from a small bird.

Body size and temperature. The body temperatures at which birds live are size-independent, 40 ± 1.5°C when resting, 43 ± 0.5°C when heat-stressed or highly active. The heat production which supports the body temperature (T_b) is a by-product of metabolism. The basal (minimal) metabolic rate is proportional to $M^{3/4}$. When the environmental temperature (T_e) is below a critical lower limit (T_{lc}) this metabolic rate is insufficient to maintain the body at 40°C, and shivering commences in proportion to the difference ($T_b - T_e$) and is inversely related to the amount of insulation contributed by the plumage, a resistance (R) to heat flow.

Consideration of the plumages of a goose and a tit tells us that the larger the bird, the thicker its insulation. The thermal insulation R is generally proportional to the square-root of body mass, $M^{1/2}$, that is to say it does increase with size, but not as much as body mass or body surface ($M^{2/3}$). Consequently, the goose produces more heat and loses more heat than does a tit, and a big tit loses more heat than a little tit. A male Black-capped Chickadee *Parus atricapillus* in Alaska weighing 11.1 g exposed to 0°C would lose heat at a rate of 0.66 watts, while at the lower latitude of Ohio, USA, the chickadee weighs 10.0 g and exposed to 0°C, loses heat at a rate of 0.63 watts (Calder 1974).

How then can the size increase that is correlated with lower environmental temperature be interpreted? The amount of energy reserves a bird can store as fat and in the crop and gut contents is at least a linear function of body mass, that is to say, amount of energy $\propto M^{1.0}$. The rate of their depletion during a fast imposed by blizzards or ice-storms is proportional to the metabolic rate, rate $\propto M^{3/4}$. Endurance time equals amount/rate, $M^1 \div M^{3/4} = M^{1/4}$. This positive fractional exponent says that the larger tit will survive longer.

Ecological consequences of size: lifespan. The larger the bird, the longer its lifespan ($M^{0.2}$, Lindstedt and Calder 1976 (see also AGE)). The allometry of maximum longevity data from birds indicates that birds survive 61% longer in captivity than in the wild (bird-ringing records). The difference between wild and captive longevities must reflect the effects of disease, predation, and (or) uncertainties of food supplies in natural environments. In captivity, birds have maximum lifespans well over twice those of mammals of the same body size. If fertile lifespan was a similar proportion of total lifespan in both classes, the birds would have a greater opportunity for successful reproduction.

Ecological consequences of size: reproduction. The larger the bird, the larger the egg ($\propto M^{0.77}$) and the longer the incubation period ($\propto M_{body}^{0.17}$ or $M_{egg}^{0.22}$). Compared on a body mass-equivalent basis, incubation of bird eggs is considerably more expeditious than gestation in mammals, requiring only 41% as much time. This perhaps reflects a natural selection that reduced the period of exposure to predation.

Ecological consequences of size: territory. Both territory and home range increase with increasing body size. When food habits were not considered, Schoener (1968) found that both territory ($\propto M^{1.09}$) and home range ($\propto M^{1.16}$) increased in greater proportion than body mass. Treated separately, territory and home range of birds consuming animal food increased even more disproportionately with body mass increase ($\propto M^{1.31}$, $M^{1.39}$, respectively), while territories of omnivores and herbivores increased in a less than linear fashion ($\propto M^{0.35}$, $M^{0.70}$, respectively).

Obviously, on a given amount of land of suitable habitat, there will be more small birds with small territories than large birds with large territories. Thus, the larger the bird, the fewer its numbers. This would mean that other things being equal, larger birds would be generally more vulnerable to extinction, and large carnivores would be especially vulnerable. To this effect may be added the previously mentioned correlation of long incubation period with large bird size, which could increase the vulnerability. Certainly many birds listed as extinct, vanishing, or endangered were or are large, absolutely or within their taxa: moas, elephant-birds, Dodo, Arabian Ostrich, Whooping *Grus americana* and Japanese Cranes *G. vipio*, the bustards Otididae, Takahe *Notornis*, California Condor *Gymnogyps californianus* and Ivory-billed Woodpecker *Campephilus principalis*.

Other considerations. There are sex differences in size (see SEXUAL DIMORPHISM). Full size is attained before fledging of altricial species or by the time of replacement of down by feathers in precocial species (see GROWTH; YOUNG BIRD). SKEIN: see ASSEMBLY, NOUN OF.

SKELETON, POST-CRANIAL: the internal framework (endoskeleton) of the body which, along with the SKULL protects and supports its soft structures. Together with the muscular system (see MUSCULATURE), it forms an integrated system for exerting force and movement (see LOCOMOTION, TERRESTRIAL; FLIGHT).

Nature and development. The skeletal system is composed of bone, cartilage, and ligaments. Bone is a living tissue composed of an inorganic mineral (hydroxyapatite: $Ca_{10}(PO_4)_6(OH)_2$), laid down in an organic matrix (collagen fibres). Together these substances form fibrils. In lamellar bone the fibrils lie parallel to each other, whereas in woven bone they are tangled more or less at random. The composite structure of bone makes it more rigid than collagenous fibres, more flexible and resistant to fracture than mineral, and more versatile in the kinds of loads it can withstand than either of its components alone. The red marrow found within bones is the primary blood-forming organ in the adult (see BLOOD), and bones may serve as storage areas for calcium and phosphorus.

Most bones have a complex organization (Fig. 1). On the outside is a tough fibrous membrane (periosteum). Mature bone is composed of an outer layer of dense, ivory-like, compact bone and an inner network of thin sheets of bone (trabeculae) and intercommunicating spaces (cancelli) which together form spongy bone. The spongy bone often has a hollow central cavity which contains marrow or fat or outgrowths of the air sacs (see PNEUMATIZATION OF BONE; RESPIRATORY SYSTEM).

The greater part of the skeleton is first laid down in the embryo (see DEVELOPMENT, EMBRYONIC) as a cartilaginous framework and later converted into bone by the process of ossification. Most bones thus ossify in cartilage and are called cartilage bones. Some, however, ossify directly without going through a cartilaginous stage, and these are known as membrane bones; except for the clavicle, they are confined to the SKULL, where they make up the roof, parts of the side walls, and most of the jaws and palate. In the adult, cartilage is found mainly as articular pads which serve as shock absorbers and to reduce friction between bones.

Bones begin to appear early in embryonic development, but many of them are not completely ossified until maturity. The ossification of a cartilage bone, such as a limb bone, begins in the middle of the shaft, the ends remaining cartilaginous for a time. The bone grows longer as the result of the proliferation of cartilage near the ends and, as new cartilage is formed, it is progressively converted into bone.

In addition to growing in length, a bone also grows in thickness as new material is deposited beneath the periosteum. As the entire structure increases in size, it is remodelled so that it retains its shape, bone tissue being added in some places and removed in others. A bone and its internal structure will develop normally only under the influences of the surrounding muscles and soft tissue.

Two types of ligaments have been reported in birds: collagenous-fibre ligaments, which are highly elastic and noncompliant, and yellow elastic ligaments, which are elastic and relatively compliant. Little is known of the properties and distribution of yellow elastic ligaments; they are known from the avian neck and may be found in the wings of some birds.

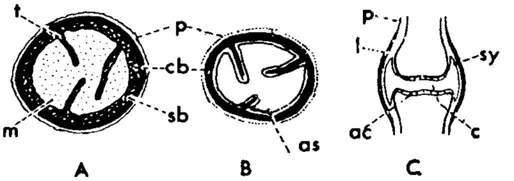

Fig. 1. A, B. Transverse sections through mid-shaft of femur (A) not pneumatized, and humerus (B) pneumatized, of fowl *Gallus*. The thickness of the bone wall, and the relative thickness of the compact and spongy bone, varies in different specimens, especially in the femur. (Partly based on data from A. S. King.)

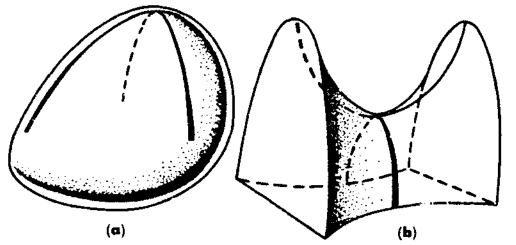

Fig. 2. Two fundamental geometric types of articular surfaces. (a) Ovoid, which may be convex (male) or concave (female). Note that the solid body presents ovoid profiles in two planes at right angles and that the curvatures of the two may be different. (b) Saddle-shaped surfaces, which are concave-convex. In practice both types of surfaces may vary from only slightly to highly curved. Thus ovoid surfaces may be 'almost flat' or 'almost spherical', but the majority show intermediate grades of curvature, and much variation in change of radius from place to place. (Courtesy of Williams & Warwick, 1973, and Longman Group Ltd.)

Most avian ligaments are collagenous-fibred bands between bones; articular ligaments and linkage ligaments are the two main kinds. Articular ligaments bind the bones of the skeleton together; they prevent the articulations from being disrupted under stress and fix the type and extent of movement between two bones at an articulation. Linkage ligaments are known only from the head; they span two or more articulations and limit or couple the movement of the bones they join.

The joints between bones differ greatly in their structure and mobility. The arrangement of a typical freely moving joint is shown in Fig. 1c. Contact between the two bones is made by cartilaginous surfaces on their ends. The surfaces have a low coefficient of friction and are lubricated by the viscous synovial fluid. The joint is enclosed in a fibrous capsule, lined by the synovial membrane and usually strengthened with ligaments. Sliding, angular, circumductional, and rotational movements at joints may be combined to produce an almost infinite variety of movements. Two fundamentally different articular surface shapes, ovoid and saddle-shaped (Fig. 2), make these movements possible. Ovoid surfaces are either convex in all directions (male ovoid) or concave in all directions (female ovoid) whereas saddle-shaped surfaces are convex in one plane and concave at right angles. In addition to allowing motion between bones, articulation, along with ligaments and muscles, reduces stress and redistributes forces within the skeleton.

Factors influencing form and structure of bones. The shape of bones and joints and their internal structure are adapted to the functions which they have to perform and the strains to which they are subjected in life. The degree to which this is the result of hereditary factors or of use during embryonic or later life has been extensively studied. A femur of relatively normal shape will develop from isolated fragments of limb bud removed from the embryo and grown in a tissue culture, despite the absence of muscles and of the possibility of movement. In cultures of limb-bud material the skeleton will differentiate into the elements of the thigh and leg, and joint rudiments will appear at the appropriate places. On the other hand, the finer details of the normal skeleton do not develop perfectly. The rudimentary joints tend to fuse, although they can be made to develop more normally if the bones are artificially moved.

The shape of bones and the amount of bony material present in a skeletal bone depend to a great extent upon the magnitude of the forces acting upon the skeleton. For example, the surface markings of bones reflect the shape of the attached connective tissue structures: depressions (fossae) are produced by fleshy muscular attachments; elongated (crista), pointed (process), or rounded (tuberosity, tubercle, or trochanter) elevations are usually associated with the attachment of tendons. The thickness of the wall of bones and the arrangement of the internal trabeculae are readily modified by changes in stress patterns. Bone apposition by osteoblasts and bone resorption by osteoclasts are in balance under normal conditions. Under greater-than-normal strains bone apposition will predominate; under decreased stresses bone absorption will predominate. Weak but steady compression may cause erosion; a steady tension may cause the appearance of bony processes at muscle attachments, ossification of collagenous tissue, and formation of sesamoid bones; and new articulations may develop when two bones contact one another and continue to rub together. The arrangement of the internal trabeculae has been shown to correspond to the lines of force acting on the bone. When local stresses are applied, trabeculae may undergo a corresponding condensation and reorientation.

The evidence thus indicates that the major features of the skeleton's architecture are determined by heredity, but many of the finer details that appear later in the embryo or after hatching depend for their proper development on environmental factors such as movement and mechanical stress. Skeletal structure is also affected by diet and by the action of chemical substances (hormones) secreted into the bloodstream by certain ductless glands such as the pituitary, parathyroids, and sex glands (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM). Adequate supplies of calcium and of vitamins such as A and D are necessary for normal ossification and growth, and (as in mammals) rickets and other deficiency diseases will occur in their absence.

Changes in the composition of the adult skeleton are associated with physiological processes accompanying such activities as moulting and egg laying. In chickens and pigeons, additional bone tissue (medullary bone) is laid down in the marrow spaces of limb bones before the eggs are laid, and this is subsequently reabsorbed and the calcium thus liberated used in the formation of the eggshell. A similar condition may be artifically induced in male or immature female birds by the use of hormones.

Evolutionary history. The skeleton of birds most closely resembles that of reptiles, especially that of members of the subclass Archosauria (e.g. dinosaurs, pterosaurs, crocodiles). Birds share the following skeletal characteristics with reptiles:

1. The skull and atlas are articulated by a single occipital condyle.
2. The lower jaw is composed of several elements and is hinged on a movable quadrate bone.
3. The ear has a single ossicle, the columella (or stapes).
4. The ribs have uncinate processes, a characteristic found elsewhere in only a few reptiles.
5. The ankle is formed by an intertarsal joint.
6. The pubic bone slants backward as in some dinosaurs.

Until recently it was generally accepted that birds arose from the pseudosuchian thecodontians, a group of primitive archosaurian reptiles. Recent reevaluation of the fossil record strongly indicates that the immediate ancestor of birds was among the small coelurosaurian theropod dinosaurs (see EARLY EVOLUTION OF BIRDS).

The Jurassic bird *Archaeopteryx* possessed a remarkable combination of reptilian and avian features (see ARCHAEOPTERYX). There is great diversity in the form of avian skeletons, which is evident when the skeletons of ratites, penguins, or hummingbirds are compared with those of typical songbirds. Many of our ideas about the relationships of the higher categories of birds are based on characteristics of the skeleton. Most of these ideas were developed at the turn of the century, after which morphological studies generally declined. Recently systematists have shown renewed interest in using skeletons for a variety of taxonomic and evolutionary ecological studies. Skeletons offer a wider variety of measurable characteristics than do skins for those interested in variation among and between populations and a host of qualitative characters for those interested in phylogenetic studies. Unfortunately, few such studies have considered the physiological adaptations of bone mentioned above. Thus, similarities between species which use similar environments, such as grebes (Podicipedidae) and divers (Gaviidae), or flamingos (Phoenicopteridae) and avocets (Recurvirostridae), are as likely to be the result of adaptations as they are to be the result of common ancestry. Current museum skeletal collections are grossly inadequate for the work which needs to be done.

Special avian features. Most of the striking features of a bird's skeleton are associated with its two independent and specialized methods of locomotion, flying with the forelimbs and walking with the hind ones. In typical birds, both fore and hind limb girdles are stoutly built, since each has to support the whole weight of the body alone when the bird is, respectively, flying or walking. The shoulder (pectoral) girdle and sternum form a unit that is firmly (although not immovably) attached to the ribs, and the pelvic girdle is rigidly fastened to a long segment of backbone. Birds have forelimbs with highly modified skeletons in which the arm, forearm, and hand all play a part in supporting the wing (see WING, COMPARATIVE ANATOMY OF).

The hindlimb is also specialized. Some of the metatarsals, which actually belong to the foot, are fused and lengthened so that the leg, like those of certain dinosaurs and running mammals, appears to contain an extra segment. The vertebral column, except for the neck region, is comparatively immobile, and many of the vertebrae are fused. As in pterosaurs, the skeleton of many birds is lightened by extensive pneumatization.

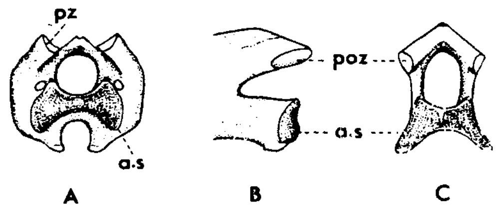

Fig. 3. Neck vertebra of bird: (A) from in front, (C) from behind; (B) shows hind part of vertebra from the side.
as. articular surface; **pz, poz.** pre- and post-zygapophyses.

Vertebrae and ribs. The vertebral column of birds is usually subdivided into cervical (neck), thoracic (chest), lumbar (loins), sacral (hip), and caudal (tail) regions. The total number of vertebrae varies between about 40 and 60; most of the difference is due to variation in the number of cervical vertebrae. The joint surfaces of most of the unfused vertebrae are heterocoelous (saddle-shaped) (Fig. 3), but in penguins, waders or shorebirds (Charadrii), and parrots some of the thoracic vertebrae may have opisthocoelous (hollowed out behind = ovoid) joints. The first two cervical vertebrae (atlas and axis) differ in structure from the rest; in the hornbills (Bucerotidae) they are fused into a single bone. Some of the

neck vertebrae are highly modified in the darters (Anhingidae), most cormorants (Phalacrocoracidae) and herons (Ardeidae), in which the neck is permanently kinked but can be partly straightened suddenly to capture fish. The rib-bearing thoracic vertebrae have little movement, and some of them may be fused. The ribs articulate with the vertebrae by two heads and are divided into dorsal (vertebral) and ventral (sternal) segments which are jointed together (Fig. 4). The sternal segments are bony, unlike the corresponding costal cartilages of mammals; possibly their ossification, although it also occurs in ratites, is an adaptation to the stresses of flight. Most of the ribs have uncinate processes, each bound by ligaments and muscles to the rib behind, which help to strengthen the chest.

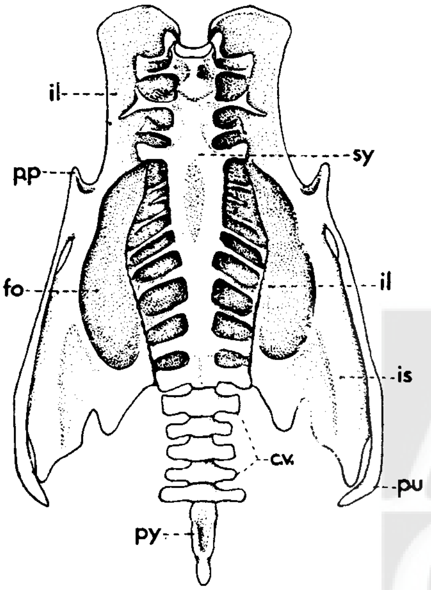

Fig. 5. Pelvis and synsacrum of fowl, seen from below.
cv. caudal vertebrae; **fo.** fossa for part of kidney; **il.** ilium; **is.** ischium; **pp.** pectineal process; **pu.** pubis; **py.** pygostyle; **sy.** synsacrum.

A number of posterior thoracic, lumbar, sacral, and anterior caudal vertebrae are fused together to form the synsacrum (Fig. 5). This is ancylosed or at least very firmly attached to the pelvic girdle, so that the weight of the body when borne by the legs is widely distributed along the backbone.

Behind the synsacrum are a number of movable tail vertebrae and then a structure composed of several fused elements known as the pygostyle (plough-share bone). This bone carries the tail feathers, and its movements are important to flight.

Sternum. The sternum or breastbone has a well-developed keel (carina) in modern flying birds (carinates), to which are attached the strong pectoral muscles. Its posterior end varies in shape, having one or two notches or holes (fenestrae), or one of each, on each side in many species (Fig. 4). In swans (*Cygnus* spp.) and some cranes (Gruidae) it is hollowed in front to contain folds of the trachea. There is no sternal keel in ratites; the sternum is flat ('raft-like') or slightly bossed.

Pectoral girdle and wings. The pectoral girdle (Fig. 4) consists, on each side, of the scapula, coracoid, and clavicle. The scapula is very long and firmly attached to the ribs by muscles and ligaments; the coracoid extends down from the front of the scapula to the sternum. The glenoid cavity, with which the head of the humerus articulates, is situated at the junction between scapula and coracoid. It is shallow, allowing the limb free mobility. Each clavicle articulates with the front of the coracoid and scapula so that a hole, the foramen triosseum, is enclosed between the three bones. The tendon of the supracoracoideus muscle passes through this hole and, curving backwards, is attached to the head of the humerus; this muscle gives the wing power on its upstroke (see FLIGHT).

The two clavicles are usually fused in the midline forming the furcula ('wishbone' or 'merrythought'). The angle of the furcula is generally widest in birds with strong flight, the bone acting as a curved strut to brace the wings apart. The clavicles are much reduced in a few flying birds (e.g. some parrots). Reduction or loss of the clavicles is also seen among certain ground-living birds; these include the ratites, in which the two bones do not even approach one another in the midline. In ratites the forelimb as a whole is reduced, especially in the kiwis (Apterygidae) and the giant extinct moas (Dinornithidae); in the latter the skeleton of the arm and hand seems to have been entirely absent.

The head of the humerus is expanded and has crests for muscle attachments. Its outer end articulates with the radius and ulna. The latter is the stouter of the two forearm bones and often bears a row of quill knobs where the secondary flight feathers attach. The relative lengths of the wing segments (arm, forearm, manus) vary widely among birds, the functional significance of which needs more work; they are said to be correlated with the type of flight. Generally, in strongly flying birds (e.g. swifts) the forearm and hand are longer than the humerus; in soaring birds (e.g. albatrosses Diomedeidae) the reverse is true.

The carpal bones of the wrist are reduced in the adult to two (radial and ulnar complexes), although others occur in the embryo and later either disappear or fuse with each other or with the metacarpal (to form a carpometacarpus). Only three of the fingers are present; whether these represent the I, II, and III or the II, III, and IV digits of the series is in dispute. (The II, III, and IV convention is used here.) Each digit is represented by a metacarpal and one or more phalanges. Metacarpal II is fused with the base of III, and III and IV are partly fused. The II digit has some power of independent movement and carries the bastard wing (alula). In a few birds one or more of the digits are clawed. The nestling Hoatzin *Opisthocomus hoazin* uses these for scrambling about after leaving the nest. (See also WING.)

Pelvic girdle and hindlimbs. As in other vertebrates, the pelvic girdle

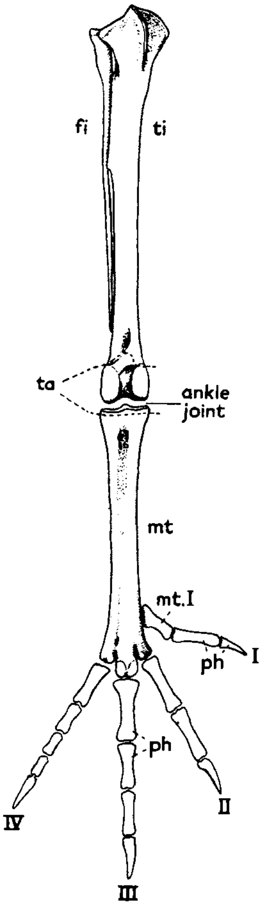

Fig. 6. Right leg and foot of fowl, seen from in front.
fi. fibula; **mt.I.** first metatarsal; **mt.** fused metatarsals; **ph.** phalanges; **ta.** tarsal contribution to tibiotarsus above and tarsometatarsus below shown between the interrupted lines. **ti.** tibia. **I-IV**, digits.

is formed, on each side, by the ilium, ischium, and pubis, which are partly fused. The pubis has a most unusual orientation, found elsewhere only in some dinosaurs: it lies parallel to and beneath the ischium (Figs 4, 5). Except in the Ostrich *Struthio camelus*, the pubic bones do not meet to form a symphysis enclosing the pelvic outlet; this condition may be related to the size and hardness of the bird's egg. The acetabulum, into which the head of the femur fits, lies at the junction of the three pelvic bones and is perforated. Behind it there is usually a large ischiatic foramen. The proximal end of the femur has a prominent process (trochanter) to which muscles are attached. Many species have a kneecap, or patella.

The condyles of the femur articulate with the tibia and fibula at the knee. The tibia, the inner of these bones, is much the larger. In most birds the fibula ends as a thin splint about two-thirds of the way down the tibia (Fig. 6), though in a few (e.g. penguins) it may reach the ankle (intertarsal joint).

A bird's ankle is constructed very differently from that of a mammal. In most vertebrates a series of small bones, the tarsals, is arranged in two rows between the bones of the leg and those of the foot. In birds, however, some of the tarsals of the proximal row have disappeared while others have fused with the lower end of the tibia. Thus the tibia referred to in the previous paragraph should, strictly speaking, be termed the tibiotarsus.

Similarly, some of the bones of the distal tarsal row have become fused with the metatarsus. Consequently, the ankle joint is actually situated between the proximal and distal rows of tarsals, instead of between the proximal tarsals and the leg bones as in man. These observations have been derived mainly from the study of embryos and cannot be verified from adult skeletons.

Most birds have 4 toes, each represented by a metatarsal element and a number of phalanges. The fifth toe is normally absent. The metatarsals of the second, third, and fourth toes are very long and fused; some of the tarsals are fused with their proximal ends. The result is a single bone known as the tarsometatarsus; its compound nature is apparent at its distal end, where it divides into three pulley-shaped processes or trochleae, each corresponding with one metatarsal (Fig. 6). In penguins the metatarsals are less closely fused than in other birds; this is no longer regarded as a primitive feature, since it has been shown that the fusion was often more complete in fossil than in living forms.

The second, third, and fourth toes each articulate with the appropriate metatarsal pulley and generally point forward. They contain 3, 4, and 5 phalanges, respectively, the distal one being clawed. In many birds there is also another toe, the first (hallux), which is short and points backward. Its metatarsal is small and attached to the back or side of the tarsometatarsus; it contains at most only 2 phalanges. Since it is opposed to the other toes, it may be an important aid in perching. It tends to be reduced in birds that do not perch and may be elevated some distance above the other toes. In ratites (except kiwis) it is absent. The Ostrich is peculiar in having only 2 toes, probably the third and fourth. Special modifications of the feet in various birds are described in LEG.

Pneumatization. Some of the bones in birds contain extensions from the nose and middle ear (in the case of the skull bones) or from the air-sacs that originate from the lungs (see RESPIRATORY SYSTEM). During the process of pneumatization, which begins in the late embryo and is not completed until some time after hatching, these extensions grow into the bones. The holes through which they enter may be seen in the dry skeleton; in the humerus, for example, there is a large pneumatic foramen on the inner aspect of the proximal end. The number of bones that become pneumatized varies greatly, but accurate data on the extent of pneumaticity are available for only a few species (see PNEUMATIZATION OF BONE). J.G.S.

A general account of the skeleton, with extensive references to the literature, is given by the first four of the following:

Black Skimmer *Rynchops niger*. (*B.P.*).

SKIMMER: substantive name of the 3 species of the family Rynchopidae (Charadriiformes, suborder Lari); also called shearwater, sea dog, or scissorbill. The Indian Skimmer *Rynchops albicollis* inhabits India, Pakistan and Burma; *R. flavirostris* is African; and the Black Skimmer *R. niger* has several races in eastern North, Central and South America.

Characteristics. Skimmers, *c.* 40 cm long, are brownish-black above with white underparts, face and forehead. Their bills are yellow or red with black or yellow tips, and their small, moderately webbed feet are also red. Similar in body weight to a medium-sized tern or small gull, they appear deceptively large because of their relatively long, pointed wings and long, deep, laterally compressed bill. Females resemble males but are markedly smaller, averaging 250 g as opposed to 350 g for males of North American *niger*. Juveniles differ from adults in having dark bills and feet and the upper parts streaked with brown and buff. Skimmers are unique among birds in that the pupil closes to a narrow, vertical slit in bright light. Anatomical and behavioural studies show affinities with gulls, terns, and skuas, and suggest an early departure of the skimmer line from the ancestral Lari.

Habitat. In South America and the Old World skimmers frequent lakes and rivers, breeding on sand bars exposed during the dry season. When rivers run high during the rainy season they move to estuaries and the coast. Perhaps because high river water coincides with the breeding season of North American skimmers, they are exclusively coastal,

breeding on barrier islands and dredge banks. The more northerly and southerly populations of *niger* perform north–south migrations.

Food. In bill structure and feeding behaviour *Rynchops* is unique. The lower mandible is laterally flattened like a knife blade and it protrudes well beyond the upper, which itself is narrow and oval in cross section (Fig. 1). A skimmer can raise its upper jaw about 45° above the closed position while depressing the lower jaw. Skimmers catch their prey (fish and shrimps) by flying low over the water with the upper jaw raised and the lower jaw open and immersed. When the sharp edge of the lower mandible strikes prey the head doubles under the body of the flying bird and the jaws snap shut (Fig. 2). The prey is drawn out of the water while the bird's head faces back or down, and is swallowed in flight or after the bird alights. Motion of the head cushions the shock and enables the shorter upper mandible to reach prey struck beyond its grasp. With the upper jaw raised during skimming, the lower jaw cuts the water unobstructed and the chance of striking prey is increased. The oft repeated statement that fish slide up the inclined edge of the lower mandible is incorrect.

Usually skimmers feed in shallow water containing high concentrations of prey. Flying in ones or twos, or sometimes in loose flocks, they cut a straight path apparently without seeing individual prey, but the birds are attracted to surface disturbances caused by swarms of fish. Their essentially tactile method of foraging permits them to feed also at night, which they do even under the darkest conditions. The lower jaw of a foraging bird may strike submerged obstacles or the muddy bottom, and the head then doubles under the body. Breakage and abrasion at the tip of the rapidly growing rhamphotheca of the lower jaw control its length. Fishing rates in the Black Skimmer have been measured under various conditions at one fish per half minute (rarely much faster) to one per 6 minutes of skimming. Sometimes a catch is lost through kleptoparasitism by gulls.

Behaviour. When not feeding, skimmers typically preen, bathe, or rest in a dense flock facing into the wind.

The Black Skimmer exhibits a variety of displays associated with aggression, pair formation and maintenance, territorial defence, and copulation. These show little correspondence to displays of the black-capped terns, but resemble those of noddies *Anous*, gulls, and skuas. Only with the latter do they share a distraction display when the young are threatened.

Voice. The voice of *niger* is a short or protracted *arp*, *arp* . . ., and of *albicollis* a nasal *kap*, *kap* . . . recalling the yapping of young fox hounds; that of the smaller *flavirostris* is a sharp *kik kik* . . ., or a harsh, tern-like *kreeep*.

Breeding. Skimmers nest in loose colonies, generally on open sand or shell, but *niger* occasionally nests on seawrack in salt marsh with terns, or even on gravel roofs. Colonies vary in size from only a few birds to many hundreds or several thousands. In mixed colonies Common Terns *Sterna hirundo* usually outnumber the Black Skimmer and are more aggressive, affording the skimmers protection from predatory gulls. The African Skimmer, however, is known to mob and chase away such predators as Sacred Ibis *Threskiornis aethiopicus*, herons, monitor lizards, and crocodiles. Mortality of eggs is caused by sudden rain squalls, and some colonies are subject to destruction from storm tides. Skimmers are single-brooded but they will lay again after destruction of eggs during a period of about 2 months in eastern North America.

The nest is a hollow maintained by kicking sand back while the bird squats or incubates. Eggs are creamy white marked with an endless variety of brown, black, and lilac spots and blotches. In North America clutches are usually 4 (2–5); in Africa and Asia usually 3 or less (1–4). Both sexes incubate and care for the chicks. Incubation begins with the first egg and lasts about 3 weeks. One study of *niger* showed a hatching success of about 80%, but 10 of 11 surviving fledglings were the first hatched of the brood, which pecked and chased younger siblings at feeding time. It is stated of *flavirostris* that the first chick wanders off within a day of hatching and the remaining eggs are abandoned. Parents are known to wet their feet and belly feathers while flying over water before returning to incubate or brood, presumably to promote cooling of the eggs or young; out of the breeding season wetting of these parts probably serves to wash off mud (see BELLY SOAKING). Chicks, difficult to see in their cryptic down, squat and dig into a hollow in the sand, sometimes kicking sand on to their backs. They are offered freshly-caught fish or shrimps carried from the feeding ground crosswise in the adults' bills. The mandibles of chicks are of nearly equal length, permitting them to take food from the adult or from the ground (Fig. 1). Young begin to fly at about 5 weeks and at this time the differentiation in mandible lengths is under way. Fledged young continue to beg from their parents or other adults, but they also engage in skimming. A young bird flying with its parents probably learns quickly the most auspicious places in which to forage. R.L.Z.

SKIN: the protective and containing integument of the body, consisting of an underlying dermis and an overlying epidermis. The dermis is relatively thick and highly organized, being supplied with muscles, blood vessels, and nerves. The thinner and simpler epidermis consists of layers of cells, renewed by proliferation from the basal (Malpighian) layer as the outer layers die and become horny (keratinized). The epidermis of birds is notable for the special external structures to which it gives rise and by which it is almost wholly covered—especially the feathers, but also the horny sheathing of the bill, legs, and feet, with the claws on these last (see FEATHER; BILL; LEG). Correlated with the presence of this covering is the almost complete absence of skin glands; the exceptions are a few small glands within the external auditory meatus and the oil gland on the rump (see OIL GLAND). The skin of birds thus does not perform the function of sweating, which has an important physiological role in mammals, and does not produce a sebaceous secretion for lubrication of its surface or outgrowth; nor can it play a great part in heat transmission (see HEAT REGULATION). The skin is, however, supplied with tactile nerve-endings or 'Herbst's corpuscles' (see TOUCH). Its blood vessels give the skin, at least in some instances, the capacity of exhibiting transient colour changes (flushing), visible on bare patches or even through the horny covering of bill and legs (see HERON; OSTRICH). In some birds there are such appendages as spurs, wattles, combs, lappets, sacs, or pouches (see INTEGUMENTARY STRUCTURES). For care of the body surface generally see under COMFORT BEHAVIOUR.

'Skin' is also the term applied to the usual unmounted study specimen of a bird (see MUSEUM).

SKUA: substantive name, especially in British usage, of all members of the Stercorariidae (Charadriiformes, suborder Lari); in the plural, general term for the family. Usage in North America and elsewhere prefers the name 'jaeger' (German word meaning 'hunter') and restricts

Great Skua *Stercorarius* (*Catharacta*) *skua*. (*B.P.*).

'skua' (from Icelandic word 'skufr') to *Catharacta*. The family contains 2 genera, *Catharacta* (not recognized elsewhere in this work) and *Stercorarius*; the latter has 3 species, all northern: the Arctic Skua (or Parasitic Jaeger) *S. parasiticus*, the Pomarine Skua (or Pomarine Jaeger) *S. pomarinus*, and the Long-tailed Skua (or Long-tailed Jaeger) *S. longicaudus*. *Catharacta*, formerly considered to be a superspecies with one boreal representative and several forms in the far south, is now divided into 3 species. (1) *C. skua* comprises 4 allopatric sub-species distinguished by plumage and measurements: *C. s. antarcticus* (Falkland Skua), *C. s. lönnbergi* (Brown or Subantarctic Skua), *C. s. skua* (Great Skua), and *C. s. hamiltoni* (Tristan Skua). (2) *C. maccormicki* (South Polar or McCormick's Skua) breeds on the Antarctic continent, overlapping *C. s. lönnbergi* with limited hybridization on the Antarctic peninsula. (3) *C. chilensis* (Chilean Skua) overlaps with *C. s. antarcticus* in Patagonia, also with some hybridization.

Characteristics. The skuas are sometimes treated as a subfamily of the Laridae. They are similar to gulls in size (lengths 50–58 cm) but have dark plumage, and a faster, stiffer wingbeat. They are widely known for their habit of chasing other seabirds in flight until they disgorge food (see PIRACY). Like gulls, they are chiefly associated with the sea, but may breed far inland.

In *Stercorarius*, adult plumage varies between a light phase, with the underparts and collar creamy or almost white and the head conspicuously dark-capped, and a dark phase with the whole plumage almost uniformly dark (see POLYMORPHISM). The dark phase is very rare in *S. longicaudus* and possibly does not occur in adult plumage; in the other 2 species the proportion of light and dark birds varies from area to area. In Shetland less than one fifth of the Arctic Skuas are light, but further north the proportion is generally higher, up to almost 100% in Svalbard and arctic Canada. In *Stercorarius* the primary shafts and bases are always white, but less prominent than in *Catharacta*; the 2 central rectrices are much elongated—pointed and fluttering in *S. longicaudus* but twisted through 90° and appearing clubbed in *S. pomarinus*. The bill is gull-like, unusually soft in its basal half, where a pair of separate thin plates overlie the nostril area, but hard and rather strongly hooked towards the tip. The feet are gull-like also, but with more strongly curved, sharp claws. Juveniles of all *Stercorarius* species are barred below. Barring may be retained in immature plumage and is found in a very small proportion of breeding adults. During winter adults may become somewhat barred below, apparently due to partial moult of body feathers. Among *Catharacta*, only juveniles of *C. chilensis* show any barred plumage, and this is confined to the back and scapulars. In *Catharacta* the plumage is generally brown, with conspicuous white wing patches at the base of the primaries. *C. maccormicki* is dimorphic, with light phase birds increasing in frequency at higher latitudes. The wings appear a characteristic velvety-black, contrasting with the body colour. *C. chilensis* adults are decidedly rufous in body colour, have cinnamon under wing coverts and the head has a markedly capped appearance. *C. s. lönnbergi* is a large, heavy form with a fairly uniform medium brown plumage, *C. s. antarctica* relatively small with a stubby deep and powerful bill, while *C. s. hamiltoni* is intermediate in appearance between *C. s. lönnbergi* and *C. s. skua*; adults of the latter can be identified by their conspicuously streaked plumage.

Habitat. All skuas are marine outside the breeding season, but probably frequent areas less than 50 km from coasts, although they remain entirely independent of land. *Catharacta* breeds socially, although nest dispersion varies greatly between and within species. Colonies are often adjacent to bird cliffs or penguin rookeries, on open ground. The Arctic Skua nests in colonies on moorland in association with seabird communities in Scotland, the Faeroes, Iceland and elsewhere, but also nests in well dispersed territories on arctic tundra. Pomarine and Long-tailed Skuas are exclusively tundra nesters.

Distribution. The 3 *Stercorarius* species are northern circumpolar breeders. Their ranges overlap widely. *S. longicaudus* generally extends furthest north. The breeding of all 3, but especially *S. pomarinus* is influenced by local fluctuations in lemming *Lemmus* abundance. The 3 species exclude each other from their territories. *S. pomarinus* is highly nomadic and moves to areas of lemming abundance. In years when it breeds, it excludes the 2 smaller species from the area. *Catharacta skua* is notable for having a bipolar distribution. *C. s. skua* is confined to the North Atlantic, nesting in Shetland, Orkney, Caithness, Sutherland and the Outer Hebrides, the Faeroes, Iceland, and has recently colonized Bear Island, Svalbard and north Norway. Non-breeders may appear anywhere in the North Atlantic, from Svalbard to Brazil. *C. s. hamiltoni* nests only on Gough and Tristan, *C. s. antarctica* nests on the Falkland Islands and adjacent coast of South America, and *C. s. lönnbergi* nests on part of the Antarctic peninsula, and on subantarctic islands all round the continent. *C. maccormicki* nests on the Antarctic continent. *C. chilensis* nests along the west and south coasts of South America south of 35°S, and on the east coast between Puerto Deseado and Puerto Gallegos.

Populations. On the edge of its range, in Scotland, numbers of Arctic Skuas have increased a little this century, lately to around 2,400 breeding pairs, but in the Faeroes numbers have declined considerably in recent years. In the Arctic, numbers of the 3 *Stercorarius* species are unknown, but presumably large. *C. s. skua* has a total population of 12,000 breeding pairs, half nesting in Britain, with the largest single colony of 3,000 pairs on Foula (Shetland). *C. s. hamiltoni* numbers less than 6,000 breeding pairs, *C. s. antarctica* between 3,000–5,000 pairs, *C. s. lönnbergi* about 20,000 pairs, *C. maccormicki* about 7,000 pairs and *C. chilensis* at least 10,000 pairs. In addition, each population contains large numbers of immature birds, perhaps about equal to the number of breeding pairs.

Movements. *Stercorarius* spp. are all long-distance migrants. *S. pomarinus* has a well-marked winter concentration off the highly productive coast of West Africa between 25° and 5°N, and non-breeders occur there in summer also. *S. parasiticus* winters further south, commonly on the continental shelves of southern Africa and Australia, but dark phase birds apparently move less far south than light phase individuals, indicating a leap-frog migration. Fledglings of *C. s. skua* migrate to south-west Europe in winter, with most ringing recoveries off the coast of Iberia, while some move as far as Brazil, Guyana and the Cape Verde Islands. In summer the immatures move northward again, many 2 to 4 year old immatures visiting high latitudes between Greenland and Svalbard. A high proportion of adults remain in British waters throughout winter. Icelandic birds show similar movements to the British population but with a large number of birds migrating down the west coast of the Atlantic, where very few British Great Skuas are found.

Food. *S. pomarinus* feeds largely on lemmings in summer and by predation on small seabirds (notably phalaropes) in winter, less regularly by fishing or piracy. *S. longicaudus* lives on lemmings, insects, berries, small birds and eggs in summer and by piracy, chiefly on terns, in winter. In arctic tundra areas *S. parasiticus* feeds on insects, berries, small birds and eggs and only to a limited extent on rodents. In coastal areas, such as Orkney and Shetland, it subsists largely by piracy on terns, auks and Kittiwakes *Rissa tridactyla*, similarly in winter. *C. s. skua* variously splash-dives for surface fish, preys directly on seabirds and terrestrial mammals, robs gulls, auks and Gannets *Sula bassana* of food and scavenges, e.g. behind fishing boats. Southern *Catharacta* have a similar range of feeding habits; *C. s. lönnbergi* is particularly associated with penguin rookeries, but *C. maccormicki* survives largely by catching food for itself at sea.

Behaviour. Skuas are normally monogamous and pair for life. In *C. s. skua* a few exceptional cases have been recorded where a male paired with 2 females which layed in the same nest; in *C. s. lönnbergi* colonies on islands off New Zealand and on Marion Island, such trios have also been found to occur regularly, as have others comprising 2 males and 1 female, although this social system is not found in any of the other *Catharacta*. Distances between skua nests vary from the extreme spacing on arctic tundra, where nests are often 2 km or more apart and skuas defend at least 1 sq km against congenerics (hunting over some 3 sq km), down to a spacing of nests only 5 m apart, in rare cases within colonies on small islands off north Scotland. On Foula, 306 pairs of Arctic Skuas bred in a colony occupying 1.7 sq km, or approximately the area defended by a single pair breeding on arctic tundra. A partial explanation for the variation lies in the fact that the birds nesting in Shetland do not obtain a significant amount of food within the territory, but feed at sea. There have been detailed studies of the behaviour of each species of skua. Most exhibit the same display patterns, although only the smaller species use a 'distraction display' as well as diving on intruders near the nest. Whether standing, swimming or flying, *Catharacta* typically display their white wing patches by stretching their wings vertically upwards, back to back, an advertisement posture found in less intense form in the Pomarine Skua, but not found in Arctic or Long-tailed Skuas.

Voice. Skuas are very vocal at their breeding places, but are usually silent elsewhere. *Stercorarius* spp. make high-pitched cat-calls and harsh, deeper notes. *Catharacta* spp. have a short grunting call and a long display call which is used in mate-greeting and indicating ownership of territory or food items.

Breeding. As skuas have only two brood patches, birds with 3 eggs usually fail to hatch any. Clutches of 2 are normal with about 10% laying only 1 egg. Although hatching success of skua clutches is normally high, in *Catharacta* colonies, where food is short, usually only one chick is fledged by each successful pair; the second-hatched chick, younger by one or 2 days, is often killed by its sibling. *S. parasiticus* begins to breed (on Fair Isle) at between 3 and 6 years of age (most at 4), but apparently at a younger age in arctic Russia. *C. s. skua* begins to breed (on Foula) at between 5 and 10 years of age (most at 7 or 8), but a year earlier in the small colony on Fair Isle between Orkney and Shetland.

SKULL: the bony and cartilaginous elements of the head, housing the brain and special sense organs, and providing a rigid framework for the feeding apparatus (jaws and hyoid). The remainder of the bird's skeleton is treated separately (see SKELETON, POSTCRANIAL). General topography and nomenclature of parts are considered first, followed by a review of mechanical properties. The positions of most of the skull bones (the majority paired, occurring on each side) are shown in Fig. 1, and only a few are named in the text. On the whole, they are similar to those of reptiles, although certain reptilian bones such as the postorbital are absent, and the temporal region is much modified. The skull is light, and often extensively pneumatized (see PNEUMATIZATION OF BONE), with a compact, rounded braincase. It is pierced by various foramina which transmit cranial nerves and blood vessels. Usually, the cranial sutures

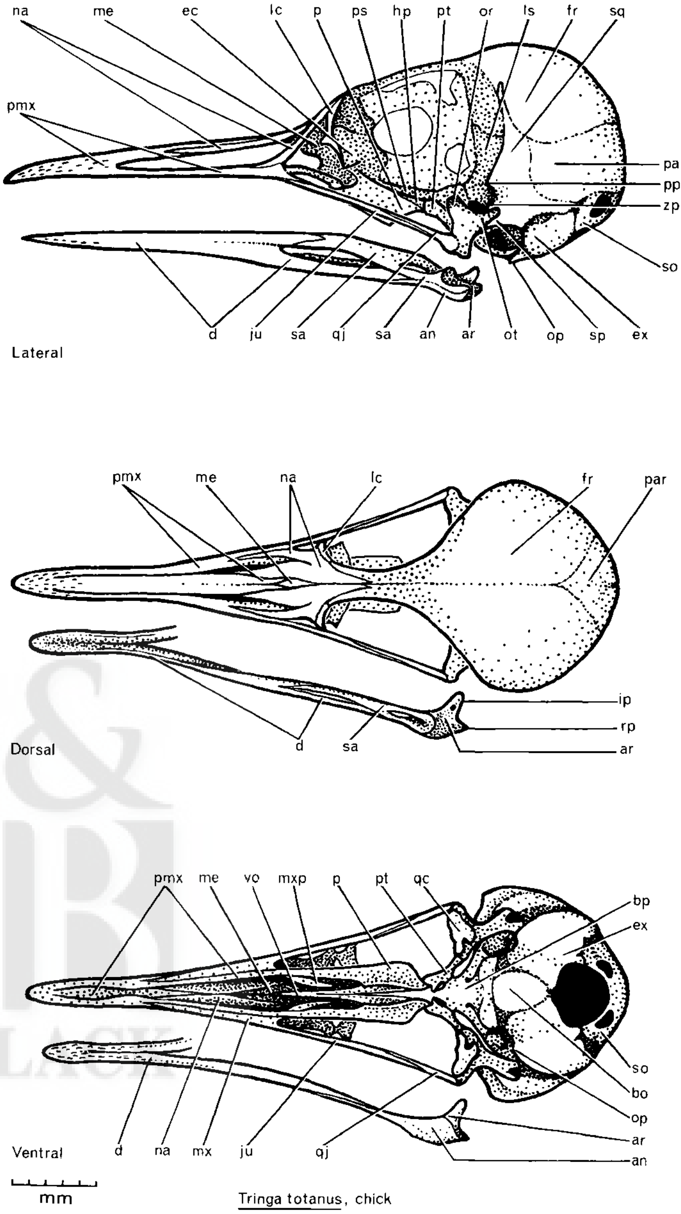

Fig. 1. Skull of Redshank *Tringa totanus* chick, a few days old, to show bones of the skull and important features referred to in the text. At this age, sutures between cranial bones are still clearly visible. This skull is rhynchokinetic, with bending zones in the upper jaw well forward of the craniofacial hinge—contrast with the prokinetic skull of *Ara* in Fig. 2.

close early in life, so that identification of the various bones in the adult may be difficult. Articulation with the atlas is by a single occipital condyle.

Orbits and nares. The orbits are usually very large, and, except in a few forms such as parrots, are not completely ringed by bone. They are separated from each other by a vertical plate known as the interorbital septum or mesethmoid bone; this is generally incomplete, the gaps being filled in life by connective tissue or cartilage. In the kiwis *Apteryx*, which have (for birds) very small eyes, this septum is absent, and the orbits are separated mainly by the very large nasal cavities; this is a specialized condition associated with the great development of the organs of smell (see SMELL).

The external nostrils are set back near the base of the bill, except in the kiwis where they are at its tip. In some birds, e.g. gannets *Sula* spp., the nostrils become closed by the growth of the surrounding bones (see RESPIRATORY SYSTEM). The nasal cavities, which are lined by mucous membrane, and the cartilaginous nasal capsule that invests them, are situated inside the bones of the bill. Each nasal cavity opens in front at the external nostril and on the palate at the internal nostril; it is separated from that of the opposite side by a cartilaginous septum. Turbinal cartilages project into each nasal cavity from its outer wall, increasing the area of mucous membrane. In some birds, the nasal capsule and septum are poorly ossified.

Upper jaw and palate. The skeleton of the upper jaw is formed mainly by the premaxillae, which in life are sheathed by the horny rhamphotheca. The attachment of the upper jaw to the skull is flexible, so that, as in many reptiles, it is able to move relative to the braincase; this property, known as cranial kinesis, is discussed further below. Key elements in kinesis are the quadrates, which articulate with the cranium at the rear of the orbit. Their lower ends in turn articulate with the jugal bars (jugal and quadratojugal), and with the pterygoids, which rostrally articulate with the palatines. Other elements of the palatal complex and their variations are treated separately (see PALATE).

Lower jaw. The lower jaw, on each side, is usually made up of 6 bones, the front one being the dentary (generally the largest) and the rear one the articular. The latter may be produced backwards as a retroarticular process, giving increased attachment area and leverage for M. depressor mandibulae. This increases the force of jaw opening—a feature of birds which excavate for food by 'gaping', i.e. inserting the closed jaws into a substrate, then opening them. Articulation with the rest of the skull is between the quadrate and the articular. The two halves of the lower jaw meet in a symphysis of varying length rostrally. In several groups, lateral flexion can occur along the free ramus on either side, permitting the gape to be widened, a mechanism discussed further below. Teeth are unknown in any recent bird, though some workers have claimed to identify rudimentary tooth-germs in bird embryos.

Hyoid skeleton. The tongue is supported by a median bone, the entoglossum; this is often partly cartilaginous, and may take the form of paired bones linked by cartilage or ligament, as in many parrots. It articulates with another median element (the basibranchiale) from the caudal end of which arise the paired cornua or hyoid horns, each consisting of a ceratobranchiale anteriorly, articulating with the epibranchiale posteriorly. The horns curve out, then round the posterior end of the mandible to lie near the occipital region of the cranium. In WOODPECKERS, the entoglossum itself is tiny, but the basibranchiale and horns are greatly elongated, giving them the ability to protrude the tongue for great distances; at rest, the horns extend round the top of the skull, in some species even entering a nostril or curving far round the orbit.

Ossicles. As in amphibians and reptiles, there is only a single bone, the columella (stapes), for conducting sound vibrations from the eardrum to the inner ear; the form of this ossicle has some value as a taxonomic character (see Feduccia, 1980). The extra 2 mammalian ear ossicles, the incus and malleus, are represented in birds by the quadrate and articular respectively. In some owls, the bony ear region is asymmetrical on the two sides of the head, a condition probably associated with their highly developed ability to locate sound sources.

The sclerotic coat of the eye is cartilaginous, and the front of the eyeball is reinforced by a series of usually 16 to 18 small, overlapping bony plates known as scleral ossicles. They assist in the process of visual accommodation (see VISION). In some birds there is also a small horseshoe-shaped bone (os opticus) in the sclera, surrounding the optic nerve as it enters the back of the eyeball. Sesamoids are present at the quadrate/mandible articulation in many birds, and are exceptionally highly developed in the Kokako *Callaeas cinerea* of New Zealand.

Cranial kinesis. Despite claims that have at times been made that some birds have akinetic upper jaws, it appears that the ability to move the upper jaw relative to the braincase is of universal occurrence throughout the class. For detailed accounts of the mechanism of kinesis, see Bock (1964) and Bühler (1981). Compared with the condition in which only the lower jaw moves, as in mammals, kinesis confers several advantages, viz:

(a) Maintenance of the primary axis of orientation. When the jaws are opened, the position of their long axis changes relatively little in position, in contrast to the situation in a mammal, in which it is considerably displaced as the lower jaw moves downward. This property may have great value when fast moving prey has to be captured.

(b) In general, cranial kinesis permits a wider gape when the jaws are opened—a feature of special significance in some specialized methods of feeding.

(c) Maintaining the mandible in the closed position. Coupling of upper and lower jaws (see below) permits a considerable reduction of the muscular effort needed to hold the jaws closed; if the upper jaw is heavier than the lower, this effort will in fact be nil.

(d) Faster closing jaws.

(e) A shock absorbing mechanism for all forces acting on the jaws, permitting a lighter skull construction than in mammals. Lightness is also aided by the wider spread of jaw muscle attachments in the kinetic skull, which reduces stress per unit area.

Two main types of kinesis are usually recognized. In *prokinesis*, exhibited by the majority of birds, the whole upper jaw moves about its articulation with the cranium. The articulation is usually formed by a narrow strip of flexible bone though, in large parrots, a set of synovial joints is present instead. Force to raise and lower the upper jaw is provided mainly by muscles attached to the palatines, pterygoids and quadrates (see MUSCULATURE), and is transmitted to the upper jaw via the palatines and jugal bars. In *rhynchokinesis*, the musculature and palatal complex function in essentially the same way, but the base of the upper jaw is rigid, and bending takes place further forward along the jaw. To make this possible, the upper jaw is separated for much of its length into a median dorsal bar, and paired ventral bars. Backward or forward movement of the ventral bars is permitted either by a flexible nasal bar, or (as in ratites and tinamous) a gap in the nasal bar. Rhynchokinesis occurs in the Gruidae, Charadriiformes, and Trochilidae, and in ratites and tinamous. It reaches its most sophisticated level of development in long-billed sandpipers, such as Snipe *Gallinago gallinago* or Curlew *Numenius arquata* (Burton 1974). The bending zone in such species is situated very far forward, enabling the distal region only of the jaws to be opened to grasp subterranean prey while probing. Alternatively, retraction of the upper jaw in highly rhynchokinetic species enables its tip to move backwards relative to the lower, a facility which can be used in shifting food towards the mouth, or in manipulating awkward objects.

Lower jaw movements. The simplest and most basic lower jaw movement is depression, in which the whole jaw is rotated downwards about the quadratomandibular articulations. In some birds, notably parrots and finches, these articulations also permit gliding movements, so that the jaw can additionally be moved backwards and forwards. More complicated is the action of lateral spreading, in which the mandibular rami are bowed outwards to enlarge the gap between them. This action is possible only in birds possessing two pairs of flexion zones within the mandibular rami, and is seen in various groups which regularly have to swallow large objects (e.g. many fish-eating birds, gulls and fruit pigeons *Ptilinopus*) or as an adaptation to special feeding methods (e.g. nightjars, pelicans). Spreading of the mandibles is achieved in most cases by the action of part of the pterygoideus muscle, which pulls the medial process of the lower jaw forwards, causing the rear part of the mandibular ramus to swing outwards. In gulls, this action is also aided by a guiding effect of the quadratomandibular articulation, and in barn owls *Tyto* is entirely produced by this means, taking place automatically as the lower jaw is depressed. An excellent detailed account of lower jaw structure and mobility is provided by Bühler (1981).

Jaw coupling. It is possible for the actions of upper and lower jaws to be coupled, that is to say, mechanically linked so that elevation of the upper jaw cannot occur without depression of the lower. Typically, such coupling is effected by the postorbital ligament, when loaded by muscle

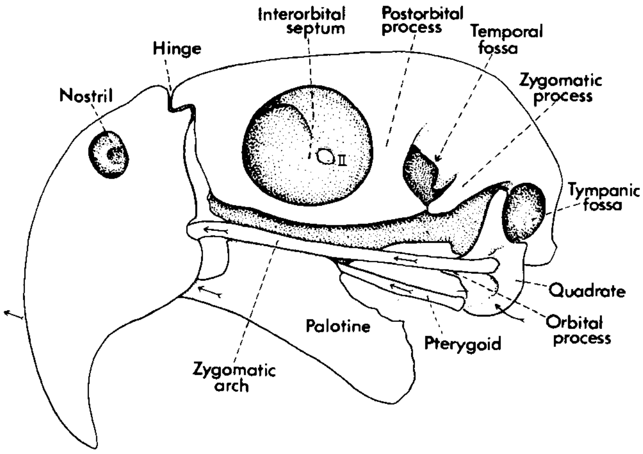

Fig. 2. Skull of Macaw *Ara* sp. showing mechanism of kinesis. Arrows indicate direction of bone movement.

action. (In ducks, its function is complemented or even replaced by a lacrimomandibular ligament, rostral to the orbit.) If the pattern of muscle contraction leaves the ligament unloaded, the jaws are able to move independently. Coupling is important where complicated actions of jaw and tongue have to be integrated with perfect precision, as in the straining actions of ducks (Zweers 1974) or seed opening by finches. Independent jaw action, on the other hand, is necessary if the jaws are to vary their angle relative to one another for manipulative purposes. This is especially so if the upper jaw is to be depressed past its normal closed position. Independence is also necessary, for instance, when both jaws are lowered simultaneously, as occurs during the mandibular spreading of gulls. The majority of birds probably have the option of either coupled or uncoupled jaw action, but this is not so in groups (e.g. various procellariiforms and ciconiiforms) which achieve coupling by means of a specialized form of quadrato-mandibular articulation. This arrangement is best seen in the Shoebill *Balaeniceps rex*, in which the lower jaw is so securely locked on to its articulation that even in a dried skull it is impossible to depress it by hand.

Stops and guides. In a complex and delicate system of bony levers such as that seen in avian jaw structures, some inbuilt safety devices might be expected. Fisher (1955) who examined those in a few easily obtained species concluded that most limitation on movement was imposed by soft parts of the head. However, protraction stops (e.g. orbital process of the quadrate abutting against the orbital wall) and retractor stops (e.g. nasal process abutting against lacrimal) are present in many birds. Some other features which may act as guides or constraints on movement are less well understood. The basipterygoid processes, which form a short region of contact between the basitemporal region of the skull and the pterygoids, are a case in point. Though they are undoubtedly of primitive origin, their form in many birds indicates that they are more than mere relics; in the Oilbird *Steatornis* for example, the pterygoid bears a clasp-like device enclosing the basipterygoid process. Many birds, however, including all passerines, fulfill a wide range of jaw actions without them. The os uncinatum, interposed between the lacrimal and jugal in the Musophagidae and some other families, is another example of a presumed bony guide whose function is not well understood (Burton 1970).

Secondary jaw articulations. First described in the Black Skimmer *Rynchops niger* in which it is well developed, a secondary articulation of the mandible occurs in a wide range of birds. These have been listed by Bock (1960), who referred to this articulation as the 'medial brace' of the mandible. It is between the tip of the medial process of the mandible and the basiparasphenoid bone, and is termed Artc. mandibulosphenoidalis in the *Nomina Anatomica Avium*. Another secondary articulation (Artc. ectethmo-mandibularis) occurs between the ectethmoid and the dorsal border of the mandible in honeyeaters (Meliphagidae). A description of this, and a functional discussion of both secondary articulations is provided by Bock and Morioka (1971). P.J.K.B.

SLEEP: a state of immobility accompanied by high arousal thresholds and eyelid blinking (Amlaner and McFarland 1981). This state occurs especially during ROOSTING. Most birds spend approximately one-third of the 24 hour cycle engaged in some form of loafing (see ROOSTING) and/or roosting behaviour, the duration varying greatly between species, and also with season, breeding condition, latitude, and other factors. A comprehensive review of sleeping in wild birds has been conducted by Amlaner and Ball (1983).

In the sleep posture, the bird sits, stands or perches (on one leg or two) or floats, with—often depending on species—its bill pointed backwards, tucked under the scapulars, under folded wings, resting on the back, or straight forward. The bill may be hooked behind the wing if the scapulars are indistinct, as in penguins. Most birds perch horizontally when sleeping, but woodpeckers and treecreepers cling vertically, while *Loriculus* parrots hang upside down like bats.

In the typical sleeping state, the eyelids usually blink slowly, but during a disturbance birds will keep them open, i.e. 'pseudo-sleep', a state of wariness. In the similar-looking rest-sleep posture, the bird again sits, stands, perches or floats, but with its head drawn into the breast and bill pointing forwards. Head and bill are lowered below the horizontal.

In the head-on-ground posture the bird lies with its head and neck extended along the ground. The feet may be tucked under the body or stretched behind the bird. This posture is normally assumed by young birds and by large flightless species, e.g. Rhea *Rhea americana* and Ostrich *Struthio camelus*.

Sleeping on narrow perches is facilitated by a special mechanism which automatically locks the toes in a gripping position. As the leg muscles relax and the tarsal joint flexes, the flexor tendons are automatically stretched and tightened. In addition, the under-surface of some portion of the flexor tendons is ridged, and corresponding ridges on the tendon sheaths in the region of the metatarso-phalangeal joint, where the body weight presses the joint against the perch, mechanically 'lock' the tendon in position.

Evidence for sleeping on the wing is inevitably circumstantial as, for example, the suggestion that the pelagic Sooty Tern *Sterna fuscata* may sleep aerially since it quickly becomes waterlogged on the water surface. Rheinwald (1975) found that House Martins *Delichon urbica* descended to the breeding colony early in the morning from great heights; he concluded that they were unlikely to roost elsewhere than on the wing. Evidence from eye-witnesses and from radar observations exists to suggest that Swifts *Apus apus* can sleep on the wing, a view strongly endorsed by Lack (1956) and others. Against this, it has been argued that the birds may descend after observations cease and that radar identification is not unequivocal. Certainly Swifts do also roost in their nest sites.

The 'quality' of sleep may be inferred from rates of eyelid blinking (i.e. the duration and frequency of eyelid closure). Hamerstrom and Janick (1973) assumed that a Barred Owl *Strix varia* slept when its eyes remained closed and 'dozed' when its eyes were 'partly closed'. Herring Gulls *Larus argentatus* do not close their eyelids completely for more than about 60 seconds, but there does appear to be a difference in the quality of sleep depending on whether they tuck their bill under the scapulars or place it forward (Amlaner and McFarland). Sleeping while standing or sitting is also a means of determining quality of sleep—deeper perhaps when sitting, and lighter and more vigilant when standing. Duration of sleep bouts, as determined by length of continuous eyelid closure, has been reported to be up to 2–3 hours (Klima 1966) or to last from only a few seconds to several minutes (Hamerstrom and Janick).

Birds may sleep by day, by night, or both by day and night. For discussion of the timing of roosting and sleep, see ROOSTING. Bird activity in Arctic and Antarctic summers of continuous daylight has been reviewed by, e.g. Armstrong (1954) and Cullen (1954). Nearly all workers agree that birds have a period of inactivity but not all that birds sleep during this time. Birds that do sleep spend fewer hours asleep than their counterparts at lower latitudes (Pohl and West 1978); for example Eiders *Somateria mollissima* slept for 3–5 hours in the arctic summer, but for 7 hours during the day and most of the night further south in Norway. Most species studied in continuous light conditions had an inactive period slightly after midnight, e.g. Wheatear *Oenanthe oenanthe*, Meadow Pipit *Anthus pratensis*, Lapland Bunting *Calcarius lapponicus*, while a few had sporadic sessions of inactivity throughout the 24 hours (e.g. Arctic Tern *Sterna paradisaea*).

Little is known about the development of sleep in wild birds. Herring Gull chicks appear to sleep longer than adults but not in the same postures. Gull chicks sleep in the head-on-ground posture. Only when several weeks old do they attempt to place their bills on their backs.

Delius (1970) likened sleep to a displacement activity such as grooming or pecking. He suggested that the origin of this association was obvious because much of an animal's other behaviour can be assumed to have high priority and require a high degree of responsiveness to stimuli. Sleeping, on the other hand, many not be so dependent on precise timing, and consequently might have a low priority; it could therefore be postponed until higher priority activities like feeding and drinking had taken place.

Tinbergen (1951) suggested that sleeping should be regarded as instinctive. This concept is central to the immobilization theory (Meddis 1975) which suggests that sleep acts mainly to preserve inactivity and does not necessarily conver any unique physiological benefit. Sleep reduces the wastage of energy by ensuring that the animal is unaware of surrounding stimuli which might provoke action. The sleep instinct enables an animal to choose a site which is well protected from inclement weather and will conserve energy. The sleeping posture is also chosen to reduce energy waste. Torpor (see TORPIDITY) occurs during sleep and is a significant means of reducing energy consumption.

The study of sleep in birds poses several problems. First, knowledge has hitherto been derived mostly from laboratory studies, using environmental factors inferred from the literature. Furthermore, sleep is not a mutually exclusive behaviour; while asleep, birds may, for example, also digest food or sit in their territory, thus complicating functional interpretations. Lastly, sleeping animals are difficult to observe and are easily disturbed if approached.

SMELL: a sense for which the receptive surface is the sensory lining of the nasal passages. The olfactory organs of birds are well developed and are situated in the paired nasal cavities that open by the nostrils (external nares) at the base of the bill (see BILL; NARIS; SKULL). The nasal cavities are separated by a median partition, the nasal septum, and they communicate posteriorly with the roof of the mouth by paired openings, the internal or posterior nares (or choanae). Each cavity is divided into three distinct regions or chambers whose walls are enlarged by the formation of folds from the lateral walls (the nasal conchae). Generally, each region contains one concha. The surface area in many species is further increased by the coiling of the conchae, or by the development of longitudinal furrows as in the Ostrich *Struthio camelus*.

The first two chambers appear to serve only respiratory functions and are of importance in warm-blooded animals, since they act as an air-conditioning apparatus (see RESPIRATORY SYSTEM). The lining epithelium has a rich blood supply and the removal of dust particles from the inhalant airstream is effected here, probably with the aid of the secretions of the nasal glands, which open into the first chamber. These glands are small in terrestrial species, but are well developed in marine birds and play a part in the elimination of excess salt (see EXCRETION, EXTRARENAL).

Only the third (dorsal) chamber is lined by olfactory epithelium. Its concha is usually a prominent tubercle, but in some procellariiform birds and the Turkey Vulture *Cathartes aura* it is developed into a turbinal system. In the nocturnal kiwis *Apteryx* spp. the concha of the olfactory chamber consists of about 5 transverse folds which are greatly enlarged in comparison with the size of the remaining respiratory area. Avian olfactory receptors are usually distributed on the epithelial surface of the posterior concha, the nasal roof and the upper septum. The olfactory epithelium is similar to that found in mammals; the olfactory receptors contained in it are pigmented and are long, narrow, columnar cells surrounded by columnar supporting cells. Information gathered by the olfactory receptors is carried to the brain by the olfactory nerve, non-medullated fibres of which form a plexus in the olfactory mucosa.

The size of the olfactory bulbs in the brain is extremely variable when compared with the size of the forebrain (see NERVOUS SYSTEM). They are largest in the Apterygiformes, Procellariiformes, Podicipediformes, Caprimulgiformes and Gruiformes, perhaps denoting a well-developed olfactory sense in these groups, and smallest in the Pelecaniformes, Piciformes, Passeriformes and Psittaciformes. Bang and Cobb (1968) for example suggested that the large and well innervated nasal organs of the Turkey Vulture, the Oilbird *Steatornis caripensis* and the albatrosses *Diomedea immutabilis* and *D. nigripes* indicate that these species have a good sense of smell.

However, although birds apparently possess adequate olfactory organs, early experiments produced conflicting evidence concerning the sense of smell in birds and it was not until about 1965 that a clear picture began to emerge. These more recent studies include detailed electrophysiological and behavioural investigations.

Tucker (1965) recorded electrically the nervous impulses travelling in the primary olfactory nerve of a number of different species of birds, ranging from those with small olfactory bulbs, such as the House Sparrow *Passer domesticus*, to the Black *Coragyps atratus* and Turkey Vultures with relatively large olfactory bulbs. Nervous activity was recorded in all species when presented with amyl acetate and other, unspecified, odours. Recordings from single olfactory units (as distinct from the whole nerve) in vultures have produced more detailed results; the sensory thresholds vary between units and, whilst in some units the rate of firing increases with the intensity of the stimulus, other units respond by a reduction in frequency when the concentration of the odour is raised.

Wenzel and Sieck (1972) have used electrodes implanted in the olfactory bulb of the brain to test the sense of smell in a number of species (pigeon *Columba livia*; chicken *Gallus gallus*; Mallard *Anas platyrhynchos*; Manx Shearwater *Puffinus puffinus*; Black-footed Albatross *Diomedea nigripes*) and all, irrespective of the relative size of the olfactory bulb, showed the bursts of nervous activity on inspiration of odours that are typical of vertebrates. They responded to such artificial stimuli as pyridine, methyl salicylate, octanol and amyl acetate, but not if the olfactory nerves were cut or the nostrils plugged.

Walter (1943) obtained entirely negative results in a series of investigations with pigeons, using the technique of conditioned reflexes. More recently, however, the heart rate of pigeons and the pattern of respiration of Greylag Geese *Anser anser* have been reported to change consistently in response to various odours in carefully controlled experiments; and similar results of behavioural changes have now been reported with a range of species. Both the trigeminal and olfactory nerves have been shown to be involved in the detection of the odours in these experiments.

Other behavioural studies (although they have been criticized and some workers have not achieved the same results in similar experiments) have demonstrated that certain species (pigeon; Bobwhite Quail *Colinus virginianus*; chicken) can use olfactory stimuli as cues for learned responses. For example pigeons have been trained to respond differentially to an airstream that was bubbled through distilled water or an artificial odorant. On balance, the evidence suggests that under careful experimental conditions some species can form associations between olfactory stimuli and specific responses, although they probably do this less readily than to visual and auditory stimuli.

Certain avian species (all with large olfactory bulbs) have long been believed to locate either their food or nest site by their sense of smell, and carefully controlled experiments with these birds under natural conditions are of particular interest. Turkey Vultures were seen to collect above upcurrents of ethyl mercaptan released from hidden sites in a canyon. Kiwis *Apteryx australis* readily and accurately distinguished between dishes that contained food and those containing only earth, although the birds had to break through stiff netting covering the containers to reach the food, this procedure ensuring that visual, tactile and gustatory discrimination was not possible. Leach's Petrels *Oceanodroma leucorhoa* walk upwind to their burrow and, in a Y-maze, captive birds chose an air current coming from their own nest material in preference to one from similar materials collected from the forest floor. The same birds, however, did not respond positively in the Y-maze to air currents from their own stomach oil or preen gland oil. Petrels taken from their burrows did not return within a week if their external nares were plugged or if their olfactory nerves were transected, although they did return if only sham-operated (Grubb 1974). Petrels and shearwaters have also been reported to make positive responses to airborne odour trails from sponges soaked in cod liver oil. Papi (1974) and his colleagues suggest that olfaction plays a part in the navigational ability of pigeons, the birds learning the odour prevailing in the area of the loft.

Finally, the olfactory system may have other physiological roles. Pigeons have been trained to detect X-rays, although they require higher doses and longer training than mammals; birds that learned to respond lost the ability after section of the olfactory nerves. Removal of the olfactory bulbs or sectioning of the olfactory nerves of pigeons also has an effect on the ability of the birds to learn operant procedures. They are slower to adapt to new situations and it has been suggested that the olfactory system may serve a wider function than simply processing information about odorous stimuli.

Wenzel (1971) has concluded from anatomical and electrophysiological studies that the avian olfactory system is broadly comparable to that of reptiles and mammals, and it is certain that many species can detect a variety of odours. However, so far, the sense of smell has been shown to be important in the lives of only a few species and in all (except perhaps the kiwis) it is probably of much less importance than vision and hearing.

SMEW: *Mergus albellus* (see DUCK). See photo DISPLAY.

'SMOKE-BATHING': term used, often uncritically, for a variety of reactions by birds to smoke and hot air rising from chimneys, etc. In the Rook *Corvus frugilegus* and a few other passerines, aberrant ant-application behaviour (see ANTING) seems to be involved at times but in most cases the behaviour appears to be a type of thermo-regulatory heat-basking akin to sun-basking (see SUNNING) performed mainly in cold weather. Any function in feather maintenance (see COMFORT BEHAVIOUR) remains to be demonstrated. K.E.L.S.

(For further references, see ANTING and SUNNING.)

SNAKE-BIRD: alternative substantive name of species of Anhingidae (see DARTER); also a popular name in Britain for the Wryneck *Jynx torquilla* (see WOODPECKER).

SNIPE: substantive name (commonly unchanged in the plural) of species of *Gallinago* (*'Capella'*) and allied genera, and also sometimes misapplied to the dowitchers *Limnodromus* spp. (see under SANDPIPER; for other families see PAINTED SNIPE and SEEDSNIPE).

See photos COMFORT BEHAVIOUR; FACILITATION, SOCIAL.

SNOWCAP: *Microchera albocoronata* (for family see HUMMINGBIRD).

SNOWCOCK: substantive name of *Tetraogallus* spp. (see PHEASANT).

SOARING: see FLIGHT. See photo FLIGHT.

SOCIAL DISPLAY: see FLOCKING; LEK.

SOCIAL FACILITATION: see FACILITATION, SOCIAL.

SOCIAL NESTING: see COLONIALITY.

SOCIAL ORGANIZATION: see AGGRESSION; COLONIALITY; DISPLAY; DOMINANCE (2); FLOCKING; RECOGNITION; TERRITORY; VOCALIZATION; also CROW (1); PENGUIN; ROOSTING.

SOCIETIES, ORNITHOLOGICAL: see ORNITHOLOGICAL SOCIETIES.

SOCIOBIOLOGY: on Edward O. Wilson's definition, the systematic study of the biological basis of all social behaviour. Biologists had been studying the basis of social behaviour for several decades before the word 'sociobiology' was shot into our everyday vocabulary by the publication of Wilson's *Sociobiology* in 1975, but the word has come to refer not to a scientific discipline but to a particular set of ideas about the evolution of behaviour. In a more popular context, sociobiology means the application (and misapplication) of biological, particularly evolutionary, ideas to explain human behaviour.

Evolutionary ideas. A series of theoretical developments in the 1960s and early 1970s revolutionized evolutionary explanations of social behaviour. The new theory applies with renewed vigour the Darwinian principle that behaviour must be explained by its benefit to no larger entities than individual organisms. Group selection, which explains traits by their benefit to groups, was criticized both for being implausible in theory (for it requires unnaturally high rates of group extinction) and superfluous. Traits such as altruism, territoriality, reproductive rates and dominance were reconciled with natural selection by the work of W.D. Hamilton, J. Maynard Smith, R.L. Trivers, G.C. Williams and others; this theoretical reconciliation provides the stuff of sociobiology.

The systematic comparative studies of mating systems, started by J.H. Crook and David Lack on birds, provide the other principal component of sociobiology. These studies explain evolutionary trends of convergence and divergence in social behaviour by the species' ecology.

Human sociobiology. Superficially, it looks as if the sociobiological ideas could help to understand human behaviour, and indeed many arguments have been made about how human behaviour might be adaptive. An acerbic 'sociobiology controversy' has been inspired by several confusions on the part of both critics and advocates. Human sociobiology can only describe and explain human adaptations; but it has been criticized for (and sometimes unscientifically advocated as) morally upholding the inegalitarian social order. Similarly, evolutionary arguments often posit a certain kind of 'selfishness', in that the effects of behaviour benefit the organism's genes. Sociobiology has been criticized for the claim that humans are fundamentally selfish in motivation. The kind of selfishness that features in sociobiological explanation, when correctly understood, is not one of motivation, and is quite compatible with humans being fundamentally unselfish. M.R.

Wilson, E.O. 1975. Sociobiology. Cambridge, Mass.

SOFT PARTS: see BARE PARTS; INTEGUMENTARY STRUCTURES. For care of, see under COMFORT BEHAVIOUR.

SOFTTAIL: substantive name of *Thripophaga* spp. and allies (see OVENBIRD (1)).

SOFTWING: substantive name sometimes used for *Malacoptila* spp. (see PUFFBIRD).

SOLAN GOOSE: former alternative name (misnomer) for *Sula bassana* (see GANNET).

SOLITAIRE: substantive name of 2 species of the extinct family Pezophapidae, previously Raphidae (see under DODO); and, in America, of *Myadestes* spp. (for family see THRUSH).

SOMATERIINI: see DUCK.

SOMITE: see DEVELOPMENT, EMBRYONIC.

SONAGRAM: see VOCALIZATION.

SONAGRAPH: a machine which produces on paper a visual representation of a sound (sonagram), with time on the horizontal axis and frequency on the vertical axis; regularly used in the analysis of bird VOCALIZATIONS.

SONG: see VOCALIZATION.

SONGBIRDS: term often used for the suborder Oscines (see PASSERIFORMES).

SONG FLIGHT: display flight involving song.

SONGLARK: substantive name of *Cinclorhamphus* spp. (see WREN (2)).

SONG PERIOD: the part of the year during which the song of a particular species can be heard.

SONG-SHRIKE: sometimes used, in the plural, as a general term for the CRACTICIDAE.

SORA: name, alternatively 'Sora Rail', of *Porzana carolina* (see RAIL).

SOUND RECORDING: one of the more recently evolved methods of collecting information about birds.

History. The earliest bird recording known still to exist is that of a captive Common Shama *Copsychus malabaricus* made in Germany in 1889 by Ludwig Koch on an Edison wax cylinder. The earliest reference in ornithological literature to the reproduction of a bird sound is in the account of the 16th Congress of the American Ornithologists' Union in 1898, which mentions a 'graphophone demonstration of a Brown Thrasher's song'. The first recordings of wild birds made anywhere are probably those of Cherry Kearton, who in England in about 1900 captured on wax cylinders a few Song Thrush *Turdus philomelos* notes and the song of the Nightingale *Luscinia megarhynchos*.

The earliest recordings of wild birds in the Nearctic and Afrotropics were made in 1929, in the Australasian region in 1931, in the Antarctic in 1934, in the Orient in 1937, and in the Neotropics in the early 1940s.

At least one sound has been recorded (up to mid 1982) from over half the world's 9,000 living bird species. The approximate figure is 5,000 species. The recordings are housed, usually on tape, in the collections of national institutions, universities, broadcasting organizations and private individuals. The total number of individual recordings may be of the order of 100,000.

Published recordings. Recordings of about 2,500 species have been published on about 1,160 gramophone records and cassettes, 1910–1982. The earliest 'bird' gramophone records (issued from 1899 onwards) were of human imitations of birds (see HUMAN IMITATION OF BIRD SOUNDS).

Between 1910 and 1913 recordings were made of captive Nightingale *Luscinia megarhynchos*, Thrush Nightingale *L. luscinia*, Canary *Serinus canaria* and others at the Karl Reich aviary at Bremen and published on HMV gramophone records. The first publications to present selections of recordings of wild birds were Brand and Keane's 'Bird Songs recorded from Nature' which appeared in the USA in 1931, Weismann's set of 5 discs produced in Denmark in 1934 and Heinroth and Koch's 'sound book' published in Germany in 1935. These were followed by many more selections of commoner wild species. A few discs have been devoted to individual species—one as early as 1931 to the Lyrebird *Menura novaehollandiae*, 4 to the Mocking-bird *Mimus polyglottos* (most recently Grimes' 1979 LP on which mockers copy 86 other species), one to the Great Northern Diver *Gavia immer* (1980), and so on. The first attempt at faunistic treatment—195 species on thirteen 78s—was that of North and Simms: '*Witherby's Sound-Guide to British Birds*' (1958). This was closely followed (1959) by Kellogg and Allen with their '*Field Guide to Bird Songs of Eastern and Central North America*' (305 species on two LPs), and Kellogg's (1962) western Nearctic album (515 species on three LPs), both issued by the Laboratory of Ornithology, Cornell University. The largest such treatment is the European '*Field-guide*' (1981) which gives 612 species on 16 cassetttes; it is published by the Swedish Broadcasting Corporation. A record by Borror and Gunn introduced, in 1958, the specialized treatment of individual variation in song; '*Warblers*' gives songs by 150 individuals of 38 species of parulid. The first attempt to present the species' repertoires of the birds of a country was Victor Lewis's '*Bird Recognition: an Aural Index*' published in Britain in 1966. In the 1970s a number of records appeared which had the more serious educational purpose of presenting the biology of bird sound communication: Borror's '*Bird Song and Bird Behavior*' (1972), a quartet of small German discs devised by Thielcke and Bergmann (1973–78) called '*Biologie der Vogelstimmen*'; and Jellis's '*Bird Sounds and their Meaning*' (1977), an LP accompanied by a book. There is a Russian disc (about 1976) designed to scare off unwanted species, and in contrast a cassette by Gibson from Canada the purpose of which is to lure species into birdwatchers' ken. Since the first in 1971 more and more bird recordings have been published on tape cassettes. The most recent development is electronically enhanced human mimicry as an aid to field identification—a British record/cassette called '*Big Jake Calls the Waders*' offers almost unbelievable verisimilitude. The most prolific publishers have been the Laboratory of Ornithology at Cornell in the USA and Jean-Claude Roché in France. The best selling birdsong discs are almost certainly Veprintsev's first three in his '*Voices of Nature*' (1960–62) series each of which had sold over 250,000 copies (mainly within the USSR) by 1982.

Sound libraries and collections. The number of scientifically significant collections is about 50. The oldest and largest, the Library of Natural Sounds at Cornell University Laboratory of Ornithology, Ithaca, in the USA, established in 1931 by Allen and Kellogg, had accumulated by 1982 approximately 35,000 recordings of about 3,750 bird species. The Americas and eastern Africa are particularly well represented at Cornell. The largest personal collection must be that of Claude Chappuis of France who by 1980 had made 12,000 recordings of about 2,000 species in 40 countries. The British Library of Wildlife Sounds in London, inaugurated in 1969, contained by 1982 tape recordings of about 1,600 bird species. The Soviet equivalent was started in 1973 by Veprintsev at Puschino, near Moscow, and by 1982 had 450 species on tape. Sizeable other Palearctic collections also exist in Britain (BBC), France (Chappuis, Roché), Estonia (Jüssi), Denmark (Bondesen), Sweden (Astrom), East Germany (Wallschläger), Austria (Jilka), Hungary (Szöke) and Japan (Nakatsubo, Kabaya). In the Nearctic there are a number of notable sound libraries besides Cornell's: W.W.H. Gunn's in Ontario, the Borror Laboratory of Bioacoustics in Ohio, the Florida State Museum Bioacoustic Archives, and others in Berkeley, Los Angeles, Ottawa, San Francisco and St Johns. In Australasia, the CSIRO in Australia and the Wildlife Service in New Zealand have good archives. Major Neotropical collections include those of L.I. Davis (from Central America and held in Louisiana), T. Davis (from Suriname, held in New York), Coffey (northern Neotropics and held in Tennessee), Schwartz (Venezuela and held at Cornell), Parker (Peru and Bolivia and held at Cornell), Reynard (Caribbean and held in New Jersey), Vielliard (taped and held in Brazil), and Straneck (taped and held in Argentina). In the Orient there is Roberts' Pakistan collection and Scriven's at the University of Malaya, Kuala Lumpur. Large Afrotropical collections include those of North (held at Cornell, copy in London), Chappuis, Stjernstedt and McVicker. In South Africa there is the Fitzpatrick Bird Communication Library at the Transvaal Museum (800 birds on tape). Two archives (Cornell and Borror) have computerized data.

Numbers of Bird Species whose Voices have been Recorded

Region	*Total*	*Published*
Palearctic	850	800
Nearctic	800	600
Australasian	600	250
Neotropical	1,650	550
Afrotropical	1,500	650
Oriental	450	125
Antarctic	50	15

Note: no totals are given because some species will have been recorded in more than one region.

Technique. The earliest recordings were made on wax cylinders, later superseded by wax discs. These were followed by magnetic wire (very occasionally), optical sound film (much used in the 1930s by Cornell), acetate discs, and finally—and most important of all the modern developments—magnetic tape, which was first used for bird-sound recording by Palmér in Sweden in 1946. Most recordings have been made on 6.25 mm wide tape recorded reel-to-reel; but 4 mm wide tape cassette recordings can now also be technically acceptable. The parabolic reflector, which acts like a great mechanical ear, enables the recordist to work at distances from the singing bird up to 40 times as great as would be necessary with an open microphone. Dynamic microphones are still widely used, but transistorized condenser microphones—'gun mikes'—which incorporate a directional effect otherwise achieved by the parabolic reflector, are being used more and more. The parabolic reflector was first tried by the Cornell workers in 1932 and is now regarded as an indispensable tool. Brand and Kellogg of Cornell were also the first workers to transmit the sounds of a bird by short-wave radio for the purpose of recording them; this was in Canada in 1936. Later, this method was used by Weismann in Denmark in 1947, by Palmér in Sweden in the same year, and by Simms in England in 1954. The earliest stereo recordings of birds were made in about 1959 and a number have been published, the first selection on Wahlström's disc in 1963. Wahlström also designed and used the first stereo parabolic reflector.

In addition to the use of the reflector and short-wave transmitter, field techniques include hiding the microphone near known singing places or the nest, and playing back in the field to territorial and other species recordings of advertising sounds in order to stimulate a reply and lure the birds within range of the microphone (see PLAYBACK).

Purposes. The ultimate scientific aim must be to record the full vocabulary, vocal and instrumental, of every species, with all the major individual, seasonal, and geographical variations. With the ever-increasing likelihood of extinctions, the taping of, for example, tropical rain forest species becomes more important. The uses of recordings are many and varied. They are employed for purposes of personal pleasure, education and identification; also in studies on bird behaviour, ontogeny, learning ability, heredity, and taxonomy. For the use of the sound sonograph in technical analysis see VOCALIZATION. Sound sonagrams have now found their way into a field guide, monographs and two regional handbooks, and they are a central feature of a specialist bird voice field guide (Bergmann and Helb 1982).

The Puerto Rican Whip-poor-will *Caprimulgus noctitherus*, thought for over 40 years to be extinct, was rediscovered in 1961 by means of a sound recording of its voice. The recordings also have mundane applications, as for example, in scaring gulls *Larus* spp. from airfields and Starlings *Sturnus vulgaris* from orchards and buildings (see SCARING).

For the production of sound by birds, see VOCALIZATION and MECHANICAL SOUNDS. For musical use of bird recordings see MUSIC, BIRDS IN.

SOUNDS: see ECHO-LOCATION; HEARING AND BALANCE; MECHANICAL SOUNDS; MIMICRY, VOCAL; VOCALIZATION.

SOUND SPECTROGRAPH: term no longer generally used for SONAGRAPH.

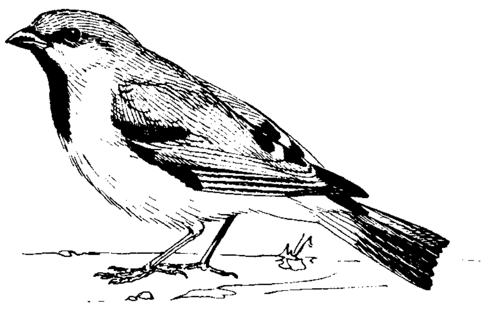
SPADEBILL: substantive name of *Platyrinchus* spp. also called 'flatbills' (see FLYCATCHER (2)).

SPARROW (1): substantive name for most species of Passeridae (Passeriformes, suborder Oscines); in the plural, general name for the family. The Passeridae show affinities both to the finches (Fringillidae) and the weavers (Ploceidae), though how far these are genuine and not adaptive is not agreed. Until the relationship has been resolved it seems better to treat the sparrows as a separate family (Voous 1977). The family can be conveniently placed into 3 genera: the true sparrows, genus *Passer*, in which 16 species have been recognized, though recent investigations (Hall and Moreau 1970) suggest that one of the African species, the Grey-headed Sparrow *P. griseus*, may be a superspecies of 5 different species exhibiting some sympatry in their ranges, thus bringing the total to 20; the rock (or bush) sparrows, genus *Petronia*, 6 species, and the snow finches, genus *Montifringilla*, 7 species. The SPARROW-WEAVERS AND SCALY-WEAVERS, comprising 10 species in 5 genera, *Plocepasser*, *Histurgops*, *Pseudonigrita*, *Philetairus* and *Sporopipes*, are included in this work in the subfamily Plocepasserinae of the Passeridae. The true sparrows appear to be a comparatively recent family and studies by R.F. Johnston and R.K. Selander have shown changes suggesting that measurable evolution has occurred in the House Sparrow *Passer domesticus*, in the 100 or so years since the species was introduced to America (see Johnston and Klitz 1977).

Characteristics. The species are small (10–20 cm long with one exception) and—except for the white on the snow finches—have plumage mainly of brown and grey hues, but sometimes with black and, in a few species, yellow. *Montifringilla* and *Passer* share the characteristic that the bill of the male changes from horn-coloured to black during the breeding season. The main feature distinguishing the sparrows from the weavers is that the first primary is much reduced and placed dorsally; in this and a number of other characteristics they resemble the finches. In the structure of the palate, form of nest and social behaviour they are closer to weavers. The rock sparrows, snow finches and about half of the Afrotropical sparrows are monomorphic. In the remaining Afrotropical sparrows the males have characteristically a black throat and chin with some black on the head; this pattern occurs in all the Palearctic and Oriental sparrows and in one species, the Tree Sparrow *P. montanus*, it has been adopted by both sexes.

Habitat. The sparrows are mainly birds of open country, ranging from high mountains in the case of the snow finches, which are among the highest-living birds, nesting from 2,000 to 4,500 m, through rocky semi-arid country to light scrub in the case of the rock sparrows, to cultivated and even highly urbanized areas with the true sparrows. The true sparrows, more than any other group of birds, have colonized man's urbanized habitat. In the House Sparrow the extent of this adaptation is quite remarkable, not only is it found in the centre of extensive built-up areas, but even inside large buildings such as railway stations, factories and stores, and recently some birds that became trapped in a coal mine not only survived for some years 600 m below the surface, but a pair actually bred successfully in this alien environment.

Distribution. The sparrows, apart from recent introductions (see below), are restricted to the Afrotropical, Palearctic and Oriental Regions, and probably have an Afrotropical origin. The rock sparrows are all found in Africa, but 3 extend to Asia and one, the Rock Sparrow *Petronia petronia*, occurs in southern Europe as well. The greatest



Desert Sparrow *Passer simplex*. (*C.E.T.K.*).

concentration of *Passer* species occurs in the Afrotropical Region; the Golden Sparrow *P. luteus*, is predominantly African, but extends into Arabia; the Desert Sparrow *P. simplex* is found in the Sahara and Asian deserts. The remaining 7 species are found in the Palearctic and Oriental Regions, the House Sparrow and Tree Sparrow being very widely distributed, the Spanish Sparrow *P. hispaniolensis* being mainly western but extending to Afghanistan and Turkestan; in contrast the remaining species have rather restricted, widely separated distributions in Asia, though they all overlap with one or more of the 3 widespread species. In comparatively recent times (since 1850) the ranges of 2 of the already widespread species have been extended by introductions to other parts of the world. The House Sparrow has been extremely successful in this, taking over the otherwise unoccupied urban niche, and is now probably the most widespread species of land bird, being found in all major settled areas with the exception of China and Japan; the Tree Sparrow has been less successful, but is established in the USA, Australia, and may also have been introduced to, rather than spread to, Borneo, Sulawesi and the Philippines. The House and Spanish Sparrows bear an interesting relationship to each other. In Europe and Asia where they occur together they behave as good species, ecologically separated, the House Sparrow living in towns and villages, the Spanish Sparrow in the surrounding countryside with a preference for moister conditions: in Morocco the same situation occurs, but in eastern Algeria and Tunisia the species interbreed, producing a complete range of intermediates. The Italian Sparrow *P. d. italiae*, a well-differentiated form occurring in Italy and Crete, appears to be a stabilized intermediate between House and Spanish Sparrows and stable populations, very similar in appearance, are also found at the isolated southern Algerian oases (Johnston 1969). The snow finches inhabit high mountainous country from the Pyrenees to Mongolia.

Population. Within their ranges some of the sparrows are among the more common birds, so that they reach pest proportions in those species that inhabit cultivated land, though not to the extent of some of the highly gregarious weavers. Population density has been most closely studied in the House Sparrow; it ranges from about 0.05 birds per ha in open farmland to over 1 bird per ha in highly cultivated land and built-up areas.

Movements. As a general rule the sparrows are mainly sedentary, though most of the Palearctic species make minor seasonal movements: the snow finches to lower ground and most of the true sparrows some southward extension of range in the winter, though the Spanish Sparrow is a regular winter visitor to the Nile valley, eastern Arabia and north-western India. The House Sparrow throughout most of its range is extremely sedentary, the majority of individuals spending their lives within a compass of a few km. At high latitudes and altitudes it builds winter nests, where it roosts protected against long cold nights.

Food. The sparrows are largely seed-eaters, with the *Passer* sparrows showing a marked preference for cereals. House and Tree Sparrows living in the more built-up surroundings exist mainly on such 'unnatural' foods as bread and household scraps; the young nestlings are fed at first principally on insects, but they are regularly given bread and it is a major part of the diet of some young born in highly urbanized districts.

Behaviour. There is a widespread tendency in the sparrows to form extensive foraging flocks, frequently involving 2 or more species and often in association with finches. In many cases large communal roosts are formed. A characteristic of *Passer* is the tendency to associate with man; at least 10 (13 if 20 species are recognized) of the species regularly nest in the eaves of inhabited buildings. This trait is so marked in the House Sparrow that it can be fairly described as a commensal of man and it is to be found breeding away from man only in exceptional circumstances. The Tree and Spanish Sparrows fill the same niche in those parts of their ranges where the House Sparrow is lacking. Despite their close association with man, sparrows are extremely wary birds; they are not easily tamed and do not readily settle down and breed in captivity.

Voice. The members of the genus *Passer* are somewhat noisy birds using a variety of rather harsh chirping calls. There is no true song, though the chirping notes are strung together to serve in this function. The other members of the family have rather more varied songs, but their calls tend to be somewhat harsh.

Breeding. Many of the sparrows are gregarious and breed in colonies although, in general, the nests are discrete and not communal structures such as are found with some of the weavers. The Spanish Sparrow is the most social; colonies of several hundred nests of this species have been found in a few trees or bushes. Nests are found in a variety of situations, but most frequently in holes in rocks, banks, buildings and in trees. In *Passer* the nests are typically bulky, domed and made of dried grasses and lined with feathers; in the other 2 genera, however, the nest may be reduced to a mere pad of grasses, although again lined with feathers. The clutch ranges from 2–7. Both sexes co-operate in nest building and care of the young. With the hole nesters the same hole is regularly used from year to year and, provided they survive, by the same pair. The incubation periods average 12–14 days; nestling periods range from *c.* 15 days in the House Sparrow to as many as 24 days in the Cape Sparrow *Passer melanurus*. See photo PARENTAL CARE. SPARROW (2): substantive name used in America for many species of Emberizinae found there (see BUNTING).

SPARROW (3): name applied or misapplied to some other birds than those comprised in the two groups dealt with above, e.g. the Hedge-sparrow (or Dunnock) *Prunella modularis* in the family Prunellidae (see ACCENTOR), and the Java Sparrow *Padda oryzivora* and other species of Estrildidae (see ESTRILDID FINCH; and CAGE BIRD).

SPARROWHAWK: *Accipiter nisus*, a widespread small hawk of the Palearctic region. The same name, usually spelt as two words, was formerly used for *Falco sparverius*, a small falcon widespread in the New World, now usually known as the American Kestrel.

SPARROW-WEAVER AND SCALY-WEAVER: general terms for members of the subfamilies Plocepasserinae (Sparrow-weavers) and Sporopipinae (Scaly-weavers) of the Passeridae, Passeriformes, suborder Oscines (see WEAVER). They are endemic to the Afrotropical Region and placed in 5 genera; *Plocepasser* with 4 species, *Pseudonigrita* with 2 species, *Histurgops* and *Philetairus* with one species each, and *Sporopipes* with 2 species. They differ from the true sparrows (*Passer*) in tongue structure (Bock and Morony 1978).

Characteristics. All but one of the species are 12–15 cm long, the exception being the Rufous-tailed Weaver *Histurgops ruficauda* (20–23 cm). They are drab-coloured birds, brown above and white below, with species-specific markings confined mainly to the head and wings. The Rufous-tailed Weaver, besides its relatively longer tail, is greyer, and has a heavy scaly pattern over all of its underparts. The sexes are alike in all species. All are notably gregarious.

Habitat and distribution. All are found in the dry regions of Africa. The most widespread species is the White-browed Sparrow-weaver *Plocepasser mahali*, ranging from Ethiopia southwards to northern Cape Province. Its range in Ethiopia overlaps with that of the Chestnut-crowned Sparrow-weaver *P. superciliosus*, which occurs across the whole of the savanna belt north of the Equator, but appears to prefer higher altitudes than *mahali*. In Kenya the range of *mahali* completely overlaps that of Donaldson-Smith's Sparrow-weaver *P. donaldsoni* which, however, prefers a drier habitat.

The Grey-capped Social Weaver *Pseudonigrita arnaudi* and the Black-capped Social Weaver *P. cabanisi* are confined to north-eastern Africa, the Rufous-tailed Weaver to a small area of northern Tanzania and the Sociable Weaver *Philetairus socius* to the drier regions of south-western Africa.

Movements. No movements from the home range take place; the birds of a colony reside in one tree the year round, sleeping in their nests, and forage within a few km of the tree.

Food. All species forage on the ground for seeds and insects. In the Social Weaver adults depend more on insects (80% of food intake) than seeds and feed their young entirely on insects.

Behaviour. The White-browed Sparrow-weaver forms small colonies of 5–7 birds which defend a group feeding territory. They build several nests communally in which they sleep separately. Both of the *Pseudonigrita* species form colonies, ranging in size from a few to 50 or more nests in one tree. Birds from different colonies forage together in large flocks on communal feeding grounds; this behaviour occurs also in the Sociable Weaver. Nests of the Grey-capped Social Weaver are sometimes closely packed, with 10 or more nests clumped together, and are often used for roosting by more than one bird at a time.

All members of a new colony of Sociable Weavers join in the initial construction of the nest chambers. After some days, each bird restricts its activity to a few chambers only. During the breeding season only the breeding pair maintains the nest chamber, whereas any bird in the colony may repair any part of the superstructure of the nest mass. The number of birds per colony is highly variable, but may be as high as 500.

Voice. Only a few details are known. The male White-browed Sparrow-weaver gives a pleasant canary-like song from an elevated position, often singing after dark. A wide variety of calls are used by the Sociable Weaver and consist of staccato chipping notes, somewhat metallic in quality. The male's short, melodious song advertises ownership of a nest chamber and attracts a mate.

Breeding. All species build roofed nests that are thatched, rather than woven, from grass stems, the nest chamber being lined with softer materials. The nests of all species, except the Sociable Weaver and the scaly-weavers have two openings, one of which is closed when eggs are laid and opened again when the young fledge.

In a colony of the White-browed Sparrow-weaver there is only one brood nest, and one female incubates, although all or most members of a group will help feed nestlings. In contrast to this, a breeding colony of Grey-capped Sparrow-weavers may contain several breeding groups in the same tree. Only the pair incubates, but young of preceding broods help feed the nestlings.

The nest of the Sociable Weaver is the largest nest of any passerine; it may be as much as 9 m in length and 1.5 m high, and contain over 100 individual nest chambers. Small twigs are added to the thick dome-shaped roof which helps shed rain, gives shade from the hot sun, and protection from predators other than cobras. The larger the nest mass the more stable is its internal temperature. These colonial nests persist from year to year; one camelthorn acacia was known to have contained a colony for 100 years. The species is monogamous; both sexes incubate and feed nestlings which are also sometimes fed by young of previous broods hatched in the same breeding season.

The clutch-size in *Plocepasser* species is usually 2, the eggs are cream or pinkish white, and usually speckled with red and grey, forming a ring at the large end; in *superciliosus* the eggs are more heavily blotched. Clutch-size in *Pseudonigrita* species is in the range 2–5; the eggs are usually white or pinkish spotted with brown. The most frequent clutch-size of the Sociable Weaver is 4; the eggs of *Histurgops* are pale blue with scribblings and a few blotches of reddish-brown; its clutch-size is 3. Incubation takes 13–14 days in the Sociable Weaver and its young leave the nest 21–24 days after hatching.

Scaly-weavers. The 2 species of scaly-weavers *Sporopipes* are of uncertain systematic position. They have been considered to be a link between the true weavers (Ploceidae) and the waxbills (Estrildidae); their nest construction is similar to the sparrow-weavers'. Both species are endemic to the Afrotropical region, inhabiting the dry belt south of the Sahara (Speckle-fronted Weaver *S. frontalis*) and south-west Africa (Scaly-fronted Weaver *S. squamifrons*). They breed either singly or in small loose colonies in thorn trees, sometimes under the eaves of houses.

SPECIATION: the process whereby new biological species are evolved (see EVOLUTION; SPECIES). Speciation is believed to proceed as follows: an existing species becomes subdivided by some extrinsic factor, the isolated populations diverge genetically, and finally some form of intrinsic isolation, such as sexual isolation or genetic incompatibility, evolves among the populations. The newly separated populations can then evolve independently and may achieve ecological compatibility, allowing invasion of each other's geographic ranges without extirpation or extinction. Three modes of speciation are theoretically possible: allopatric, parapatric, and sympatric (Bush 1975, Endler 1977, Mayr 1963, White 1978). These modes differ primarily in the geographic relationships among the differentiating populations. Allopatric populations are geographically disjunct, parapatric populations are in contact along a common boundary, and sympatric populations overlap over most of their area. There is a great deal of controversy about the relative frequency of the various modes of speciation, and in some ornithologists' opinion only the allopatric mode has occurred.

Sympatric speciation involves the splitting up of different groups of individuals even though they are physically close enough to interbreed. This mode of speciation depends on assortative mating, or the tendency for individuals to mate more often with others of the same variety than those which differ. There is evidence for assortative mating within species, for example in the Blue—Snow Goose complex *Anser caerulescens—hyperborea*. Such mate preference is never complete nor continuous enough to allow intense genetic differentiation and full speciation without some additional factor; the 'wrong' matings still take place at a significant frequency. The only evidence for sympatric speciation comes from insects, and seems to involve a very strong host-plant specificity. A new species may be formed when a group of individuals invade a new host-plant species. This yields perfect assortative mating and complete isolation because mating normally takes place only on the host species that the parents ate as larvae. It is only where one finds strong microhabitat segregation associated with assortative mating that sympatric speciation seems to be possible. Birds are not nearly so microhabitat specific; therefore it is unlikely that sympatric speciation has played any role in the generation of bird diversity.

Allopatric and parapatric speciation involve geographical separation among the diverging populations, and differ only in the amount of physical restriction to movement among populations. Physical restriction to dispersal is complete in allopatric speciation and weak or absent in parapatric speciation. There are many intermediates between the two modes, and they collectively can be called geographic speciation.

In allopatric speciation the ancestral species is divided into two or more populations by a complete geographic barrier such as a mountain range, ocean, or extremely unsuitable habitat. This may happen by geological or climatic changes, or by dispersal across barriers. Dispersal of a small group of individuals, with (by chance) a genetic composition different from the ancestral species, may result in rapid divergence of the newly isolated population. This may be a more common mode of differentiation than the addition of a physical barrier to an existing species range (Mayr).

In parapatric speciation a complete physical barrier is not necessary because there is isolation by distance. Very few species are so geographically restricted in the breeding season that all the individuals meet with each other and can mate at random. Most species have a sufficiently large breeding area so that individuals from a given place are more likely to mate with those from the same area than with others further away. Even in migratory birds such as the Guillemot *Uria aalge*, it has been shown by ringing studies that matings between birds born in nearby sites are considerably more frequent than those between birds born in nests separated by long distances. The average nett distance travelled from birth to reproduction may be called the gene flow distance because it is proportional to the average distance traversed by genes per generation. If this distance is large relative to the size of the geographic range of a species, then there is no isolation, and speciation cannot occur. A good example is the Long-tailed Duck *Clangula hyemalis*, which often breeds thousands of kilometres from its birthplace. But, except for ducks, individuals of most species breed within a few kilometres of their parental nest; the gene flow distance is relatively small. In the latter case, many hundreds or even thousands of generations may be required for genes from one population to move into another. For example, populations of Asian Wheatears *Oenanthe oenanthe* are effectively isolated from the European populations, even though their ranges are continuous. Thus in parapatric speciation the barrier is one of time and distance rather than the physical obstruction to dispersal of allopatric speciation (Endler, White).

In general, the earth's surface is heterogeneous in climate, physiography, flora and fauna, and it is more likely than not that each population will be subject to different factors of natural selection. If selective factors vary geographically, and there is not a high rate of intermixing of genes from widely different habitats, then populations can diverge. There is extensive and convincing evidence for this (see Mayr, and DISTRIBUTION, GEOGRAPHICAL). In allopatric speciation, breeding sites are completely isolated, so there is no intermixing at all. In parapatric isolation, intermixing between populations in different environments proceeds so slowly that the groups isolated by distance can diverge nearly as much as if they were completely isolated. In the latter case the amount of differentiation is determined by the degree of environmental differences between populations and the gene flow distance (Endler). If this distance is small, then differentiation can proceed rapidly. If genes move a long distance every generation, then differentiation proceeds more slowly. Thus it is not surprising that there are many subspecies and species of sparrows *Zonotrichia* etc., there are relatively fewer geographic variants of geese, and ducks are the least differentiated geographically; these 3 groups illustrate increasing distance from fledging to breeding. Another example is the Australian bird fauna; sedentary species show more geographic variation and subspecies than migratory or vagrant species.

Geographic divergence can have a variety of causes. Habits and morphology may vary in relation to climate, available foods, or the presence or absence of other species. For example, in Germany, where 2 nightingales *Luscinia megarhynchos* and *L. luscinia* are found together, one keeps to drier woods and the other to wetter, although each is widespread in moist woods outside the area of overlap. Geographically, varying foods are associated with variation in bill size and shape in DARWIN'S FINCHES *Geospiza* spp. Predation appears to affect the colour patterns in relation to habitat in the Song Sparrow *Melospiza melodia*. Such differentiation may evolve rapidly; since their introduction into North America a century ago, various populations of the House Sparrow *Passer domesticus* have evolved a significantly different morphology in response to varying climate.

When two populations have diverged but remain geographically separate, it is not possible to decide with any certainty whether they are species or only subspecies. For example, Scrub Jays *Aphelocoma* are distributed throughout western North America, but are not found east of the Rocky Mountains except in southern Florida. These disjunct populations are morphologically similar but significantly different in behaviour. When a barrier is removed, so that the two populations actually meet in the wild, a definite conclusion may be possible. The two populations may (i) fuse together into a single hybrid swarm, (ii) there may be only a limited zone of hybridization, or (iii) they may remain distinct as breeding populations. Respectively, examples are (i) the flickers *Colaptes cafer* and *C. auratus*, (ii) the Hooded and Carrion Crows *Corvus corone* and *C. cornix*, and (iii) the ladder-backed woodpeckers *Picoides nuttalli*, *P. scalaris*, and *P. borealis*. In the first case they cannot be regarded as separate species; we find a broad zone of intergradation. In the second the process of speciation has advanced considerably further; the zone of intergradation is restricted to a narrow band, but sexual isolation has not evolved. The presence of all degrees of intermediate forms in the zone of contact indicates that species status has not been reached. In the third example there are 3 parapatric 'good' species, though of course we do not know whether they originated in allopatry or in parapatry. See Short (1969) and HYBRIDIZATION, ZONE OF SECONDARY for a discussion of contact zones and taxonomic decisions.

If there is only a limited degree of hybridization, and the hybrids are definitely inferior to either parental form (in the wild), then there will be selection against mating between the forms (Dobzhansky 1970, Endler). Those individuals which mate preferentially with their own kind will leave greater numbers or more vigorous progeny than those mating with the other kind. For this reason natural selection results in the continual improvement of sexual discrimination between the two forms. This has been verified experimentally with fruit flies *Drosophila* and crop plants. Eventually this can eliminate hybridization between the two forms. When this happens, the two forms (now 'good' species) have evolved isolating mechanisms specifically against each other.

In parapatric speciation, differentiating populations are separated initially by populations which are intermediate between them. As two populations become more and more different from each other, interbreeding may result in genetic incompatibility. Eventually the accumulation of genetic differences is great enough so that interbreeding results in fewer or weaker offspring, and specific isolation mechanisms can easily evolve. Of course, if genetic differences are not sufficient or appropriate, intrinsic isolation may not evolve; this may be the case in the European *Corvus*. From experiments we know that sexual isolation can evolve in less than 100 generations, so we are unlikely to see intermediate stages in parapatric speciation. Even so, ring-species are known in birds and other organisms and provide some support for this speciation mode. Ring-species exhibit a continuous series of differentiated parapatric subspecies, but the end forms overlap without interbreeding (see RING-SPECIES). An example is found in the Herring and Lesser Black-backed Gulls *Larus argentatus* and *L. fuscus*.

In allopatric speciation, two populations evolving in complete isolation from one another (e.g. on two different islands) cannot build up an isolating mechanism specifically against each other. In the course of time they may diverge sufficiently so as to be unrecognizable to each other as the same species if they come together. The results of hybridization among such populations may be a complete failure owing to accumulated genetic differences. Such differences may not necessarily evolve in allopatry, and are fortuitous by-products of differentiation in isolation. Because they result from chance differentation, it is also possible that any sexual isolation which evolves in allopatry may be asymmetrical. For example if one of two isolated populations loses some male behavioural elements needed in the courtship ritual, then males of that population will not be accepted by females of the other population, whereas mating may be normal in the reciprocal cross. For these reasons, mechanisms which specifically isolate populations from one another are not as likely to evolve in allopatry as they are in parapatry. Of course if a physical barrier disappears, then sexual isolation can evolve rapidly.

Specific isolating mechanisms can only evolve between two groups if they interbreed, if such hybridization does not result in 'swamping' of one set of genes by another, and if the hybrids are inferior in some way. 'Swamping', or overwhelming of one population by the genes from another, will only occur if there is a large gene flow distance. If this distance is small, 'swamping' is prevented by the long time required for genes from one population to invade the other. But if populations are never in contact there is no opportunity for natural selection to promote sexual isolation, and speciation can only occur by the fortuitous development of genetic, morphological, or behavioural incompatibility. Thus, although morphological differentiation can evolve rapidly in allopatry, parapatry or sympatry are more likely to favour the evolution of species-specific isolating mechanisms. Perhaps the most rapid way new species can be generated is by allopatry followed by parapatry. We cannot test this hypothesis because the biogeographic and genetic patterns produced by this sequence would not be different from that produced by 'pure' allopatric or 'pure' parapatric speciation (Endler).

The presence of sexual isolation between species has an important consequence, at least in bisexually reproducing organisms such as birds. Each species is a separate line of evolution, and does not exchange genes with any other species to any important degree. A species consists of an array of geographically and genetically definable populations that either do actually interbreed freely or would be expected to do so should they ever meet in the wild (see SPECIES). Sexual isolation does not necessarily mean that there are huge genetic differences among the isolated populations; genetic or sexual incompatibility and morphological differentiation may evolve more or less independently. Intrinsic isolating mechanisms may be present with minimum morphological differentation, as in sibling species. Examples are the Reed Warblers *Acrocephalus palustris*, *A. scirpaceus*, and *A. dumetorum*, the Chiffchaff and Willow Warbler *Phylloscopus collybita* and *P. trochilus*, and the Black-capped and Carolina Chickadees *Parus atricapillus* and *P. carolinensis*. Alternatively, sexual isolation may be as strong as morphological differentiation, for example the Blue-winged and Golden-winged Warblers *Vermivora pinus* and *V. chrysoptera*. Even morphological differentiation is no guarantee of sexual isolation; although *V. pinus* and *V. chrysoptera* are very distinct in appearance, they hybridize in disturbed habitats in certain parts of eastern North America.

Speciation is a continuing process, and we can find most stages of speciation in nature. This makes it difficult to decide whether two geographically isolated but nevertheless related populations should be considered as two subspecies of the same species, two semispecies, or as two species of a superspecies. Semispecies are populations which are just about to break apart into 'good' species, and superspecies are arrays of geographically replacing forms, some of which are too different to be regarded as the same species. Ring-species are a nuisance to a taxonomist, as it is necessary to make an arbitrary decision about the status of the various populations which contradicts a minimum of facts. But, biologically, ring-species are simply stages in geographic divergence of populations and may be an intermediate stage in the speciation process.

At any one place it is rarely difficult to distinguish the separate species, but difficulties appear when the same criteria are applied to large areas. One possible reason for this may be competition, which favours divergence in morphology, habits, and ecology among forms living together, but not among those living apart (see COMPETITION). Competition may directly favour divergence and speciation because hybrids between parental forms will be more similar to the parental species than the parents are to each other. Competition intensity is proportional to similarity, so hybrids will be at a disadvantage, favouring sexual isolation. Ecological factors act on a local scale, are unlikely to be uniform over large areas, and are therefore an additional factor promoting geographic differentiation and speciation. If two sister species evolve under different ecological conditions, then they may eventually diverge sufficiently to achieve ecological compatibility, making coexistence possible. This may result in the invasion of each other's geographic ranges without local extirpations or the extinction of one of the species.

The prime characteristic distinguishing species from differentiated populations is the presence of intrinsic isolating mechanisms. Once speciation is complete, physical or distance barriers between the species become relatively unimportant to genetic interchange, the populations may invade each other's geographic ranges, and further evolution and divergence can continue more rapidly. Speciation is important because the genetic independence of the new lineages allows rapid diversification and the invasion of new habitats. J.A.E.

SPECIES: in simple terms, a 'kind' of bird (or other organism). The word has a variety of technical meanings and this has caused much confusion in the literature. To most biologists, species are groups of interbreeding natural populations that are reproductively isolated from other such groups (Mayr 1969). This is the biological species definition. The term has several other meanings, depending on the use to which it is put, and the way in which the entities are distinguished.

The biological species concept has two important properties. It treats species as cohesive and interacting units independent of other such units, and it treats them logically as individuals rather than as a class. Another definition of the biological species is: the most extensive units in the natural economy such that reproductive competition occurs among their parts (Ghiselin 1974). Mayr's definition emphasizes their reproductive independence from other such groups, and Ghiselin's emphasizes the fact that species are a closed system. The most important property of species is that they represent an evolutionarily independent entity.

To a naturalist working in a particular place, it is rarely if ever difficult to distinguish between species; they are distinctly different kinds of animals, with characteristic morphology, habits, and habitat, which remain constant from year to year (Mayr). Their most characteristic attribute is that they are separated from other species by gaps in the normal variation among individuals. One can always tell a Blackbird *Turdus merula* from a Song Thrush *T. philomelos* and both from a Mistle Thrush *T. viscivorus*. It is possible that such gaps in variation are caused by COMPETITION, or the genetic and developmental limits to adapting to a specific niche (see ECOLOGY), but we actually do not know the reason for this phenomenon.

A rather different way to explain the observed variation pattern is the typological species concept. This originated with Plato and Aristotle and regards species as representing some ideal form or *eidos*, and individual variation as merely the imperfect expression of the ideal form. Thus, by the typological definition, a species is a class of objects which represent to varying degrees the ideal type. This definition applies to inanimate objects (such as minerals) as well as organisms. It is very convenient for identification of objects whose characters are determined by purely physical and chemical events and independent of history. It is entirely inappropriate for organisms because they are influenced by genealogy as well as physics and chemistry. The typological species concept has virtually disappeared from current usage (Mayr). As a vestige of the typological species concept (used by Linnaeus), a bird is identified with reference to a TYPE SPECIMEN and a TYPE LOCALITY. In present usage these serve as signposts to the entity we call a species, and in fact a given bird may be quite different from the type specimen and still obviously be a member of the same species.

There are several empirical species concepts which are based upon gaps in variation, and some of these have typological overtones. The morphological species is a group of individuals that resemble each other in most of their visible characters, sex for sex and variety for variety, and such that adjacent local populations within the group differ only in variable characters that intergrade marginally (Simpson 1961). This can be interpreted as an empirical method for distinguishing species, but has also been used in a typological sense (see Sneath and Sokal 1973). Species can also be separated by physiological and molecular techniques. Such methods can be useful as clues to variation, but must be used with caution. Note that all the empirical species concepts treat the species as a class of individuals with defining properties, and they ignore the effects of common descent. They therefore suffer from the same problems as the typological species concept.

Typological and empirical species definitions depend upon physical resemblance and are part of a classification system which is based upon a hierarchy of similarity. This is adequate for classification of inanimate objects, where a particular degree of similarity reflects the effects of the same degree of similarity in the processes which formed the objects. Quartz is the same in Europe as in North America, but 'blackbirds' are not. Organisms belonging to the same species share a common ancestor. Variation in rates of evolution may result in marked CONVERGENCE among unrelated species, divergence within species, and closely related species may or may not resemble each other in appearance. For example, birds are often found which are quite different from the main population in morphology or habits (perhaps due to POLYMORPHISM or age differences), yet they are clearly part of the same species. In addition, sibling species may hardly differ from another in morphology, yet never interbreed, and are clearly separate entities. One of the purposes of modern taxonomy is to form a classification which reflects phylogeny rather than mere similarity of appearance (see TAXONOMY). Only the biological species concept is appropriate in this case.

An additional problem with the naturalist's typological and empirical species definitions is that they all break down when one attempts to apply them over a broad geographic range, or over geological time. Species are not constant in space or time, they change in morphology, behaviour, and habitats. Such changes in space are called CLINES, are a normal part of the differentiation process, and may occur in SPECIATION. For example, Flickers *Colaptes cafer* have yellow tail and wing linings in eastern North America, but this grades into red and orange in the west and southern parts of the continent. Individuals from different parts of the geographic range are sufficiently different to look like different species and in fact there has been much argument about the status of the forms. The naturalist's typological and empirical species definitions cannot accommodate such variation as they require the species to be a class with defining properties rather than an integrated unit or individual in the logical sense. The biological species concept avoids this problem.

With respect to taxonomy, species are quite different from other categories. Species are the only category which represents a functional unit. Lower categories (subspecies, races, etc.) may not evolve independently of each other and their boundaries may be arbitrary. Higher categories (genera, families, orders, etc.) consist of a number of independent entities and are therefore classes with defining properties, yet they attempt to reflect the degree of relatedness among their component parts (see TAXONOMY, GENUS, NOMENCLATURE). Like species, higher taxa are historical units.

The most important property of a biological species is that it is a separate line of evolution, with little or no exchange of genes with other species. This allows more rapid evolution than would be possible if all organisms exchanged genes, because it allows genetic adaptation to local conditions and to new habitats. The biological species definition is not intended to provide an infallible criterion. There will always be a residue of borderline cases for which the decision will be arbitrary. This difficulty comes from the species being not fixed but evolving (Dobzhansky). Species change in time, and can give rise to new species. It is the intermediate stages in speciation which cause the most difficulty in classification and identification, just as during cell division it is a matter of opinion whether there is one cell or two (see SPECIATION; HYBRIDIZATION, ZONE OF SECONDARY; RING-SPECIES; SEMI-SPECIES; SUPERSPECIES). The non-existence of borderline cases would mean only that evolution had run its course and was no longer happening (Dobzhansky).

Sneath, P.H.A. & Sokal, R.R. 1973. Numerical Taxonomy. San Francisco.

SPECIES DIVERSITY INDEX: a mathematical index which describes, in somewhat abstract terms, the numbers and relative abundances of bird species in a habitat. A large number of equally common species yields a much higher index of diversity than a small number of species dominated by one very common form, and several rare ones. Intermediate levels of abundance and/or dominance yield intermediate values. Several alternative indices with these properties have been proposed, of which the most widely used in the ornithological literature is the Shannon-Wiener index (H'):

$$H' = -\sum_{i=1}^{i} p_i \log p_i$$

where $p_i = N_i/N$
N_i = Number of individuals in the i^{th} species
N = Total number of individuals of all species

SPECIES GROUP (1): with reference to the ranks of taxa, term embracing the categories species and subspecies (see NOMENCLATURE).

SPECIES GROUP (2): in taxonomy, a group of closely related species, less definite than a subgenus and not constituting a formal taxon for purposes of nomenclature. See also SUPERSPECIES.

SPECIES PAIR: two very closely related and very similar species.

SPECIES SPECIFIC: confined to one particular species.

SPECIFIC: in taxonomic terminology, appertaining to a species, e.g. 'specific name' (see TAXON); more generally (in one of the everyday senses), characteristically peculiar to some mentioned category. The two meanings are combined in the expression 'species specific', i.e. specific (in the second sense) for a species.

SPECIFIC ACTION POTENTIAL: 'the state of the animal responsible for its readiness to perform the behaviour patterns of one instinct in preference to all other behaviour patterns; this specific readiness diminishes or disappears when the consummatory act of the charged instinct has been performed' (Thorpe 1951). The term has fallen into disuse because of its association with the outdated concept of 'specific drives'.

SPECIFIC NAME: see NOMENCLATURE.

SPECKLE-BELLY: a name in North America for the Whitefronted Goose *Anser albifrons* (see under DUCK).

SPECTACLE-BIRD: name used for some species of Zosteropidae (see WHITE-EYE (1)).

SPECTROGRAPH, SOUND: obsolete term no longer generally used for SONAGRAPH.

SPECULUM: a patch of distinctive colour on the wing, in some plumage patterns, especially the metallic patch seen in dabbling ducks.

SPEEDS OF FLIGHT: see FLIGHT, SPEEDS OF.

SPEIROPS: substantive name sometimes used for the 3 species of *Speirops*, a genus of white-eyes confined to the islands of the Gulf of Guinea and Mt Cameroon (see WHITE-EYE (1)).

SPERMATOZOON: (plural 'spermatozoa') or 'sperm', a male germ-cell (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; and GENETICS). Also called 'spermatozoid' in the free-swimming stage, e.g. when in the female reproductive tract after copulation and before union with an ovum.

McFarlane, R.W. 1963. The taxonomic significance of avian sperm. Proc. XIII Int. Orn. Congr., Ithaca, N.Y., 1962: 91–102.

SPHENISCI; SPHENISCIDAE: see below.

SPHENISCIFORMES: an order, alternatively 'Sphenisci', comprising only the family Spheniscidae (see PENGUIN); the group is placed by Wetmore in a superorder, Impennes, of its own, but this view has been abandoned by most authors and their possible relationship with the Procellariiformes stressed. They are marine birds, with wings modified as flippers, and restricted to the Southern Hemisphere.

SPIDER-HUNTER: substantive name of *Arachnothera* spp. (see SUNBIRD).

SPINAL CORD: see NERVOUS SYSTEM.

SPINEBILL: substantive name of *Acanthorhynchus* spp. (see HONEYEATER).

SPINETAIL: substantive name of Synallaxinae spp. (see OVENBIRD (1)); also sometimes used (Africa) as an abbreviation of 'spine-tailed swift', substantive name of species in more than one genus (see SWIFT).

SPINIFEXBIRD: *Eremiornis carteri* (see under WREN (2)).

SPLITTER: a taxonomist who prefers a nomenclature that recognizes fine distinctions between taxa—in contrast to a LUMPER.

SPOONBILL: substantive name for the 6 species of Plataleinae in the Family Threskiornithidae (Ciconiiformes, suborder Ciconiae).

Characteristics and distribution. Spoonbills are long-legged water birds, about 70–85 cm in length, with a distinctively long and flattened, spatulate bill. They fly slowly, with outstretched necks, and can both glide and soar; and they occasionally swim. They are rather silent, except for low grunting sounds uttered at their nesting colonies. Spoonbills occur primarily in the warmer regions throughout the world. All 5 Old World species of spoonbills are in the genus *Platalea*, and are similar in that each has a mostly white plumage and a nuchal crest during the breeding season. The most conspicuous physical difference between adults of these 5 species is in the colour of the bill, legs and unfeathered facial region, which are predominantly red in the African Spoonbill *P. alba*, yellow in the Yellow-billed Spoonbill *P. flavipes* of Australia, black in both the Royal Spoonbill *P. regia*, occurring from Australia to Indochina, and the Black-faced Spoonbill *P. minor*, found from eastern China and Cambodia to the Philippines, and black and yellow in the Eurasian Spoonbill *P. leucorodia*. The one New World species, the Roseate Spoonbill *Ajaia ajaja*, occurring from the southern United States to northern Argentina, is primarily vivid pink with red upper wing and tail coverts, bare-headed, and has a tuft of elongate feathers on the lower neck. Adults and juveniles of the 5 *Platalea* species, as well as juvenile Roseate Spoonbills, have mostly feathered heads.

Habitat. Spoonbills are birds of coastal and freshwater wetlands, often nesting and roosting in large and remote, permanently flooded marshes or swamps, which are located adjacent to lake or river shorelines or in estuarine regions. Several *Platalea* species typically nest in expansive thickets of rushes and reeds, or in patches of dense, woody vegetation encompassed by marshes, while the Roseate Spoonbill and Black-faced Spoonbill more often nest in coastal regions, including for the former such diverse habitats as mangrove swamps and scrub-clad islands. All species feed in shallow flooded, calm or slow moving water, where aquatic and emergent vegetation is sparse or absent.

Populations and movements. Although numbers of Eurasian Spoonbills have fluctuated during recent decades in some parts of their range, possibly due to regional differences in water levels between years, this species has declined in numbers throughout much of its range due principally to habitat losses and direct human disturbance. In parts of the south-eastern United States the Roseate Spoonbill has shown a continuing recovery of numbers and reoccupation of former range following the cessation of plume-hunting and disturbance to nesting colonies. Spoonbills show regular, short-range dispersals following nesting, mainly by younger birds, and occasionally wander for long distances. Populations that breed in more temperate regions are migratory, including the Eurasian Spoonbill which leaves many parts of its breeding range between August and October, and returns in March and April. Its wintering areas are in southern Asia, the Mediterranean region and tropical Africa. The winter-nesting population of Roseate Spoonbills in southern Florida arrives at the nesting colonies during October and November, and departs in March and April.

Food. Spoonbills feed by actively wading through shallow water, sweeping the bill, which is held almost vertical and partly open, from side to side through water and silt. Food consists of aquatic insects and insect larvae, small fish, and small crustaceans, and to a lesser degree aquatic snails, frogs, tadpoles, worms and possibly some plant material.

Behaviour. Spoonbills are gregarious in much of their activities. They nest either in single species colonies or with other colonial nesting water birds. Spoonbills often fly in flocks, and may feed individually or in groups depending upon food densities. Temporary, monogamous pair bonds are established and maintained through each breeding season.

Breeding. Both members of the pair share building the nest, commonly a platform of sticks in a tree or bush, but also among reeds or even on the ground, incubation, care of the nestlings and defence of the immediate nest site. Clutches usually contain 2–5 eggs, most frequently 3. Incubation lasts between 21 and 25 days, and young fledge 40–50 days after hatching. Spoonbills become fully mature at 3 to 4 years of age. Spoonbill *Platalea leucorodia*. (*R.G.*).

SPORT, BIRDS IN: a subject not, in general, covered by this work; but see FALCONRY; GAMEBIRDS; UTILIZATION BY MAN; WILDFOWL.

SPOTBILL: *Anas poecilorhyncha* (see DUCK).

SPOTTED CREEPER: see CREEPER, SPOTTED.

SPRAYS, AGRICULTURAL: see TOXIC CHEMICALS.

SPREO: sometimes used as substantive name of African glossy starlings of the genus *Spreo* (see STARLING).

SPRIG: a name in North America for the Pintail *Anas acuta*, a drake of the species being known to some American sportsmen as a 'buck sprig' (see DUCK).

SPRING: see ASSEMBLY, NOUN OF.

SPROSSER: German name often used as English (in preference to the fabricated 'Thrush Nightingale') for *Luscinia luscinia* (for subfamily see THRUSH).

SPSHING: see SQUEAKING.

SPUR: see INTEGUMENTARY STRUCTURES; LEG; WING.

SPURFOWL: substantive name of *Galloperdix* spp., and in Africa of *Pternistis* spp. (for family see PHEASANT).

SQUAB: an unfledged nestling, particularly of pigeons (Columbidae).

SQUACCO: or Squacco Heron, *Ardeola ralloides* (see HERON). See photo FEEDING HABITS.

SQUAMOSAL: a paired bone of the SKULL.

SQUAW, OLD-: the American name of the long-tailed Duck *Clangula hyemalis* (see DUCK).

SQUEAKER: popular alternative name for *Strepera versicolor* (see under CURRAWONG).

SQUEAKING: the practice of attracting passerine birds close to the observer by repeated squeaks.

STAGEMAKER: alternative name of *Scenopoeetes dentirostris* (see BOWERBIRD).

STANDARD DEVIATION: see BIOSTATISTICS.

STANDARD DIRECTION: see MIGRATION (Distances and directions).

STANDARD ERROR: see BIOSTATISTICS.

STANDARD METABOLIC RATE: the rate of energy production measured in a resting, post-absorptive animal at any stated ambient temperature. In endotherms like birds SMR is equivalent to the Basal Metabolic Rate within the Thermoneutral Zone (see METABOLISM), but it increases both at lower ambient temperatures to compensate for increased heat loss (but decreasing in torpor) and under heat stress above the thermoneutral zone (see also ENERGETICS; HEAT REGULATION).

STANDARDWING: substantive name of *Semioptera wallacei* (see BIRD-OF-PARADISE).

STAPES: the ear ossicle (see SKULL).

STARCHY: *Nesocichla eremita*, the endemic THRUSH of the Tristan da Cunha group in the South Atlantic.

STARFRONTLET: substantive name of some *Coeligena* spp. (for family see HUMMINGBIRD).

STARLING: substantive name of many species of Sturnidae (Passeriformes, suborder Oscines); used without qualification (Britain) for the common Palearctic species; in the plural, general term for the family. The name has also been used for other birds similar in appearance to starlings or once believed to be allied to them, e.g. the Military Starling (or Red-breasted Blackbird) *Leistes militaris* (see ORIOLE (2)). The 2 African tickbirds or OXPECKERS of the genus *Buphagus* are aberrant and have been assigned to a separate subfamily of their own (Buphaginae). By origin, the name starling belongs to the European *Sturnus vulgaris*, which ranges across Europe and the Middle East to Asia as far as Mongolia. The family comprises about 110 species, in 25 genera, restricted to the Old World except for human introductions.

Characteristics. Starlings are of small to medium size (16–45 cm in length). Usually heavily built, they have strong legs and bill. Many are blackish but often with iridescent plumage; in the glossy starlings (in the genera *Aplonis*, *Lamprotornis* and *Spreo*) the iridescence may be highly developed with vivid greens, blues, purple and orange in the plumage. Many of the African starlings are among the most beautiful of the family. The Superb Starling *Spreo superbus* of East Africa is iridescent blue and glossy orange and the Emerald Starling *Lamprotornis iris* of West Africa is brilliantly metallic green. The Long-tailed Glossy Starling *L. caudatus* has a flowing purple and blue tail that may attain 35 cm in length in the male. The Rose-coloured Starling *Sturnus roseus* has a glossy black head and wings and a pale pink body. Other species have areas of bare skin around the eye, lappets, wattles, or bristly feathers on the head and some have erectile or permanent crests. Towards the breeding season, the Wattled Starling *Creatophora cinerea* loses the feathering of the head and long wattles grow, while in the non-breeding season the wattles are resorbed and feathers grow anew: these properties have been used in research on cancer and on cures for human baldness respectively. In many species the sexes are indistinguishable while in others females are duller; in some, females and juveniles are markedly different from the iridescent adult males. Many of the tropical species are largely arboreal but some starlings, especially *Sturnus* and *Acridotheres*, are equally at home on the ground where they walk rather than hop. In the round-winged arboreal species flight is direct, but it is faster in the inhabitants of open ground with their more pointed wings.

Habitat. The mainly arboreal species frequent tropical forest edges, while others inhabit temperate grasslands which have been made more extensive by man's activities.

Superb Starling *Spreo superbus*. (*D.A.T.*).

Distribution and movements. The starlings are entirely Old World and primarily tropical, although a few reach Europe, China and Japan. Part of the population of the Shining Starling *Aplonis metallica* migrates from New Guinea to breed in Queensland, the only incursion into Australasia. The family is well represented in Africa but the greatest diversity occurs in the Oriental zoogeographical region. One genus, *Aplonis*, is widely spread in Polynesia and had reached even Tahiti, although it is now extinct there. Four species, 2 from the Mascarene islands and 2 from Polynesia, have become extinct in the last 200 or so years, and Rothschild's Mynah *Leucopsar rothschildi*, from the Indonesian island of Bali, is classed as 'endangered'. Other starlings are eminently successful, and the European Starling, with a huge breeding area in Eurasia and populations established elsewhere by introductions, is now one of the world's most numerous species of bird.

Most starlings are resident but some undertake local movements, while others are obligate or partial migrants. An interesting Afrotropical species is the nomadic Wattled Starling, immense flocks of which search for concentrations of migratory locusts. When locusts lay their eggs in an area where rains have led to abundant grass growth, Wattled Starlings also nest and later feed their young on the flightless immature 'hoppers'. In such circumstances, each tree in an area may contain several nests of the Wattled Starling. Another species that establishes breeding colonies where locusts abound is the Rose-coloured Starling. It winters in India and breeds in central Asia and eastern Europe, but since its breeding distribution is dependent upon a good supply of locusts, an area which held a large colony one year may be deserted the next.

Several of the starlings, including the European Starling and the Indian Mynah *Acridotheres tristis*, have established a more or less commensal relationship with man. In countries where it has been introduced, the European Starling has become not only an agricultural pest but also a serious competitor of native birds, such as the bluebirds *Sialia* spp. in North America. In New Zealand, however, the European Starling is encouraged, by the provision of nest boxes, on account of its consumption of an insect pest of grassland. In the north of its ancestral range, the European Starling is regarded as beneficial, but on migration and in its wintering areas it is a serious pest of vineyards, olive groves, cherry orchards and cattle feeding areas. The Indian Mynah has been introduced to many tropical islands, ostensibly to control locusts, but this species has also usually become a pest in these areas.

Food. Starlings are omnivorous, with most eating fruit and insects, while some take pollen, nectar and seeds; some are important pests of cultivated fruit and cereals.

A contributory factor to the European Starling's success may have been the evolution, notably in the genera *Creatophora*, *Acridotheres* and *Sturnus*, of a feeding method called 'prying' or 'open-bill probing'. In these genera the muscles that open the bill, the protractors, have become well developed in comparison with those in the frugivorous and insectivorous, mainly arboreal species. This enables the bill to be forcibly opened after it has been pushed into the soil surface, thereby exposing soil organisms.

Behaviour. Most starlings nest in colonies, feed in flocks and roost communally: winter roosts of the European Starling may contain over a million birds.

Voice. None has a really accomplished song but many utter a variety of pleasing whistles. Some mimic other species and the Hill or Talking Mynah *Gracula religiosa* can imitate human speech (see MIMICRY, VOCAL).

Breeding. Most species nest in holes, especially in trees, but holes in cliffs and buildings may also be used, as may holes bored by other species like woodpeckers and barbets. Within the cavity a bulky nest is built. The Bank Mynah *Acridotheres ginginianus* digs its own burrows in river banks and the Woodpecker Starling *Scissirostrum dubium*, of Sulawesi, bores holes in dead trees like woodpeckers, except that these starlings are highly colonial so that a tree may be riddled with nest holes. Some species, like the Superb Starling, build domed nests and the Shining Starling builds pendulous nests like those of weavers (Ploceidae). Two to 6 eggs are laid, with tropical species generally laying smaller clutches. The eggs are generally pale bluish-green with brownish spots, but in *Sturnus*, *Acridotheres* and *Creatophora* the eggs are unspotted. Both sexes usually incubate for 11–18 days, but the female takes the greater share, and both parents usually feed the young, which fledge in 18–30 days. In the European Starling polygyny is quite frequent and mates may be changed between nesting attempts within a breeding season, while some females are parasitic, laying eggs in other European Starlings' nests. Co-operative breeding has been documented in several African starlings in the genera *Cosmopsarus* and *Spreo*: in the Chestnut-bellied Starling *S. pulcher* a breeding pair may be assisted by as many as 12 non-breeding or immature birds.

See photos FEEDING HABITS; ROOSTING; TAIL. C.J.F.

STARRING: see HATCHING.

STARTHROAT: substantive name of *Heliomaster* spp. (for family see HUMMINGBIRD).

STATISTICAL POPULATION: term used to denote the universe of objects (birds, eggs, nests, etc.) from which some sample under study has been drawn. See BIOSTATISTICS.

STATISTICAL SIGNIFICANCE: the probability that the observed result of a statistical test has arisen by chance, in the absence of causal effects. See under BIOSTATISTICS. If this probability is low enough—conventionally below 0.05 (whence the notation $P < 0.05$)—the presence of a biological effect is more believable than is the null hypothesis. For example, statistical calculation predicts that an unbiased coin tossed 5 times will yield 5 heads in 3 of every 100 such series, but most people would suspect a coin to be biased on seeing it come up with 5 heads in a row.

STEAMER-DUCK: substantive name of 2 species of ducks of the genus *Tachyeres*, confined to southern parts of South America and the Falkland Islands. The smaller species, *T. patachonicus*, occurs on both inland waters and along the coasts and can fly; the larger species, *T. pteneres*, is confined to coastal waters and is flightless. Three species are sometimes recognized (see DUCK).

STEAMING: term applied to the mode of progression of steamer-ducks *Tachyeres* spp. (see DUCK; FLIGHTLESSNESS).

STEATORNITHES; STEATORNITHIDAE: see under CAPRIMULGIFORMES; OILBIRD.

STEGANOPODES: see PELECANIFORMES.

STENOECIOUS: occupying a narrow range of the habitats available in an area, i.e. showing 'narrow habitat tolerance'—contrasted with EURYOECIOUS.

STENOTOPIC: more or less equivalent to STENOECIOUS (see above).

STEPPE: treeless uncultivated plain, usually as found in Central Asia.

STERCORARIIDAE: see under CHARADRIIFORMES; SKUA.

STERNIDAE: see CHARADRIIFORMES, suborder Lari; TERN.

STERNUM: the breast-bone (see SKELETON, POST-CRANIAL; and CARINATE; RATITE).

STIFFTAIL: substantive name of the White-headed Stifftail *Oxyura leucocephala*; in the plural, general term for the Oxyurini (see DUCK).

STILT: substantive name of some species of Recurvirostridae (see under AVOCET).

STIMULUS: see RELEASER; SIGN STIMULUS.

STINT: substantive name (in British rather than American usage) of certain small sandpipers assigned to the genus *Calidris* or to '*Erolia*' (see SANDPIPER).

STITCHBIRD: *Notiomystis cincta*, a New Zealand HONEYEATER.

STOMACH: a mammalian organ of which the equivalent in birds is the proventriculus and ventriculus (gizzard) considered together (see ALIMENTARY SYSTEM).

STONECHAT: substantive name of some *Saxicola* spp.; used without qualification, in Britain, for *S. torquata* (see CHAT (1); THRUSH).

See photos SEXUAL DIMORPHISM.

STONE-CURLEW: usual or alternative substantive name for species of Burhinidae; applied without qualification, in Britain, to *Burhinus oedicnemus* (see THICKKNEE).

STOOPING: term used of a bird-of-prey descending steeply on its quarry from a greater height in the air (see FALCONRY) or of any bird making a real or threatening attack in like manner ('dive-bombing').

STORING OF FOOD: see FOOD STORING.

STORK: substantive name for most of the 17 species in the Ciconiidae (Ciconiiformes, suborder Ciconiae).

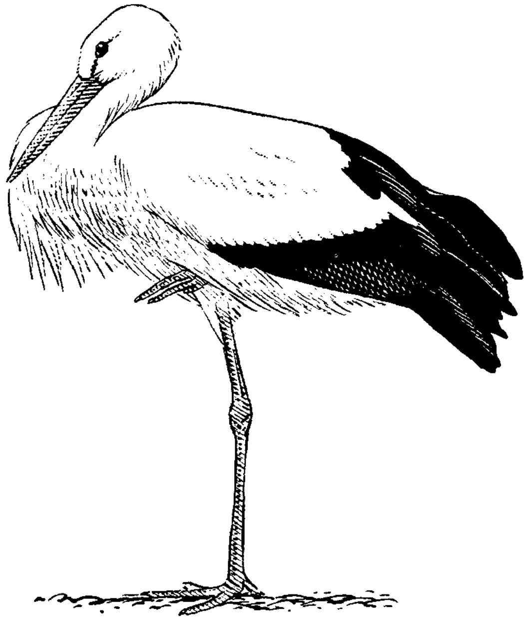
Characteristics. Storks are large birds (up to 100 cm long and standing from 60 to 120 cm tall) with long bills, necks, and legs and with webbing at the base of the toes. They have long, broad wings, short tails and elongate undertail coverts, and fly with a slow flapping or soaring flight, often at great heights. Twelve species have essentially all black and white plumages; the other 5 are the all-white Jabiru *Jabiru mycteria*, the all-black African Openbill Stork *Anastomus lamelligerus*, and 3 largely grey and white species, the Marabou Stork *Leptoptilos crumeniferus* and the closely related Lesser and Greater Adjutant Storks *L. javanicus* and *L. dubius*. Males of all species tend to be slightly larger than females and, except for sexual dimorphism in the eye colour of the Saddlebill Stork *Ephippiorhynchos senegalensis* and Black-necked Stork *E. asiaticus*, the sexes are similar in appearance. Although superficially resembling large herons, and often occurring in the same habitats, storks differ chiefly in being heavier bodied and having the head more extensively bare while most species fly with neck extended.

The storks are most appropriately divisible along morphological and behavioural lines into 3 distinct groups. The tribe Mycteriini is composed of 4 species of wood storks *Mycteria*, and 2 species of openbill storks, *Anastomus*. The wood storks are quite similar in appearance, behaviour and ecology, all species having unfeathered heads as adults, heavy, slightly decurved bills, and varying amounts of pink, yellow, or salmon-coloured feathers during the breeding season. The openbill storks have mostly feathered heads and a long specialized bill with a conspicuous gap between the central portion of the upper and lower mandibles. The tribe Ciconiini consists of 5 species of 'typical' storks, *Ciconia*, characterized by a relatively thin and straight bill, a ruff of feathers on the lower neck, and a mostly feathered head. The third tribe is the Leptoptilini, composed of 3 rather diverse genera, which exhibit ties along behavioural lines. The Black-necked Stork and Saddlebill Stork are tall, slim-bodied species with feathered heads and similar iridescent black and white plumage patterns, including strikingly marked white wings with black linings. Both have long and slightly recurved bills, while the Saddlebill has a broad fleshy lappet, yellow in colour, at the base of the upper mandible. The remaining 4 species in the tribe have bare or sparingly feathered heads and necks, and massive bills, slightly recurved in the Jabiru and Lesser Adjutant Stork. The Marabou Stork and Greater Adjutant Stork possess inflatable, pendent throat pouches, which are suggested to have a role in courtship displays.

Habitat. Storks generally are characteristic of mixed woodland and savanna regions, that include various amounts of wetland, although the Black Stork *C. nigra* occurs in extensive forests in parts of its range and the Abdim's Stork *C. abdimii* is found in drier regions than the other species. Most storks nest in trees and feed in shallow water, although there are notable exceptions. Black Storks may nest on cliffs, Abdim's Storks on rocky islands and village huts, the Maguari Stork *C. maguari* may nest on the ground in dense marsh, and the White Stork *C. ciconia* is famous for nesting on rooftops and other elevated, man-made structures. Some storks also feed in non-aquatic sites, notably Abdim's Stork, the Woolly-necked Stork *C. episcopus* and White Stork, which feed in varying degrees in dry fields, and the Marabou Stork and the 2 adjutant storks, which are attracted to carrion and human rubbish dumps. Tree-nesting species often locate their nests and roosts either near the tops of tall trees or in woody vegetation on islands or over standing water.

Distribution. Storks are primarily an Old World family, the greatest number of species occurring in tropical and subtropical regions of Africa and south-eastern Asia. In the tribe Mycteriini, the American Wood Stork *Mycteria americana* occurs from the southern United States to Argentina, the Yellow-billed Stork *M. ibis* is widespread in Africa south of the Sahara, and the Milky Stork *M. cinerea* and Painted Stork *M. leucocephala* are in south-eastern Asia, the former occurring between Indochina and Java, and the latter more widely distributed between India and China. The Asian Openbill Stork *Anastomus oscitans* is found from India to Indochina, and the African Openbill Stork occurs throughout most of tropical Africa and Madagascar. Of the typical storks, the Black Stork breeds across Eurasia and in southern Africa; the small Abdim's Stork in central Africa north of the Sahara and in the south-western Arabian Peninsula; the Woolly-necked Stork is widespread in much of tropical Africa and in south-eastern Asia as far east as the Philippines; the Maguari Stork occurs east of the Andes in South America, and the White Stork breeds across Europe and temperate Asia, formerly east to Japan (the far eastern birds may be specifically distinct) and in north-western Africa, with a small isolated population nesting in South Africa. The 6 species in the Leptoptilini are all tropical species, with the Black-necked Stork breeding from India to the Indochina region, and disjunctly in New Guinea and northern Australia, while the Saddlebill Stork occurs throughout tropical Africa. The monotypic Jabiru occurs in the New World tropics between southern Mexico and northern Argentina, the 2 adjutant storks are in tropical south-eastern Asia, and the Marabou Stork is widespread in tropical Africa.

Population. Quantitative information on numbers of birds and population trends are only known in portions of the ranges of 3 species. White Storks have shown the greatest decline or been extirpated as breeders mainly in north and west Europe, China and Japan. Populations in eastern Europe have shown more varied trends, including slow declines, areas of stability and some local increases, but overall numbers have also declined in this region. International censuses in Europe in 1934 and 1958 revealed an approximately 50% total decline in breeding White Storks. Black Storks have also declined or been locally extirpated in western Europe, but have increased in numbers in some east European countries, mainly since the 1930s. American Wood Storks numbered approximately 30,000 breeding pairs in the United States during the 1930s, but had declined to 10,000 pairs by 1960, and 5,000 pairs in 1978. One large nesting colony of Wood Storks in southern Mexico has been roughly stable since the early 1970s, with between 5,000 and 8,000 pairs annually. No regional numbers are available for other species, but no species is thought to be seriously threatened, although the decline of the White Stork and Black Stork, in portions of their range, and of the disjunct United States population of Wood Storks, is likely to continue, due to habitat loss.



White Stork *Ciconia ciconia*. (*R.G.*).

Movements. Only the White Stork, Black Stork, and Abdim's Stork are truly migratory. White and Black Storks migrate from their Eurasian breeding grounds to spend the winters in eastern and southern Africa and southern Asia. Neither species makes long flights over large bodies of water, so many thousands of birds circumvent the Mediterranean Sea by crossing at the Straits of Gibraltar and the Bosphorus. Abdim's Stork is a transequatorial migrant in Africa, where it breeds north of the Equator and migrates into the Southern Hemisphere during the northern dry season.

The movements of other species of storks are dispersals rather than true migration. Species or populations respond to the seasonal nature of rainfall characteristic of tropical and subtropical regions by moving to locations where surface water conditions favour optimum feeding. Where seasonal rainfall patterns are regular between years, the movements of storks may also be regular, and appear similar to true migration, but these same species may also perform more irregular movements in response to less regular rainfall or drought conditions. For example, American Wood Storks that breed in Mexico and southern Florida abandon their nesting grounds and disperse northward at the time when heavy summer rains cause disruption of local feeding conditions. The magnitude of the dispersal, both in terms of numbers of birds and distance travelled, generally varies in direct relationship to the amount and extent and timing of rains on the nesting grounds. Likewise in Africa, Marabou Storks abandon portions of their range during periods of heavy rainfall, when certain live prey becomes less available.

Food. Availability of food may be the single most important factor that regulates the movements of most storks and the timing and success of nesting. In Florida, up to one-half of the total Wood Stork population may not nest in years when water conditions do not provide adequate food. White Storks in Europe produce fewer young per nesting pair in cooler and wetter years, when food resources are apparently adversely affected.

Most storks obtain food by slowly walking through suitable habitat until visual contact is made with a prey item, which is quickly captured with the tip of the bill and swallowed with the aid of a backward toss of the head. Typical storks *Ciconia*, with the exception of Abdim's Stork, hunt at ponds, marshes, river edges and wet and dry fields, and capture such diverse food items as fish, insects, frogs, snakes, mice and lizards. The somewhat more specialized Abdim's Stork preys upon insects captured at upland sites but, like the White Stork, especially on locust swarms. The Black-necked and Saddlebill Storks and Jabiru usually hunt for food in shallow water, and feed more exclusively on fish and some frogs. The *Leptoptilos* storks are carrion feeders, although the Lesser Adjutant is less so, and all 3 species may capture frogs or fish when nesting.

The species most specialized in food preference and feeding techniques, notably the 4 wood storks and the 2 openbill storks, are the most colonial in nesting habits and may congregate in large numbers at feeding sites. American Wood Storks may fly up to 110 km between colony and feeding site, although shorter distances are much more usual. Wood Storks wade through shallow water where fish are concentrated, holding their partially open bills vertically submerged. When a small or medium-sized fish strikes the bill, the stork instantly snaps shut upon it. When groping for fish in this manner the stork may stir the bottom with one foot, which increases movement by the fish and apparently improves the chance that one will strike the bill. Openbill storks feed to a large extent on freshwater molluscs, which they capture by probing along the bottom of ponds and streams and are able to open with their specialized bill.

Behaviour. Wood storks, openbill storks, the 2 adjutant storks and the Marabou Stork are colonial nesters, and may feed either individually or in groups depending upon distribution of food. The *Ciconia* storks are solitary nesters, except for Abdim's Stork which often forms nesting colonies, and the White Stork and Maguari Stork which occasionally occupy sites where several active nests are within sight of one another. The Black-necked and Saddlebill Stork and Jabiru are solitary nesters. Non-colonial nesters may maintain pair-bonds through several years, while colonial species apparently do not; probably related are the more elaborate pair-bond displays among colonial species. Typically the male arrives first at the beginning of each breeding season. In colonial species the male rigorously defends the site against intrusion from adjacent males, but eventually accepts the approach of the more passive and persistent female. The common nest-site greeting display among all species is an up-down ceremony, where both sexes raise and lower their heads, sometimes with the bill reaching a vertical position, and often accompanied by vocalizations or bill-clattering.

Voice. Adult storks are generally silent except for calls given during nest-site displays. These are most often given during the up-down display, and include whistles by the *Ciconia* storks, hissing by the wood storks, nasal honking by openbills, and squeals and low groaning calls by the *Leptoptilos* storks. Nestling American Wood Storks utter a loud, repetitive bleating call, especially in response to approach by an adult, which produces a chorus audible at long distances.

Breeding. Storks that breed in tropical and subtropical regions are either dry season or wet season nesters, depending upon the effect that rainfall and high or low water levels have upon food resources. Thus Asian Openbill and Abdim's Storks nest in wet seasons when molluscs and insects, respectively, are more available or abundant. The American Wood Stork and Marabou Stork are dry season nesters when fish and other foods are concentrated in drying pools, and scavenging is best. Both sexes share in nest building, incubation and feeding young. Old nests may be reused, especially by solitary nesting species. Egg-laying and hatching are asynchronous, incubation beginning with the first or second egg. Most species lay 3–5 eggs, and incubation lasts 28–36 days. Adults feed chicks several times daily by regurgitating food on to the floor of the nest. Often one or more young fail to survive to fledging, usually due to inadequate food. The nestling period ranges from approximately 50 days in the smaller species to over 100 days in the Marabou and other large species. First breeding by young storks often occurs from between 3 and 5 years of age, although White Storks may occasionally begin nesting at 2 years.

STORK, HAMMER-HEADED: see HAMERKOP.

STORK, SHOE-BILLED or WHALE-HEADED: see SHOEBILL.

STORM-PETREL: substantive name of species of Hydrobatidae (Procellariiformes); in the plural, general term for the family (see PETREL).

STRATEGY: in a biological or evolutionary sense, a behaviour or complex of behaviour patterns which confers or might be supposed to confer a selective advantage on the individual employing it. In analyses of the survival value of a behavioural or any other trait it is often useful to compare the observed trait with hypothetical alternatives. One can then ask why natural selection has favoured one alternative rather than another. The 'alternatives' in such an analysis are sometimes referred to as strategies. For example two alternative reproductive strategies for a male bird might be to defend a territory and advertise for mates, or to attempt to 'parasitize' other territorial males by stealing matings when females approach.

STREAMCREEPER: *Lochmias nematura* (see OVENBIRD (1)).

STREAMERTAIL: *Trochilus polytmus*, a Jamaican HUMMINGBIRD notable for the extraordinary elongation of the 4th pair of tail-feathers in the male.

STRIATED: streaked.

STRIGES; STRIGIDAE: see below.

STRIGIFORMES: an order, alternatively 'Striges', comprising 2 families, Tytonidae and Strigidae (see OWL).

STRIGOPINAE: see PARROT.

STRUCTURAL COLOURS: see COLOUR.

STRUTHIONES; STRUTHIONIDAE: see below.

STRUTHIONIFORMES: an order, alternatively 'Struthiones', of 'ratite' birds, comprising 4 suborders: Struthiones, Rheae, Casuarii, Apteryges, and 6 families: Struthionidae (OSTRICH), Aepyornithidae (extinct) (ELEPHANT-BIRD), Rheidae (RHEA), Dromaiidae (EMU), Casuariidae (CASSOWARY), Dinornithidae (extinct) (including Anomalopteryginae, Dinornithinae) (MOA), Apterygidae (KIWI). Flightless, cursorial birds, including the largest living birds (African Ostrich *Struthio camelus*). As the flight-muscles are reduced, the breast-bone has no keel—hence the old name Ratitae, from *ratis* (raft), in distinction from other birds collectively known as Carinatae, from *carina* (keel). There are no ordinary flight-feathers, but differences in this respect between families are great. Anatomical structure (e.g. bony palate) and morphology are usually considered primitive, but opinions differ on which of the characteristics are really old and which are secondary adaptations to cursorial life. The relationship between the suborders has been much discussed. Current opinion favours the theory of phylogenetic affinity. Recent distribution is mainly in southern continents, often in relict areas, such as Madagascar (Aepyornis, extinct), New Guinea (CASSOWARY), Australia (CASSOWARY, EMU), New Zealand (KIWI and extinct MOA).

STRUTTING GROUND: special term in North America for the social display ground of the Sage Grouse *Centrocercus urophasianus* (see GROUSE; LEK).

STUMP-TAIL: in the plural, alternative general term for the crombecs *Sylvietta* spp. (see WARBLER (1)).

STUPEFYING BAITS: see PESTS, BIRDS AS; TRAPPING.

STURNIDAE: a family of the PASSERIFORMES, suborder Oscines; see STARLING.

STYMPHALIAN BIRDS: see FABULOUS BIRDS.

SUB-ADULT: an imprecise, but often useful, term for a bird which is not in fully adult plumage.

SUBCLASS: see under CLASS; TAXON.

SUBCUTANEOUS FAT: see ENERGETICS; MIGRATION.

SUBFAMILY: see under FAMILY; NOMENCLATURE; TAXON.

SUBGENUS: see under GENUS; NOMENCLATURE; TAXON.

SUBMERGENCE: see SWIMMING AND DIVING.

SUBORDER: see under ORDER; TAXON.

SUBOSCINE: term applied collectively to the suborders of the Passeriformes other than the Oscines (see PASSERIFORMES).

SUBSONG: see VOCALIZATION (Song development); BEHAVIOUR, DEVELOPMENT OF (subsong).

SUBSPECIES: a population of which the members can be morphologically distinguished, if sometimes only on average, from the members of other populations of the species to which all belong; the term 'race', or 'geographical race', is used synonymously and is in some ways a truer representation of the concept. In Mayr's (1959) words, subspecies are 'geographically defined aggregates of local populations which differ taxonomically from other such subdivisions of a species'.

Subspecies are designated trinominally, a third term being added to the specific binomen; the subspecific form corresponding with the original description of the species is treated as the 'nominotypical subspecies', the third term of the trinomen being a repetition of the second. An early notion that the nominotypical subspecies was 'the species'—other races representing, as it were, departures from the orthodox—was based on a misconception; the original choice of a particular population as the basis of the specific name was of course purely fortuitous. The nominotypical subspecies has in reality no greater importance than others, and it is 'typical' only in a nomenclatural sense.

Ornithology passed through a phase, earlier in the present century, when there was a tendency—not yet completely defunct—to treat the subspecies as the natural unit, losing sight of the fact that the species is the only taxon that can be defined in objective terms (see SPECIES). As Mayr has said: 'Four features of geographic variation make it difficult to delimit a subspecies objectively: (1) the tendency of different characters to show independent trends of geographic variation; (2) the independent re-occurrence of similar or taxonomically indistinguishable populations in widely separated areas (polytopic subspecies); (3) the occurrence of micro-geographic races within formally recognized subspecies; and (4) the arbitrariness of the degree of distinction selected by different authors as justifying subspecific separation of slightly differentiated local populations.'

The subspecies is therefore 'merely a practical device for the taxonomist', and many that have been described have since proved to be no more than samples arbitrarily taken from a population continuum showing clinal variation (see CLINE). Attempts have been made by taxonomists to give an appearance of objectivity to such subspecies by applying an arbitrary rule that 75% (some say 50%) of specimens must be identifiable. On the other hand, a geographically isolated population, whether or not it has been recognized as subspecifically distinct (or as including more than one subspecies), may be an incipient species and thus of potential importance as an evolutionary unit (see SPECIATION; also RING-SPECIES).

Mayr, E. 1982. Of what use are subspecies? Auk 99: 593–595. (See also discussions on the same topic by other authors, *ibid*: 596–615).

SUBSTANTIVE NAME: see NAME, SUBSTANTIVE.

SUGARBIRD: (1): substantive name of the 2 species (*cafer* and *gurneyi*) of *Promerops*, at present placed in the Promeropidae (Passeriformes, suborder Oscines) representing the only family of birds peculiar to South Africa. The evolutionary history of *Promerops* has been much debated, with a recent study (Sibley and Ahlquist 1974) suggesting that the sugarbirds are related to the starlings (Sturnidae) and not to the Australasian honeyeaters (Meliphagidae) as was thought formerly.

Characteristics. Sugarbird males are larger than females and total length exceeds 23 cm. They are readily distinguished from sunbirds (Nectariniidae), by being larger, by having a generally dull brownish plumage, long decurved beak and elongate tail feathers. The tail in males is normally considerably longer than in females, and can attain a length of 30 cm in the Cape Sugarbird *Promerops cafer*. Gurney's Sugarbird *P. gurneyi* is shorter tailed and redder on the chest and crown than *P. cafer*.

Habitat and distribution. Both species live in close association with *Protea* vegetation. They are found usually where proteas are in bloom, mainly along mountain slopes. The Cape Sugarbird is common in the southern and south-western Cape Province of South Africa. Gurney's Sugarbird, which replaces *P. cafer* in eastern Cape Province, occurs in Natal, the eastern and north-eastern Transvaal, and as far north as the eastern highlands of Zimbabwe. No long distance movements are known, or suspected, but populations undertake regular, altitudinal migration, up and down mountains, in association with seasonal variation in the flowering phenology of proteas. Dense concentrations of birds are found locally at stands of flowering proteas during the non-breeding season.

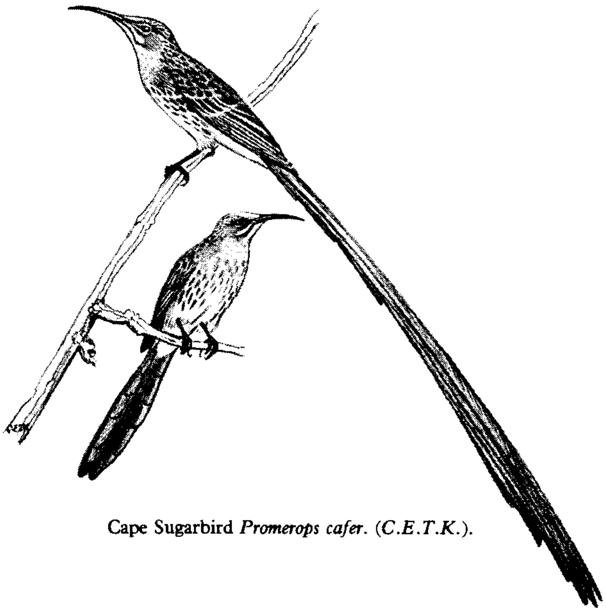
Food. Sugarbirds are adapted (e.g. tongue structure) for feeding on nectar, especially of proteas, and it is likely that they are important POLLINATORS of many species in the genus *Protea*. They also take insects and spiders, usually by probing in protea inflorescences, especially during the breeding season when the females require extra supplies of protein for the formation of eggs and for feeding young.

Voice. The song of Gurney's Sugarbird consists of 3 or 4 ascending notes, the last repeated several times, whereas *P. cafer* sings a series of jangling metallic 'gratings' and churrings. The alarm call is somewhat like the squeak of a rusty gate.

Behaviour. Both species are territorial and monogamous when breeding. The males of *P. cafer* perform a very conspicuous display flight in which the tail is held over the back of the bird while the wings are clapped vigorously. The fifth primary has a wide bulge, which is functionally concerned with this display.

Breeding. In the winter-rainfall region of South Africa the breeding season of *P. cafer* extends from February to August, with a peak in April–June when certain *Protea* spp. are flowering in the lowlands. During this period, the weather tends to be cool and wet and sugarbirds choose relatively sheltered microhabitats in selecting sites for their open, cup-shaped nests which are normally placed 90–160 cm above the ground in dense protea bushes (Burger *et al* 1976). Only the female builds, depositing grass and small dead twigs, and then pressing and moulding them with her body into the required shape. The nest lining invariably consists of a thick layer of protea seed pappi or fluff. The usual clutch is 2, and the eggs vary from light buff to reddish-brown, covered with blotches of dark purple or fine brown spots and lines. Only the female incubates, and the eggs hatch on the 17th day after incubation began.

The young are at first sparsely covered with long, thin, grey down. The female frequently covers them during the day, as well as by night, for the first 6 days. Both parents feed the young, but the female does the bigger share; some nectar is brought, but chiefly insects and spiders. Faeces are removed to a particular bush at the boundary of the territory. The young leave the nest after 18–20 days, but receive parental attention for about 3 weeks more. The attitude of the parents to the young then becomes



Cape Sugarbird *Promerops cafer*. (*C.E.T.K.*).

aggressive; but it sometimes happens that the female has started to incubate the second clutch while the young of the first brood are still dependent. Sugarbirds are normally double-brooded, and male and female remain paired for the whole of the breeding season. W.R.S.

SUGARBIRD (2): used, especially by aviculturists, as substantive name for species of Thraupinae in the genera *Dacnis*, *Chlorophanes* and *Cyanerpes* (see HONEYCREEPER) and for *Coereba flaveola* (see BANANAQUIT).

SULIDAE: see under PELECANIFORMES; GANNET.

SUNANGEL: substantive name of *Heliangelus* spp. (see HUMMINGBIRD).

SUN BATHING: see COMFORT BEHAVIOUR.

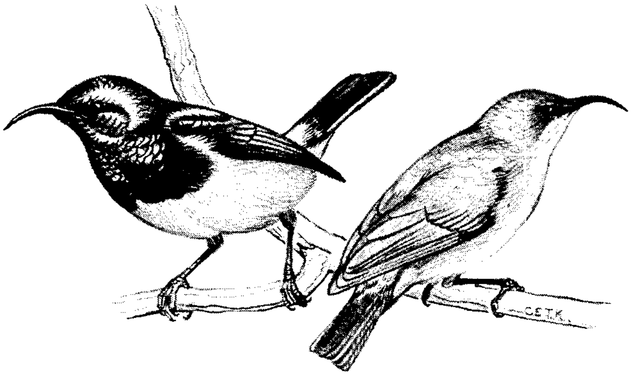
SUNBEAM: substantive name of *Aglaeactis* spp. (for family see HUMMINGBIRD).

SUNBIRD: substantive name of most species of Nectariniidae (Passeriformes, suborder Oscines); in the plural, general term for the family. A few species in south-east Asia are called 'spider-hunters'. For well over a hundred years, the name sunbird has been applied to this family of brightly plumaged little birds of the Old World tropics and adjacent parts of the Middle East and the Indian subcontinent. The family was the subject of a beautifully illustrated monograph by Shelley in 1876–1880. The African species were revised by P.L. Sclater and the whole family by Delacour in 1944. Delacour's revision reduced the number of full species to 106 and the genera to only 5; *Cinnyris* was lumped with *Nectarinia*. In the latest authoritative classification of the family, A.L. Rand (1967) followed Delacour's generic groupings, but resurrected *Hypogramma* and referred *Neodrepanis* (the false sunbirds, see ASITY) to the Philepittidae.

Characteristics. Except for the spider-hunters (*Arachnothera*), sunbirds are a well-characterized, uniform group of passerine birds. They are small (*c.* 16 cm) to very small (*c.* 8 cm) passerine birds, most of which weigh less than 20 g and have long, thin, curved bills. Fine serrations are present on the bills of most genera, probably to enhance capture and holding of the hard-bodied insects; the nostrils are oval, placed in a groove and covered with an operculum; the tongue is tubular in its anterior two-thirds and split near the end; rictal bristles are absent. The tarsus is strong and scutellate; the toes are short and stout with sharp nails. The rounded wing has 10 primaries. The tail is square, rounded or graduated; the 2 central rectrices are narrow and lengthened in males of some species. The plumages of males are usually bright, iridescent and sometimes velvety, but plumages of females are usually dull without metallic lustre. In a few species, both sexes are dull plumaged. The structural basis of iridescence in sunbird feathers still awaits study.

Generic limits and species groupings are based on differences in bill morphology, tail length and shape, and texture and patterns of male plumage. For example, those species placed in *Anthreptes* have shorter, less curved bills than those placed in *Nectarinia*. The presence or absence of coloured pectoral tufts seems to have little value as a taxonomic criterion. Delacour emphasized female rather than male plumage characters. Spider-hunters are quite distinct from other sunbirds; they lack bright plumage colours and have larger and stronger, decurved bills. Their nests are cup-shaped, not hanging domed structures, and they sew leafy nest material together with cobwebs. Both male and female spider-hunters incubate, unlike any other sunbird.

Sunbirds have long been allied with FLOWERPECKERS (Dicaeidae) which they strongly resemble in morphology, habits and nest structure. Conversely, sunbirds are not closely related to other Old World nectar-feeding birds like the Australian honeyeaters (Meliphagidae) or white-eyes (Zosteropidae). The sugarbirds (*Promerops*) of South Africa, false sunbirds (*Neodrepanis*) of Madagascar, and Fire-tailed Myzornis *Myzornis pyrrhoura* of the Himalayas are all convergent forms derived from other passerine families. C.G. Sibley's biochemical data suggest that sunbirds may be related to ploceine weavers.



Variable Sunbird *Nectarinia venusta*, male (left) and female. (*C.E.T.K.*).

Habitat. Sunbirds inhabit most habitats including primeval and second growth lowland forest, clearings, parklands, thorn scrub, gardens and the moorlands on the highest mountains in Africa. In general, and particularly in Africa, the brilliant species are found in the more open habitats, while the plain-coloured species inhabit shady, heavy forest. Some species are canopy dwellers, others live primarily in the lower strata of forests. The habits of many African species are described in detail by Bannerman (1948) and Skead (1967).

Distribution. Currently 116 species of sunbirds are recognized. Most occur in Africa and its islands, including Madagascar, but other species are distributed through the Middle East, India, Sri Lanka and Burma to Malaysia, the East Indies, New Guinea and Australia. One species related to the African forms is found in Israel and Palestine; 4 species occur in Arabia, and one of the many Indian species is found in Baluchistan. The genus *Aethopyga* is confined to India and south-east Asia while members of the genus *Arachnothera* are found primarily in Malaysia. A few sunbirds coexist with small, sunbird-like honeyeaters (*Myzomela*, Meliphagidae) in New Guinea and the Bismarck Archipelago. The largest species in the Ethiopian region is the Sao Thomé Giant Sunbird *Nectarinia thomensis*, restricted to the island of Sao Thomé in the Gulf of Guinea; males measure 22 cm in length and with their strongly graduated tails resemble little WOODHOOPOES (Phoeniculidae). Other large species are found in the mountains of East Africa, where more than 25 species are found in a limited geographical region. Three medium sized *Nectarinia* species of West Africa are also renowned for their spectacular colours, the Superb Sunbird *N. superbus*, the Splendid Sunbird *N. coccinigaster*, and Madame Verreaux's Sunbird *N. johannae*.

Movements. The Pygmy Long-tailed Sunbird *Anthreptes platura* moves south from the Sudanese arid belt to the Uelle district of Zaire in December to breed. Its 3½ month stay in Zaire is timed to the flush of flowering by savanna trees and bushes. Regular altitudinal movements in relation to flower availability also occur in East Africa in such species as the Golden-winged Sunbird *N. reichenowi* and the Red-chested Sunbird *N. erythrocerca*.

Food. Sunbirds feed on insects and nectar, the relative importance of which varies among the different species. Small, short-billed species search actively for insects in the foliage and crevices and feed opportunistically at a wide variety of flowers, including many small, insect-pollinated flowers with minute nectar volumes. Large, long-billed species are more dependent on the nectar in long corollas of large, conspicuous, red or orange flowers, which in turn may depend on the sunbirds for pollination. Short-billed sunbirds often pierce the base of long flowers with otherwise inaccessible nectar. Typical sunbird flowers in Africa include species of *Erythrina*, *Spathodia*, *Symphonia*, *Loranthus*, *Aloe*, *Leonotis*, *Kniphofia*, *Strelitzia*, *Lobelia*, *Protea*, *Tecomaria*, *Halleria*, *Burchellia* and *Schotia*. Flower choice is affected by details of fit between a species' bill and floral corollas, which determine the potential rate of nectar uptake. Sunbirds normally perch while feeding at such flowers; they rarely hover like hummingbirds.

Behaviour. Non-breeding sunbirds often defend feeding territories centred on favoured flowers; these are defended against sunbirds of all species. Territory size appears defined by an individual's or pair's energy requirements. Such aggressive activity is determined in some cases by economic considerations based on the intensity of competition for nectar (Gill and Wolf 1979). The effectiveness of territorial defence depends on the dominance relations of different sized species.

Although many sunbirds may aggregate at suitable flowers, they rarely if ever form cohesive flocks. Some species, especially *Anthreptes*, may join mixed species parties. Many species are highly nomadic and wander great distances in search of nectar; it is not unusual to hear individuals flying high overhead from one horizon to another.

Voice. Sunbirds have sharp metallic voices. Many species have loud, high-pitched, fast-paced, tinkling songs. Accompanying Skead's monograph on South African sunbirds is a record of their vocalizations. Vocal dialects have been described for the Splendid Sunbird by Grimes (1974).

Breeding. Breeding seasons relate to rainfall patterns and especially to peaks of flower and insect availability. Subordinate species in East Africa may breed opportunistically when possible in the absence of dominants that would usurp energy supplies. Some species may breed at almost any time of the year. Pairs are often double-brooded and may raise as many as 5 broods in succession. The asynchronous prolonged nature of breeding often produces, in local populations, a mixture of individuals of many different ages and stages of moult. In contrast to the promiscuous mating systems of hummingbirds, sunbirds typically form monogamous pair bonds; no examples even of polygamy have been documented. Male sunbirds feed the young, but do not help with incubation or nest building. The male often accompanies the female on trips to gather nesting material, but this is interpreted as defence against cuckoldry, since the male merely consorts but does not help (Wolf and Wolf 1976). The males defend flowers from which their mates obtain nectar; breeding male sunbirds have a reputation for being extremely pugnacious. The courtship displays of some species are described by Skead. Vent pecking following copulation is common.

All sunbirds build a covered or oval nest which is suspended from a bough or leaf of a tree, less often from a bush. It is usually an elaborate structure decorated or held together by cobwebs, and often has a porch-like projection above the lateral entrance. In many nests the outside has a ragged appearance and in some, a tail of loose building material is suspended. The eggs are normally 2 in number, more rarely 3; they are spotted or blotched, or streaked longitudinally on a ground which is usually white or pale bluish-white. A close association between several species of nesting sunbirds and aculeate Hymenoptera has been noted. Incubation lasts 13–15 days in South African sunbirds; the nestling period lasts from 14–19 days. Several of the African species are parasitized by cuckoos.

Moult. Males of some sunbird species moult into a dull-coloured plumage resembling that of females after breeding. These off-season plumages have been called eclipse plumages and compared to the dull post-breeding plumages of ducks. The details of plumage sequences in sunbirds still require study; the presence of eclipse plumages varies among closely related species and even among populations of the same species. Presumably, the costs of moult are off-set by advantages of camouflage and social interactions in some situations but not others.

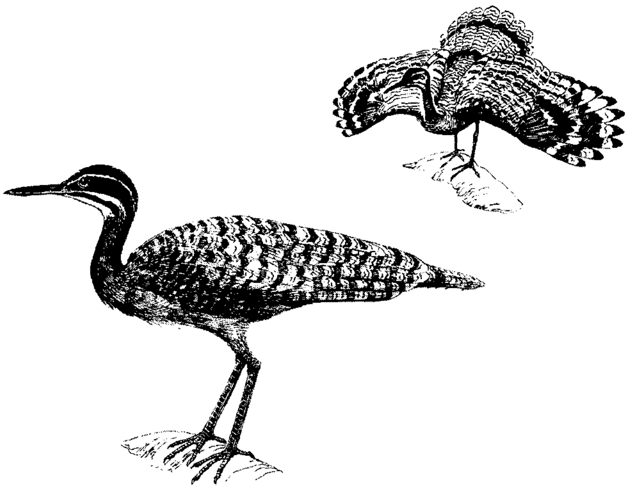
SUNBIRD, FALSE: name sometimes applied to *Neodrepanis* spp. (see ASITY).

SUNBITTERN: *Eurypyga helias*, sole member of the family Eurypygidae (Gruiformes, suborder Eurypygae).

Characteristics and distribution. It is found in the forested regions of America from southern Mexico to Bolivia and central Brazil and is represented by three races. About 46 cm long, this graceful, stout-bodied, long-necked, long-legged, largely ambulatory bird is most intricately barred, spotted, and mottled. The sexes are alike. The head is almost black, with a narrow white superciliary stripe and a broader white stripe along the lower edge of each cheek. The neck, shoulders, and breast are brown. The throat, abdomen, and under tail coverts are white and pale buff. The remaining plumage is largely grey and olive in general tone, with prominent black bars and white spots; and the long tail is crossed by two broad black bands. Only when the Sunbittern spreads its wings does it reveal its brightest colour, a large round shield of deep orange-chestnut set in an area of pale orange-buff in the middle of each wing, like a sun darkly glowing in a sunset-tinted sky. The upper mandible of the long, straight bill is largely black and the lower is orange. The eyes are deep red, and the long, naked legs are bright orange.



Sunbittern *Eurypyga helias*. (*C.J.F.C.*).

Habitat. Singly or in pairs, Sunbitterns forage along watercourses that traverse the forests, up to an altitude of 1,000 m (rarely 1,800 m in northern Venezuela). With slow, sedate steps, they walk along the muddy shores of sluggish streams and over the exposed rocks in rushing mountain torrents, where they fly across the deeper pools but wade through shallow water. They also frequent swampy areas in woodland.

Food. Their food, which consists largely of insects, spiders, small crustacea, minnows and the like, is caught beneath shallow water or gathered from exposed mud and rocks, with heronlike jabs.

Voices. Generally silent, the Sunbittern is reported to utter soft, long-drawn whistles, low trills, plaintive pipings, and a loud, ringing *ko wáy*.

Behaviour. From the nature of their habitat, it seems that Sunbitterns must pass most of their lives in the shade, but they are said to seek sunny openings in the forest, where they sometimes display. Widely spreading their wings with the richly coloured upper surface tilted forward, they fan out the raised tail to fill the gap between them, thereby forming a semicircle of plumage, in the midst of which the head stands.

Breeding. Although there are reports of Sunbitterns breeding on the ground, usually the nest is built in a tree or bush. One beside a Costa Rican mountain stream was precariously saddled upon a 5 cm branch about 6 m above the ground. The dark, roughly globular structure, about 30 cm in diameter, was composed of decaying leaves and stems, some green moss, and apparently also mud. In the top of the bulky mass was a shallow depression lined with green leaves, on which 2 eggs rested, apparently the usual number. The nearly oval eggs are buffy or clay-coloured, with darker spots and blotches. The most complete available account of the nesting of this bird is that of a pair who bred in the Gardens of the Zoological Society of London more than a century ago. Both sexes built the nest of vegetable materials and mud, and they alternately incubated an egg which hatched after 27 days. The newly hatched young was thickly covered with short down and resembled the chicks of plovers (Charadriidae) and snipe (Scolopacidae). Fed by both parents with food carried in the bill, it remained in the nest until, at the age of 21 days, its wing feathers had expanded and it could fly to the ground. It is remarkable that, although the young Sunbittern resembled a precocial chick, it was attended like an altricial nestling; but it is not known whether the behaviour of this captive pair was typical. SUN COMPASS: see ORIENTATION.

SUNGEM: *Heliactin cornuta* (for family see HUMMINGBIRD).

SUNGREBE: see FINFOOT.

SUNNING: behaviour by which a bird deliberately positions itself in the sun, often adopting a special posture. The synonym 'sun-bathing' is also widely used but the term 'bathing' is better restricted to true bathing in water; see COMFORT BEHAVIOUR. There are two types of sunning: (1) sun-basking and (2) sun-exposure, each being basically a reaction to the sun as a precisely identified source of heat.

Sun-basking. Unlike sun-exposure (see below), this is mainly a form of thermoregulatory behaviour together with other forms of heat-basking such as SMOKE-BATHING, the sunning bird absorbing heat from the sun and hence reducing the metabolic expenditure needed to maintain its optimum body temperature—especially in cool or cold conditions. Often overlooked by ornithologists, particularly in the smaller species, such simple and casual sunning is widespread among birds. It may occur during loafing and preening spells at any time of the year (in temperate areas, especially in spring, autumn, and winter) and at any time of the day (in tropical areas, especially early and late—particularly if the nights are cold). Use is often made of sheltered 'sun-traps', that also provide background reflected heat, or of other sunny places out of the wind. During the heat of the day, however, the birds often seek cool shade if possible unless they deliberately perform sun-exposure behaviour. It seems likely that sun-basking is the more primitive type of sunning from which sun-exposure behaviour developed; though quite distinct in its basic function, sun-basking could share other functions with sun-exposure.

Sun-exposure. At times, birds deliberately position themselves in the full heat of the sun when heat absorption is evidently not the main purpose of the behaviour. Passerines and other landbirds especially often frequent favourite 'hot-spots', typically on the bare ground and usually near cover into which they retreat if they become overheated or danger threatens; the temperature at such sunning sites can be many degrees higher than the air temperature. This form of sunning is widespread and is the one most often seen. In temperate areas, it occurs mainly when the sun is high in the hemisphere and mainly during those hours of the day when the sun is also high in the sky and at its hottest. Early and late in the day, and on cooler days with fitful sun, the birds may show low-intensity sun-exposure or a combination of sun-basking and sun-exposure behaviour, or fluctuate between the two. The basic function of sun-exposure would seem to lie in the realm of feather maintenance (see COMFORT BEHAVIOUR), especially with the effects of the sun's heat on the feathers—principally the wings and perhaps also the tail, the areas that sunning birds display most to the sun. The maintenance of the good condition of the remiges in particular could well be a major function of sun-exposure behaviour in birds generally. In griffon vultures *Gyps*, for example, it has been demonstrated experimentally that sun-exposure rapidly restores the flight-feathers to their original shape after they have become deformed by the stresses of flight, and this could well apply to other birds too, especially large species that soar or flap for long periods. Like sun-basking, sun-exposure helps to dry the plumage at times. It has also been suggested that sunning increases the flow of preen-oil and causes ectoparasites to become more active or to disperse from those areas of the plumage that are inaccessible or difficult to reach with the bill; both the preening directed to feathers near the neck and wings, and the frequent head-scratching that accompanies or follows the sunning, could well be components in a functional chain of feather-maintenance activities, though it is possible that such behaviour is merely an incidental response to irritation caused by the sun on the skin or by the displacement of feathers. It has been further suggested that the effect of the sun's non-thermal rays (particularly in the ultra-violet range) on the plumage or skin is beneficial, either directly in some way or indirectly by acting upon the organic lipids (preen-oil, etc.) for the synthesis of Vitamin-D or other purposes. Finally, attempts have been made to establish a functional correlation between sunning and moulting; although sunning birds are sometimes in moult, and the beneficial effects of sun-exposure could well be of relevance to that state, the correlation may well be merely seasonally coincidental, as in the case of ANTING and moulting, while speculation that sunning and anting are complementary 'comfort-motivated' activities that soothe the skin during feather replacement seems particularly ill-founded.

Yellow-crowned Night Heron *Nycticorax violaceus* female sunning on rocky shore, Galapagos. (*Photo: N. van Swelm*).

Sunning postures. When sun-basking, the bird may orientate itself at any angle to but often facing the sun. Though it may show no special behaviour otherwise, it often fluffs the feathers of head and body—at times, while trying to reduce heat loss by keeping the wings and legs covered by the plumage; or it will squat or sit down with feathers slightly erected and both wings drooped close to its sides so that the back is exposed, this simple 'wings-down' sunning posture being found in many birds, both passerine and non-passerine. Some species that sun-bask, e.g. the Greater Roadrunner *Geococcyx californianus* and certain grebes (Podicipedidae), have associated areas of black-based feathers or black-pigmented skin that facilitate the absorption of the solar energy when exposed. During the early morning hours, and intermittently during the day in cool clear weather, the roadrunner (a desert bird subject to low night temperatures) sun-basks with slightly drooped wings held away from the body and the mid-dorsal feathers erected, its back orientated perpendicularly to the sun; it does not sun itself when the ambient temperature is in or above its zone of thermoneutrality—unlike species that show deliberate sun-exposure behaviour. The grebes that sun-bask do so on the water, back to the sun, with the closed wings lifted and the feathers of the lower back and flanks erected.

The wings-down and other simple sunning postures are also shown at times by birds that are sun-exposing. Most sun-exposure postures are more elaborate however, typically involving the extension of one or both wings (exposing their dorsal or ventral surfaces), the spreading of the tail, and the erection of the head, neck, and body feathers, often exposing the

Blackbird *Turdus merula* female sunning. (*Photo: R.J. Chandler*).

oil-gland; they may be accompanied by gaping and panting or gular-fluttering. The postures of most passerines are of two distinct types: a 'lateral' one, in which the sunning bird squats or sits down, usually on the ground, and leans to one side away from the sun with the flank exposed or with the 'sun-wing' lowered and partly unfolded and the fanned tail brought round to the same side; and a 'spread-eagled' one—most often adopted when the sun is near or at its zenith—in which it squats or lies flat with both wings right open and extended outwards and the tail fanned. In a few species, including the Dunnock *Prunella modularis* and presumably other accentors (Prunellidae), the spread-eagle posture is replaced by a 'raised-wing' one, the bird leaning over with the sun-wing partly open and lifted more or less vertically. A fuller raised-wing posture is used by pigeons (Columbidae) both for sunning and rain-bathing (see COMFORT BEHAVIOUR). A number of large non-passerines—including pelicans (Pelecanidae), cormorants (Phalacrocoracidae), darters (Anhingidae), storks (Ciconiidae), herons (Ardeidae), New World vultures (Cathartidae), and the hawks and allies (Accipitridae, including the Old World vultures *Gyps*, etc.)—adopt more elaborate 'spread-wing' postures for sunning (of both types) and other purposes, including wing-drying: a shield-like 'delta-wing' position, with wings half open and primary tips crossed under the tail, and a 'full-spread' one, with wings stretched open at right angles to the body. When sun-exposing thus, the bird typically faces the sun so that the undersurfaces of the wings are exhibited. Among tropical seabirds, frigatebirds *Fregata* also adopt full-spread sun-exposure postures facing the sun with the wings twisted 'inside-out', boobies *Sula* a delta-wing one with back turned to the sun so that the uppersurfaces of the wings are shown, and noddies *Anous* a lateral one side-on to the sun.

Birds engaging in sun-exposure behaviour often stare at the sun. They clearly suffer from heat stress at times and some features of their postures—feather ruffling, exposure of the oil-gland, gaping, panting—are obviously, in part at least, superimposed thermoregulatory components facilitating the loss of excess heat. Finally, birds suffering from extreme heat stress when they cannot get out of the sun use sunning-like spread-wings postures at times both for heat-dumping and to shield the young. K.E.L.S.

(For further references see ANTING; COMFORT BEHAVIOUR; SMOKE-BATHING).

SUPERCILIARY: term applied to a marking, in some plumage patterns, above the eye.

SUPERFAMILY: see under FAMILY; NOMENCLATURE; TAXON.

SUPERORDER: see under CLASS; TAXON.

SUPERSPECIES: a grouping of species, of lesser rank than a subgenus and having no nomenclatural status; the term was introduced by E. Mayr and defined as a 'monophyletic group of very closely related and largely or entirely allopatric species'. It is implied that the included species are geographical representatives of a common stock, but have at least probably attained true reproductive isolation and are not merely subspecies of a single polytypic species. 'Artenkreis' is a partly equivalent term. A 'species group' (in one sense of the term) differs in that the included species may be less closely related and often sympatric (see SPECIES GROUP (2)).

SUPPLEMENTARY PLUMAGE; see PLUMAGE.

SUPRAOCCIPITAL: a paired bone of the SKULL.

SUPRASPECIFIC: general term applied to taxa higher than the species (see TAXON).

SURANGULAR: a paired bone of the lower jaw (see SKULL).

SURFBIRD: *Aphriza virgata* (see SANDPIPER).

SUTHORA: former generic name sometimes used, in the plural, as a general term for the Paradoxornithinae (see PARROTBILL).

SWALLOW: substantive name of most species of Hirundinidae (Passeriformes, suborder Oscines). The long-tailed species are often termed swallows and their shorter-tailed relatives called martins but the division is inconsistent and taxonomically unsound. In many aspects of morphology, habits, and their insect diet taken on the wing, they are convergent with the swifts (Apodidae).

Characteristics. Swallows are usually rather small, typically weighing 20 g and measuring *c.* 15 cm (plus tail streamers) but ranging overall from 12–23 cm. The family is characterized by having more or less complete bronchial rings. Half-rings are found amongst other Oscine families and anomalously in one hirundine genus, the river martins *Pseudochelidon*. The plumage is commonly dark blue or green and glossy above, paler below and sometimes streaked. In several species there is a conspicuous pale rump. The first year plumage may be brownish and readily distinguishable from the adults (e.g. Tree Swallow *Tachycineta bicolor*). The bill is short and compressed, with a wide gape. The compact streamlined body, long narrow wings and the tail, usually forked and often bearing streamers, confer highly efficient flying, gliding and turning capabilities. The outermost of 9 primaries is much reduced. Serrations on the outer primaries are present in 2 rather dissimilar genera, *Psalidoprocne* and *Stelgidopteryx*, the rough-winged swallows. The tarsi are short and with the feet are sometimes feathered (e.g. House Martin *Delichon urbica*). The feet are not powerful but strong claws characterize burrowing and cliff-dwelling species. The sexes are usually similar, in some cases distinguishable by the length of the tail streamers (longer in males) or other features, but often only in the hand during breeding by brood-patch size. There is a single post-nuptial moult: for North Temperate species this is suspended and mainly or wholly occurs in winter quarters. There are 74 recognized species, currently split into 17 genera. The largest genus is *Hirundo* containing the Common or Barn Swallow *Hirundo rustica*, one of the most widely distributed of all bird species. Intergeneric hybridization is comparatively frequent (e.g. Common Swallow × House Martin) and serves to emphasize the taxonomic uniformity of the family.

Habitat. Swallows are usually found in open country often near fresh-water. Riversides, lakes, marshes, cliffs, savanna and forest edge are typical habitats, whereas closed-canopy forest, barren lands and marine environments tend to be avoided. Extremes of latitude and oceanic islands have few or no swallows although altitudes in excess of 3,000 m are exploited by feeding hirundines in more favourable environments. In the breeding season segregation by habitat often follows from nest-site specialization. Thus in areas relatively free from the influence of man, the House Martin, for example, selects rocky cliffs for nest building whereas the Sand Martin or Bank Swallow *Riparia riparia* excavates its nests in sandy banks. But the widespread habit of swallows nesting on buildings or within excavations in association with man often provides a variety of nest sites in one place, and sympatry is then common. Hybridization occurs most frequently under these conditions (e.g. Common Swallow × Cave Swallow *Petrochelidon pyrrhonota*).

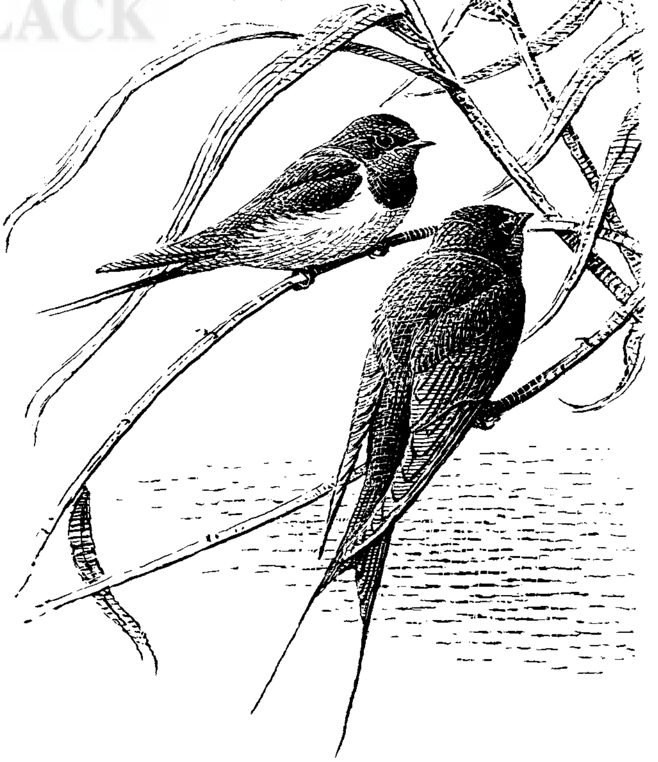
Distribution. The genus *Hirundo* is truly cosmopolitan, being found in all the zoogeographical regions of the world except Antarctica. *Petrochelidon* and *Riparia* are also widely distributed but others are restricted to the Old World (e.g. *Delichon*, *Psalidoprocne*) or to the New World (e.g. *Progne*, *Tachycineta*). The White-eyed River Martin *Pseudochelidon sirintarae* is a recent addition to the world avifaunal list being discovered in 1968 wintering in Thailand. Elsewhere the distinctive hirundine genus of *Pseudochelidon* occurs only in central Africa. The Afrotropical region holds the most varied fauna, supporting nearly 50% of hirundine species at some stage of their annual cycle.

Movements. Conspicuous migratory behaviour characterizes temperate representatives, whereas tropical species are more often sedentary. The Common Swallow is a widely recognized harbinger of the North Temperate summer, albeit, with a caveat: Aristotle, 'One swallow does not make a spring' (elsewhere 'summer'), related to the unpredictability of spring weather (Aristotle, Nicomachean Ethics, Book 1). Northbound movements of swallows are nevertheless closely linked to the northward shift of warm weather itself encouraging the emergence of insect food. Occasionally, unseasonal weather causes widespread mortality in early spring and late autumn amongst early arrivals and late departures. In winter quarters, which are either in tropical regions or exploiting the Southern Hemisphere summer (conversely Southern Hemisphere breeders move northwards to the tropics) catastrophic mortality can occur (e.g. amongst Common Swallows and House Martins). The migratory patterns of the Common Swallow are amongst the best known of all birds. Populations from the Western Palearctic mostly move south of the Equator in winter and discrete breeding populations show a greater or lesser attachment to specific wintering sites. Although some tropical species are believed to be sedentary (e.g. some African *Psalidoprocne* species) many migrate in response to the rains.

Food. Swallows specialize on day-flying insects taken while in sustained flight but will take grit and occasionally food from the ground and elsewhere. Wind-drifted spiders (Araneae) and lepidopteran larvae suspended from leaves do appear in the diet but prey are otherwise winged and mainly Diptera, Hymenoptera, Hemiptera and Coleoptera. Diptera tend to predominate at high latitudes whereas Hymenoptera are most frequent in tropical environments: a trend probably related to differences in insect availability. Fruit is sometimes taken by one species, the Tree Swallow of North America. There is evidence of insect size and taxon specialization for both tropical and temperate species. The height, proximity to both vegetation and nest sites and the manner of feeding correspond to the distribution of preferred prey: specialists on small items for example tend to feed higher, less vigorously and further from the nest. Amongst European hirundines at least, those with stouter bills take larger insect prey. Colonial breeding species often form feeding flocks but even solitary breeders will feed communally outside the breeding season.

Physiology. Swallows share with swifts a striking energetic economy in flight. During sustained flight the House Martin, for example, expends less than half the energy of other passerines under comparable circumstances: flight costs are often reduced by frequent gliding. Torpidity has been reported for the White-backed Swallow *Cheramoeca leucosternum* and evidently characterizes the massed huddling groups which occur under exceptionally severe conditions (e.g. Common Swallow, House Martin). The degree of hypothermia is generally slight however (30–35°C) and cannot be compared with the nightjars, hummingbirds or swifts (see TORPIDITY); in the wild it commonly precedes death in both adults and mature nestlings, even though recovery is possible if food and warmth are restored. Heat stress, mainly sustained in tropical or sub-tropical environments, may lead to leg exposure during flight to encourage heat dissipation. Diurnal migration, allowing periodic feeding, leads to comparatively undramatic fat deposition, compared

Swallow *Hirundo rustica*. (*D.W.*).



with nocturnal migrants, prior to the birds' conspicuous migratory departures.

Behaviour. Monogamy is typical and, although polygamy has been recorded, it is rare. Male Sand Martins and perhaps other species pursue a mixed reproductive strategy; holding a single female and competing for supplementary matings with other females. Kin altruism is widely reported for Common Swallows and House Martins, evidenced by young birds from the first brood feeding the second brood. Hirundines are commonly gregarious when feeding, collecting nest material, breeding, roosting and to a lesser extent on migration: gatherings in excess of a million birds have been reported away from breeding areas. Whether the function of aggregations is mainly protection from predators, enhances foraging efficiency or serves some other primary purpose is not established. Solitary breeding species hold conventional territories around the nest-site but may share feeding areas. In colonial species the territory comprises the nest interior, exit hole and approach route alone with no exclusive feeding areas. Dense flocks can form to mob aerial or, less commonly, ground predators. When roosting away from the nest site, emergent vegetation, buildings, vacant nests, telegraph wires and trees are favoured. Although all species are diurnal, some may stay aloft at night in the manner of SWIFTS (Rheinwald 1975).

Voice. Song is often poorly developed but may be a more or less melodious chirping or twittering, uttered in flight or from a perch or nest. Alarm calls are usually given at the approach of predators or when the nest is threatened and are typically brief and emphatic.

Breeding. Three nest types can be distinguished: (i) 'natural' holes (with or without additional mud around exit), (ii) excavated burrows and (iii) mud nests. 'Natural' holes may be in trees, caves on cliffs or buildings, or be vacated woodpecker or kingfisher excavations. Burrows are in soft ground, ancestrally in river banks and the like but now frequently in sand quarries. Mud constructions range from a simple bracket cup to an enclosed chamber with entrance passage. They are placed on trees, cliffs and typically nowadays on buildings, invariably sheltered from rain. The thixotropic properties of mud (i.e. liquifies under pressure) are exploited by swallows which agitate the moist material and thereby establish a secure bond between the numerous mud pellets used in nest construction. Evolutionary grouping on the basis of nest type has been proposed by Mayr and Bond (1943): natural holes characterizing the primitive, generally solitary, species, burrows being intermediate, while mud nests typify the most advanced, usually gregarious species. Patterns of nest dispersion range from generally solitary, through loosely colonial to massive dense coloniality. Loose coloniality, such as can often be found in Common Swallows, appears to result from limited nest sites. Sand Martins however will form dense colonies, at times with more than 1,000 pairs, even if suitable sites are abundant. The degree of coloniality in hirundines appears to be linked to the type and predictability of the food supply; mainly colonial species exploit unpredictable insect supplies.

Clutch sizes range from 1–8 eggs with 4–5 most common in temperate regions and 3 in the tropics. Single, double and occasionally triple broods are attempted. Incubation, lasting 12–16 days, is frequently by the female alone. Generally in social species both male and female incubate with the latter taking the greatest share. The nidicolous young spend 15–30 days (and longer if severely undernourished) in the nest and lose weight in the latter stages. The recession involves at fledging a loss of 15–27% of the peak weight, itself greater than the adult weight, mainly brought about by desiccation of the integument. An allied feature is the nestling's fat store. Carcass analyses have revealed lipid indices (lipid/lean dry weight) of 0.4–1.0 compared with 0.1–0.5 for a typical passerine nestling at the same stage: this is established as an insurance against food scarcity and to sustain fledglings while they learn to forage. Parental feeding continues for several days after fledglings leave the nest.

SWALLOW-SHRIKE: see WOOD-SWALLOW.

SWALLOWTAIL: *Eupetomena macroura* (for family see HUMMINGBIRD).

SWALLOW-TANAGER: *Tersina viridis*, a bird of uncertain systematic position, now placed in the tanager family (Thraupidae; Passeriformes, suborder Oscines).

Characteristics, habitat and distribution. The Swallow-tanager, a bird about 15 cm long, bears some resemblance to the tanagers (Thraupinae) but—in addition to having a very peculiar palate—differs in being longer-winged and short-legged, as well as in having a wide flattened bill slightly hooked at the tip; in its nesting habits, also, it stands apart from the tanagers. The male is mainly a brilliant turquoise blue, with a black face and throat, and black bars on the flanks; the female is green above and yellowish below with green barring. The Swallow-tanager is found in northern parts of South America up to Panama, and in Trinidad. The birds are migratory, at least in parts of the range; they breed in the mountains, where they prefer wooded country with clearings, and spend the non-breeding season in the humid lowlands.

Food. The Swallow-tanager is both an insect-eater and a fruit-eater. Insects are captured on the wing, a method of feeding which gives the bird its name; fruit is taken from a perched position. The method of eating fruit is peculiar: the bird holds the whole fruit in the widely opened bill and turns it about until all the pulp is scraped off. The seed is not swallowed, as it is by many frugivorous birds, but is dropped after the flesh has been eaten off it. Relatively large masses of fruit are swallowed and held in a distensible throat-sack.

Behaviour and voice. The Swallow-tanager's calls are varied but unmusical: the song of the male is poorly developed. During the breeding season territories are held.

Breeding. The nest is built at the end of a horizontal burrow in a bank or in an artificial hole in a wall or similar structure. Holes in earth banks, the natural site, may be excavated by the birds themselves or taken over from other species. The nest is a cup-shaped structure made of a variety of materials such as rootlets, grasses, and vegetable fibres. The eggs, usually 3 in number, are glossy white. Incubation is by the female alone; but the male takes a part, smaller than that of the female, in feeding the young. Outside the breeding season Swallow-tanagers are highly social, forming flocks that—unlike those of most other tropical passerine birds—never associate with other species. D.W.S. (1)

SWALLOW-WING: *Chelidoptera tenebrosa* (see PUFFBIRD).

SWALLOW, WOOD-: see WOOD-SWALLOW.

SWAMPHEN: substantive name used in Australia for *Porphyrio* spp. (see RAIL).

SWAN: substantive name of *Coscoroba coscoroba* and *Cygnus* spp., all in the tribe Anserini (with the 'true geese') of the subfamily Anserinae of the Anatidae (see under DUCK). 'Swan' is of common gender, but 'cob' and 'pen' are sometimes used as special terms for male and female swans and 'cygnet' for the young. See photo FEEDING HABITS.

SWIFT: substantive name (varied to 'SWIFTLET' in some cases) for the species of Apodidae and Hemiprocnidae (Apodiformes, suborder Apodi); in the plural, general term for the suborder. The swifts form a very well defined group of birds with purely superficial resemblances to swallows (Hirundinidae). Swifts are usually united in one order (Apodiformes) with the hummingbirds (Trochilidae), an often debated relationship on which the dust has yet to settle. Both swifts and hummingbirds have an extremely short, thick humerus, a short ulna with short secondary feathers, and a long carpus with 10 primaries; the wing is narrow, with a shallow camber, adapted for high-speed flight. However, while swifts have long wings and are primarily adapted for sailing through the air, hummingbirds have relatively much shorter wings and are specially adapted for hovering; further, in breeding and feeding habits, in coloration, and in form of bill, the two groups are extremely different. Swifts are usually regarded as constituting a suborder, of which the Hemiprocnidae (crested swifts) include only 1 genus of 4 species, and the Apodidae (true swifts) include all the rest.

Characteristics. The Apodidae is best considered as consisting of 3 subfamilies—the Cypseloidinae, Chaeturinae and Apodinae. The Cypseloidinae and Chaeturinae have an anisodactyl foot (3 toes forward and 1 behind); the Cypseloidinae are diastataxic and have soft rectrices and rather weak feet while the Chaeturinae are eutaxic (see WING) and most (not *Collocalia*) have stiffened tail feathers with spiny tips that, along with their strong feet, help the bird support itself against vertical surfaces. The Apodinae, which also lack the stiffened rectrices and spiny tips, are eutaxic, have a reduced number of toe phalanges, and possess a unique form of grasping foot in which toes 1 (hallux) and 2 oppose toes 3 and 4 (as in heterodactyly; see LEG). However in these swifts the grasping motion is lateral inward, not front to back as in most birds, a motion which is highly adapted to holding on to the soft plant materials and feathers which they glue together to make their nests. When not grasping (and in museum specimens), the toes of the Apodinae lie together giving rise to the often repeated misconception that swifts have all 4 toes pointed forward (Pamprodactyly).

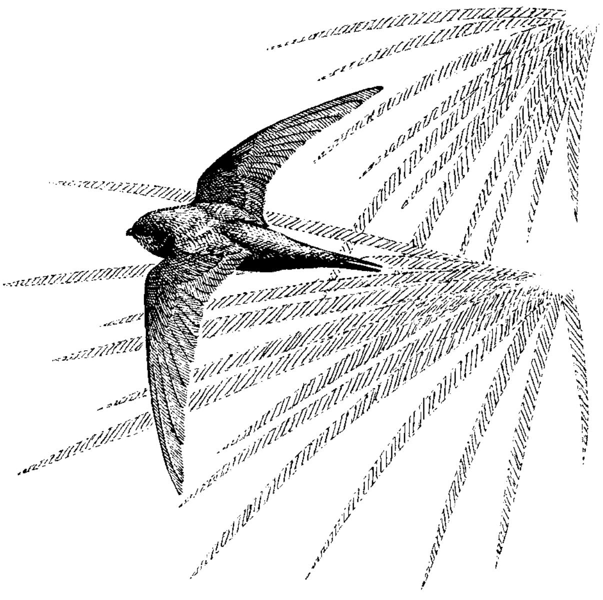
Distribution and characteristics. In all there are some 82 species in 18 genera, spread through Eurasia, Africa, North and South America; none breed in Australasia except in the extreme north. The majority of species are tropical, but a few breed in northern parts of Europe, Asia and North America and overwinter in the tropics or in the southern hemisphere after a transequatorial migration.

Apodidae. The true swifts are the most aerial of all birds, feeding entirely in the air, drinking and bathing by descending to water, and regularly spending the night on the wing (see FLIGHT). They range in size from 10.5 to 25 cm in length with extremes represented by the diminutive Glossy Swiftlet *Collocalia esculenta* (7.5 g) and Pygmy Palm Swift *Tachornis furcata* (weight unknown), and the giant White-naped Swift *Streptoprocne semicollaris* (175 g) and Purple Needletail *Hirundapus celebensis* (180 g). All are predominantly sooty or brown in colour, with some patches of white or pale grey: some species have a marked iridescence which changes colour during feather wear. The legs are extremely short, the strong claws being adapted for clinging. They do not normally settle on the ground or vegetation, although some of them roost on vertical cliffs or more rarely on trees. Contrary to many accounts, swifts can take off from flat ground, although with difficulty.

Swifts are apparently unique in copulating in the air (although also in the nest), and spending the night on the wing. In northern regions they may travel hundreds of kilometres to avoid depressions, returning after these have passed.

Adult survival rates are high, frequently above 80% per year, and life expectancy is very good for such small birds. Swifts have few regular predators but small falcons at times take considerable numbers. All swifts are subject to a variety of endo- and ectoparasites including at least occasionally cestode tapeworms, cimicid bugs, and an array of feather mites (Acarina; Eustathiidae). Swifts commonly host feather lice (Mallophaga) with up to 2 species of *Dennyus* and 1 of *Eureum* being recorded from a host species; these genera of lice are confined to swifts. The most striking ectoparasite of the Common Swift *Apus apus* is the flightless hippoboscid louse-fly *Crataerina*, of which 12 may be found on a single young bird and over 20 on an adult. Although bloodsucking, *Crataerina* seldom causes the death of its host, to whose life cycle its own is beautifully adapted.

Food. Swifts gather all their arthropod food on the wing, usually well above ground; they occasionally glean from a water surface, tree foliage, and under eaves of buildings. Ballooning spiders are taken when available, but insects are the usual food items with the orders Diptera, Hymenoptera, Coleoptera and Homoptera predominating; day to day variability is great.



Palm Swift *Cypsiurus parvus*. (*N.A.*).

Behaviour and voice. The extreme mobility of swifts has hindered study of their social and display behaviour. Although some species appear to be solitary breeders, most are more nearly colonial and can be observed in closely packed, vocal flocks particularly early in the morning or at roosting time dashing past their nesting sites. The vocalizations of the Chaeturinae are a rapidly repeated series of sharp chips, while those of the Apodinae, particularly *Apus*, can best be described as a drawn out buzzy *scree* or scream. Mixed flocks of swifts of several species as well as other birds can be observed where food is abundant or locally concentrated. Resource partitioning seems more a matter of the size, rather than taxonomy, of the food items taken, and of the foraging area typically utilized by each swift species.

Breeding. Most swifts glue their nest-material together with saliva produced by seasonally enlarged salivary glands. The material in many cases is collected in the air. Clutch size varies from 1 in *Cypseloides* to 4–6 in *Aeronautes* and some *Chaetura* spp. The incubation period is rather long for the size of the bird, being 19–20 days in *Apus* and 22–23 in *Cypseloides*. The nestling period is also long, and is unusually variable (from 5–8 weeks, depending on the weather) in *Apus apus*. When feeding young, swifts return to the nest with a food bolus consisting of possibly several hundred food items glued together with saliva and carried in the distended sublingual region of the mouth. Feeding rates vary from one visit every 15–20 minutes to once every few hours or longer.

The Common Swift has several adaptations for an unusually variable food supply, since air-borne insects are plentiful in warm, dry and calm weather, but very scarce in cold, windy, and wet weather. The interval between the eggs, normally 2 days, is lengthened to 3 days if food is short. The parents normally relieve each other in turn on the eggs, but if food is short they leave the eggs unbrooded, these being unusually resistant to cooling. The young can likewise be left unbrooded, and can also withstand several days of starvation by utilizing their fat reserves and retarding their rate of development. Further, feathered young can, if starved, loose their temperature control and become temporarily poikilothermic, while the adults can clump together in a semi-torpid condition, although for how long is not known (see TORPIDITY).

Nest sites for the hole-nesting swifts may be in short supply; inter- and intraspecific competition appearing at times to be severe. Prolonged grasping-grappling fights for a nest site, sometimes lasting for several hours, have been reported for *Apus apus* during the pre-nesting period. Similar contests with other species, particularly Starlings *Sturnus vulgaris*, have been recorded; the Horus Swift *Apus horus* regularly evicts bee-eaters to obtain suitable nesting burrows. Once obtained, nest sites are faithfully reutilized for several years in succession, even in migratory species.

Cypseloidinae. The genera *Cypseloides* and *Streptoprocne* include 12 species only one of which is not confined to the neotropics; *C. niger*

Moustached Crested Swift *Hemiprocne mystacea*. (*N.A.*).

migrates and breeds as far north as Alaska. The mossy nest of these swifts contains little or no salivary glue and is placed on a damp rock surface or ledge close to water, frequently near or behind waterfalls but occasionally on sea cliffs or in caves.

Chaeturinae. The several genera in this group include some 23 species in Asia, Africa, and North and South America, the best known of which is the Chimney Swift *Chaetura pelagica* of eastern North America; under natural conditions nearly all nest inside hollow trees, but several now use chimneys, the bracket shaped nest of twigs being attached to the vertical inner surface. *Collocalia* includes an additional 20 small species of cave swiftlets in south-east Asia and the islands of the Pacific and Indian Oceans (see SWIFTLET).

Apodinae. The genus *Apus* comprises 10 Old World species, most of them in Africa, and includes the Common Swift (or 'Swift' unqualified in Britain) *A. apus*. They usually nest in holes in cliffs or buildings, one species *A. horus* in burrows, and several in old nests of hirundines.

Cypsiurus consists of 2 small African and Asian palm swifts with long forked tails; they build a small open nest on the inner side of a palm leaf, the egg being glued to the nest with saliva (in Africa), and the bird brooding vertically. Of the other 3 small genera, all in the New World, *Aeronautes* nests in holes in cliffs; *Panyptila*, with a long tail-fork, builds a hanging sleeve some 60 cm long under a branch or rock ledge, with a nest chamber near the top and entrance at the bottom; while *Tachornis* places a bag-shaped nest in palm foliage.

Hemiprocnidae. The crested swifts *Hemiprocne* spp. in this small separate family are found in south-eastern Asia and the western Pacific, from India to the Solomon Islands. They do not show such extreme specialization for an aerial habit as the true swifts, are capable of greater manoeuvre, perch freely on trees, and have patches of bright colour and crests. The tiny cup-shaped nest is just large enough to hold the single egg; it is attached to the side of a lateral branch of a tree, the branch taking the weight of the brooding bird which straddles the nest.

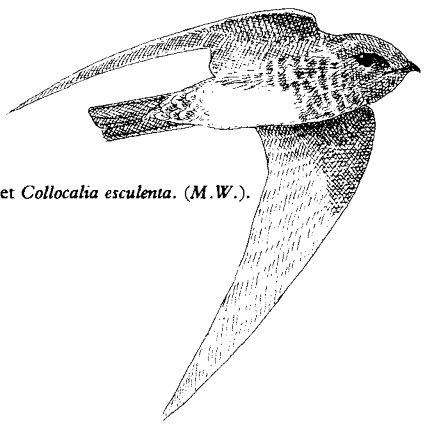
SWIFTLET: substantive name of a group of small swifts (Apodidae) formerly placed in a single genus *Collocalia*, but recently allocated to the tribe Collocaliini and subdivided into 3 genera: *Collocalia* (*sensu stricto*), *Aerodramus* and *Hydrochous* (Brooke 1970; Medway and Pye 1977).

Characteristics and distribution. The tribe contains some 15 species of Old World distribution ranging from islands of the western Indian Ocean (Seychelles) through southern continental Asia, the Philippines and the Indo-Australian Archipelago to northern Australia and the west and southwest Pacific. In body-length they range from *c.* 7.5–13 cm. Their plumage is usually dull blackish brown to glossy black, some species showing a limited area of white or dull grey on the belly and rump. The wings are long and pointed, adapted to aerial feeding, the tail is short and usually square-cut, rarely furcated. Morphological differences, in particular in the medium-sized uniform dull blackish-brown species, are unobtrusive, making identification in the field often impossible. Even in the hand, the differences are minute and for this reason the taxonomy of this group has for a long time been confused. The present classification is based on some minor morphological characters, but primarily on nest type (see EDIBLE NESTS) and the ability to echo-locate (see ECHOLOCATION).

The largest genus, *Aerodramus*, contains 12 species. The Three-toed Swiftlet *A. papuensis* is the only member of its family with 3 toes (all other swifts have 4) and may not be closely related to other *Aerodramus* species, but is provisonally allocated to this genus (see Somadikarta 1967). Three of the *Aerodramus* species are well known for their edible nests (see EDIBLE NESTS). The genus *Collocalia* contains only *esculenta* (Glossy Swiftlet) and *troglodytes* (Pygmy Swiftlet), while the genus *Hydrochous* contains only *gigas* (Giant Swiftlet). This largest of the swiftlets has a wing-length of 142–159 mm, body-weight 35–38 g, followed by the uniform blackish-brown *Aerodramus* species: *maximus* with wing 125–140 mm, weight 11.5–14 g; *vanikorensis* with wing 115–123 mm, weight 9–13.5 g; and *fuciphagus* with wing 110–118 mm, weight 8–9.5 g. The smallest are those of the genus *Collocalia*, with *troglodytes*, wing *c.* 90 mm, weight unknown, and *esculenta* with wing 95–100 mm, weight 7–7.2 g.

Behaviour and food. Swiftlets are mainly active by day, although some have rather acute vision in dim light. Thus the Giant Swiftlet, a species with relatively large eyes, is sometimes a crepuscular feeder, and the Indian Edible-nest Swiftlet *Aerodramus unicolor* has been recorded feeding by night with the assistance of artificial illumination. Feeding is strictly aerial as in the other swifts, although there is one observation of the Glossy Swiftlet climbing upside down along a ceiling of a house (constructed of dry palm leaves) searching for insects (Spennemann 1928). Caged swiftlets usually creep along the walls and hang on the ceiling upside down, and even die firmly attached in this position. Swiftlets of the various genera are ecological specialists. Some, like the Glossy Swiftlet, usually forage alone or in aggregations at low elevation in cultivated areas over open water but also over fig trees at times when winged figwasps (Hymenoptera, Agaonidae) are swarming. *Aerodramus* species forage more dispersed, often singly, above the tree canopy, often over virgin rainforest areas, and only aggregate near their breeding sites at the dusk inrush. The main prey items are Hymenoptera, which sometimes make up 99% of the food items, followed by Ephemeroptera (mayflies), Homoptera and Diptera, while other insect orders are rather poorly represented. The larger species, especially the Giant Swiftlet, specialize on Isoptera (flying termites) and Hymenoptera (Formicidae; flying ants). The food is given to the young in the form of foodballs, as in other swifts. In the Edible-nest Swiftlet *Aerodramus fuciphagus* foodballs average 0.57 g in weight and contain *c.* 500 prey items (range of 100–over 1,200); the heaviest foodballs contained either flying ants (Formicidae, including the hard-headed carpenter ants) or flying termites (Isoptera) (Langham 1980). It has been estimated that the *c.* 4,500,000 swiftlets



Glossy Swiftlet *Collocalia esculenta*. (*M.W.*).

breeding at Niah cave, Borneo, eat *c.* 5,000 kg of insects daily, comprising not less than 10^8 individuals (Harrisson 1974). Such a vast consumption of insects must have a significant ecological impact.

Voice. The usual call of the Glossy Swiftlet is a low chirp, infrequently uttered. Cave-breeding species which nest in complete darkness produce bursts of sharp clicks, the so-called rattle call, for orientation in the dark (see ECHOLOCATION). Giant Swiftlets aggregate at dusk or shortly after sunset near the breeding or roosting place (i.e. near waterfalls) in noisy flocks. The birds produce loud, rising and falling trilling flight-calls in chorus, reminiscent of the Swift *Apus apus* but higher in pitch (Becking 1971, and unpublished).

Breeding. Swiftlets nest gregariously, mainly in caves (both sea caves and inland in limestone outcrops) but also in old buildings in Chinese quarters (Edible-nest Swiftlet), while the Glossy Swiftlet occasionally also breeds in occupied houses, under bridges and in drainage tunnels etc. The Giant Swiftlet breeds on ledges under or near waterfalls, sometimes having to dive through a curtain of falling water to reach the nest (Becking 1971). Some species, especially the Black-nest Swiftlet *Aerodramus maximus* and Edible-nest Swiftlet, nest in pitch darkness deep inside caves, sometimes 400 m or more from the entrance, where they orientate by means of echolocation, a faculty which they have developed to a higher degree than any other bird species. The Giant Swiftlet and Glossy Swiftlet lack the ability to echolocate, and consequently breed in the open or near the entrance of caves, in dim light.

Breeding is the best known in the Edible-nest Swiftlet. This species has two peaks of maximal breeding activity, the first October–December, the second February–April. Nest-building takes at least a month (Franck 1926, Medway 1962) and incubation starts usually with the first egg. The 2 eggs are laid with *c.* 3-days interval and incubation lasts 23 ± 3 days. The fledging period is *c.* 43 ± 6 days, giving the rather protracted incubation and fledging period of *c.* 70 (65–75) days (Langham 1980). This period is estimated at over 90 days for the larger Black-nest Swiftlet at Niah, Borneo (Medway 1962). In a study of the Edible-nest Swiftlet in Malaya the overall breeding success was found to be *c.* 48% (Langham 1980). Eggs are eaten by a cave cricket (*Rhaphidophora oöphaga*), which sometimes also attacks young, and many young die by falling and then being eaten by cave snakes or in houses by shrews (*Suncus* spp.) and rats, but they seldom fail in the final exit flight, their first, which sometimes involves negotiating half a kilometre or more of dark tunnels.

SWIMMING AND DIVING: terms that cover the methods of aquatic locomotion, broadly comprising: (a) swimming on the surface; (b) diving from the surface and swimming under water; (c) plunging into the water from a height. At least 390 species, in 9 orders, habitually swim, while many others can do so. About two-fifths of the regular swimmers seek their food by diving, the remainder normally feeding on the surface, or upending in shallow water, or plunging from the air. The surface-feeders show comparatively minor adaptations to this mode of life, the most obvious being in the position and proportions of the hind limbs and in the webbed feet or lobes on the toes to increase their effective area (see LEG). Diving and plunging birds show more extensive modifications in structure and physiology. Effective diving requires the specific gravity of the bird to approach that of water (normally it is much less). This minimizes the energy used simply to remain submerged. Unlike many diving mammals, birds dive after inhalation, but in these birds this volume of air is somewhat less than that in other birds owing to the decreased pneumaticity of their bones and to a corresponding simplification of the air-sac system (see PNEUMATIZATION OF BONE and RESPIRATORY SYSTEM). Immediately before submerging, diving birds reduce their specific gravity by compressing their body plumage thus forcing out most of the air normally trapped within it. (For eye adaptations to diving, see VISION.)

Emperor Penguins *Aptenodytes forsteri* can descend to at least 265 m and remain submerged for over 18 min under natural conditions; and some diving birds can stay alive for as much as 15 min when forcibly held under. Several physiological adaptations make this possible. While under water important sources of oxygen are oxyhaemoglobin and oxymyoglobin stored in the muscles. The latter is particularly high in penguins, approaching the amounts in diving mammals. Diving birds can obtain energy from anaerobic, as well as the usual aerobic, breakdown of glycogen. In addition, the regulation of the circulation is so modified that in diving the flow of blood to the muscles and perhaps to other organs can be greatly reduced, the supply being reserved mainly for the central nervous system and heart. Heat loss from the limbs to the water may be reduced by cooling the blood entering the limbs. This is done in a network of blood vessels in which arterial blood to the limbs gives off heat to the cooler venous blood returning to the body.

Most diving birds use either the wings or the feet, but not both, for propulsion while under water. Wing-propelled diving birds are largely marine whereas foot-propelled ones predominate in fresh water. Among living birds, the penguins are supreme as wing-propelled divers, literally flying under water. Their flippers distal to the shoulder are relatively inflexible, lack normal flight feathers and have remarkably flattened bones. The leading edge is raised on the upstroke and lowered on the downstroke, thus acting as a hydrofoil producing thrust on both strokes. As in other birds with a powered upstroke, the supracoracoideus muscle, which raises the wing, is large. On the surface, penguins float low in the water. Their high density results from the reduced pneumaticity of the bones and the short body feathers, which trap relatively little air. A thick layer of subcutaneous fat compensates for the reduced insulating function of the feathers.

The divers or loons (Gaviidae) are perhaps the most specialized of living, foot-propelled diving birds. The feet are set far back and the shanks are bound to the sides of the body, which is thus considerably wider than deep and relatively stable when on the surface.The front toes are fully webbed and alone are used for steering as well as propulsion under water. The grebes (Podicipedidae) superficially resemble the divers, but differ greatly in the structure of their limbs and limb girdles. Their toes are lobed distally and joined by webs proximally. The independent derivation of diving birds from different groups of swimming birds is a recurrent theme in avian evolution. Striking examples are the early foot-propelled Hesperornithiformes and the wing-propelled Plotopteridae (Pelecaniformes) (see FOSSIL BIRDS).

Red-throated Diver *Gavia stellata* swimming on fresh water. (*Photo: H.E. Grenfell*).

The petrels (Procellariiformes) float high on the water and swim easily. A few, like the Sooty Shearwater *Puffinus griseus*, pursue their prey by diving, and are unusual in having both the wings and feet modified for use under water. The 4 diving petrels (Pelecanoididae) are small, wing-propelled divers which are remarkably similar to the small species of auks and occupy a corresponding niche in the Southern Hemisphere. These petrels are short-winged, with a whirring flight in the air. They may dive from the wing into the sea, continue to 'fly' under water, and emerge flying in the air.

Tropicbirds (Phaethontidae) feed by plunging into the sea from heights of 15 m or more, but are comparatively poor swimmers and divers. The young seem unable to dive. Brown Pelicans *Pelecanus occidentalis* feed by plunging from the wing, but other Pelecanidae feed by dipping their long bills and necks while floating high on the surface. Their legs are short and stout, not laterally compressed as in most swimming birds; the feet are large, and webbed between all 4 toes.

Gannets and boobies (Sulidae) feed by plunging, sometimes from over 30 m. As they are large birds, their momentum on striking the surface is considerable, and they show special adaptations to prevent damage on impact, notably strengthening of the skull, imperforate external nares and a remarkable system of subcutaneous air-sacs which are thought to be primarily shock-absorbing. They sometimes pursue fish under water, and may use wings as well as feet in swimming. Cormorants are largely foot-propelled. They ride low in the water and dive from the surface, often remaining under for more than a minute and at times reaching depths of about 10 m. Unlike that of most aquatic birds, the plumage of cormorants readily becomes sodden. The long, stiff tail is used as a rudder: in most other diving birds the tail seems to be unimportant. Darters, like cormorants, ride low in the water, and often only the head and neck remain visible; underwater they swim with the wings slightly expanded. Like cormorants, they too become sodden.

Screamers (Anhimidae), although marsh birds, only occasionally swim. All ducks, geese, and swans (Anatidae) swim, and possibly all can dive, although only about one-third of the 148 species habitually do so. Accomplished divers are found among many of the groups: the White-backed Duck *Thalassornis* (Dendrocygninae), steamer ducks *Tachyeres* (Tadorninae), Torrent Duck *Merganetta* (Anatinae), and all the Merginae and Oxyurinae. The Long-tailed Duck or Oldsquaw *Clangula hyemalis*, like the Great Northern Diver or Common Loon *Gavia immer*, is a deep-diving bird, apparently feeding down to 160 m in the Great Lakes of America. Most diving ducks are foot-propelled while under water, although eiders *Somateria* and scoters *Melanitta* dive with their wings partly opened but with the carpal joint flexed so that the primaries lie beneath the secondaries, making a smaller, stronger paddle or steering mechanism. Steamer ducks use their wings partially extended while under water.

Nearly all rails swim well, although only the gallinules *Gallinula* spp., *Porphyrio* spp., etc. and coots *Fulica* are primarily aquatic. The gallinules are swimmers, with the long toes typical of the family increased in swimming efficiency by narrow strips of skin extended laterally. They rarely dive when feeding but may do so if disturbed, when they sometimes flap the wings slowly in swimming under water. The coots, which have lobed toes, are habitual divers; they do not use their wings while submerged. Coots are less adept at diving than other bottom-feeders; in a given depth of water the duration of their dives is much less; food plants are brought to the surface rather than eaten at the bottom.

The 3 species of finfoot (Heliornithidae) are good swimmers with broadly-lobed toes. They swim very low in the water. Their ability as divers is in dispute. The jacanas (Jacanidae), normally using their extraordinarily long toes to walk on floating plants, are like the Moorhen *Gallinula chloropus* in their ability to swim and to dive in escaping danger.

Among the waders (Charadrii), the phalaropes are the only group strongly specialized for swimming. They have lobed, semi-palmate toes, flattened tarsi, and dense body plumage. They feed afloat, sitting high on the water, commonly turning rapidly about and picking up small invertebrates near the surface. Avocets and stilts (Recurvirostridae) and the Crab-plover *Dromas ardeola* also swim well and more frequently than other waders. The Black-winged Stilt *Himantopus himantopus* can dive well.

Skuas, gulls and terns all have fairly short legs and fully-webbed feet. The gulls swim very much more than the others. Some gulls, skuas and many terns plunge for food but none go deep or travel far under water.

The 22 species of auks are highly specialized divers, using their wings for underwater propulsion at relatively high speeds. Except for *Cepphus*, they tend to feed pelagically rather than at the bottom. Their short wings with very short inner secondaries are folded when used underwater, providing a smaller, stouter paddle than the spread wing during aerial flight. The feet are used primarily for steering underwater. The dense body plumage of auks is less obviously compressed prior to diving than is that, for example, of grebes.

Little Pied Cormorant *Phalacrocorax melanoleucos* diving for Minnow or Mosquito Fish *Gambusia affinis* in experimental tank. (*Photo: G.F. van Tets*).

The remaining orders contain only 2 families of regularly aquatic habit. In the Coraciiformes, the 87 species of kingfishers include a number of fish-eaters that feed by plunging either from a perch or while hovering over water. Other members of the family are non-aquatic woodland birds, feeding by pouncing on insects and other prey on the ground or by pursuing them in the air. Some bee-eaters also fish. The techniques and structure of the fish-eaters show only very minor adaptations, for the prey is taken with the bill at or close to the surface and prolonged immersion does not occur. Unlike most other plunging birds, they do not regularly swim; that is true also of the fish-eaters among the Acciptriformes and owls, which grasp their prey with their talons.

Among the Passeriformes, the 5 members of the family of DIPPERS are aquatic. They swim well, using their feet when on the surface and in walking on the bottom, but they rely on their wings for progression under water and to keep them submerged. Their plumage is very dense, like that of phalaropes, and they float high in the water as a result of the large amount of air trapped among the feathers. Some approach to similar habits is found in the little-known *Enicurus* spp. (Turdinae) and in *Cinclodes* spp. (Furnariidae) (see THRUSH; OVENBIRD (1)). Otherwise no members of the order are aquatic, although some frequent the vicinity of water and some tyrant-flycatchers (*Pitangus* spp. and *Lessonia rufa*) regularly take food from the surface. SWORDBILL: *Ensifera ensifera*, a large Andean HUMMINGBIRD with a remarkably long bill, as long as the head and body combined and far longer than that of any other hummingbird.

SYLPH: substantive name of *Aglaiocercus* spp. (for family see HUMMINGBIRD).

SYLVIIDAE; SYLVIINAE: family and subfamily of PASSERIFORMES, suborder Oscines; WARBLER (1).

SYMBIOSIS: association of two organisms, the result of which are beneficial to each. See under BROOD-PARASITISM; NESTING ASSOCIATION.

SYMPATHETIC NERVES: see NERVOUS SYSTEM.

SYMPATRIC: occurring in the same geographical area—in contrast to ALLOPATRIC.

SYMPHYSIS: union or junction of two bones (see SKELETON, POST-CRANIAL).

SYNALLAXINAE: see OVENBIRD (1).

SYNANTHROPIC: see under EUSYNANTHROPIC.

SYNAPOSEMATIC: see under APOSEMATIC.

SYNCHRONIC: existing at the same level of geological time—contrasted with ALLOCHRONIC.

SYNCHRONOUS HATCHING: see HATCHING.

SYNDACTYL; SYNDACTYLOUS: having two toes (III and IV) coalescent for part of their length. See LEG.

SYNECOLOGY: term for the ecology of communities—contrasted with AUTECOLOGY; see also ECOLOGY.

SYNONYM: see NOMENCLATURE.

SYNSACRUM: the long fused portion of the vertebral column to which the pelvic girdle is firmly attached (see SKELETON, POST-CRANIAL).

SYNTYPE: see TYPE SPECIMEN.

SYRINX: the organ of voice or song (plural 'syringes'). It differs from the mammalian larynx in both situation and structure; the larynx in birds lacks vocal cords and has little or no role in voice production. The syrinx is situated at or near the bifurcation of the windpipe (trachea) into 2 bronchi and typically comprises a resonating chamber (tympanum), vibrating membranes, and control structures of varying complexity, including cartilages and muscles. Syringes traditionally have been classified on the basis of location, as tracheal, bronchial or tracheo-bronchial, but studies in the mid-20th century showed these distinctions to be less clearcut than previously believed. Even the terms 'trachea' and 'bronchus' are difficult to apply consistently in the area where these passages meet. The division of the single passage into two often does not coincide with the transition from single ('tracheal') rings into paired ('bronchial') rings or semirings. It is common to apply the adjective 'tracheo-bronchial' to any syrinx that appears to contain components derived from both tracheal and bronchial tissues.

The syrinx in taxonomy. From the middle of the 19th century on, certain features of the syrinx figured prominently in bird taxonomy, especially within the order Passeriformes. Beddard, Garrod, Forbes and other late-19th century anatomists considered the number and position of insertion of the syringeal muscles to be taxonomically significant. More recently, work by Miskimen, Ames (1971), Warner and others has shown that the extent and type of variation must be determined before syringeal structure is used for taxonomic decisions.

In general, the gross characteristics of the syrinx are quite consistent within a family, but many details may be rather variable. The extent of fusion and the sculpturing of cartilaginous elements may be highly variable within a single species in one case, yet uniform across an entire family in another.

Myological characters have been central to the taxonomic use of the syrinx. The muscles are considered *extrinsic* if they originate off the syrinx (e.g. on the sternum) and insert on the syrinx (or on an otherwise unmodified part of the trachea near the syrinx). *Intrinsic* muscles originate and insert within the specialized area defined as the syrinx. (There is some circularity in this, for the muscles themselves also serve to define the syringeal region.) In all but a few groups (e.g. parrots) there are two pairs of extrinsic muscles: the Mm. sternotracheales, which connect the syrinx to the sternum or to the intercostal muscles, and the Mm. tracheolaterales, which originate on or near the larynx and lie on the lateral surfaces of the trachea, inserting in the syringeal region.

Intrinsic muscles vary greatly from one order to another and sometimes within an order. Where clearcut intrinsic muscles are lacking, their position, and probably their function, is often occupied by the Mm. tracheolaterales, suggesting that intrinsic muscles evolved through segmentation of the tracheolateral muscles. In the simplest condition of intrinsic muscles, found in many non-passerines and a few passerines, each intrinsic muscle is merely a specialized terminal segment of the tracheolateral muscle. Only a few groups have been found with more than one pair of intrinsic muscles: parrots and most passerines.

Types of syringes.

Tracheo-bronchial syringes. This type of syrinx is the most widespread and is so variable that a generalized description is impossible. The lowest rings of the trachea are often fused into a cylindrical tympanum, somewhat flared posteriorly, where it is movably connected with the adjacent 'bronchial bars' ('intermediary bars' of some authors). The medial surfaces of the bronchi usually are membranous and these 'internal tympaniform membranes' (ITM's) are the basic vibrating elements in the oscine syrinx and probably in most others. Work by W.B. Gross in the 1960s showed that in the chicken the external tympaniform membranes (ETM's) are the sound sources. The same may well prove true of pigeons and parrots, in which the syrinx contains large lateral membranes.

Other components frequently present are the *pessulus*, a bony bar lying at the junction of the ITM's, the *bronchidesmus*, a ligament connecting the bronchi to each other and usually to the oesophagus, and up to five pairs of intrinsic muscles, which function to control the tension of the membranes or to close the aperture of each bronchus, through movements of modified cartilages.

Tracheal syringes. In this group the presumed vibratory membranes lie among modified tracheal cartilages. Most syringes in this structural group contain modified bronchial elements and many have tracheo-bronchial muscles. ITM's usually are present but their vocal function remains uncertain. In the best known group, the New World antbird-ovenbird group (suborder Furnarii of the order Passeriformes), the lower trachea is dorsoventrally compressed and provided with membranous 'windows' (with or without narrow crossbands of cartilage), which most authors since Johannes Muller (1847) have believed to be vibratory.

Bronchial syringes. In this type of syrinx the vibratory membranes are located well posterior of the tracheo-bronchial junction and intrinsic muscles, if present, originate and insert on the bronchi. There is no fusion of tracheal elements into a tympanum. To date, this type of syrinx has been clearly identified only in certain cuckoos.

Syringeal operation. Much recent research has focused on the mechanisms of syringeal modulation and on the roles of the trachea, bronchi and air sacs in sound production. Most of the *in vivo* and *in vitro* work in the laboratory has utilized the chicken or readily obtainable songbirds as subjects. Even this limited sample has yet to produce consistent information on the complex interrelationships of the various components of the vocal system.

Greenewalt (1968) was the first to use modern electronic techniques to analyse the calls of a wide array of birds, from grebes to songbirds, in search of a unified theory of sound production. He concluded that the same basic mechanism could produce all of the sounds that he examined. He postulated that the basic vibratory membranes, the ITM's, are bulged inward by pressure of the interclavicular air sac. Thus stretched, the ITM's are set into vibration by the moving stream of exhalant air. Amplitude (volume) and pitch (frequency) are modulated by three interrelated mechanisms, singly or in combination: by altering the pressure of the air sac relative to that in the bronchi, by occluding the air passages with the external labia and by tension of the syringeal muscles, acting on the cartilages supporting the ITM's. Greenewalt suggested that when the ITM vibrates freely without touching the bronchial wall, 'whistled' song is produced, relatively free of harmonics. As the bulging ITM is pushed closer to the outer wall of the bronchus, harmonics appear and the output enters the harsher 'harmonic' domain.

A number of workers before Greenewalt had noted that certain birds are capable of producing two or more harmonically unrelated sounds, indicating the presence of as many independent oscillators. Thorpe (1961) suggested that there might be as many as four such sources. Greenewalt demonstrated that this 'two-voice' phenomenon is present in a great many birds over a wide taxonomic range. Evidently the right and left halves of the syrinx are acoustically and neurologically independent.

In a number of separate studies in the 1960s and 1970s, Brackenbury (1978) and the Gaunts (1977) have used advanced instrumentation to record synchronously in live birds the actions of syringeal muscles, changes in air pressure in various parts of the vocal system, and output sound characteristics.

These workers have demonstrated that the extrinsic muscles function to regulate the position of the syrinx in the neck and, in some species and situations, to control the tensions of vibrating membranes through relative movements or rotations of syringeal components.

The air pressure events are similar in the chicken and the Starling *Sturnus vulgaris*, but in the latter the external labium (EL), absent in the chicken, controls air flow more precisely than in the chicken. This increases loudness while conserving air. In both birds the pressure in the interclavicular air sac is high before and during calling and drops at the end of the call. Tracheal pressure in the chicken is elevated above atmospheric pressure but in the Starling, apparently due the action of the EL, it remains at atmospheric pressure. P.L.A.

SYSTEMATICS: the aspect of biological work dealing with the systematic description of the forms of life, and also with their orderly arrangement (see CLASSIFICATION). The latter is the special concern of taxonomy, but as it permeates the whole that term is often used synonymously with systematics (see TAXONOMY). The handmaid of systematics is NOMENCLATURE.

Systematic work is a basic necessity for other kinds of ornithological endeavour, as it defines the subjects of study. It is itself grounded largely on morphology and geographical data, as the museum specimen is of necessity the main material in the descriptive or analytical phase, as well as being the permanent record. In the taxonomic or synthetic phase, however, ornithological systematists—although primarily using morphological criteria—have increasingly drawn upon the data of field studies to assist in elucidating problems of phylogenetic relationships; various laboratory tests are also being increasingly invoked (see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA). What has been called 'the new systematics' goes further, into a third phase in which the aim is to investigate the factors influencing the evolution of the different forms. The systematic biologist of today has thus to take account of ecological, ethological, physiological, and genetic data bearing on the problems that the results of earlier faunistic and morphological labours suggest.

In ornithology, systematic work in the old Linnean tradition has been pursued with notable assiduity—so much so that it has been claimed that birds are better known taxonomically than any other class of animals. This places a heavy responsibility on the ornithological systematist to make the fullest use of the opportunity for making still further contributions to general biological knowledge. To do this he must abjure conservatism in his concepts of taxonomy, the limitations of the typological approach, and the pedantry of regarding nomenclature as more than a means to an end. It has been well said by Stresemann that 'whoever wants to hold firm rules should give up taxonomy. Nature is too disorderly for such a man.'

The present tendency is, indeed, towards a much more fluid concept of 'population systematics'. In this study, as Mayr has pointed out, cognisance must be taken of three major phenomena: (1) the geographical isolate, possibly an incipient species (see SPECIATION); (2) the population continuum, subject to clinal variation (see CLINE); (3) the zone of secondary intergradation, due to isolates re-establishing contact (see HYBRIDIZATION, ZONE OF SECONDARY). An isolate may or may not have been formally recognized as a subspecies, or it may comprise more than one; a continuum, likewise, may or may not include forms that have been accorded subspecific rank (see SUBSPECIES).

See references under TAXONOMY.

T

TACHURI: substantive name of the 2 South American tyrant-flycatchers of the genus *Polystictus* (see FLYCATCHER (2)).

TACTILE SENSE: see TOUCH.

TADORNINI: see DUCK.

TAGS: see MARKING.

TAIGA: coniferous forest-land, typical of vast areas of the North Temperate Zone, lying south of the TUNDRA.

TAIL: in descriptive ornithology the conspicuous feather appendages, protruding from the fleshy tail proper which is organized around the shortened hindmost portion of the vertebral column. The plumage elements are the large tail quills (rectrices) and the rows of major and minor covert feathers (tectrices) that overlap the bases of the rectrices. The elongate tail of *Archaeopteryx* has undergone a dramatic transformation, culminating in the inconspicuous, stubby tail of recent birds. A particularly remarkable part of the transformation is the derivation of the bulb of the rectrices, the mechanism that provides the anatomical basis for the array of positions and movements of the tail during flight and its other specialized activities.

In the conversion of the avian tail to its present compact form, several important modifications have taken place: (1) truncation of the tail having the effect of concentrating the whole tail mass nearer to the centre of gravity of the trunk. This truncation involved consolidation of the terminal vertebral segments, producing the pygostyle, as well as incorporation of the proximal caudal vertebrae into the synsacrum; (2) liberation of most of the rectrices from direct attachment to the caudal vertebrae; (3) evolution of the paired rectricial bulbs into which the tail quills became implanted; and (4) development of a highly mobile joint between each rectricial bulb and its socket.

Generalized topography of the avian tail. The width of the avian fleshy tail is more than one-half that of the pelvis. Viewed from above, its caudal border, where the rectrices are inset, varies from semicircular to angulated. From the rear, the follicles of the right and left rows of rectrices intersect one another producing a tent-shaped configuration (Fig. 1). The lateral borders of the tail exhibit pronounced bulges marking the underlying rectricial bulbs. In most birds more or less distinct constrictions exist at the tail–trunk junction (e.g. *Gallus*); in others (e.g. *Anas*) the tail merges imperceptibly into the pelvic part of the trunk. In profile, the vent protrudes from the abdominal wall just inferior to the fleshy tail mass; the uropygial gland rests on the pygostyle (see SKELETON, POST-CRANIAL) and the two central rectrices (Fig. 1). *Rhea*, a so-called tail-less bird, possesses rudimentary tail muscles attached to the reduced free caudal vertebral column at the end of the rump.

Structure of the tail. The following descriptions are based on the pigeon *Columba livia*. Examples of charadriiform, anseriform, gruiform, accipitriform, falconiform, galliform, psittaciform, and passeriform birds have been compared. The tail structure of all of them is essentially the same as that of the pigeon; however, in smaller forms, the morphological details are less well defined.

The endoskeletal framework of the tail consists of a series of 6 free caudal vertebrae, articulating with one another, with the terminal pygostyle (coccyx) and with the last synsacral caudal vertebrae. The slightly moveable joints between the bodies of the free vertebrae are ligamentous, connected to one another by fibrous discs, contrasting with the synovial joints of the cervical and thoracic regions.

The intrinsic tail muscles are modified axial muscles originating from the synsacrum and proximal free caudal vertebrae and inserting into the more distal vertebrae, pygostyle, rectricial bulb, and rectrices. The extrinsic tail muscles arise from lateral pelvic elements (ala of ischium, shaft of pubis) and the femur, inserting into rectrices, fasciae and aponeuroses of the intrinsic muscles. Some of the extrinsic muscles participate in cloacal function and support of the body wall in the region of the vent. More of the tail musculature is concerned with depression than with elevation of the tail (see later: Movements of tail feathers). Actions of the muscles are inferred, based on anatomical evidence and observations made during manipulations of the tail of fresh specimens. The names themselves of the tail muscles provide some information on their attachments or actions.

The intrinsic muscles (Figs. 1–3) are the paired M. levator caudae, M. depressor caudae, M. lateralis caudae, M. adductor retricium, and M. bulbi rectricium. M. depr. caud. is somewhat unusual in that its superficial tendon decussates with its opposite counterpart on the lower surface of the rectricial bulbs, forming the expansive cruciate aponeurosis; its deep tendon inserts directly on the pygostyle. Contraction of both depressor caudae muscles causes the wings of the cruciate aponeurosis to draw down the lateral part of each bulb, enhancing tenting of the tail feathers, then rotates each bulb, depressing its rectrices and ventrally flexing the entire tail. Acting unilaterally M. caudofemoralis deviates the tail to its side with the assistance of the ipsilateral M. pubocaud. int. M. bulbi rectr. initiates spreading of the rectrices; M. lat. caudae carries out the rest of this action. The non-striated M. add. rectr. extends transversely from one rectrix to the next, paralleling the elastic interrectricial ligament; both of these structures adduct the rectrices, folding the outspread tail.

The paired extrinsic tail muscles (Fig. 1), M. pubocaudalis externus, M. pubocaudalis internus, and M. caudofemoralis act with M. depressor caudae in ventral flexion of the tail. Acting unilaterally, M. pubocaud. ext. and M. dep. caud., and the contralateral M. lev. caud. tilt the tail, i.e., rotate the entire tail around its longitudinal axis. An exaggeration of such rotation is exhibited during soaring by the Black Kite *Milvus migrans*. M. pubocaud. int. has a complex structure, its superior and inferior bellies being joined by a tendinous intersection. Not only does this muscle contribute to depression of the tail, but it affects the shape of the cloaca (see below).

Rectricial bulb (Fig. 2). The rectrices and their major coverts on each side are embedded in the Bulbus rectricium, a well-organized fibro-adipose body enveloped by its capsule of striated muscle. Only the central pair of rectrices that flank the pygostyle has any ligamentous

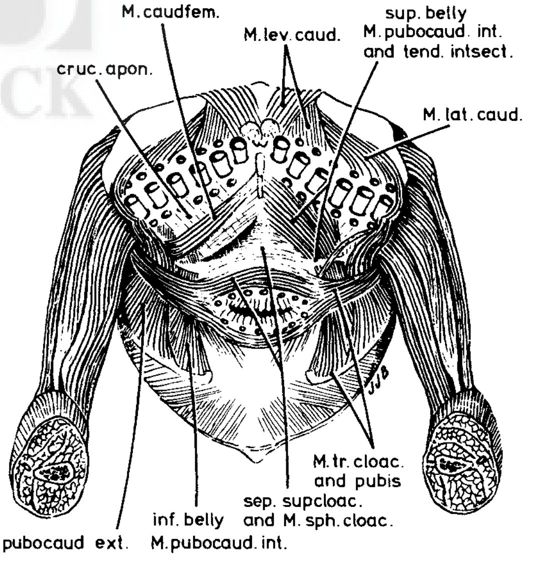

Fig. 1. Tail muscles of the pigeon *Columba livia*. Caudal view; tail somewhat elevated; vent drawn inferiorly; legs sectioned slightly distal to knee. Superior belly of M. pubocaudalis internus has been removed on left side to display the deeper lying structures. Note narrow M. levator cloacae (unlabeled) passing deep to M. sphincter cloacae on right side.

Abbreviations: cruc. apon. = cruciate aponeurosis; M. tr. cloac. = M. transversus cloacae; Sep. supcloac. = Septum supracloacale; Tend. intsect. = tendinous intersection.

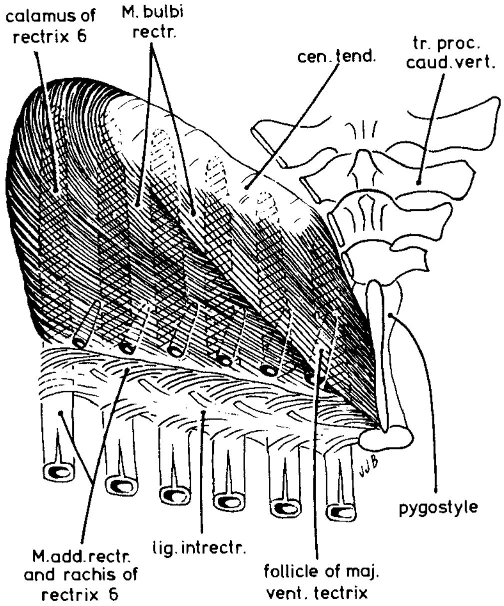

Fig. 2. Bulb of the rectrices (Bulbus rectricum) of the pigeon *Columba livia*. Right side, ventral aspect. Portions of transverse processes cut off; bulb drawn laterally away from pygostyle to demonstrate attachment of part of M. bulbi rectricum to pygostyle.

Abbreviations: caud. vert. = caudal vertebra; cen. tend. = central tendon; Lig. intrectr. = Ligamentum interrectriciale; tr. proc. = transverse process.

attachment to the tail skeleton. The bulb is dorsoventrally compressed, and viewed from above it is somewhat rhomboid. The socket of the bulb is located between the levator caudae and depressor caudae muscles which form its roof and floor. The medial wall of the socket is formed by the pygostyle and the dorsal processes of the adjacent vertebrae; its lateral wall is the inner surface of M. lat. caud. The bulb and its socket form an ellipsoid 'joint' in which rotatory movements bring about elevation and depression of the bulb and its implanted feathers.

Symmetrical movements of elevation and depression of the folded tail, involving dorsi- and ventriflexion of the tail vertebral column and rotation of the bulbs, takes place about a transverse axis projecting through the apices of the two bulbs. The oblique axis of rotation of the bulb is used for elevation–depression movements of the outspread tail. This axis projects in an infero-latero-cranial direction from the caudo-dorsal corner of the pygostyle, forming an angle of about 45° with the median plane of the body and about 20° with the dorsal (horizontal) plane. From the neutral position of the tail, more elevation of the tail feathers is possible than depression, since depression is limited by contact of the tail with the underlying rear of the trunk and the vent. On account of the obliquity of the axis, during downward rotation of the bulb the lateral rectrices descend farther than the more medial ones, increasing tenting of the tail. Movements of one bulb may be independent of the opposite bulb.

The interior of the bulb (Fig. 3) is compartmentalized, i.e. subdivided into fat-filled locules; the calami of the rectrices are suspended in the fibrous partitions separating the locules. The basal ends of the calami are embedded in a tough, deformable fibro–adipose mass, the basal pad, which binds the tips of the calami together as a unit, but is flexible enough to permit movements of the individual calami. Individual movements of the calami are also accompanied by displacement of locular fat and deformation of the walls of the bulb. Side-to-side movements of the rectrices during spreading and folding of the tail, as well as their elevation–depression movements take place within the bulb. The lateral rectrices are more mobile than the medial ones because of the fixation of the central rectrices to the pygostyle. Therefore, during depression, this extra mobility of the lateral rectrices yet further accentuates the tent-shaped lower surface of the tail. This is additional to that caused by the obliquity of the axis of rotation of the bulb and the action of the depressor caudae muscles. Conversely, elevation tends to flatten the lower tail surface. Part of M. bulbi rectricium anchors the bulb to the pygostyle (Fig. 2); this muscle also appears to help M. lat. caud. in spreading the rectrices, initiating abduction of the rectrices by drawing the tips of the calami together and, by means of its slips, inserting on the calami and the fibrous partitions within the bulb, stabilizes the rectrices.

Summarizing the foregoing, the avian tail demonstrates combinations of: (1) gross movements of the entire tail, i.e., depression, elevation, tilting and lateral deviation; (2) movements of each rectricial bulb in its socket, mainly producing elevation and depression of the tail feathers; and (3) movements of individual rectrices within the bulb as in spreading–folding and elevation–depression of the rectrices themselves.

Tail–cloacal interrelationships. Movements of the tail are not only associated with defaecation and copulation but influence these activities. In its neutral position the tail proper compresses (flattens) the adjacent cloaca, cloacal bursa (Fabricii) and duct. The muscles on the lower surface of the tail are separated from these organs by M. sphincter cloacae and Septum supracloacale; the latter is a transverse fibrous sheet connected laterally with the tendinous intersection of each M. pubocaud. int. (see Fig. 1). Elevation of the tail to its upright position brought about by the Mm. levatores caudae decompresses the cloaca, enlarging its dorso–ventral dimension. Simultaneous contraction of the Mm. pubocaudales internus and externus on each side draws these muscles away from the cloaca, lifting the lateral margins of the supracloacal septum and the sphincter muscle. Thus pressure on the sides of the cloaca is also relieved, increasing the lateral dimensions of the cavity of the cloaca.

Nerves and vessels of the tail. The blood supply of the tail, including its integument, is largely derived from intersegmental rami of the median caudal artery and to a lesser degree from the lateral caudal artery, a branch of A. iliaca interna. From these sources two prominent arteries pass to each rectricial bulb: A. dorsalis bulbi is an enlarged dorsal ramus of an intersegmental branch of the median caudal artery that serves the part of the bulb dorsal to the implanted calami of the rectrices. A. ventralis bulbi stems from the lateral caudal artery and enters the ventrolateral aspect of the bulb. Rami to the follicles of the rectrices and the major coverts from these arteries become hypertrophied during replacement of these feathers after their moult.

The intrinsic tail muscles and integument of the dorsum of the tail are innervated by the segmental caudal spinal nerves. The ventral rami of the caudal nerves communicate, forming the caudal plexus. Dorsal and ventral Nn. bulbi rectricum arise from the caudal plexus. Rami of these nerves are distributed to M. bulbi rectricium, the socket of the bulb, and to the perifollicular tissues. Presumably those to the socket and the follicles of the rectrices and major coverts are proprioceptive afferent

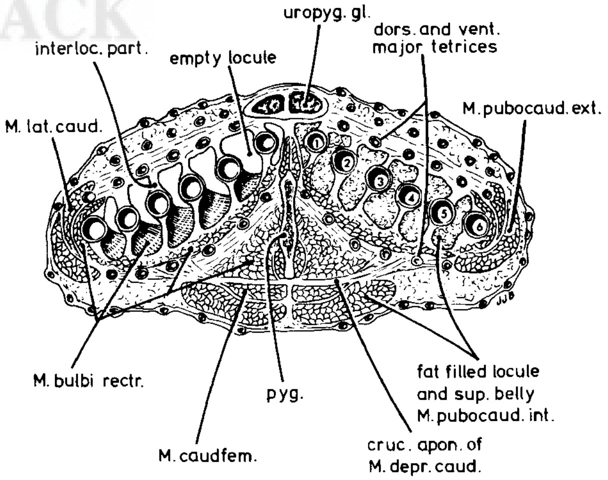

Fig. 3. Cross section of tail of the pigeon *Columba livia*. Level of section through the lamina of pygostyle; section approximately 3 mm thick. Rectrices are identified by numerals. Note deep parts of M. bulbi rectricum extending from follicles of rectrices to adjacent interlocular partitions. Note also attached to base and apex of pygostyle small attachments of M. levator caudae and M. depressor caudae (unlabeled).

Abbreviations: cruc. apon. = cruciate aponeurosis; interloc. part. = interlocular partition; pyg. = pygostyle; uropyg. gl. = uropygial gland.

nerve fibres, conveying impulses centrally about the position and movements of the bulb and the rectrices. The extrinsic muscles of the tail, the integument of the lateral and ventral aspect of the tail and the vent and surrounding region are innervated mainly by branches of the pudendal nerve plexus.

Shape of tail. Kiwis, cassowaries, emus, and rheas are practically tailless, no special tail feathers being recognizably differentiated from the general plumage covering the hinder parts; the Ostrich *Struthio camelus* is an exception among the 'ratite' birds in having something of a tail. In grebes the quills are rudimentary; and in many aquatic birds the tail is very short, e.g. in divers and in penguins.

Tails may be rather short and stumpy, of moderate or substantial length, or greatly elongated. Very long tails are found, for instance in the tropicbirds, in many true pheasants, in certain parrots, in the mousebirds (Coliidae), and in species of various passerine families—e.g. in tyrant flycatchers of the genus *Muscivora* in the New World, and in the Paradise Flycatcher *Terpsiphone paradisi* and the Paradise Whydah *Vidua paradisaea* in the Old World. (The Japanese have a breed of domestic fowl with a 'train' of enormous length, in which the feathers grow continuously without moult.) Elaborate tails are often much more highly developed in the male of a species.

The end of the tail, depending on the relative lengths of the paired rectrices, may be square or rounded, forked or wedge-shaped—examples are too well known to need citation. Very long tails are sometimes due to elongation of the central pair of rectrices, whether the others be graduated or of uniform length. In some fork-tailed species, however, it is the outer rectrices that are very long.

Modifications of rectrices. Various modifications occur in the shape of separate rectrices. Sometimes the distal part of the rachis carries no web but projects as a spine, e.g. in the spine-tails of the family Furnariidae and in the spine-tailed swifts (Chaeturinae). Some other birds are 'racket-tailed', notably the motmots; here the terminal part of the shaft in the 2 central rectrices carries a web on both sides, but there is a sub-terminal part that is bare, thus isolating the 'racket' (or 'raquet') from the main web. In the male Marvellous Spatuletail *Loddigesia mirabilis*, a hummingbird, it is the outer pair that carry raquets at the end of long wire-like shafts that cross over. Sometimes certain rectrices may be twisted in the vertical plane, e.g. the somewhat elongated central tail feathers of the Pomarine Skua *Stercorarius pomarinus*. In some birds-of-paradise the central tail feathers are elongated in wire-like or narrow ribbon-like form, often much twisted or curled.

In several different groups of birds that either climb or cling to vertical surfaces, such as tree-trunks or walls, the tail is used as a prop; and the rectrices tend to be stiffened in adaptation to this habit. Examples are the woodpeckers, spine-tailed swifts (Chaeturinae), woodcreepers, tree-creepers, and oxpeckers.

Ornamental tail plumes are by no means always modified rectrices. In the male Peacock *Pavo cristatus*, for instance, the gorgeous feathers of the train are greater upper tail coverts. The ornamental plumes of the male Ostrich have probably this same homology. In some species, the birds at rest may appear to have ornamental tail feathers but these in fact belong to the wings, as can be seen when the latter are unfolded. This is exemplified in the cranes; thus in *Grus grus* one of the most noticeable characters is what appears to be a large and loosely feathered tail, but the plumes are actually elongated secondary wing feathers. In the Pennant-winged Nightjar *Macrodipteryx vexillarius* it is an enormously elongated primary on each side that, in the breeding male, extends beyond the tail when the bird is at rest.

Movements of tail feathers (see above). In flight the tail forms part of the surface on which the air presses, and it can give some assistance to the wings in steering and braking (see FLIGHT). The tail tends to be broad in soaring species and short in rapid flyers. The tail, when of some length, may also be used in helping to balance a perched bird.

The tail in some birds is normally cocked up, as for instance in the Wren *Troglodytes troglodytes*, the Grey Gallito *Rhinocrypta lanceolata*, and the Rufous Scrub-bird *Atrichornis rufescens*. Among the stiff-tailed ducks (Oxyurini), e.g. in the North American Ruddy Duck *Oxyura jamaicensis*, the tail of the swimming bird may be either cocked up or extended horizontally. Other birds momentarily cock up the tail, e.g. on alighting—the familiar characteristic movement of the Blackbird *Turdus merula*. Many birds also raise the tail to a greater or lesser extent in the act of defaecation. The female's tail is usually, and that of the male sometimes, deflected laterally during copulation.

Grey Starling *Sturnus cineraceus* male at nest hole. Note support given by tail. (*Photo: Y. Shibnev*).

In many different kinds of birds there is a repeated or continual wagging, shaking, or flirting of the tail. These movements are often associated with bobbing or twitching of the whole body; indeed, the tail is in some instances not moved separately at all but merely serves to accentuate the movement of the body. The continual up and down movement of the tail in wagtails *Motacilla* spp. is familiar, and is performed while the bird is otherwise still. In the forest wagtails *Dendronanthus* spp. the tail has been described as being wagged from side to side; but here it is in fact the whole body that is continually swung, through a horizontal arc, on motionless legs. The function of such movements is not understood, but it has been remarked that the tendency seems to be especially common among birds that have their usual habitats in the neighbourhood of running water. Apart from the wagtails, one thinks at once of the 'teetering' of sandpipers of the genus *Actitis*, the similar movements of waterthrushes *Seiurus* spp. (Parulidae), and the bobbing dippers *Cinclus* spp.; and those furnariids of aquatic habits, *Cinclodes* spp., are not called 'shaketails' without reason. Yet examples among birds not particularly associated with water are not lacking; for instance, the African Pitta *Pitta angolensis*, a bird of thickets and dense woodland, constantly bobs its body and flirts its tail like a dipper.

If the tail is of any considerable size, whether it has ornamental plumes or not, it commonly plays a large part in display postures, particularly those of males in courtship performances; it is often erected, sometimes depressed, and generally spread fanwise in addition (see DISPLAY). It may also be quivered by females or young in solicitation or begging postures. For sounds made by the tail, e.g. the drumming of snipe *Gallinago* spp., see under MECHANICAL SOUNDS. TAIL COVERTS: see TOPOGRAPHY.

TAIL STREAMER: a slender elongated tail feather.

TAKAHE: *Notornis mantelli* (for family see RAIL).

TALKING BIRDS: see under MIMICRY, VOCAL.

TALON: a claw (toe), especially of a bird-of-prey and mainly used in the plural.

TAMENESS: toleration by birds of the close presence of human beings, in some instances amounting to a positive tendency to seek such presence. A substantial degree of tameness is characteristic of certain species, and this is presumably genetic. Tameness may also be acquired by individuals or communities of a species in favourable circumstances; again, however, there seems to be a genetic element, in that some species become tame much more readily than others.

An innate lack of fear of man may be shown by birds inhabiting remote islands or other relatively inaccessible places. The tameness of birds on the Galápagos Islands has been remarked on by visitors from Charles Darwin onwards. In the case of large species breeding in such places, e.g. boobies (Sulidae) and penguins, a reaction to predators of any kind, if these do not normally intrude on the nesting grounds, may be absent from the birds' psychological make-up.

On the other hand, the many species of birds that have become adapted to using houses and gardens, finding their nesting sites and feeding opportunities in the vicinity of man, show various degrees of toleration of the presence of the human beings who also live there. Similarly, the birds will follow the gardener or agricultural worker to take the food-prey that he incidentally disturbs or uncovers—much in the way that the Cattle Egret *Bubulcus ibis*, for instance, accompanies grazing mammals, domesticated or wild. So also there may be a great attendance of gulls at a fishing harbour; and so on. It is clear that there is an advantage in the association with man; and where the latter is friendly in his attitude towards the birds, tameness may become normal behaviour.

Special interest attaches, however, to the differences between species in their natural tameness or capacity to acquire tameness. In Britain, where the Robin *Erithacus rubecula* is mainly a garden bird, the species is outstanding in its capacity for familiarity with man; as has been said, it is never the Dunnock *Prunella modularis* that perches on the gardener's spade. In truly wild habitats in northern Europe, the amazing tameness of the Rednecked Phalarope *Phalaropus lobatus* and the Purple Sandpiper *Calidris maritima* contrast with the extreme wariness of some other species of 'waders' (Charadrii) breeding on the same ground. Found from the Sahara to India, the House Bunting *Emberiza striolata* is a remarkably tame bird, feeding inside houses.

There are also some interesting geographical differences in this respect within a single species, and these are not easily explicable. Thus the Robin, so tame in Britain, is a shy woodland bird over much of Continental Europe, including countries in which it is subject to no persecution. Likewise, the Moorhen *Gallinula chloropus* readily becomes accustomed to man in the populous areas of Britain and some other parts of western Europe, but is elsewhere a notably timid bird. In North America, the Florida race of the Scrub Jay *Aphelocoma coerulescens* is described as bold and confiding, and the Great Basin race is furtive and shy.

As regards tameness acquired by individuals, it was pointed out by Edward Grey (1927) that birds became tame in relation to places rather than persons; he instanced the behaviour of the same individual ducks *Anas* spp. towards the same people at different points on his lake. The present writer has had eight Speckle-fronted Weavers *Sporopipes frontalis* come unhesitatingly on his hand, outstretched with crumbs, on the verandah of a house in Tanzania that he had never visited before but where the hostess regularly fed the birds.

It is better to discount as exceptional those cases in which a human being has taken more than usual pains to win the confidence of a wild bird or birds, thus establishing something like a personal relationship (cf. L. Howard 1956). Sometimes there may even be an abnormal factor in that the bird has become conditioned to accept a certain person as a substitute mate or parent (see IMPRINTING). One has also to allow for possible differences in temperament between individual birds of the same species. Residual tameness on the part of a bird that has been released from captivity is also outside the general picture considered here.

Further, it is necessary to distinguish boldness from tameness—the urge to continue sitting on eggs, or to remain with the young, or to seize prey, is for the time being stronger than the urge to flee. That there may be little real toleration in such cases is shown by the fact that in some species the passive role can give place to an attack on the human intruder; also by the fact that an incubating bird may desert its nest permanently if its capacity for sitting tight is strained to breaking point.

Of the acquisition of tameness by a local population of a species, habituated to human presence in places where no hostile action towards birds ever occurs, there can be no better example than the Woodpigeon *Columba palumbus*—so wild and wary in the countryside, so extremely tame in the public parks of London. It was noticed that during the Second World War, when steps to keep down these birds were taken, the degree of tameness became much less; but it has since become re-established.

There are some interesting points about the tameness or otherwise of young birds, including those reared in captivity. Interpretation is difficult, however, in the absence of controlled experiments. For the question of habituation see under LEARNING.

Wild birds, like various other animals, show little fear of vehicles, and can often be approached much more easily in a motor car than on foot. The shape of the vehicle apparently evokes no predator response.

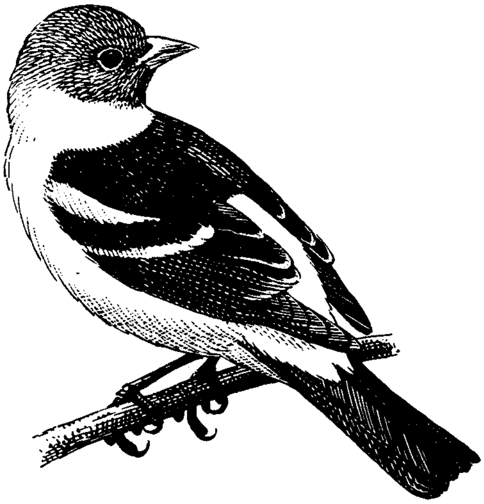
TANAGER: substantive name of species of Thraupinae and, in the plural, general term for the group—here treated as a subfamily of the Thraupidae (Passeriformes, suborder Oscines) but commonly given separate familial rank. The name comes from 'tangará' in the language of the Tupi Indians of Brazil. The tanagers are 9-primaried arboreal song-birds, confined to the Western Hemisphere (including the Antilles) and very largely to its tropical portion. Systematists now usually include in this subfamily certain genera of honeycreepers but for the present purpose it is convenient to give separate treatment to these small birds with bills and tongues highly modified for drawing nectar from flowers (see HONEYCREEPER, ORANGEQUIT). Another distinct genus, *Tersina*, which is here also included in the subfamily Thraupinae, is also given separate treatment (see SWALLOW-TANAGER). With these exclusions, the subfamily contains 54 genera and 215 species.

Characteristics. The tanagers, ranging in size from about 10 cm to (rarely) 28 cm in length, contribute more than any other family to the brilliant colour displayed by tropical American birds; although hummingbirds are more numerous in species and individuals, they are smaller and their bright metallic colours can be appreciated only in special conditions. For variety of colours and diversity of patterns, the 46 species of small tanagers of the genus *Tangara* (the largest genus) are outstanding even in this highly endowed family. One of the most gorgeous of these is the Paradise Tanager *T. chilensis*, the *siete colores* of South Americans. This 14-cm bird has the head largely golden-green. Its upper plumage is largely black, with a bright red lower back and red or yellow rump; the chin and throat are light purple; and the remaining under plumage is chiefly turquoise blue. The sexes are alike, or nearly so, as seems to be true throughout this brilliant genus, in which adults wear the same bright colours at all seasons.

The genus *Euphonia* also contains a number of small and colourful species, the 'euphonias'. Less varied in coloration than the aforementioned group, the males are mostly black, glossed with violet, blue, or green, on the upper parts and sometimes also on the throat; the forehead and more or less of the crown, and the underparts, are chiefly bright yellow. Female euphonias are usually greenish and yellowish, far duller than the males. *Ramphocelus* is a genus of larger and stouter tanagers, of which the males, but not the females, are richly coloured. The male Scarlet-rumped Tanager *Ramphocelus passerinii* of Central America is everywhere velvety black except the vivid rump, but the female is clad in shades of brown and olive. Both sexes of the widespread



Western Tanager *Piranga ludoviciana*. (*R.G.*).

Blue, or Blue-grey Tanager *Thraupis episcopus* have blue-grey body plumage with bright sky-blue wings and tails. Some races have a large white patch on each wing.

The male Summer Tanager *Piranga rubra* of southern United States is wholly red; the female, yellowish. The male of the Scarlet Tanager *P. olivacea*, which breeds in the United States and southern Canada, is brilliant scarlet with black wings and tail. It is of interest that this, the most migratory species in a generally nonmigratory family, is the only one known to undergo great seasonal changes in coloration; in the months of the northern winter, which the species spends in South America, the males are clad in greenish and yellow, much like the females. In the Western Tanager *P. ludoviciana*, which breeds on the Pacific side of temperate North America and migrates to Central America in winter, the annual changes of the males are less pronounced.

Among the less usual types of coloration in this extremely varied subfamily may be mentioned the Magpie-tanager *Cissopis leveriana*, widely distributed in South America, in which both sexes are largely white, with the whole head, upper back, and breast blue-black. The wings and the long, graduated tail of this exceptionally large tanager are black and white. Both sexes of the Orange-eared Tanager *Chlorochrysa calliparaea* of the eastern foothills of the Andes are largely brilliant metallic green, with a bright orange spot on the crown, a metallic orange patch on the rump, and a black gorget bordered with orange. By no means all tanagers are brightly coloured. The prevailing colour of the bush-tanagers of the genus *Chlorospingus* is olive-green, with white or blackish marks on the heads of some species. These plain little tanagers are found chiefly in the high mountains, where a few brilliant species also occur; but the subfamily is best represented at low and middle altitudes.

Habitat. Relatively few tanagers dwell in the dark depths of heavy forest. Many wander in mixed flocks through the upper levels of the forests and, like other treetop birds, they may forage and even nest in scattered trees and shrubbery of neighbouring clearings, plantations, and gardens. Many tanagers inhabit low, bushy growth; but only a few atypical members of the family, including the widespread Rose-breasted Thrush-tanager *Rhodinocichla rosea* and the Chat-tanager *Calyptophilus frugivorus* of Hispaniola, are primarily ground foragers.

Food. Tanagers as a whole are largely frugivorous, but probably all of them vary their diet with insects, which are sometimes captured on the wing, especially by the Summer Tanager. This species frequently tears open nests of small wasps to extract larvae and pupae. Grey-headed Tanagers *Eucometis penicillata* and some populations of *Habia* follow army ants (*Eciton*) in company with antbirds (Formicariidae), woodcreepers (Dendrocolaptidae), and many other small forest-dwellers, capturing the insects and spiders driven from concealment by the hunting ants rather than the ants themselves. The euphonias feed largely on the berries of mistletoes (Loranthaceae), the seeds of which pass through their alimentary tracts enclosed in a viscid envelope which attaches them to trees, so that these birds are important disseminators of the parasites. Tanagers are readily attracted to feeding trays where bananas and halved oranges are offered; over the years, 11 kinds have visited a single tray in southern Costa Rica.

Behaviour. Many species of tanagers remain mated throughout the year, but others travel in flocks in which pairs are not evident. In those that are constantly mated, the male sometimes feeds his partner, especially as the nesting season approaches. Nuptial feeding has been observed in species of *Tangara*, *Thraupis*, *Eucometis*, *Piranga*, *Euphonia*, and *Chlorophonia*.

Tanagers roost in trees and bushes, never in holes, as far as known; although euphonias snuggle into dense masses of moss, liverworts, or small orchids on epiphyte-laden boughs. Mated individuals rest near their partners rather than in contact with them. At times a number of pairs gather to roost in an attractive tree.

Voice. The tanagers as a whole are poorly endowed with song, and this is especially true of the most brilliant genus, *Tangara*, some of whose members are quite devoid of melody. A few species in other genera are known to have pleasing songs, among them the Scarlet Tanager, Grey-headed Tanager *Eucometis penicillata*, and the ant-tanagers of the genus *Habia*, which sing most persistently at dawn. Vocal mimicry has been reported for several species of euphonias. The poorly developed voices of many tanagers appear to be correlated with year-long pairing and weak territorial defence or absence of territoriality.

Breeding. Most tanagers build open, cup-shaped nests, high in trees, in low shrubs, rarely on the ground; no species (except the SWALLOW-TANAGER) is known to build habitually on or in the ground. The chief exceptions to this rule are the euphonias and chlorophonias, which construct covered nests with an opening in the side, embedded in moss on a trunk, in a cranny in a tree or post, or even in a tunnel in the ground. The Palm Tanager *Thraupis palmarum* builds its cup-shaped nest in a hole in a tree or other cranny. The versatile Blue Tanager may nest in an open shed, and sometimes it wrests a nest from some smaller bird and hatches its eggs and feeds its young along with those of the dispossessed builder. The nest is built by both sexes in numerous species of *Tangara*, *Thraupis*, *Eucometis*, *Euphonia*, and *Chlorophonia*; by the female alone in *Ramphocelus*, *Piranga*, and *Habia*.

Tanagers' eggs may be bright blue, blue-green, blue-grey, grey, cream, or white, and they are nearly always spotted, blotched, or scrawled with brown, lilac, or black. They are usually laid early in the morning, before or soon after sunrise, on consecutive days. The clutch consists of 2 or, more rarely, 3 eggs. Larger clutches, up to 4 or 5, are laid by the euphonias and chlorophonias, and by the migratory species of *Piranga* which breed beyond the tropics. The eggs are incubated by the female alone, who through the day takes a number of short sessions, often lasting from 20–30 min and rarely exceeding an hour. She keeps her eggs covered for about 60–80% of the daytime. Two female Blue Tanagers, attached to the same male, alternately incubated a double set of eggs. In another of the rare cases of bigamy recorded in this family, a male Red-crowned Ant-tanager *Habia rubica* had 2 mates and 2 nests simultaneously. Although there is no well-authenticated instance of incubation by a male tanager, he is actually attentive to his mate, sometimes bringing her food, or else, as in *Rhamphocelus*, presenting it to the eggs while she is absent, seeming thereby to anticipate the hatching of the nestlings. Recorded incubation periods of species with open nests range from 12–14 (rarely 15) days; but in the closed nests of euphonias they are often 16–18 days.

The nestlings hatch with tightly closed eyes and sparse (very sparse in *Euphonia*), loose down. The interior of the mouth is red. Brooded by the female only, they are fed by both parents, the chief known exceptions to this rule being certain nests of the Scarlet-rumped Tanager and the related Silver-beaked Tanager *Rhamphocelus carbo*, in which females are more numerous than males, with the result that some of the former rear their young without a mate's help. Food is brought to the nest in the parent's bill or mouth, except in the euphonias and chlorophonias, which regurgitate to the nestlings. Droppings are swallowed or carried away in the bill, and the nest is kept clean.

Juvenile or adult nest helpers have been found in a number of species. Immature Red-throated Ant-tanagers *Habia gutturalis* feed nestlings, probably their younger siblings, and they may even help to build. Likewise, first-brood young of the Golden-masked Tanager *Tangara larvata*, still in immature plumage, may help to feed a later brood of the same season. In this and several related species (e.g. Plain-coloured Tanager *T. inornata*, Speckled Tanager *T. guttata*, and Turquoise

Tanager *T. mexicana*) 3 to 5 individuals in adult plumage sometimes attend 1 or 2 young. At least 3 of a group of 7 apparently adult Dusky-faced Tanagers *Mitrospingus cassinii* fed 2 nestlings.

The nestling period varies in an interesting manner according to the form and site of the nest. It is shortest, 10 (rarely 8–9) to 13 days, in species that build low, open nests, including *Rhamphocelus*, *Eucometis*, and *Habia*. In the higher, open nests of *Tangara* and *Thraupis* it is longer, 14–20 days. In the covered, often high nests of *Euphonia* and *Chlorophonia* it is longest, 17–24 days. Tanagers scarcely ever give distraction displays when their nests or young are, or appear to be, in danger; but such displays have been witnessed in the ant-tanagers *Habia* spp. Euphonias and chlorophonias may take more than a year to acquire adult plumage, and the males sometimes breed in transitional attire. Many species of tanagers have more than one brood. A.F.S.

TANAGER, SWALLOW: see SWALLOW-TANAGER.

TAPACULO: substantive name of some species of Rhinocryptidae (Passeriformes, suborder Deutero-Oscines, infraorder Furnarii); in the plural, general term for the family. This group of less than 30 species is considered to be related to the antbirds (Formicariidae).

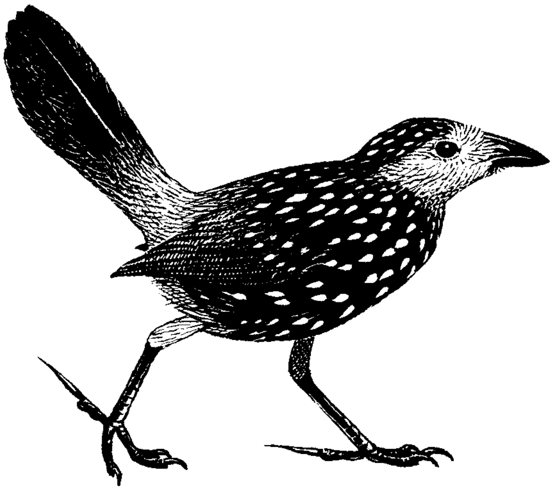
Characteristics, habitat and distribution. Tapaculos are ground-dwelling birds of South and Central America, from about the size of a wren *Troglodytes* sp. to that of a thrush *Turdus* sp. (12–25 cm in length). One of the special morphological characteristics of the tapaculos is a large movable flap (operculum) which covers the nostril completely and gave rise to the name currently used for the family (previously called Pteroptochidae). Another structural characteristic is that the back edge of the sternum (metasternum) has 4 notches.

The legs are long, indicating that locomotion is almost solely by them. Some species have strikingly large and strong feet that serve well for scratching on the ground. They move more by running than by hopping. They fly very little; their wings are short and rounded. Many species (*Scytalopus*) have a short tail, others have a strikingly long one (*Merulaxis*, *Psilorhampus*). The tail is always soft and therefore not very helpful to steering in flight. One of the special characteristics of the tapaculos is that they cock up their tails when they get excited, which is particularly impressive with the long-tailed species; in this respect they resemble the wrens (Troglodytidae), to which they have other similarities. It is this characteristic that has given them the name 'tapaculo', from the Spanish.

The tapaculos are usually dark, some species (certain *Scytalopus* spp.) being almost uniformly black; these birds spend their life hidden in dark thickets. Other species like the Barrancolino *Teledromas fuscus*, which live in the dry bush pampas, have a light colouring like that of larks, in keeping with the light-coloured surroundings in which they live. In this they resemble certain ovenbirds (Furnariidae), with which they share this habitat. Males and females are often coloured alike (e.g. *Liosceles thoracicus*), but sometimes not (e.g. *Merulaxis* spp.).

Food. The food consists mostly of insects, including larvae, and spiders; in some cases stomach contents have been found to include fibres and seeds.

Voice. It is as easy to hear the tapaculos as it is difficult to see them. Their song consists of more or less continuous monotonous calls. These are rather rough, as with *Scytalopus* spp., or melodious (e.g. the turcos *Pteroptochos* spp.); certain species produce a strikingly pure scale, going up or down (*Merulaxis ater*). The females also sing. Frequently the voice, like that of a ventriloquist, is hard to localize. They have sharp monosyllabic call-notes for attracting and warning.



Ocellated Tapaculo *Acropternis orthonyx*. (*P.J.K.B.*).

Breeding. The tapaculos build their nests on the ground, sometimes in burrows which they dig (e.g. *Scelorchilus* spp.), or in hollow trees (*Pteroptochos* spp.). There are some species (*Eugralla paradoxa*) that build a ball-shaped nest, with a side opening, in thickets about 1 m from the ground. For building material, the birds use moss, twigs, and so on. The 2–4 eggs are relatively large and uniformly white, although they get quite dirty at times and then appear to be spotted. Both parents share in incubation and raising the young.

Systematic characteristics. There are 12 genera with 28 species from Costa Rica to Patagonia. Half of the genera are monotypic. Chile, with 8 species, has particularly many tapaculos. On the western coast of South America they occur from sea level to an altitude of 4,000 m.

The Huet-huet *Pteroptochos tarnii* has the upper parts and foreneck very dark brown; crown, rump, and belly dark rust-coloured, partly with black bars. It is about 23 cm long and lives like a rail in the heavy underbrush of the forests of Chile and western Argentina, where it is well known because of its loud call; it sounds like *wed-wed-wed*, hence Huet-huet. They have other striking calls also. The nest is in a burrow as much as 50 cm deep, or in a hollow tree-trunk as much as several metres above the ground. Egg measurements are 37 × 29 mm.

The Grey Gallito *Rhinocrypta lanceolata* has a crested head, rust-coloured with white shaft-stripes; the upper parts are greyish olive, the under parts grey, the middle of the belly is white, and the flanks are chestnut. The length is about 20 cm. It is a common inhabitant of some dry grassy and bush-covered plains of Argentina, where it runs about rapidly with crest erect and tail cocked above the back, resembling a tiny domestic fowl (hence its name). It utters chirping calls and builds a large covered nest in thorny thickets.

The male of the White-breasted Babbler *Scytalopus indigoticus* is coloured like a Dipper *Cinclus cinclus*, but is much smaller (length about 10 cm). The female is more dully coloured. The birds live completely hidden in the thickest brush of eastern Brazil, where they move about like mice without making a sound. The song resembles that of the antshrikes *Thamnophilus* spp., consisting of a series of scratchy syllables, gradually gaining in speed. The nest is built on the ground. H.S.

TARGET TISSUE: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

TARSAL: name of the bones of the 'ankle' (intertarsal joint), the proximal row in birds being fused in the tibiotarsus and the distal row in the tarsometatarsus (see SKELETON, POST-CRANIAL; and LEG).

TARSOMETATARSUS: the bone of the part of the leg commonly spoken of as the 'tarsus', in birds formed by a fusion of tarsal and metatarsal elements (see SKELETON, POST-CRANIAL; and LEG).

TARSUS: see above.

TASTE: the sensory receptors for taste are located in taste buds and the buds consist of a well-defined group of cells in the oral epithelium often associated with the excretory openings of the salivary glands. At the base of the taste bud there is a nerve plexus which gives rise to the fine fibres entering the bud. The shape of the taste buds and the nature of the cells within the bud differ in different bird species. The taste buds consist of a discrete group of modified epithelial cells ovoid in shape with long spindle-shaped receptor cells in the centre in some species (e.g. Mallard *Anas platyrhynchos*) whereas in other species (e.g. Chicken *Gallus*) the receptor cells are conical in shape. The base and sides of the receptor cells are protected by follicular cells which are continuous with the germinal layer of the epithelium. At the top of the bud there is an outer pore which connects the bud to the surface of the mouth. In comparison with mammals, birds have relatively few taste buds (Man, 9,000; Rabbit, 17,000; Hamster, 723; Rat, 1,265; Chicken, 340; Parrot Psittacidae, 350; Mallard, 375) and in many species (e.g. Chicken and Mallard) the majority of taste buds are not in the tongue but in the palate and oral mucosa of the sides of the lower jaw. The taste buds relay gustatory information to the brain in both the glossopharyngeal and facial nerves. Taste buds in the tongue and pharynx are innervated by the lingual and laryngo–lingual branches of the glossopharyngeal nerve and those in the more anterior parts of the mouth by the facial nerve.

Taste sensitivity of birds has been investigated using a number of different techniques. The nature and concentration of chemical solutions the taste receptors are able to detect can be assessed by recording the electrical activity in the nerves which serve the taste buds. Kadono *et al* (1966) showed in the chicken the following response thresholds: sodium chloride 0.025 Molar (m), sucrose 0.125 m, quinine hydrochloride 0.01 m. Responses have been obtained with 0.1 m acetic acid, 0.05 m citric acid and 0.01 m hydrochloric acid. Another electrophysiological method of measuring taste sensitivity is to record the gross electrical activity of the brain surface, the electroencephalogram (Gentle 1975). This provides a measure of sensitivity which is intermediate between the receptor threshold and behavioural measures and may provide a measure of perceived sensitivity. Using this technique, a clear response was obtained with 0.05 m acetic acid, half the concentration which gave a clear response using recordings from the lingual nerves.

Behavioural techniques have also been used to measure taste sensitivity. Mariotti and Fiore (1980) used an operant conditioning technique and have shown discrimination thresholds of 0.034 m sodium chloride solution and as little as 0.005 m for potassium hydrogen carbonate. Oral behaviour has been used successfully (Vince 1977) to measure taste sensitivity in the embryo of the domestic fowl. The number of beak claps shown by the embryo following oral stimulation was used to measure the response to hydrochloric acid, fructose, sodium chloride and quinine hydrochloride at least 2 days prior to hatching.

The preference or aversion shown by birds to a variety of chemical solutions has been investigated using behavioural technique. In some experiments the birds were offered a choice between the test solution and water whereas in other experiments, following a period of water deprivation, they were given either water or the test solution. In both of these experiments it is the amount of fluid drunk which gives a measure of preference. In many species of birds (e.g. Great Tit *Parus major*, House Finches *Carpodacus mexicanus*, pigeon *Columba*, chicken) salt solutions tend to be selected indifferently at low concentrations and rejected at higher concentrations. Some individual chickens have been observed to show a preference for 0.1 m sodium chloride over water and a marked preference for this solution is seen in the pigeon and bantam (Duncan 1962). Herring Gulls *Larus argentatus* have been observed to drink sea water (sea water approximately 0.5 m sodium chloride). Many birds will tolerate a wide range of acidity in their drinking water and Bobwhite Quail *Colinus virginianus* show a preference for sour stimuli. Domestic fowl chicks will tolerate strong mineral acids of pH 2 but in general chickens and pigeons show a pattern of indifference to low concentrations and aversion to higher concentrations. Pigeons show a significant rejection of hydrochloric acid at 0.0075 m and acetic acid at 0.01 m which are comparable in value to 0.005 m acetic acid solution that only just tastes sour to humans. Quail *Coturnix*, Great Tits, chicken and pigeon all reject substances which taste bitter to man, e.g. quinine hydrochloride, sucrose octoacetate. The chicken will reject quinine hydrochloride at a concentration of 0.001 m. The response of birds to sweet solutions is complex. Preferences for some concentrations of sugar solutions are shown by Bobwhite Quail, Great Tit, pigeon, chicken, parrots, Budgerigars *Melopsittacus undulatus* and Broad-tailed Hummingbirds *Selasphorus platycercus*. With regard to hummingbirds it is interesting to note that the nectar of most flowers in Arizona is composed of sucrose, glucose and/or fructose. Indifference to sucrose has been reported in many species including the Herring Gull, Starling *Sturnus vulgaris*, goose *Anser*, Siskin *Carduelis spinus* and Laughing Gull *Larus atricilla* (Kare 1965).

The diet of birds provides a complex mixture of gustatory stimuli which react together. Chickens reject a 10% glucose solution in preference to water (39% preference) as well as a 0.3 m solution of acetic acid (24% preference) whereas a mixture of these solutions results in an intermediate preference value (35.6%). The addition of sodium chloride may make a sucrose stimulus more discriminable to Red-winged Blackbirds *Agelaius phoeniceus*.

The preference or aversion birds show to a gustatory stimulus can be altered by their nutritional state. Short periods of water deprivation (as little as 6 h) significantly reduces the aversion shown by chickens to quinine hydrochloride solutions (Gentle 1976). Work by Hughes and Wood-Gush (1971) showed that chickens fed on a calcium-deficient diet developed a specific appetite for calcium which could occur using gustatory cues. Changes in taste preference for sucrose have been shown to occur in chickens fed a low-energy diet (Kare and Maller 1967). Chickens fed on an energy-sufficient diet show no preference for 10% sucrose solutions but, when fed a diet low in energy, rapidly show a preference for this sucrose solution.

The importance of the sense of taste to different avian species is difficult to assess and much more experimental work is needed on a wider variety of species. The distribution of taste buds in the mouth of the Mallard is directly related to the food pathway in the mouth and would allow the bird to monitor constantly the palatability of the food (Berkhoudt 1977). Birds rapidly learn to avoid unpalatable substances in laboratory experiments, e.g. unpalatable insects (Brower 1969). It has been proposed that taste plays a important role in the development of the system that controls food intake in domestic chicks (Hogan 1977). During the first few days after hatching the chick learns to associate ingestive consequences with the events that precede them and chains of associations are built up until gustatory cues present during ingestion become secondary reinforcers. TATTLER: substantive name of *Heteroscelus* spp. (see SANDPIPER).

TAUTONYMY: the application of one and the same name to a genus and to an included species (see NAME, SCIENTIFIC; NOMINOTYPICAL).

TAXA: plural of TAXON.

TAXIDERMY: the preparation and preserving of stuffed specimens of vertebrate animals.

TAXIS: movement directly towards or away from a source of stimulation; or 'locomotory behaviour involving a steering reaction' (compare KINESIS (2); and see FIXED ACTION PATTERN).

TAXON: general term (plural 'taxa') for any category used in classification, or any particular example of such a category (see CLASSIFICATION; NOMENCLATURE). The fundamental taxon is the species, which represents a real biological entity; this category can be defined generally in objective terms (see SPECIES), even although there is sometimes practical difficulty in applying the definition. All other taxa are either subdivisions of the species or groupings of species—concepts that cannot be defined except in terms involving subjective judgments. In many cases a subspecies may represent an objective reality, e.g. a distinctive form constituting an isolated population (possibly a species in the making—see SPECIATION); but the category in general cannot be defined in such terms. All supraspecific categories are theoretical, representing human ideas of degrees of evolutionary relationship among different species; that these ideas can sometimes be held with substantial confidence does not alter the principle.

The categories used by Linnaeus were 'classis', 'ordo', 'genus', 'species', and 'varietas'. Of these, class and species remain much as they were; order and genus are in practice applied more narrowly, and instances are thus more numerous; while varietas was rather a different concept from the subspecies or geographical race of modern taxonomists. Between order and genus the family has been added, and this taxon has acquired particular importance.

The primary taxa are thus now class, order, family, genus, species, and subspecies. The convention is that every species must be placed in a genus, family, order, and class, even if it be unique at any or all of these levels. A species may or may not be divisible into subspecific forms, i.e. it may be monotypic or polytypic.

Between these primary levels, when it is considered that relationships can be expressed in a more elaborate hierarchical system, secondary categories may be interpolated at will. Thus one may have subclass and superorder, suborder and superfamily, subfamily and tribe, subgenus and superspecies. These are, however, used only as required; it would be pedantic to name, say, a subfamily that would be the only one in its family.

The International Code of Zoological Nomenclature does not deal with any taxa higher than the superfamily (owing to a lack of general agreement); and it does not recognize, for nomenclatural purposes, any categories below the genus except subgenus, species, and subspecies. Only generic and specific names have operative significance in the nomenclature of species, with subspecific names in addition where subspecies are recognized and it is desired to refer to one separately by using a trinomen (see NOMENCLATURE).

For separate categories see CLASS; FAMILY; GENUS; ORDER; SPECIES; SUBSPECIES; also SUPERSPECIES.

TAXON CYCLE: a cyclical evolutionary sequence of expanding and contracting range, associated with diversification and specialization, postulated to account for patterns in the distribution and ecology of species. The concept has been used in analysis of the West Indian avifauna, but has been seriously called into question (Pregill and Olson 1981).

Pregill, G.K. & Olson, S.L. 1981. Zoogeography of West Indian vertebrates in relation to Pleistocene climatic cycles. Rev. Ecol. Syst. 12: 75–98.

Wilson, E.O. 1961. The nature of the taxon cycle in the Melanesian ant fauna. Amer. Nat. 95: 169–193.

TAXONOMY: orderly arrangement—the science of classification; the term is often used synonymously with 'systematics', of which study taxonomy, with nomenclature as its tool, certainly forms a large part (see CLASSIFICATION; NOMENCLATURE; SYSTEMATICS). The three phases of systematic work, defined in the article thereon, have been called 'alpha, beta, and gamma taxonomy'.

Discrimination. The taxonomist's first problem is one of discrimination; he must separate and define the forms under study, and then determine the status of each. At this stage he is concerned primarily with the question of species; he has to assign the available material to particular species, and determine the distinctness of each of these in accordance with the objective definition of that category (see SPECIES). Sometimes this may be done on morphological grounds alone, where differences are substantial and clear-cut. Very often it will be possible only with the aid of adequate data on distribution and reproductive isolation. Where such data are lacking, the decision may have to be empirical—and therefore provisional. Even if there is apparent reproductive isolation, there may be no evidence as to whether it is purely geographical (with potentiality of full interbreeding) or constitutional (see SPECIATION).

Secondarily he is concerned with differences between and within populations of a species. There may be a number of allopatric forms sufficiently distinct to be regarded as subspecies (see SUBSPECIES); or a continuous geographical grading of characters (see CLINE); or a collection of sympatric 'morphs' or phases (see POLYMORPHISM); or, again, no more than the individual variation that is never absent. In all this, of course, account has to be taken of differences that are related solely to sex, age, or season.

Phylogeny. The taxonomist's second problem is that of classification, based on his estimate of probable phyletic relationships. For this purpose he requires different criteria; whereas for discrimination it is both convenient and proper to use readily visible characters, provided that they are not too variable, it now becomes necessary to consider what characters are fundamental rather than superficial. This question becomes increasingly important the higher the taxonomic category that is being considered—what shared characters can be regarded as primitive and so probably derived from a common ancestor? Here one must remember that a character is not necessarily primitive merely because it appears to be simple.

Much earlier work on these lines went astray through lack of appreciation of the effects of adaptive convergence; it is now realized that this may produce most striking similarities between species that are only distantly related (see CONVERGENCE). Sometimes the adaptation to a similar mode of life may lead to resemblance in a whole 'constellation of characters', which if reckoned separately might appear to establish a very strong case for relationship. There is the further point that some differences between species, without being fundamental, may not be directly (or at least obviously) adaptive; they may be by-products of the gene pattern, linked constitutionally with characters having adaptive value for natural selection (see GENETICS; NATURAL SELECTION).

Taxonomic characters. Towards the solution of these problems, the taxonomist has an increasing variety of criteria. General characters of external morphology remain predominant, as they are the most readily described and the most convenient to preserve for record in the museum specimen. In dealing with the more distant relationships, involving the higher taxonomic categories, greater recourse will be had to internal anatomy, and here osteological characters are particularly convenient. Research may, however, have to extend as far as cytological and embryological characters, or invoke laboratory tests for physiological differences such as in the chemical composition of the tissues (see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA).

The trend, however, is not all towards the laboratory. Increasing taxonomic use is made of characters of the living bird observed in the field. Knowledge of geographical range is in any event essential. Among the ecological factors, parasites may be particularly helpful, in that their own phylogeny may be parallel to that of their hosts (see ECTOPARASITE). In the ethological sphere, behaviour related to sex (song, display) is of special importance owing to the part that it plays in the crucial matter of reproductive isolation. A.L.T.

TAYLOR-BIRD: substantive name of *Orthotomus* spp. (see WARBLER (1)).

TCHAGRA: substantive name of *Tchagra* spp. (see SHRIKE).

TEAL: substantive name (unchanged in plural) of various small species of duck, properly of some in the genus *Anas* (used without qualification in Britain for *A. crecca*) but also applied to others (see DUCK).

TECTRIX: (plural 'tectrices') a covert, i.e. one of the feathers fulfilling the function of upper or lower wing coverts or tail coverts (see TAIL; WING).

TEETH: (plural of 'tooth'), not found in recent birds, even as embryonic rudiments. Teeth of reptilian type were, however, characteristic of earlier forms (see ARCHAEOPTERYX; FOSSIL BIRDS). In the modern bird the place of teeth is taken by the cutting edges (tomia) of the horny mandibles; and in some groups there are also ridges or papillae, which may even be partly calcified (see BILL). For another structure, in no sense truly dental, see EGG-TOOTH.

TELEMETRY: see RADIO TRACKING AND BIOTELEMETRY.

TELEOPTILE: term applied to plumage subsequent to (and especially that immediately following) the 'neossoptile' or natal down plumage, if any (see PLUMAGE).

TEMPERATURE, BODY: see GROWTH; HEAT REGULATION; TORPIDITY; also INCUBATION; MEGAPODE.

TENDON: see under MUSCULATURE.

TERN: substantive name of most species of the family Sternidae (Charadriiformes, suborder Lari); in the plural, general term for the family. The group is treated as a tribe of the Larinae (see GULL) by some authors including Moynihan (1959). The other substantive name used is 'noddy' for one genus. Some terns, like the Caspian Tern *Hydroprogne caspia*, the biggest representative, and Gull-billed Tern *Gelochelidon nilotica*, are conspicuously gull-like. Skimmers (Family Rynchopidae) are also close relatives, bearing most resemblance to one monotypic genus, the Large-billed Tern *Phaetusa simplex*.

General and systematic characteristics. Terns and noddies comprise 42 medium-sized species (20–56 cm). The sexes are alike throughout. Most (22 species) belong to the 'black-capped' *Sterna* group which, with long pointed wings, deeply forked tail, light build, and graceful, buoyant flight has earned the common name 'sea swallows'. The best known Palearctic representatives are the Common Tern *S. hirundo* and Arctic Tern *S. paradisaea*. With the exception of 3 'brown-winged' species, the typical plumage is white below, grey mantle and upper wings, with a black crown in breeding dress. Out of the breeding season, obvious changes are the whitening of the forehead, and darkening of bill and leg colour where yellow-red in the breeding season. The black cap is smooth in *Sterna* spp., but partly erectile in the *Thalasseus* group ('crested terns', 7 species), represented in Europe by the Sandwich Tern *S. sandvicensis*. The generic separation of *Thalasseus* from *Sterna* is by no means widely recognized, but is finding increasing favour on various behavioural grounds. The classic foraging technique of *Sterna* spp. and their close allies is plunge-diving head first into water from a height to seize small fish in the slender, tapering bill. Immersion is brief, with no propulsion underwater other than initial impact. Accomplished hovering in some species facilitates hunting. The feet are webbed, with the hallux vestigial. 'Marsh terns' (*Chlidonias*, 4 spp.) of which the Black Tern *C. niger* is the most familiar, and noddies (3 *Anous* spp., 1 *Procelsterna*), are distinguished from *Sterna* spp. by behaviour and morphology, both showing varying degrees of darker plumage. With all dark-brown bodies and whitish caps, the *Anous* spp. are virtually the 'negative' colour scheme of the *Sterna*/*Thalasseus* group, while their tails are wedge-shaped. Sometimes called White Noddy, the singular White (or Fairy) Tern *Gygis alba* has pure white plumage all over. Strikingly aberrant is the Inca Tern *Larosterna inca* of South America with slate-blue plumage, yellow fleshy wattles at the gape, and a white 'handlebar' moustachial plume near each eye.

Habitat and distribution. Terns and noddies enjoy world-wide distribution, from the Arctic to the Antarctic. Some, like the Little Tern *S. albifrons*, Roseate Tern *S. dougallii*, Caspian and Gull-billed Terns are, indeed, among the most cosmopolitan of all seabirds. Marsh terns, as implied, are (with the exception of the Black Tern in winter) largely independent of the sea, inhabiting freshwater marshes, lakes, and rivers right into the heart of continental land masses. Terns of the black-capped *Sterna*/*Thalasseus* group, embracing all except the highest latitudes, are essentially inshore species, favouring coastal waters, estuaries, rivers, and large inland water bodies. By contrast, the brown-winged *Sterna* spp. forage offshore in tropical and subtropical waters; among them, the Sooty Tern *S. fuscata* is the most pelagic of all terns, exploiting rich upwellings and narrow fronts often hundreds of kilometres offshore, even in the breeding season. Although also tropical and subtropical maritime terns, the noddies do not generally range so far offshore.

Populations. Total numbers vary enormously from species to species. Environmental pressures have reduced some to dangerously low levels, especially locally. According to the annual RSPB Tern Survey, Britain and Ireland supported about 2,000 pairs of Little Terns, while the total European population of Roseate Terns is only 550 pairs. Again, the Damara Tern *S. balaenarum*, endemic to southern Africa, has been reduced to 3,000 birds. By contrast, widely distributed pelagic species can number tens of millions, even locally, e.g. the Christmas Island (Pacific) population alone of Sooty Terns has been estimated at 14 million birds.

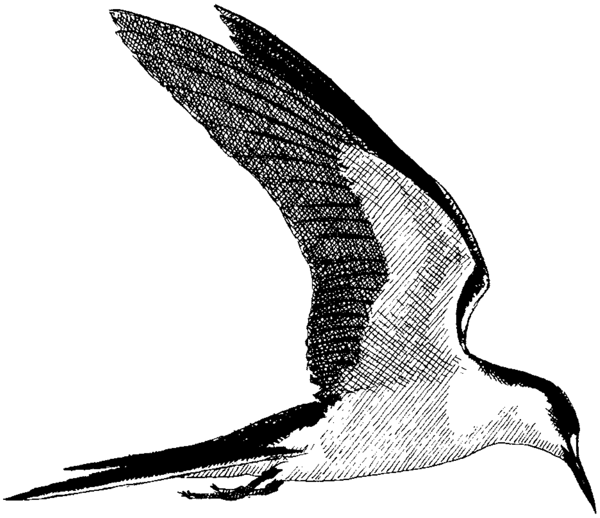
Movements. Most terns are migratory to varying degrees. The Arctic Tern is the most wide-ranging migrant known: those breeding north of the Arctic circle up to 82°N and wintering in Antarctic waters must cover a minimum of 12,800 km each way, while the round trip for some, deviating to exploit latitudinal wind belts, must entail 35,000 km. *Sterna*, *Thalasseus*, and *Chlidonias* species breeding in temperate latitudes migrate to the tropics outside the breeding season, seeking the coasts of Africa, Central and South America, India, or Australasia, depending on the longitudinal breeding range of the population. The vast majority migrate by sea though overland movements are undertaken by marsh terns, and even some marine terns. Prior to the southward migration, a post-fledging dispersal of juveniles and their parents from the natal colony has been shown for Sandwich, Common and Arctic Terns in the Northern Hemisphere, perhaps in response to local competition for food, or to exploit traditional post-breeding feeding grounds. Lateral migration is known for species confined to tropical and subtropical regions; juvenile Sooty Terns from the Dry Tortugas, Florida, cross the Atlantic to the Gulf of Guinea, and Seychelles juveniles likewise disperse east as far as Australasia. Moult of terns is typically arrested during migration; primaries are often moulted in 'periodic stepwise' fashion, which allows rapid replacement without impairing flying ability.

Food. The diet of marine terns is mainly fish, squid and crustaceans, the latter especially in polar regions, occasionally supplemented by pelagic molluscs and worms. Gull-billed Terns also feed on small terrestrial vertebrates, and insects hawked in the air, or plucked on the wing from the water surface; marsh terns likewise take insects, also small fish, frogs, tadpoles and leeches. Tropical terns are strongly, sometimes wholly, dependent on the actions of predatory fish, tuna especially, which send shoals of prey fleeing to the surface to be caught by dipping, or even in the air. Here noddies often use their feet for pattering, storm petrel style, and Common Noddies *Anous stolidus* are known to settle on the water surface and dabble. Most terns are diurnal feeders, though night feeding has been recorded in the tropics (Sooty Terns and even Palearctic terns), especially in moonlight. Birds far offshore may roost briefly on the water, but sustained flight for long periods is apparently feasible too. Prey for young are brought back crosswise in the bill by most terns, but regurgitated by noddies and 'brown-winged' terns.

Behaviour. Terns are highly gregarious, assembling to feed, roost, breed, and boldly mob predators at the colony. Essentially monogamous, pair bonds tend to persist from year to year. Breeding may begin as early as 2 years old, but commonly not till 3 or 4 in Palearctic sea terns, later in tropical terns if the Sooty Tern (4–9 years, average 6) is typical. Longevity is considerable, with up to 30 years or more recorded. Colonial breeding is normal, nesting densities varying with species and habitat. Colonies can number tens of thousands and inter-nest distance can be a mere bodylength in *Thalasseus* spp. Nesting territories serve the ground phase of courtship and pair formation, courtship feeding, copulation, nesting, and concealment and location of young. Nest-site fidelity between years is high in some species, though *Thalasseus* spp. are prone to shift the colony site altogether. Early courtship involves an elaborate climbing and gliding aerial display, ground courtship often a circling parade of partners.

Voice. Terns are highly vocal, noisy birds. The repertoire is based on harsh, clipped and drawn-out cries, or softer mewing and 'gurring' notes, serving territorial advertisement, aggression, and contact, among others. Fledged young generally have high-pitched, whistling begging notes.

Breeding. Usually seasonal, and annual, though some tropical terns breed at sub-annual intervals, with nesting usually continuous in the population as a whole. In a few cases, however, sub-annual synchronous breeding occurs, notably in Bridled Terns *Sterna anaethetus* and the highly adaptable Sooty Tern, which exhibits breeding intervals varying from 6, through 9–10 to 12 months, depending on local conditions. The nesting area is usually a flat, open piece of ground, often an island, sandy



Sooty Tern *Sterna fuscata*. (*B.P.*).

headland, shingle bed, or marsh, remote from disturbance. Noddies, however, nest on trees, bushes, and cliffs while Inca Terns, and sometimes Roseate Terns, are burrow-nesters. Noddies and marsh terns build a reasonable platform of vegetation; ground-nesting terns at best only a thinly-lined scrape, while the White (Fairy) Tern lays its single egg on the bare branch or leaf of a tree or on coral boulders and cliffs, the chick having well-developed claws for anchorage. Both sexes of terns share nesting duties from the outset. The normal clutch of usually cryptic blotched-olive eggs varies from 1 in tropical to 2–3 in higher latitudes, and incubation lasts 3–4 weeks. Downy at hatching, chicks are semi-precocial in ground nesters, occasionally crèching when older in *Thalasseus* and some *Sterna* spp. The fledging period varies from 1–2 months, but parental care (feeding) continues, sometimes for several months, and on into the winter quarters, while the young learn self maintenance.

TERNLET: name sometimes applied to the smaller noddies *Anous* spp. (see TERN).

TERRITORY: a defended area. The area occupied by an individual, a pair or a group of birds is referred to as a HOME RANGE. When this area is defended against other individuals, usually of the same species, it is called a territory. Territories are occupied in a wide variety of contexts whenever scarce resources, such as space, food or mates, are economically defendable.

Some territories provide all the resources that a bird needs; for example Tawny Owls *Strix aluco* occupy a fixed territory for the whole of their adult lives. Other territories may simply consist of a nest site (e.g. some seabirds) or a food supply (nectar-feeding birds). Many territories are fixed in space but they may also be mobile as when some birds, such as warblers, just defend the bushes in which they are foraging at the time.

The three main types of benefit from territorial defence are food, mates and predator avoidance.

Feeding territories. There have been few precise quantitative studies of the costs and benefits of the defence of a food supply. Many species have smaller territories where their food supply is more dense. Hummingbirds and sunbirds feed on nectar and although the size of their territories varies by several hundredfold, each contains approximately the same number of flowers. It can be calculated that the nectar production from this number of flowers is just sufficient to support an individual's daily energy requirements.

Many species vary their defence strategies depending on the food supply. When food levels become very high, intruder pressure increases and an owner may give up defence of the territory. At the opposite extreme, the food level may become so low that, even with territoriality, a bird is unable to meet its energy requirements and so it abandons the territory. Therefore, there is an upper and a lower threshold for economical defence.

Mating territories. In some species males defend territories to which females are attracted for mating. The territories may contain vital resources which the females require, such as food or nest sites. If the resources are patchy in distribution, then some males may be able to defend better-quality territories than others, and therefore achieve greater reproductive success (see POLYGAMY).

For example male Orange-rumped Honeyguides *Indicator xanthonotus* defend bees' nests. Females visit the bees' nests to feed on the wax and the males copulate with them on the territory. Males with the best food supplies get the most copulations. Similarly, male hummingbirds that defend the best nectar supplies attract the most females. Males of these species in effect trade food for sex.

In other species males defend potential nest sites. Polygyny may occur if the differences among male territories are so great that females do better by pairing with an already mated male on a good-quality territory rather than with a bachelor male on a poor one. In the Red-winged Blackbird *Agelaius phoeniceus* certain types of vegetation provide safer nest sites from predators, and hence result in greater fledging success. Males whose territories contain the most of this suitable vegetation attract the most females. In the Lark Bunting *Calamospiza melanocorys*, one of the major factors responsible for nestling mortality is exposure to the heat of the sun. Males defending territories with the most amount of shade may attract two mates while those with exposed territories fail to attract any females.

Not all mating territories contain resources. In some cases the males aggregate at traditional, communal display areas, or leks, where they defend patches of ground and compete for dominance status. The territories on a LEK may just be tiny bare areas no more than a metre across, but they are vigorously defended against other males. Females only visit the leks in order to mate. After copulating they leave to lay their eggs elsewhere. In all the leks that have been studied, almost all of the copulations are performed by a few males, usually those who are defending the central territories. For example, in a study of the White-bearded Manakin *Manacus manacus* where there were 10 males on a lek, over 70% of the copulations were performed by one male. Similarly, in a study of the Sage Grouse *Centrocercus urophasianus*, on a lek of 14 males, over 80% of the copulations were achieved by the 3 central males.

The most successful males on a lek are usually the older males. Young birds remain on peripheral territories and move into more central locations as vacancies arise. In the Ruff *Philomachus pugnax* there appear to be at least two different strategies on the lek. Resident males, which have dark head tufts and usually dark ruffs as well, defend territories, while satellite males, which have white tufts and ruffs, adopt the sneaky strategy of attempting to steal copulations while the residents are busy chasing off intruders.

It is likely that, with more detailed observations of individuals in marked populations, many more examples will be discovered where males employ various strategies to compete for food or mates. In some sparrows *Zonotrichia*, as well as the conspicuous territory holders, there appears to be an 'underworld' of roaming individuals.

So far, it has proved difficult to measure the reproductive success of males who employ different strategies. For example, even if territory owners in the centre of a lek enjoy the greatest mating success in any one season, this does not necessarily mean that over a whole lifetime they are the most successful. Non-territorial males may copulate less each season but live for longer because they do not incur the high costs of territory defence.

Territories and predation. By defending a territory and thereby spacing out a nest site from those of neighbours, predation may be reduced. Nests of the Great Tit *Parus major* that are spaced furthest from their nearest neighbours suffer least predation by Weasels *Mustela nivalis*. Gull nests in large territories are less likely to be plundered by predatory crows or cannibalized by other conspecifics. The reason that closely-spaced nests suffer greater predation is that whenever predators are successful in finding a nest, they intensify their search in the immediate vicinity.

When adults actively defend their nest sites, then the opposite situation may occur; pairs with small territories in dense colonies may suffer least predation because closely packed adults form a more effective means of defence (e.g. Guillemots *Uria aalge*).

Interspecific territoriality. Birds usually defend their territories only against members of the same species; this makes sense because other species usually exploit different resources and defence against them would entail costs for little resulting benefit. However, sometimes it pays to defend against other species. For example, two species that nest in similar places may defend mutually exclusive territories, perhaps because a predator could be searching for the nests of both species at the same time (e.g. Reed Warblers *Acrocephalus scirpaceus* and Sedge Warblers *A. schoenobaenus* in some habitats).

Interspecific territoriality may also occur where several species are exploiting the same food supply. In winter, Pied Wagtails *Motacilla alba* not only evict conspecifics from their feeding territories but also other insectivores including Grey Wagtails *Motacilla cinerea* and Meadow Pipits *Anthus pratensis*. Sometimes nectar-feeding birds may even evict bumblebees from their patches of flowers.

Group territoriality. Sometimes a territory is defended by a group, especially in those species where young from previous broods remain on the territory for several years (see CO-OPERATIVE BREEDING). Group territorial behaviour may occur where adult survival is high and suitable habitat is fully occupied, so that it pays the young to stay longer on their natal territory. The young may help to defend the territory as a 'payment' for the right to remain. In other species, unrelated birds may share a territory. For example, winter 'pairs' have been reported in Blackbirds *Turdus merula* and Pied Wagtails. These pairs are not concerned with breeding: they probably form simply because economical defence of a territory is only possible if the defence is shared between two birds.

Mechanisms of territorial defence. There is a three-tier system of defence in song birds. Song may act as a long-range signal that deters potential trespassers; visual displays are used to repel actual trespassers and then, if an intruder persists, it is chased and attacked. Experiments have investigated the role of DISPLAYS in territorial defence. Male Red-winged Blackbirds have a patch of bright red and yellow feathers on their wings which they display to intruders. If these feathers are painted black, the owners become much less successful at maintaining their territories. In another experiment, some males were prevented from singing by an operation which involved cutting the nerves to the vocal cords. These muted birds were less successful at keeping out intruders than were controls.

If male Great Tits are removed temporarily from their territories and replaced simply with a loudspeaker that broadcasts their song, then intruders are still kept at bay. Therefore song alone can act as a signal to tell other birds that a territory is occupied (see VOCALIZATION).

Territories and populations. In many species, when territory owners are removed experimentally or die naturally, their places are rapidly taken over by new birds. This suggests that potential settlers can be prevented from gaining a territory. In the Great Tit, the replacements come from poorer quality territories. In the Red Grouse *Lagopus lagopus scoticus* replacements come from flocks of non-territorial birds which would not have been able to breed and would almost certainly have died in the absence of a territory.

These observations show that territorial behaviour can limit population density. This does not mean that the limitation of populations is a selective advantage of territoriality. Such reasoning would imply natural selection at the level of the population and there are strong theoretical reasons for supposing that this does not normally occur. What it does mean is that the limitation of population density can come about as a consequence of territorial behaviour, which has itself evolved for some individual advantage. For example, the number of Tawny Owls in Wytham Wood near Oxford has remained constant for many years. This is because each pair requires a certain area of woodland in which to hunt. As a consequence, there is only enough room for a certain number of territories in the wood. The best-quality owls win territories and the chance to breed, while the rest are excluded and probably die. N.B.D.

TERTIARY: or 'tertial', a term preferably treated as obsolete; at one time applied to the few innermost secondary remiges, especially in cases where these are differentiated in shape and colour from the other flight feathers borne on the ulna. The term has also been applied to feathers borne on the humerus in cases where they are developed to function as additional remiges instead of merely as coverts (see PLUMAGE; WING).

TESTIS: plural 'testes'; the male gonad on each side (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

TESTOSTERONE: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; and AGGRESSION.

TETRAKA: *Phyllastrephus madagascariensis*, a BULBUL endemic to Madagascar.

TETRAONINAE: see under GALLIFORMES; GROUSE.

TETRAPOD: a technical term literally equivalent to the ordinary word 'quadruped' but used in a special sense to embrace all the classes of four-limbed, essentially terrestrial, vertebrate animals—thus including birds.

THALAMI: parts of the forebrain (see NERVOUS SYSTEM).

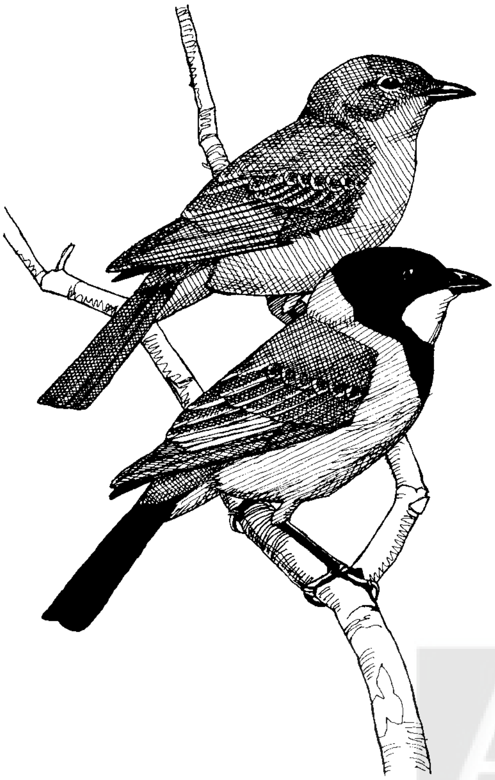
THECA: a sheath-like covering, as in such particular instances as PODOTHECA, RHAMPHOTHECA, and RHINOTHECA.

THERMOREGULATION: see ENERGETICS; HEAT REGULATION; RESPIRATORY SYSTEM; TORPIDITY.

THICKHEAD: substantive name, alternatively 'whistler', of species of the family Pachycephalidae (Passeriformes, suborder Oscines); in the plural, general term for the family. In Australia other substantive names used for several species are 'thrush', 'shrike-thrush', 'shrike-tit', and 'bellbird'. Mayr (1967) divides the group into 4 polytypic genera (*Pachycephala* with 26 species, *Pitohui* with 7 species, *Colluricincla* with 5 species, and *Falcunculus* with 3 species which are sometimes considered conspecific), and 5 monotypic genera (*Eulacestoma*, *Hylocitrea*, *Oreoica*, *Pachycare* and *Rhagologus*). The Australian robins in *Eopsaltria* are now included in the Muscicapidae, and the genera *Coracornis* and *Myiolestes* have been absorbed into *Pachycephalus* and *Colluricincla* respectively. A comparison of their egg-white proteins suggests that it is probable that most, if not all, members of the family are part of the Australian endemic complex (Sibley 1976).

Characteristics. Thickheads range in length from 12.5 cm (Golden-faced Pachycare *Pachycare flavogrisea*) to 28.0 cm (Rusty Pitohui *Pitohui ferrugineus*). All have robust bodies, thick and rounded heads, and imposing strong bills that are thick and laterally compressed in many species, and have a shrike-like hook at the tip; hence the name shrike-thrush for some species. Rictal bristles are few or absent in the Mottled Whistler *Rhagologus leucostigma*, the Wattled Shrike-tit *Eulacestoma nigropectus* and in *Falcunculus* species, but are most pronounced in the Black Pitohui *Pitohui nigrescens* which is the most shrike-like of the genus. Thickheads are relatively inactive, slow moving and tame.

The plumage colours of the majority of thickheads are dull rufous browns and greys, with some green, white and black. In contrast, the Golden Whistler *Pachycephala pectoralis*, the shrike-tits (*Falcunculus*



Golden Whistler *Pachycephala pectoralis,* female and male (below). (*N.W.C.*).

species) and the Golden-faced Pachycare all have bright yellow underparts. The Golden Whistler has the greatest geographical variation of any bird (at least 73 races have been described), the colours of the females ranging from dull rufous brown to the bright yellow of males. Conspicuous crests are found in the Crested Bellbird *Oreoica gutturalis,* Crested Pitohui *Pitohui cristatus* and the shrike-tits. The shrike-tits (*Falcunculus* species) and the Wattled Shrike-tit have wedge-shaped bills, and the latter has pink wattles at the base of its bill. The whistler on the Lesser Sunda islands, *Pachycephala nudigula,* has naked areas of skin about the throat but this and the other adornments previously listed are unusual in the family.

The sexes of several whistlers are distinguishable, females being either plain greyish or less boldly marked and coloured than the male. In the Mottled Whistler the female is much more heavily patterned than the male. In other genera the sexes cannot be easily distinguished in the field. Juveniles are deep rufous, streaked, or spotted, or else similar to the female.

Habitat, distribution and movements. Thickheads are found in a wide variety of habitats ranging from mangrove and rain-forest to much drier woodlands and riverine forests. The Brown-breasted Shrike-thrush *Colluricincla woodwardii* is found only on sandstone ranges where there are cliffs and gorges. Although they are concentrated in New Guinea and Australia, some species have a much wider distribution and the family ranges from south-east India through Malaysia, Borneo, and Sulawesi, northwards to the Philippines and eastwards to Fiji, Tonga, Samoa and other islands. Ringing studies in Malaya have shown whistlers to be resident there and this is likely to be true for most species. However, some are nomadic and the Rufous Whistler *Pachycephala rufiventris* is migratory in south-east Australia.

Food. The majority of thickheads feed on insects that are gleaned methodically either from the foliage or the branches, trunks and bark of trees or else from the ground. The Wattled Shrike-tit and the *Falcunculus* species, however, use their massive bills to strip and plough into bark for insects. The White-breasted Whistler *Pachycephala lanioides* often feeds on small crabs taken from mangrove swamps, and the Grey Shrike-thrush *Colluricincla harmonica* sometimes eats eggs, small birds, and invertebrates. In contrast, fruit is the sole diet of the Mottled Whistler and of *Hylocitrea bonensis,* and some fruit is taken by some pitohuis.

Behaviour. Whistlers, shrike-thrushes and other Australian members of the family are strongly territorial when breeding but solitary outside the breeding season. Shrike-tits and the Crested Bellbird often form parties that are thought to be families. In contrast, several pitohuis in New Guinea are always found in small parties of 3–6 individuals. They respond to playback of their calls and are often found in mixed parties containing other species of similar size and colour to the pitohuis. It has been suggested that these social groups have played a role in the evolution of similar plumage and in some cases similar voice patterns (Diamond and Raga 1978). Before its eggs hatch, the Crested Bellbird paralyses hairy caterpillars, known as bush-worms, by squeezing them. They are then put around the nest rim.

Voice. Many species of whistler are renowned for their explosions of song. Their calls are higher pitched and the sequence of notes longer than those of shrike-thrushes but these also have strong, mellow, and beautiful calls. The Crested Bellbird is ventriloquial and makes one of the most unusual and lovely sounds of inland Australia. The songs of the pitohuis are similar in quality to shrike-thrushes and at least two have a loud and striking simultaneous duet (Diamond and Raga 1978).

Breeding. Whistlers and shrike-thrushes build cup-shaped nests placed in forks of trees, in cavities or hollows. The terrestrial species use caves or cracks in rocks as nest sites. The nest of the Australian shrike-tits has a much deeper cup than the others, is decorated with moss and lichen and is placed among thin upright branchlets that are snipped off above the nest by the male. Materials used in nest construction are strips of bark, grass, rootlets, moss and other similar materials. Nests are placed at a variety of heights: 1–5 m by whistlers, up to 10 m for some shrike-thrushes, and as high as 10–20 m by Australian shrike-tits. Clutch sizes vary as follows: Bellbird, 3–4; whistlers and shrike-thrushes, 2–3, sometimes 4 or 5; and pitohuis, 1–2. The eggs have a ground colour of either cream or pearly white, sometimes tinged with pink, and are spotted with shades of browns and greys.

No incubation or nestling periods are apparently available but it is known that in most species both sexes incubate and tend the young. One exception is the White-breasted Whistler, of which the female alone takes responsibility. In New Guinea the Grey Shrike-thrush *Colluricincla harmonica* has raised 3 broods in the same nest, 2 in the spring and one 6 months later. Distraction display by both sexes of the Gilbert Whistler *Pachycephala inornata* and Buff-breasted Whistler *Pachycephala rufogularis* has been observed when ground predators have approached young.

Sibley, C.G. 1976. Protein evidence of the relationship of some Australian Passerine birds. Proc. XVI Int. Orn. Cong. 1974: 557–570.

THICKKNEE: name collectively used for members of the family Burhinidae (Charadriiformes, suborder Charadrii) based upon the characteristic thickening at the tibiotarsal joint (not the knee joint as the name implies). Other names for members of this family include 'Stone-curlew', 'Stone-plover', 'Norfolk Plover', 'dikkop' (Afrikaans origin), 'willaroo' and 'goggle-eye'.

The 9 species of thickknees are divided into 2 genera, *Burhinus* and *Esacus.* The latter has 2 species of which the Beach Curlew *E. magnirostris* is sometimes classified as *Orthorhampus magnirostris.* Also the 2 species of *Esacus* are sometimes classified as 2 subspecies of *E. magnirostris.*

Characteristics. The species in the genus *Burhinus* most closely resemble plovers (Charadriidae) being about the size of a Lapwing *Vanellus vanellus* (35.5 cm), except the larger Double-striped Thickknee *B. bistriatus* (51 cm), and having a short, stout bill. The 2 *Esacus* species are larger (up to 52 cm) with relatively long and massive bills, slightly upturned in the Great Stone-curlew *E. recurvirostris.* Thickknees have the nostrils as long slits perforated from side to side. The head is large and broad with abnormally large, staring yellow eyes, an adaptation to a predominantly nocturnal existence. The bare legs are long, yellowish or greenish, and the tarsus is reticulated all round. There is an obvious thickening at the tibiotarsal joint. There is no hind toe and the 3 toes are partially webbed, the middle one having the inner side of its nail dilated. The wings are long and pointed in some species, short and rounded in others. The plumage tends to be cryptic, blending well with the surroundings. In colour this is brown, grey-brown, or buff, barred, streaked and mottled, with a conspicuous wing and tail pattern in some species. The side of the head has broad stripes, especially noticeable in *Esacus*, *B. bistriatus* and the Peruvian Thickknee *B. superciliaris*. These species are also more uniform above with little or no streaking on the breast. The sexes are alike and the juvenile plumage resembles the adult but is usually paler. The downy young have extremely cryptic plumage, the chicks usually 'freezing' when danger threatens and relying on the mottled down pattern with dark stripes to escape detection.

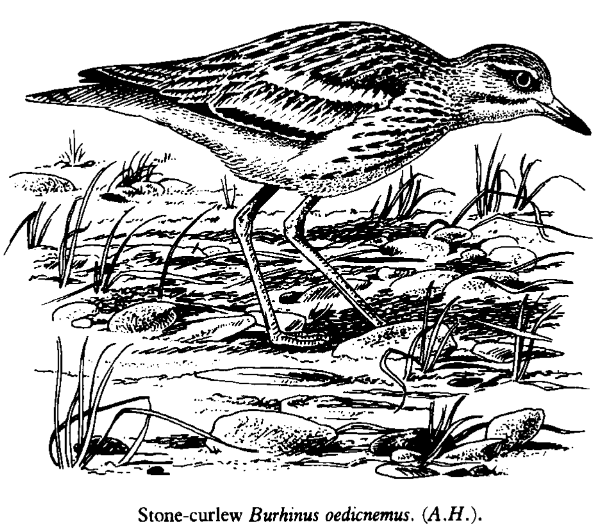
Habitat. Thickknees are mainly birds of dry, open, sandy or stony habitats. In the case of the Spotted Thickknee *B. capensis* and *B. superciliaris* scattered bushes are included in the habitat, and the Bush Curlew *B. magnirostris* is found in both sparse woodland and open country. Four species show an affinity with water: the Senegal Thickknee *B. senegalensis*, mainly along sandy river beds, the Water Dikkop *B. vermiculatus* and *Esacus recurvirostris* along river beds and the coastline, and *Esacus magnirostris*, exclusively coastal.

In Britain and some other west European countries the previous habitat of the Stone-curlew *B. oedicnemus* has undergone radical changes this century due to the ploughing of much of the stony downland and heathland to make way for forestry and agriculture.

Distribution. Thickknees are widely distributed in the Old World, with 2 species in the Neotropical Region. *B. oedicnemus* is the only representative in Europe, the breeding range extending from south-east England to North Africa eastwards to central Asia, India and Burma. In Africa there are 3 other breeding species apart from *B. oedicnemus*: *B. vermiculatus*, extending from tropical to southern Africa, *B. senegalensis* found in east Africa from Egypt to Kenya and Uganda and in West Africa to Gambia and Senegal, and *B. capensis* distributed throughout Africa south of the Sahara except in the southwest. In Asia *E. recurvirostris* is found on the Indian subcontinent and Burma and *E. magnirostris* inhabits the coasts from the Andaman Islands to the Solomon Islands, extending south to the coasts and offshore islands of north Australia. Also widely distributed in Australia is *B. magnirostris*. The 2 Neotropical species are *B. bistriatus* of Central America, including Hispaniola, and South America to north Brazil, and *B. superciliaris* found from Ecuador to southern Peru.

Populations. For most species there is very little information about populations. *B. oedicnemus* in Europe is known to have declined considerably since the mid-19th century and the species is now extinct in The Netherlands, West Germany and possibly East Germany. The decline is thought to be mainly due to an increase in cultivation and afforestation. *B. magnirostris* in Australia is also reported as becoming much scarcer in parts of its range.

Movements. Most species of thickknee are sedentary or show only local movements. The exception is *B. oedicnemus*, which is a summer visitor in the northern part of its range, although elsewhere it is considered resident. Relatively few *B. oedicnemus* have been ringed but recoveries from Britain show movement in a south–south-west direction through France in the autumn (where many are killed) to Iberia, where some certainly winter, with one interesting recovery in Sierra Leone, West Africa. There is a large influx of this species in north tropical Africa during the winter but the origins of the birds are unknown.



Stone-curlew *Burhinus oedicnemus*. (*A.H.*).

Food. Thickknees are probably opportunist feeders taking whatever they come across during their mainly nocturnal foraging. Prey is seen or heard up to several metres away and is usually approached rapidly. When close to the prey the thickknee takes on a heron-like stalking posture and stabs swiftly. Although no detailed studies of food have been made, the list of prey items recorded is long and varied; insects, especially Orthoptera and Coleoptera, worms, molluscs, crustaceans (mainly taken by *Esacus* sp.), amphibians, small reptiles, small mammals, birds' eggs and young and occasionally seeds and other vegetation. Most information on food has come from stomach analyses, but pellets of indigestible remains also contain useful information and a sample for *B. oedicnemus* from eastern England yielded 320 prey individuals belonging to at least 53 species of insect; mainly Dermaptera, Coleoptera (especially Carabidae, Staphylinidae and Curculionidae) and Hymenoptera.

Behaviour. Generally speaking, thickknees are most active from dusk to dawn and spend most of the day under the shelter of a bush, where they can be extremely difficult to detect. Sometimes they live in close association with man, *B. capensis* frequenting large lawns in city parks in some South African urban areas and *B. senegalensis* sometimes nesting on house roofs in Egypt.

Although thickknees are good fliers, they are often reluctant to fly, preferring to run, crouching low over the ground. Unless they are taken by surprise they will hide behind a bush or other cover, or flatten on the ground with outstretched head and neck until the danger has passed.

Most thickknees are gregarious in nature, forming flocks outside the breeding season, with autumn concentrations of up to several hundred birds at traditional sites. Even during the breeding season birds will meet for communal feeding and display activity. Display, involving much calling, is most intense during the early part of the breeding season although at least in *B. oedicnemus* unpaired birds and non-breeding pairs display and call much more than breeding pairs later in the season. Courtship displays and antagonistic displays between rival males make use of the bold black and white wing and tail patterns and the neck is stretched, bowed or arched in different postures.

Both sexes incubate the eggs and care for the young, the off-duty bird usually acting as a sentinel during incubation or the collecting of food for the young after hatching. Both parents react aggressively towards predators such as crow or fox and will also drive intruding sheep or cattle away from the nest.

Voice. Thickknees are generally quiet by day, unless disturbed, but may be extremely noisy at night, especially under moonlit conditions. The vocabulary is poorly understood owing to the largely nocturnal habits. The most common calls are variations of ***kur-leee***, ***ker-looo***, ***tuuee tuuee***, and various shrill whistles and excited, rapid piping and croaking calls.

Breeding. The nest is usually a shallow scrape made by the birds in open ground, often lined with small pebbles or shells. *B. vermiculatus* sometimes lays its eggs on the dried droppings of large mammals such as elephants. This species has another peculiar habit in some localities of nesting among breeding crocodiles. Two eggs are normally laid (only one in *E. magnirostris*), white to buff in ground colour and blotched with irregularly shaped brown markings, making them fairly difficult to see against a stony background. The incubating bird can be extremely difficult to pick out but both sexes incubate and change-overs occur regularly. Hatching takes place after 25–27 days' incubation and the parents carry away the egg-shells and eat them. The chicks are active within a day of hatching; they are covered with thick down and have large, strong legs. The parents take turns to guard the chicks and collect food and they may be moved considerable distances from the nest site. In *B. oedicnemus* the fledging period is approximately 6 weeks. There are records for *B. oedicnemus* of breeding at one year old but other studies suggest that first breeding may be more usual at 2 or even 3 years of age.

THIGH: see LEG; SKELETON, POST-CRANIAL.

THINOCORI; THINOCORIDAE: see under CHARADRIIFORMES; SEEDSNIPE.

THORACIC: pertaining to the thorax, or the region of the thorax.

THORAX: the 'chest', being the part of the body between the neck and the abdomen, and containing the heart and lungs (see HEART; RESPIRATORY SYSTEM).

THORNBILL: substantive name, alternately 'thornbill-warbler', of species in some genera (especially *Acanthiza*) of Acanthizidae (see WARBLER, AUSTRALIAN); also used as substantive name of *Chalcostigma* and *Ramphomicron* spp. (for family see HUMMINGBIRD).

THORNBIRD: substantive name of *Phacellodomus* spp. (see OVENBIRD (1)).

THORNTAIL: substantive name of *Popelairia* spp. (for family see HUMMINGBIRD).

THRASHER: substantive name for the genera *Toxostoma* and *Margarops*, and for *Oreoscoptes montanus*, *Ramphocinclus brachyurus*, and (formerly) *Mimodes graysoni* (see MOCKING-THRUSH).

THRAUPIDAE; THRAUPINAE: family and subfamily of PASSERIFORMES, suborder Oscines; TANAGER.

THREAT: see AGGRESSION.

THRESKIORNITHIDAE: see CICONIIFORMES; IBIS; SPOONBILL.

THROAT: see RESPIRATORY SYSTEM; TOPOGRAPHY.

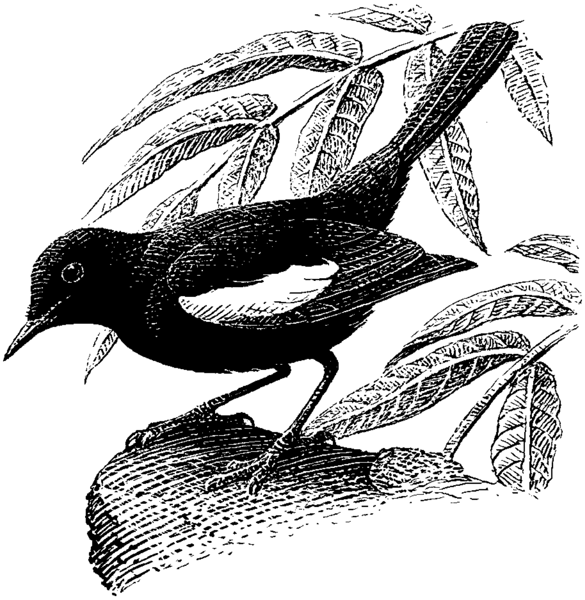
THROSTLE: archaic or poetic form of 'thrush'—cf. German 'Drossel' (see THRUSH).

THRUSH: substantive name of many typical species of the subfamily Turdinae of the Turdidae (Passeriformes, suborder Oscines); in the plural, general term for the subfamily. Many of the smaller species are known as 'chats', and others have special names. The name also appears in the compound 'water-thrush' for *Seiurus* spp. (see WARBLER (2)), and as a substantive name (sometimes 'shrike-thrush') of *Colluricincla* spp. (see THICKHEAD)—and see following entries.

Characteristics. Thrushes in general are slender-billed song-birds of medium size (12–26 cm) with 10 primaries and with a booted tarsus in most cases, the feet being ACUTIPLANTAR and well developed, without syndactyly. The tail is square, rounded, or occasionally emarginate (except in *Enicurus*, in which it is forked), and contains 12 (in one case, 14) rectrices. Rictal bristles are present. The young generally have a spotted first plumage. Adult plumages are generally patterns of black, grey, russet, earth- and olive-browns and white; a few species are largely blue or green, and several have bright patches of red or blue. Sexual dimorphism is marked in many species, the striking male patterns being less distinct or absent in females. There is a single annual moult following the breeding season (prebasic moult). In most species there is no pre-breeding (prealternate) moult; such colour change as occurs at that time is by abrasion or by casting the points of the feathers. There is, however, a partial prealternate moult, involving the body plumage, in some wheatears *Oenanthe* spp. and chats, in one of the rock-thrushes *Monticola* spp., and in White's Thrush *Zoothera dauma*. The syrinx is tracheobronchial. The tongue is non-tubular, with an extensive blade-like reedy tip.

Habitat. Many thrushes are largely terrestrial. Most are arboreal but feed, and in many cases also nest, to varying extents on the ground. They are found in almost every kind of terrestrial habitat, from arid desert or subarctic tundra to dense equatorial rain-forest. A few species occur primarily on open grassland or near water-courses. Many live in close association with man, in farmland and gardens.

Distribution. The subfamily has a world-wide distribution except for the Antarctic and New Zealand (Blackbird *Turdus merula* and Song Thrush *T. philomelos* introduced into the latter). Its approximately 300 species have been divided into several subgroups, of which the simplest arrangement comprises two: the chat-like thrushes and the true thrushes. The greatest number and variety of forms occurs in the Old World, and it may well be that the thrushes have a Palearctic centre of dispersal. Africa has also been an important evolutionary centre, particularly of the chat-like forms. From Eurasia there appear to have been several invasions into the New World, as well as into the Australasian Region and Polynesia. Remote oceanic islands such as Hawaii and Tristan da Cunha have evolved distinctive species of thrushes.



Seychelles Magpie-robin *Copsychus sechellarum*. (*D.W.*).

Chat-like thrushes. The chat-thrushes are small, with more slender legs, more varied nesting habits and plumage, and weaker song than the true thrushes. Many are highly specialized for tropical habitats. The group is diverse and presents the impression of containing more evolutionary end-lines and relict species. The exceptional cases of characters unusual for the family (e.g. unspotted young, scutellate tarsus, prominent bristles) tend to occur among the chat-like thrushes. Some genera approach the warbler family (Sylviidae), others the flycatchers (Muscicapidae). The most primitive chat-thrushes appear to be the shortwings *Brachypteryx*, small sedentary birds inhabiting tropical forest in India and south-eastern Asia through the Sunda Islands and Philippines to Sulawesi. (Another genus which has been thought to be primitive, the scrub-robins or rail-babblers *Drymodes* of Australia and New Guinea, was included in the Turdidae but has recently come under question, and is here included in the RAIL-BABBLER (see Sibley 1976)). From such rather warbler-like birds, including *Erythropygia* of Africa (see also WARBLER (1)), have perhaps come the complex of Old World robins *Erithacus* spp. and their relatives, a large group centred in Africa. Some authors separate these species of simply coloured, rather inconspicuous little birds into several genera—the nightingales, for example, in *Luscinia*. Others prefer to lump many of the genera together.

This group of robins and nightingales ranges from the taiga zone of northern Eurasia south to the Cape of Good Hope in Africa and to south-eastern Asia, the birds tending to prefer damp forest or forest edges, or well-wooded parks and gardens. Offshoots of this group are the robin-chats or forest robins of Africa *Cossypha* and *Alethe* spp., the magpie-robins (or 'shamas') *Copsychus* spp., bluish to black singers of south-eastern Asia; and the redstarts *Phoenicurus* spp., mainly rock-inhabiting birds, widely distributed in the Palearctic Region. The colourful North American bluebirds *Sialia* spp. are birds of semi-open country, and are perhaps not far removed from the solitaires *Myadestes* spp., magnificent singers of jungle and forest in western North America, the West Indies and the New World tropics. A distinct group sometimes treated as a subfamily are the forktails *Enicurus* spp., black and white birds of south-eastern Asia.

Next there are the open country or desert chats such as *Cercomela* spp., dull coloured and found primarily in Africa, and *Saxicola* spp., tending to be black and white, sometimes with brown; the latter include the Stonechat *S. torquata* and Whinchat *S. rubetra* of Eurasia. Near them come the redstarts, already mentioned, and the wheatears *Oenanthe* spp., found in deserts, tundra and meadows of Eurasia, Africa and India. They have rock-living relatives in Africa, the sooty chats ('ant-chats') *Myrmecocichla* spp., and in India the familiar Indian Robin *Saxicoloides fulicata*.

True thrushes. The true thrushes centre round the genus *Turdus*, the familiar one of Blackbird, Song Thrush, Redwing *T. iliacus*, Fieldfare *T. pilaris*, Ring Ouzel *T. torquatus* and American Robin *T. migratorius*. This central genus, distributed more widely than any other of the family, has about 63 species, many of them migratory. Round it we may group the rock-thrushes *Monticola* spp., chat-like birds of open country tending to bright blues or browns, of Africa and Eurasia, and the 'Whistling Schoolboy' or Whistling Thrush *Myiophonus caeruleus*, a plaintive and beautiful dark blue song-bird, found in south-eastern Asia. The *Zoothera* thrushes, with rounded wings and mainly non-migratory, have white bases to the primaries and underwing and are found in the Old World tropics, except for races of White's Thrush (or Golden Mountain Thrush) in the eastern Palearctic and Australia, the isolated Varied Thrush *Z. naevia* of western North America, and the Aztec Thrush *Z. pinicola* of Mexico. Near these are the forest thrushes of the West Indies *Cichlherminia* spp. and the Tristan Thrush *Nesocichla*; and finally the New World nightingale-like thrushes *Catharus* spp. (including the Hermit Thrush *C. guttata* and Veery *C. fuscescens*) and the North American Wood Thrush *Hylocichla mustelina*.

Two aberrant Asian genera, of uncertain relationships, may also be included here for convenience. The 3 species of *Cochoa* are forest-living birds with partly green, pale blue or mauve plumage, rather short-legged and with laterally expanded bills apparently adapted for taking large fruits. The single species of *Grandala*, a bird of high mountains, with very long wings, is highly aerial and social, a ground-feeder and more starling-like than thrush-like in general behaviour.

Food. Thrushes typically feed on both invertebrates and fruits. Many eat worms and snails, the Song Thrush *Turdus philomelos* in particular being a snail specialist with the ability to break open the shells by hammering them against an 'anvil'. Many of the larger thrushes can uncover hidden food by sweeping with the bill and at the same time scratching with one foot. The chats typically search the ground from a vantage point and drop down to take small exposed prey.

Behaviour and voice. Thrushes are typically monogamous, maintaining more or less strict pair bonds in the breeding season and exclusive breeding territories. Pair bonds may persist throughout the year, and from year to year, in resident species; migratory species generally live in loose flocks outside the breeding season, or may maintain feeding territories in their winter quarters (e.g. some wheatears). The loud and varied songs, for which the family is famous, proclaim ownership of territory; in addition there are in all species studied a variety of other calls, used in intraspecific interactions, and alarm calls which are often loud and staccato or, when the alarm is intense, high-pitched and drawn-out.

Courtship displays, performed during pair-formation and before copulation, involve stereotyped postures which tend to emphasize the more striking parts of the plumage, for example the red breast of the Robin *Erithacus rubecula* or the spotted breast of the Song Thrush. Feeding of the female by the male is regular in some species, for example the Robin, but does not normally occur in *Turdus* spp.

Breeding. The nest is cup-shaped and well built of grasses, moss, or kindred materials, the cup being strengthened with mud in *Turdus* spp. Nest-sites are very various: nests may be in a bush or tree, or in a recess or a deeper hole in a tree trunk, a bank or among rocks. Some species regularly build nests in niches or on ledges of man-made structures. The eggs are very variable according to the site used by the species; species nesting in deep holes tend to have immaculate white eggs; those nesting in shallow holes speckled white or blue eggs; those nesting on the ground grey or olive eggs; and those nesting in forks of trees and bushes blotched eggs with a pale greenish or bluish ground colour.

The clutch-size ranges from 2–6 eggs, occasionally more. The female is usually responsible for nest building, incubation, and brooding. The incubation period ranges from 12–15 (generally 13–14) days, and the fledging period is also typically 12–15 days, sometimes reduced in the Arctic in association with longer periods of daylight. Both sexes feed the young. Pairs usually make a succession of nesting attempts within the breeding season, which may last for only about a month at very high latitudes or, at the other extreme, for 9 months of the year in equable tropical regions.

THRUSH, ANT-: see ANT-THRUSH; ANTBIRD.

THRUSH-BABBLER: *Ptyrticus turdinus* (see BABBLER).

THRUSH-FLYCATCHER: substantive name of *Namibornis herero*, alternatively called Herero Chat, a small THRUSH of restricted range in south-western Africa.

THRUSH, GROUND-; THRUSH, JEWEL-: names sometimes applied to Pittidae (see PITTA); the former is also used instead of QUAIL-THRUSH.

THRUSH, JAY-: substantive name of some laughing thrushes *Garrulax* spp. (see BABBLER).

THRUSH, LAUGHING: in the plural, general term for *Garrulax* spp. and also *Liocichla* spp. (see BABBLER).

THRUSH, NEW ZEALAND: substantive name of the probably extinct genus *Turnagra* (monotypic; 2 subspecies), the sole genus of the family Turnagridae (Passeriformes, suborder Oscines); also known by its Maori name, Piopio, for which the Forsters, on Cook's Second Voyage, introduced the vernacular 'thrush' that was adopted by the settlers. The Piopio was a thrush-sized bird with a short stout bill, emarginate at the tip, distinct rictal bristles, yellow iris, rounded wing with long first primary, its dorsal plumage olive-brown and rufous. The South Island subspecies (*T. c. capensis*) had a speckled breast (cream spots on brown), in plumage closely resembling the Tooth-billed Catbird or Stagemaker (*Scenopoeetes*) of Queensland. The North Island Thrush *T. c. tanagra* was unspotted, its throat white, breast and abdomen olive grey.

Piopio were somewhat gregarious, feeding on the forest floor, hopping with both feet together, building substantial cup-shaped nests in crutches of small trees, laying 2 spotted eggs. Calls included a triple piping whistle (recalling that of an oystercatcher *Haematopus*), a pipit-like song, a quick *chi-chi-chit* when males chased females, and low purring distress calls. Piopio were virtually omnivorous and occasionally predatory on other birds.

First classed in Turdidae (or Timaliidae), the New Zealand Thrush was confidently transferred to Ptilonorhynchidae by Finsch in 1875, a placing confirmed by Gadow after dissecting a specimen, with reservations based on its pterylosis. E. Mayr (in Fleming 1950) considered *Turnagra* to be an overgrown relation of the Australian whistlers (*Pachycephala*), but Oliver (1955) and Falla *et al* (1979) use the endemic family Turnagridae, citing possible relationship with Ptilonorhynchidae. In its emarginate bill, yellow iris, plumage pattern, diet, voice and habits, *Turnagra* seems to combine characters of several Australian BOWERBIRDS and catbirds *Ailuroedus*. Olson *et al* (1983) confirmed that *Turnagra* belongs to the bird-of-paradise/bowerbird assemblage and is apparently its most primitive member.

The New Zealand Thrush, originally abundant throughout both main islands of New Zealand, proved vulnerable to dogs, cats and other introduced predators. The North Island Thrush was last collected in 1908, and the South Island subspecies (which ranged to Stephens Island) was fast expiring in 1905 and last reported in 1921. Subsequent sight records are unconfirmed.

THRUSH, QUAIL-: see QUAIL-THRUSH; RAIL-BABBLER.

THRUSH-TANAGER: *Rhodinocichla rosea* (see TANAGER).

THRUSH, WATER: see WATERTHRUSH; WARBLER (2).

THYMUS: a small glandular body of obscure function lying near the bronchi; as in mammals, it is best developed in the young and later diminishes.

THYROID GLAND; THYROXIN: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; also MOULT.

TIBIA: see below.

TIBIOTARSUS: a bone of the leg, in birds formed by the fusion of the tibia and the proximal tarsals; often loosely called the 'tibia' (see SKELETON, POST-CRANIAL; and LEG).

TICHODROMADIDAE: family of PASSERIFORMES, suborder Oscines; WALLCREEPER.

TICK-BIRD: see OXPECKER; STARLING.

TICKS: see ECTOPARASITE.

TIERCEL: special term for a male falcon, the latter word being used both generally and for the female only (see FALCON; FALCONRY).

TIGRIORNITHINI: see HERON.

TIMALIIDAE: family of PASSERIFORMES, suborder Oscines; BABBLER; PARROTBILL; RAIL-BABBLER.

TIME MEASUREMENT: see RHYTHMS AND TIME MEASUREMENT.

TINAMIDAE: see below.

TINAMIFORMES: an order, alternatively 'Crypturi', comprising only the Neotropical family Tinamidae (see TINAMOU). They are generally placed in taxonomic sequences next to the 'ratite' orders.

TINAMOTIS: generic name sometimes used as substantive name of *Tinamotis* spp. (for family see below).

TINAMOU: substantive name of the species of Tinamidae (Tinamiformes); in the plural, general term for the family. In the Neotropical Region, to which the family is restricted, the birds are known variously as 'perdiz' (*Rhynchotus*), 'codorna' (*Nothura*), 'inhambu' (*Crypturellus*), 'macuco' (*Tinamus*), and so on. Some of these names owe their origin to a superficial resemblance between these ground-dwelling birds and the Galliformes; in proportion and carriage some tinamous do indeed remotely resemble guineafowl (Numididae). It seems, however, that most of these similarities are the result of parallel evolution rather than phylogenetic relationship. Anatomically and biologically the tinamous are distantly related to the rheas (Rheidae). There are 9 genera and 45 species, ranging from southern Mexico to Patagonia.

Characteristics. The species of tinamou range in size (length 15–49 cm) from that of a Quail *Coturnix coturnix* to that of a male Black Grouse *Tetrao tetrix*. Male and female tinamous generally look much alike, but the females are slightly bigger and have more pronounced colouring. The bill is thin and slightly curved, the head is small, and the neck is thin. The rear part of the body seems to be high, owing to the enormous development of rump feathers; these often hide the very short and soft tail. The thick, heavy-looking legs are built for running; there are 3 short front toes, the hallux being either elevated or absent. Although tinamous are adapted for ground dwelling, running soon tires them; when chased they are apt to stumble and fall. The wings are short and rounded, with stiff, curved primaries. The flight is clumsy, and accompanied by a rumbling or whistling noise; they fly with the neck curved, and the head may be held slightly erect (*Nothura*). When frightened and flushed, tinamous sometimes collide with branches, tree-trunks, and other obstacles and may injure themselves fatally. It is strange that they fly so poorly, seeing that their flight muscles are as well developed as those of birds which fly very well; on the other hand, the heart and lungs are exceptionally small.

Tinamous succeed best in escaping the attention of their enemies by standing motionless, with the head stretched high, or by stealing away while cleverly using all available cover. They like to crouch, and rise only when one is almost upon them. Species living in open terrain sometimes hide in holes in the ground. All these modes of escape are very effective, as required, and contribute to the continued existence of a group which, in South America, is represented by a considerable number of species and individuals.

The coloration of the plumage is highly protective—brown, grey, or sand-coloured, depending on the environment, frequently with dark spots and bands. There is commonly a considerable quantity of powder down. The tinamous love to take a bath either in dust (*Eudromia*, certain of the *Crypturellus* spp.) or in water (*Tinamus*). With the exception of *Tinamus*, which uses trees, they sleep on the ground. In *Tinamus* the back of the tarsus is covered with roughened scales, which provide a firm hold when crouching down on a thick branch at night.

Food. The food is largely of vegetable origin, such as seeds and fruit, supplemented by insects and other small animals. The gape is wide enough to swallow, occasionally, even mice (*Rhynchotus*). Tinamous have a crop and large caeca. Certain species appear more inclined towards animal food (*Nothoprocta*), as are the young of some other species (e.g. *Crypturellus tataupa*). *Rhynchotus* digs for roots and termites.

Behaviour. Solitary life is the rule. With some species family groups or larger coveys are formed towards the end of the breeding period (*Eudromia*). Polygamy appears to preponderate in the family. The most general pattern seems to be that one or several females lay a clutch of eggs for a male, and then move on to mate with and lay a clutch for another male. The system is thus a combination of POLYANDRY and POLYGYNY, the conditions varying between species and probably also within species. Thus in the Ornate Tinamou *Nothoprocta ornata* a single male and female associate together for nesting, but in the Brushland Tinamou *N. cinerascens* up to 4 females may associate with a male. Unbalanced sex ratios have been reported: a preponderance of males has been noted more frequently, such as 4:1 in *Crypturellus variegatus*, but in other species such as *Nothoprocta ornata* the ratio is 1:1.

Voice. Their voice consists of a loud, melodious, usually polysyllabic whistle. In the breeding season they call often, some of them nocturnally as well as by day. They may be attracted by imitating their calls.

Breeding. The eggs are relatively large for the size of the bird, and beautifully coloured; they are indeed among the most handsome birds' eggs known. They are always unicoloured and heavily glazed as if polished. Colours include light chocolate, almost black, purple, dark bluish green, light yellowish green, and grey; the colour changes rapidly when exposed to light. The number of eggs in a clutch varies from 1–12 or more. The larger clutches are probably always the result of the efforts of more than one female. A flat, hollowed-out indentation in the ground serves as nest, and is protected by a bush, tufts of grass, or the base of a tree. The nest is poorly lined with dry matter, rarely well cushioned. Incubation is apparently done by the cock only; on the male of *Nothoprocta* an incubation patch has been noted. The cock may concentrate on brooding to such an extent that, on occasion, he allows himself to be picked up by hand. Sometimes (e.g. *Crypturellus tataupa*) the cock feigns lameness in order to distract the disturber from the nest. Some species cover the eggs with leaves (*Tinamus*) or feathers (*Nothoprocta*) when they leave the nest.

Incubation is short—in *Eudromia* 19 days, in *Crypturellus tataupa* and *Tinamus solitarius* 20 days. Led by the cock, the young leave the nest on their first or second day. The cock defends them, even against human beings. The young run very well and are guided by hearing; when danger threatens they crouch low and the colour of their down feathers blends with the ground so that they become almost invisible. While certain species (*Tinamus*) have a well-defined breeding period, others (some *Crypturellus* spp.) breed throughout the year.

Reproduction in captivity is frequently successful, even in Europe. Nevertheless, domestication has not succeeded, and the attempted introduction of the Argentine Tinamou *Rhynchotus rufescens*, e.g. into England, was a failure. All tinamous are in demand on account of their tender although oddly transparent meat. H.S.

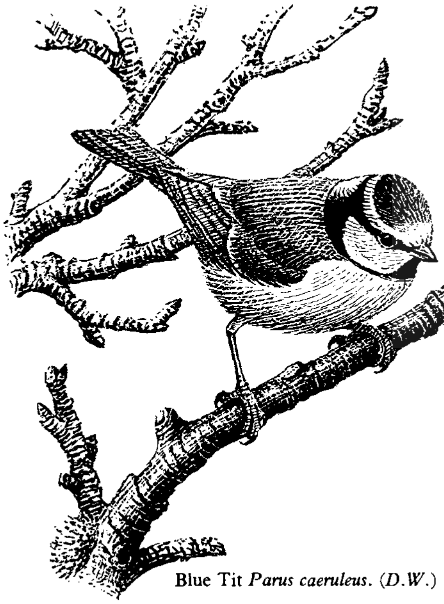
TINKER-BIRD: substantive name of *Pogoniulus* spp. (see BARBET).

TIPPET: name earlier given to a woman's cape made of the under feathers of grebes (Podicipedidae), but used ornithologically for the elongated facial feathers of typical grebes *Podiceps* spp., as distinct from other types of head-ornamentation in this group, e.g. 'facial disc' (well defined area of short feathers on the face) and 'auricular fan' (elongated feathers on side of head behind eye)—see under GREBE.

TISSUE: a more or less homogenous aggregation of cells (see CELL). Tissues form the structural basis of the organs and parts of the body. They are of four main kinds, each of which is divisible into various specialized types. (1) Epithelium occurs as a very thin covering layer, e.g. the external layer (epidermis) of the skin, or the lining of the alimentary canal (see SKIN). (2) Connective tissue has supporting and binding functions, and there may be an intercellular matrix (secreted by the cells); it occurs in many diverse forms, e.g. fibrous tissue, fatty tissue, cartilage, bone (see SKELETON, POST-CRANIAL). (3) Muscular tissue (see MUSCULATURE). (4) Nervous tissue (see NERVOUS SYSTEM).



Blue Tit *Parus caeruleus*. (*D.W.*)

TIT: substantive name, abbreviated from 'titmouse', of most species of Paridae (Passeriformes, suborder Oscines); in the plural, general term for the family. The name is strictly applicable only to the Paridae, although various unrelated but superficially similar birds are commonly called 'tits' or have names of which 'tit' forms part, e.g. Bearded Tit (see PARROTBILL), shrike-tit (see THICKHEAD), wren-tit (see BABBLER). In other cases 'tit' is a prefix with diminutive effect; it is also used as a substantive name for some Australian flycatchers. The long-tailed tits (Aegithalidae) and the penduline tits (Remizidae) were formerly classed as subfamilies of the Paridae. They are now treated as separate families; see PENDULINE TIT; TIT, LONG-TAILED.

Characteristics. Tits are small (lengths 11–14 cm except Sultan Tit *Melanochlora sultanea* which is *c.* 22 cm), active, woodland birds with stout, roughly conical bills; as in the crows the nostril is concealed by bristles. The plumage is typically olive, brown, grey or greenish above, and white, yellow or buff below. Many species have a striking black-and-white head pattern and a few have crests. The wing coverts and outer tail feathers are often pale edged and tipped.

Habitat. Tits are basically woodland species, deciduous, conifer or mixed, also occurring in more open habitats like gardens, where feeding tables attract many species especially Blue Tits *Parus caeruleus*.

Distribution. The typical tits comprise about 46 species distributed throughout North America (including parts of Mexico), Europe, much of Asia (including parts of south-east Asia), and Africa, wherever there is suitable woodland. They include such well-known species as the Great Tit *Parus major* and the Blue Tit. In North America some *Parus* spp. are called 'chickadees', the best known being the Blackcapped Chickadee *P. atricapillus* (formerly regarded as conspecific with the Willow Tit *P. montanus*). There are also some not very well known, mainly tropical, species: among them are the very large Sultan Tit of Eastern Asia, a black bird with a bright yellow crest and underparts; the local *Parus superciliosus* and *P. davidi* of the mountains along the eastern border of Tibet, unusual in having the underparts uniformly rufous; the very local *P. fringillinus* of central Africa, lacking the contrasting head markings found in all the other species of *Parus*; and the Mexican Chickadee *P. sclateri* from the mountains of Central America. There are also 2 Asian species of very atypical appearance: *Sylviparus modestus*, which resembles a warbler (Sylviinae), and *Cephalopyrus flammiceps*, which has a flame-coloured forehead and should perhaps not be included in the family at all.

Populations. The tit population of European woodlands fluctuates from year to year, but over longer periods remains remarkably constant. In Britain about 50% of adult Great Tits survive from one breeding season to the next. They are usually single brooded, and only an average of one juvenile from each brood survives to breed. In continental woods, where second broods are common, the mortality rate must be even higher. There is evidence of heavy losses of young birds soon after fledging, survival being closely linked with the supply of beech mast and other seeds which do not crop in successive years. Definite proof of 'density-dependent' mortality is hard to find, but high populations lead to reduced clutch-size, intensified predation by weasels and perhaps sometimes to food shortage in winter. The Great and Blue Tits are unusual for the family in that they reach very high breeding densities (occasionally more than 2 pairs per ha) in favourable habitats. All other species are much less abundant, a pair per 3 ha or less.

Movements. Although British tits are largely sedentary, some of the Scandinavian and North Russian populations are migratory and there are considerable local movements of juveniles elsewhere in northern Europe. Others winter even in very cold regions.

Food. In the breeding season tits feed largely on insects and other small invertebrates, but in winter some species rely mainly on seeds and other vegetable matter. Tits can open nuts by holding them down with the foot and hammering the shells, and several species, especially the northern ones, store food in times of abundance, hiding it under bark or elsewhere. Hiding places seem to be remembered for some days but recovery of food after longer periods may be fortuitous. Detailed research has been done on the diet of tits throughout the year and the interaction of predators and prey. Conclusive evidence for the control of insect pests is elusive, but abundant tits may check an incipient plague in spring and, at least in pines, reduce insect numbers significantly in winter. Some Great, Blue, Coal *Parus ater* and Marsh *P. palustris* Tits have proved surprisingly quick to solve food-finding problems involving the use of complex mechanisms, and there is at least a suggestion of 'insight learning' and imitation of other birds, e.g. in opening milk bottles.

Behaviour. Outside the breeding season Great, Blue and Coal Tits are strongly gregarious and move about in mixed flocks over a limited area through the winter with a few fellow travellers of other species. The other European tits are more sedentary and less sociable; some remain in their territories all the year round. In winter flocks break up at dusk when the birds go to their individual roosting places, usually small holes and crevices.

Voice. Flocks are kept together by a constant exchange of flight calls or alarm notes. The Great Tit has a particularly wide range of call notes and song variations which seem to be developed both by individual improvisation and by imitation. The tonal quality of the song even varies between forest and more open habitats. Some species have quite elaborate songs though most contain only a few syllables.

Breeding. All species are hole-nesters. The nest, typically a mass of moss or other soft material, with a hair, fur or feather lining, is placed in a hole in a tree or, less usually, in the ground or a wall. A few species, including the Willow Tit, excavate their own holes in rotten tree trunks. The eggs are white with small brown spots. In most species the female will cover an incomplete clutch with nest lining on leaving; she builds the nest and incubates the eggs but both parents feed the young.

Clutch-size varies from 3–4 in some tropical species to much larger in some temperate species. The average clutch of 11 (clutches of 15 are not uncommon) laid by Blue Tits in deciduous woodland in Europe is perhaps the largest of any nidicolous bird.

The fact that the Great Tit prefers nest-boxes to natural holes for breeding has enabled zoologists to make detailed long-term studies of variable factors such as date of egg-laying, clutch-size, hatching and fledging success and survival of juveniles. Although egg-laying is so timed that the nestling period roughly coincides with an abundance of caterpillars, the quantity and nutritional value of food in deciduous woods tends to decline before the fledglings are self-supporting, so earlier breeding would be an advantage. But even with the help of 'courtship feeding' female tits seem unable to produce their rather large clutches any earlier. The date of egg-laying varies with latitude, altitude and habitat, and with winter and spring temperatures. Older females lay earlier than first-year birds, small females earlier than big ones, and small tit species earlier than larger ones. Clutch-size is affected by an even more complex interaction of factors. Most tit species lay smaller clutches in southern latitudes of Europe, in less favourable habitats, when laying is later than usual, when the nest chamber is small, when one or both parents are first-time breeders, and there is a high population density of the same species. In general these variations result in tits' families being the largest that the parents can successfully raise, but the mechanism by which the females adapt their clutch size to a food supply some 5 weeks ahead is not yet understood. The incubation period is 13–14 days and fledging varies from 15–20 days, with the young continuing to be fed for a week or so after leaving the nest.

TIT-BABBLER: in the plural, a general term for the Timaliini (see BABBLER); also an alternative name for TIT-WARBLER; (see WARBLER (1)); also accepted name, in South Africa, of *Parisoma* spp. (see TIT-FLYCATCHER; FLYCATCHER (1)).

TIT, BEARDED: see BEARDED TIT; for family see PARROTBILL.

TIT-FLYCATCHER: name applied to *Parisoma* spp. (for family see FLYCATCHER (1)).

TIT-HYLIA: *Pholidornis rushiae*, a very small bird found in West African forests, of uncertain affinities. Superficially it is like a flowerpecker, with a pointed, slightly decurved bill, short tail, streaked head and breast and olive-yellow rump and belly; it has variously been associated with the sunbirds, estrildid finches and warblers. A recent appraisal (Vernon and Dean 1975) shows that in many ways it is closely similar to the penduline tits, and suggests that it is either a member of the Remizidae or a remarkable case of convergence.

Vernon, C.J. & Dean, W.R.J. 1975. On the systematic position of *Pholidornis rushiae*. Bull. Br. Orn. Club 95: 20.

TITLARK: popular name applied in Britain to *Anthus* spp., particularly the Meadow Pipit *A. pratensis* (see under WAGTAIL).

TIT, LONG-TAILED: *Aegithalos caudatus*; in the plural, general name for the family Aegithalidae (Passeriformes, suborder Oscines), consisting of the 2 genera *Aegithalos* (6 species) and *Psaltriparus* (Bushtits, 1 species, sometimes regarded as 2). The genus was previously placed close to the true tits (Paridae), or as a subfamily of the heterogeneous Muscicapid assemblage. Recent research has placed the long-tailed tits closer to the babblers (Timaliidae) on the basis of structural and biochemical characteristics. This rearrangement makes good sense from a behavioural point of view as the long-tailed tits have much in common with babblers, being almost entirely sedentary and living in persistent small groups which defend common territories and frequently indulge in co-operative breeding.

Long-tailed Tit *Aegithalos caudatus*. (*A.H.*).

Characteristics. Long-tailed tits are very small, 10–12 cm in length and averaging about 10 g in weight, with compact bodies, short wings and long narrow tails; the latter character being more pronounced in *A. caudatus* than in the other members of the genus. The body plumage is loose and fluffy, again resembling babblers, and the legs are fairly long and very slender. Bills are short, conical and somewhat laterally compressed, resembling those of the smaller PARROTBILLS (Timaliidae).

Distribution and habitat. *A. caudatus* extends over most of the boreal Palearctic region, from Britain to Japan, but the genus *Aegithalos* is otherwise confined to the Sino-Himalayan subregion, with 3 species occurring only in the Himalayas and associated ranges, one extending through China to Taiwan, and one being confined to the mountains of west and central China. The other genus, *Psaltriparus*, occurs in western North America from southern British Columbia southwards, and extends into central America as far as Guatemala. The disjunction between the 2 genera is reminiscent of the situation in the babblers where the isolated genus *Chamaea* occupies a similar range to *Psaltriparus*, while the rest of the family is concentrated in the Oriental and Sino-Himalayan regions (see BABBLER); in both cases the North American populations probably crossed from Asia via the Bering Straits during a period of climatic amelioration. In the Himalayas long-tailed tits are found in the temperate and sub-alpine forest zones between 1,800–3,400 m, descending somewhat in winter. The widespread *A. caudatus* is mainly a bird of temperate and boreal forests but also occurs in scrub, particularly where there are patches of woodland nearby, and extends into Mediterranean vegetation in southern Europe. The American species *Psaltriparus minimus* occupies dry forest near the west coast and semi-desert woodland and scrub in the interior.

Food. All species feed principally on small insects gleaned from leaves and twigs, using particularly the terminal branches of shrubs and trees and behaving very acrobatically, frequently hanging upside-down.

Behaviour. The family appears to be extremely uniform in behaviour, all species living in discrete groups of 5–20 birds, roving constantly, often in association with other small passerines, but probably occupying group territories, which have been extensively studied in *A. caudatus* (Nakamura 1969, Gaston 1973). Helpers have been recorded at the nests of 3 species and these other birds probably belong to the same winter territorial group as the breeding pair. Groups roost together, huddled in contact with one another on a branch.

An unusual display, observed in both *A. caudatus* and *A. concinnus*, consists of hovering repeatedly close to the nest after delivering food to the young. This occurs only at nests with helpers in attendance and presumably constitutes a communication between breeders and helpers, although the exact significance is not known; it facilitates finding nests with young.

Members of the family do not have a recognizable territorial song. Instead, a variety of vocalizations, mainly churring and high-pitched nasal squeaks, are given, which apparently serve to communicate within the group. Territorial confrontations between groups are accompanied by loud vocalizations on the part of all group members.

Breeding. Nests are characteristic, being domed, with a single small entrance at one side near the top. They are built largely out of moss and usually covered outside with lichens and cobwebs. The cup is lined with a dense mat of feathers and other soft material which confers very good insulation. These complex nests take a long time to build compared with many passerine nests; up to 20 days in the case of early nests of *A. caudatus* and a minimum of 5 days later in the season. Nest sites range from just above the ground in low bushes to more than 20 m up in trees, sometimes close to the main trunk, sometimes in the terminal twigs of side branches.

Eggs are laid at daily intervals and clutch sizes range from 4–12; the eggs are white with faint markings. Incubation is carried out entirely by the female and takes 13–14 days. Both members of the pair contribute more or less equally to feeding the young which fledge at 15–16 days old. Predation pressure is very heavy on populations of *A. caudatus* that have been studied, making the fledging period, close to that of the hole-nesting Paridae, somewhat surprising. Family parties remain together for at least a month after the young fledge and may form the nucleus of winter flocks.

TITMOUSE: name now usually abbreviated to 'tit' (see TIT); still used to some extent, but more often as a group term ('titmice') than as a substantive name of species.

TIT, PENDULINE: see PENDULINE TIT.

TIT, SHRIKE: alternative name of *Calicalicus madagascariensis* (see VANGA).

TIT-TYRANT: substantive name of the small South American tyrant-flycatchers of the genera *Anairetes* and *Uromyias* (see FLYCATCHER (2)).

TIT-WARBLER: substantive name, sometimes 'tit-babbler', of *Leptopoecile* spp. (see WARBLER (1)).

TIT, WREN-: see WREN-TIT; BABBLER.

TITYRA: generic name used as substantive name of *Tityra* spp. The three species of *Tityra* were formerly included in the Cotingidae, but are now placed in a subfamily of the Tyrannidae (see FLYCATCHER (2)). They are heavily-built birds of medium size (18–21 cm), the male largely pale grey or white with black crown, wings and tail, and the females duller, partly brownish or streaked. They are Neotropical forest birds, living strictly in pairs and nesting in tree holes; their calls have a peculiar grunting or croaking quality. Their closest allies are probably the BECARDS; in both, the 9th primary of adult males is much reduced and attenuated.

TOBOGANNING: in respect of penguins (Spheniscidae), see LOCOMOTION, TERRESTRIAL.

TOCOCO: *Chilia melanura* (see OVENBIRD (1)).

TODIDAE: see CORACIIFORMES; TODY.

TODY: substantive name of the 5 species of Todidae (Coraciiformes, suborder Alcedines); in the plural 'todies', general term for the family. Todies are confined to the Greater Antilles of the West Indies and form a compact group in the order Coraciiformes, where they are allied to motmots (Momotidae) of tropical America, and more distantly to kingfishers (Alcedinidae).

Characteristics and distribution. The 5 species—one each on Cuba, Jamaica, and Puerto Rico, and 2 on Hispaniola—in the single genus *Todus*, are morphologically very similar. All are small (11 cm), shining green above, with pale underparts, a prominent scarlet gorget (bib), stout bodies and long, flat, red bills. The Jamaican Tody *Todus todus* is locally called the Robin Redbreast. Differences in flank colour (pink or yellow), the presence or absence of a small blue subauricular patch, vocalizations and courtship behaviour distinguish the species. A recent large fossil, *Palaeotodus emryi* (Oligocene, Wyoming), indicates that the present range of the family is only a remnant of that found formerly, and may have included Europe as well as North America and the West Indies during the early stages of tody evolution.

Habitat. Inhabiting all major habitats from dense, moisture-saturated, mossy, elfin forest (as high as 3,200 m) down to xeric lowland forest bordering sea-level, todies prefer shady and brushy areas, generally where there is an abundance of branches, twigs and leaves, and a suitable embankment for burrow-excavation.

Food. Foraging usually occurs within a few metres of the ground. Todies are primarily insectivorous, but also eat spiders, small seeds and rarely, minute lizards. They feed opportunistically, capturing insects in an unusual manner from virtually all available substrates. They feed primarily from the undersides of leaves and twigs. They sit quietly but alertly on twigs or branches, constantly moving their heads and eyes with rapid and jerky movements, and occasionally flick their wings. Typically the bird perches with its bill pointing upwards (at angles up to 45°) and scans the lower surfaces of leaves above it. On spying an insect the tody flies up to the leaf, snaps its bill audibly, and continues in an unbroken arc to another perch. Less than 10% of the time they sally out in flycatcher fashion to capture insects on the wing. A detailed analysis of feeding behaviour reveals striking character displacement in the 2 Hispaniolan species, the Broad-billed *Todus subulatus* and Narrow-billed Todies *T. angustirostris*, over a sympatric zone of at least 1,265 m (between 465 and 1,730 m). These 2 species have diverged from other *Todus* in morphology, vocalizations, and egg-dimensions, as well as exhibiting striking behavioural divergence between themselves because of their sympatry. One can recognize either species immediately in the field merely by observing its foraging height and feeding behaviour, regardless of morphology.

Behaviour. Their flight is often accompanied by wing-rattling, a loud whirring noise probably produced by air rushing through the attenuated outer primary; this noise is under the control of the tody, and is used generally during territorial encounters and courtship. Todies are non-social birds, normally remaining paired in their home-ranges throughout the year, although the bonds are looser in the non-breeding season.

Voice. Each species has at least 6 different vocalizations, of which one is distinctive and different from the other species. The Puerto Rican and Jamaican todies utter short, loud, nasal *beeps*, whereas the other 3 species whistle much clearer two- (or more) part calls. These vocalizations, even though mostly unmusical, and the peculiar bobs that accompany them, constitute some of the most characteristic qualities of todies.

Breeding. During the nesting season (which may cover 10 months each year), todies excavate narrow, curved (usually right-angled) burrows in earth banks, using their bills and feet. These burrows are dug out in natural bare or sparsely vegetated banks, often under sheltering roots or rocks, but todies will also utilize road- or trailside cuts. Neither the banks nor burrows are high above the lower ground level (in the Puerto Rican rain forest, the average bank height is 1.6 m, and average burrow height is 0.9 m). These burrows are defended vigorously; rarely are they used more than one season. Many nests are abandoned; for example, in Puerto Rico's rain forest, todies begin three times as many burrows as are ultimately used for egg-laying. As the bird is tiny, the burrow-opening averages 3.4 cm in diameter at the exterior, but the eggs are laid in an enlarged, unlined chamber approximately 11 × 10 cm and 7 cm high. The glossy, ovate, fragile eggs (clutch size averages 2.4) are very large for such a small bird. In the Puerto Rican Tody *T. mexicanus*, each egg represents 39% of the bird's body weight (birds average 5.4 g and eggs 1.4 g). This relative heaviness is due to the large yolk reserve required for the rather long incubation period (21–22 days), which is longer than any similar-sized hole- or cup-nester, either in the tropical or temperate zones. Adults are unusually inattentive during incubation, each spending less than one-quarter of its time brooding, and only then for periods averaging 13 min at a time. However, during the nestling period they feed their chicks with remarkable speed and energy expenditure, result-

Jamaican Tody *Todus todus*. (*N.A.*).

ing in the highest rates recorded for any bird (up to 140 feeds per chick per day!). Even in the non-breeding season, todies feed constantly from early dawn to dusk to maintain their own metabolism.

Todies are often assisted at the nest by helpers, who are usually pairs from adjacent territories whose breeding has been curtailed. Breeding pairs willingly accept helpers after a few days of aggressive behaviour, and when fed by 4 adults, the nestlings emerge sooner than the normal (which is 19–20 days). Nestlings emerge with pale grey throats and short black bills; after about 6 weeks adult coloration and behaviour are attained. A.K.K.

Kepler, A.K. 1977. Comparative Study of Todies (Todidae): with Emphasis on the Puerto Rico Tody, *Todus mexicanus*. Cambridge, Mass.

TODY-FLYCATCHER, TODY-TYRANT: alternative substantive names of *Todirostrum* spp. (see FLYCATCHER (2)).

TOE: see under LEG; SKELETON, POST-CRANIAL.

TOMIUM: the cutting edge of a mandible; the upper and lower mandibular tomia on either side meet, in the closed position, in a line known as the commissure (see BILL).

TOMTIT: *Petroica macrocephala*, a small forest bird native to New Zealand (for family see FLYCATCHER (1)); also a common (but decreasing) vernacular name for the Great Tit and Blue Tit (see TIT).

TONGUE: a mobile, muscular organ situated in the floor of the mouth. It is covered with epithelium, often thick and horny, particularly towards the tip, and is supported by the entoglossum, which is often partly or entirely cartilaginous. Muscles attached to the hyoid skeleton (see SKULL; MUSCULATURE) provide for the organ's mobility. The tongue in birds is highly variable in size, form, and function. This applies particularly to the horny epithelium; its tendency to fray at the tip has been increased by selection to produce complex structures. The varied papillae and serrations are also developments of this layer.

While it is possible to describe many adaptations according to function, particularly feeding habits, there are many apparent contradictions. Thus, the penguins (Spheniscidae) have long, pointed tongues, the upper surface being covered with conical papillae pointing backwards to hold and direct slippery fish towards the oesophagus, whereas the auks (Alcidae), divers (Gaviidae), and grebes (Podicipedidae) have similarly sized and shaped tongues that are quite smooth. Other fish-eating birds, notably the Pelecaniformes and certain kingfishers (Alcedinidae), that swallow their food whole, possess only rudimentary tongues; so do the spoonbills and ibises (Threskiornithidae) and the storks (Ciconiidae), all of which feed on small animals. Any attempts to classify types of tongue are therefore bound to be unsatisfactory, and it is more helpful to consider the various functions of the organ.

Functions of the tongue. Although the tongue can be seen to move when a bird is singing, it does not in fact play any part in the production of the song (see SYRINX). The actual functions can be grouped as follows:

Collecting food. Included here are those few species that use the tongue instead of the bill for the collection of food. Selection has produced the most remarkable adaptations among these species.

Woodpeckers and wrynecks (Picidae) possess exceptionally long 'tongues' which can be thrust out for a considerable distance. These structures in fact consist of a tiny true tongue (entoglossum and associated epithelium) on the end of a greatly lengthened basihyal. Protrusion is made possible by the elongated hyoids. The highly developed salivary glands cover it with a sticky secretion. The surface of the tongue proper is roughened with hair-like papillae, and a few backward-pointing barbs near the tip. This results in increasing the thickness of the salivary coating in which the insects become stuck. The tongue of the Wryneck *Jynx torquilla* lacks barbs. The tongue is most strikingly elongated in genera taking large quantities of ants, e.g. *Picus*, *Colaptes* and *Jynx*; in the Wryneck, the tongue is nearly two-thirds the length of the bird's body (excluding tail).

Other tree woodpeckers have shorter tongues in which the terminal barbs are more developed and are of use in extracting larvae from their crevices. The sap-sucking woodpeckers have still shorter tongues, the tips of which are covered with fine hair-like processes, which draw up sap by capillary traction.

The tongues of snipe and woodcock (Scolopacinae) play an important part in extracting prey such as earthworms from soft substrates. However, long-billed waders such as curlews *Numenius* which feed in harder substrates with more vigorous actions have the bill so reinforced that only a small tongue can be accommodated, and prey are removed by bill action alone.

The tongues of sunbirds (Nectariniidae) and hummingbirds (Trochilidae) are long and bifid, folded over in the form of two tubes, the ends of which are greatly frayed and feather-like. The tongue is worked in and out of flowers at great speed, nectar and contained insects being forced into the tubes. The resemblance of this tongue to that of the nectar-sucking bee has been remarked upon. The brush-tongue characteristic of the Meliphagidae is notably different from that found in most other families of birds with like habits (see HONEYEATER), but a similar structure is found in the Zosteropidae and the Loriinae (see WHITE-EYE; PARROT).

Eating. In general, those species with relatively thick, fleshy tongues, closely conforming to the inner margin of the lower mandible, use the tongue as an eating organ, but without protruding it to take in food. The flattened tongues of the grazing geese *Anser* spp. bear serrations along the edge, corresponding with those of the lower mandible, and serve to fix and break the vegetation. Dabbling ducks *Anas* spp., with a more varied diet, have on the tongue a series of serrations and papillae that serve additionally as a sieve, this condition reaching maximal development in the Shoveler *Anas clypeata* and allied species. The slender backward-pointing barbs of the tongues of saw-billed ducks *Mergus* spp. assist in holding and swallowing slippery prey, as in the case of the penguins.

In the flamingos (Phoenicopteridae) the tongue fills the whole cavity of the lower mandible and is capable of moving only backwards and forwards. It bears many soft papillae and has closely serrated edges, being used to sift food from soft mud (see FLAMINGO).

Seed-eating species tend to have thick, fleshy tongues, that of the crossbills *Loxia* spp. playing an important part in extracting seeds from fir cones. The tongue is used by these species for discarding unwanted husks. The fleshy tongues of parrots (Psittacidae) are capable of sophisticated and versatile movements due to a highly modified and refined musculature.

Swallowing. There are a number of adaptations in the tongue that facilitate swallowing. In many species that swallow their food whole, as has already been mentioned, the tongue is very small. Many other tongues possess backward-pointing spiny papillae to direct the food towards the oesophagus, the papillae becoming more numerous around the glottis, guarding it from any obstruction.

The raised edges of the tongues of some seed-eating species give such tongues a scoop-like form in which the seeds are directed towards the oesophagus. The bifid tongues of the owls (Strigiformes), larks (Alaudidae), and swifts (Apodidae) are probably concerned with swallowing.

Taste and touch. The sense of taste seems to be poorly developed in birds, with the possible exception of the parrots, the thick, fleshy tongues of which possess more taste-buds than any other species. In birds, however, many of these are situated elsewhere in the mouth (see TASTE). Tactile end-organs are much more widespread and the tongue is definitely an organ of touch, as would be expected (see TOUCH). The tongue has possibly a temperature-perceiving function in Megapodidae (see MEGAPODE).

Nest building. In the swiftlets *Collocalia* spp. the musclaginous salivary secretion used to build their nests is deposited by the tongue (see EDIBLE NESTS).

There remain many tongues in which it is not possible to correlate function with form, e.g. the long, thin horny tongues of the toucans (Ramphastidae).

Tongue and mouth markings. A widespread characteristic of the mouths of nestling birds is that they are brightly coloured, often with a variable number of contrasting spots on the tongue and soft palate. These are considered to be directive marks or targets, revealed by the gaping response on the arrival of the parent with food. A more primitive arrangement is seen in the enlarged, light-coloured margins of the gape, as in the nestlings of thrushes (Turdinae) and many other passerines. Nestlings of some birds, e.g. the parrot-finches *Erythrura* spp., possess semi-luminous blue warts on the sides of the mandible, again to direct the parents in placing food.

It has also been suggested that the bright mouth-colouring in adult birds may serve as threat and warning coloration, the gaping response being induced as a last resort when the bird is attacked and cornered. It is also a factor in display, revealed particularly by certain sea birds, notably the auks (Alcidae). (J.G.H.) P.J.K.B.

TOOLS, USE OF: 'the use of an external object as a functional extension of the body, in attaining an immediate goal'. A recent closer definition is 'the external employment of an unattached environmental object to alter more efficiently the form, position, or condition of another object, another organism, or the user itself when the user holds or carries the tool during or just prior to use and is responsible for the proper and effective orientation of the tool' (Beck 1980). This somewhat tortuous definition points to its being a decidedly indistinct category of behaviour. It is best considered as just one aspect of object manipulation and may not necessarily be the 'highest' form.

The number of wild bird species which use tools as an established and regular piece of behaviour is extremely few. The classic case is the Woodpecker Finch *Cactospiza pallida* of the Galapagos which was observed as early as 1901 to wield a cactus spine or twig as an implement (see DARWIN'S FINCHES). The closely related Galapagos Mangrove Finch *C. heliobates* has once or twice been seen to behave similarly. The Woodpecker Finch has been studied in captivity in some detail in West Germany and the USA. When looking for prey this species first searches like a true woodpecker, using its bill to prise off bark, thus uncovering insect holes. It will then pick up accessible prey directly with the bill. If no prey is within reach the bird flies off to fetch a cactus spine which it may then use in one of three ways: as a goad to drive out an active insect (without necessarily touching it); as a spear with which to impale a slow-moving larva or similar creature; or as an implement (best named a poker?) with which to push, drag, nudge or otherwise manoeuvre an inactive insect from a crevice or hole.

In Australia several wild Orange-winged Sittellas *Daphoenositta chrysoptera* were seen successfully to insert strips of wood into cavities containing insect larvae; the probe was first held in the bill and later under toes while dislodged larvae were eaten. In the Serengeti, Tanzania, a Grey Flycatcher *Bradornis microrhynchus* was on more than one day seen to 'fish' winged termites out of holes in a concrete verandah using a grass stem. In Texas a similar method was successfully used by an adult Green Jay *Cyanocorax yncas*, and unsuccessfully by a juvenile. Each bird flew with a twig into a tree and inserted it under the bark of a branch. The adult on pulling the stick out of the small cavity found a prey item adhering to it that it then consumed. Brown-headed Nuthatches *Sitta pusilla* in North America detach bark scales and use them as levers (?crow bars) to prise other pieces of bark and thus expose invertebrate prey. The nuthatches carry their implements from tree to tree. Particularly well-known is the stone-throwing behaviour of the Egyptian Vulture *Neophron percnopterus* used to break open the eggs of the Ostrich *Struthio camelus*. These depredations are believed to be serious. The much-quoted case of the Australian Black-breasted Buzzard *Hamirostra melanosterna* dropping stones from a height on to the eggs of the Emu *Dromaius novaehollandiae* and other large ground-nesting birds has been discredited, having a basis only in Aborigine legend. White-winged Choughs *Corcorax melanorhamphus*, also in Australia, use pieces of mussel shell as thrown or dropped missiles and as hammers to break open other mussels. An apparently unique case of a wild species using an aggressive weapon concerns the Australian Brush Turkey *Alectura lathami* which will kick barrages of sandy stones and litter at monitor lizards *Varanus varius*, that compete for the birds' food.

All other cases of apparent tool use by wild birds are single instances involving an individual bird. Three of the more convincing concern a Double-crested Cormorant *Phalacrocorax auritus* that used a moulted secondary feather to 'paint' preen oil on its wings, an American Robin *Turdus migratorius* that used a twig to rake aside leaves, and an Egyptian Vulture in Israel that used a stone as a cudgel to kill a young monitor lizard. Many of the other cases scattered in the literature need to be treated with caution.

ANTING by birds can reasonably be held to be true tool use, but not the use of anvils by the Song Thrush *Turdus philomelos* and others; nor the dropping of hard-shelled objects from a height by crows and others.

A borderline case concerns the use of bait to attract prey. This behaviour is well-established for the Green Heron *Butorides virescens* in both the Old and the New Worlds; one individual used dummy bait, luring fish within range with a feather—a 'fly' placed carefully on the water surface. There is one fully authenticated case from Kenya of a Pied Kingfisher *Ceryle rudis* baiting with bread over a longish period of time.

To sum up, wild birds use the following: goad, poker, lever, rake, fishing stick, hammer, brush, thrown missile, dropped missile and kicked missile; plus bait and dummy bait. The functions include the finding, opening and moving of food; the care of the body; and the deterrence of food competitors; also the attraction of prey.

Tool use by birds in captivity is more commonly observed than among wild birds. In particular, parrots of several species use objects with which to scratch themselves; almost invariably they are specimens caged individually and which cannot indulge in mutual preening. One or two parrots use hollow objects as bailers to lift water to their bills. A Common American Crow *Corvus brachyrhynchos* filled a plastic cup by dipping in a water trough and then transported the water 5 m to tip it into a container of dried mash. At London Zoo an Oystercatcher *Haematopus ostralegus* regularly used a stick with which to probe cracks in the concrete surround of its cage; on one occasion it flushed an insect. A caged North-western Crow *Corvus caurinus* has been seen to use a probe. A detailed study of a captive Rook *C. frugilegus* showed how the bird would use a plug in a drainage hole to flood the floor of its aviary for a bath! A female Eclectus Parrot *Eclectus roratus* used a segment of palm frond to excavate a burrow in which it later laid eggs.

Tool-making (manufacture) is 'any modification of an object by the user or a conspecific so that the object serves more effectively as a tool'. Thus the simple detachment by the bird of part of an object is held to be tool making. The 2 Geospizids detach twigs and *pallida* will remove 'awkward' branching stems from a chosen twig. Similarly the Brown-headed Nuthatch detaches the flakes of bark. Certain crows and Starlings *Sturnus vulgaris* combine ants into wads to enhance their effectiveness. A remarkable case of tool-making among captive birds concerns Blue Jays *Cyanocitta cristata* that tore off strips of newspaper and used them to draw food toward themselves.

The rarity of tool use and tool-making among birds may be more apparent than real; the passage of time will bring to light additional implement-wielding birds. But it seems that only in exceptional circumstances is the employment of an external object a more parsimonious path for natural selection than the evolution of body structures or behavioural traits (other than tool-using), to solve the same problem.

TOOTH: see (plural) TEETH; also EGG-TOOTH.

TOOTHBILL: *Androdon aequatorialis* (for family see HUMMINGBIRD).

TOPAZ: substantive name of *Topaza* spp. (for family see HUMMINGBIRD).

TOPOGRAPHY: as applied to a bird, the definition of, and the terminology applied to, the various external areas and features of its plumage and bare parts. Some parts of the plumage, for example most of those on the head and underparts, are named after the approximately equivalent areas on the human body, and are thus incapable of close definition. Other parts of the plumage, for example those on the wings, are named from clearly defined groups of feathers. Topographical terms also include the names for particular plumage marks, for example the variously positioned stripes on the head of some species. Other terms refer to what are known collectively as the bare parts—the bill, the legs and feet, the orbital ring and the externally visible parts of the eye, and various unfeathered areas or specialized structures of some species; these are dealt with in separate articles (see BILL; INTEGUMENTARY STRUCTURES; IRIS COLORATION; LEG; SKIN), as also are certain of the plumage areas (see TAIL; WING; also PLUMAGE). There remain the areas, usually feathered, of the head, neck and body, and the various openings in the body surface.

Head and neck. From the base of the bill backwards, the areas are named as follows, any special adjectives referring to them being also given.

Dorsally: forehead (adj. frontal); crown (adj. coronal); occiput (back of head, adj. occipital); nape (adj. nuchal); hindneck. The forehead, crown, and occiput (the whole top of the head) are sometimes collectively called the pileum.

Laterally: (the terms are more commonly used in the plural, the two sides being similar): lore (between the upper mandible and the eye, adj. loral); ear-coverts or auriculars (behind and immediately below eye); malar region (the adjective malar, although strictly relating to the cheeks, is applied in ornithology to the area from the base of the lower mandible bordering the lower edge of the ear-coverts); side of neck.

Ventrally: chin or mentum; throat (adj. gular); foreneck or jugulum.

The whole side of the head may be referred to as the cheek and its upper part is sometimes called the temple. Other terms derive from particular plumage marks or colour patterns: some of these are shown in the chart, and there may also be a HOOD, or a CAP, or a COLLAR. Elongated feathers may constitute a CREST on the top of the head or hackles on the hindneck.

Body. Between the neck and the tail the areas are:

Dorsally: mantle or interscapular region (upper back); back; rump or uropygium.

Laterally (on each side): scapulars (between the mantle/back and wing); axillaries (between the flank and underwing); flank.

Ventrally: breast or chest (adj. pectoral); belly or abdomen; ventral region (sometimes vent, although literally this applies to the anus); crissum (vent and undertail-coverts together, adj. circumcloacal).

The need for naming different areas of the body may also depend largely on the requirements for describing a particular plumage mark or pattern. A band of colour on the upper breast may be called a breast-band or gorget. When the mantle, back and scapulars together present an area of distinctive colour, this may be called a saddle. The term mantle (pallium) is often also used when the mantle, back, scapulars and wing-coverts are uniformly coloured.

Openings. The openings in the body surface are the nostrils (anterior nares) on the upper mandible; the mouth (adj. buccal), at each side of which, at the junction of the upper and lower mandibles, is the gape (adj. rictal); the auditory meatus on each side of the head (usually hidden by feathers); the openings of the oil gland (sometimes absent) above the root of the tail; and the vent or anus, the external end of the cloaca (see ALIMENTARY SYSTEM; HEARING AND BALANCE; NARIS; OIL GLAND; TONGUE).

The primary practical application of topography is in compiling precise descriptions of birds, so that identification, ageing or sexing criteria may be clearly defined. The charts reproduced here are intended as a basis for this purpose, and show the standard terminology for the common areas and features of plumage and bare parts. All flying birds have the same basic 'map' of plumage components, but the prominence or extent of some feather groups (and the number of feathers in each group) may vary considerably from one species or family to another. A.L.T.

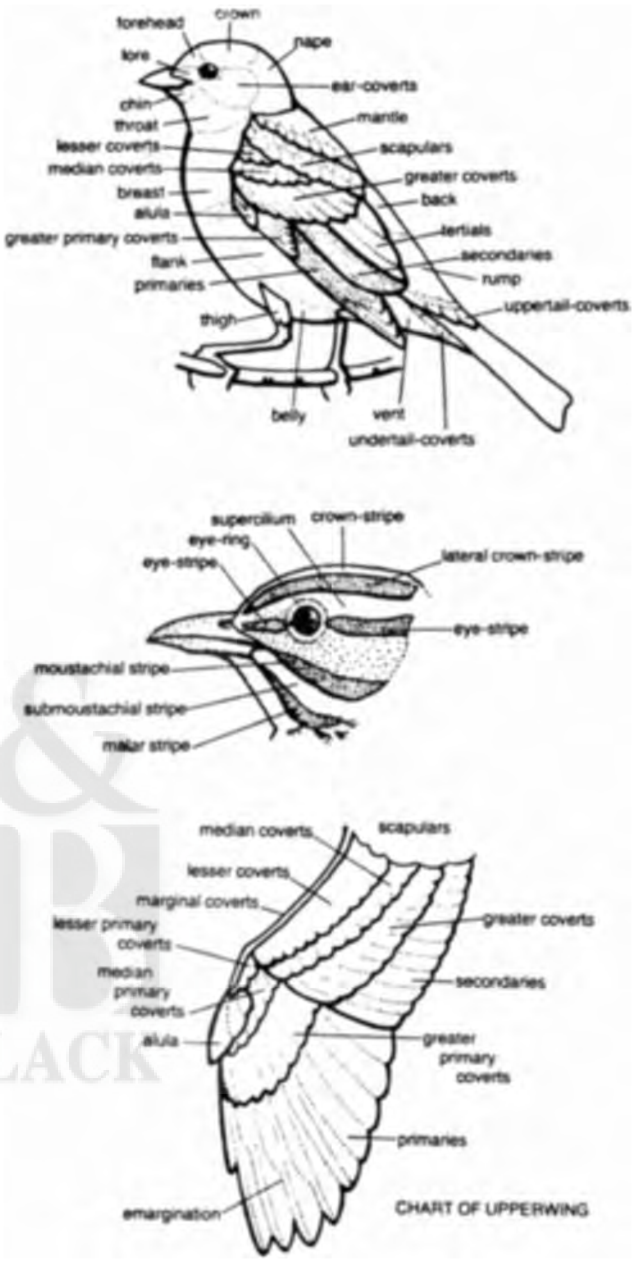

Fig. 1. Topography (above and opposite) of typical birds as published in the journal British Birds.

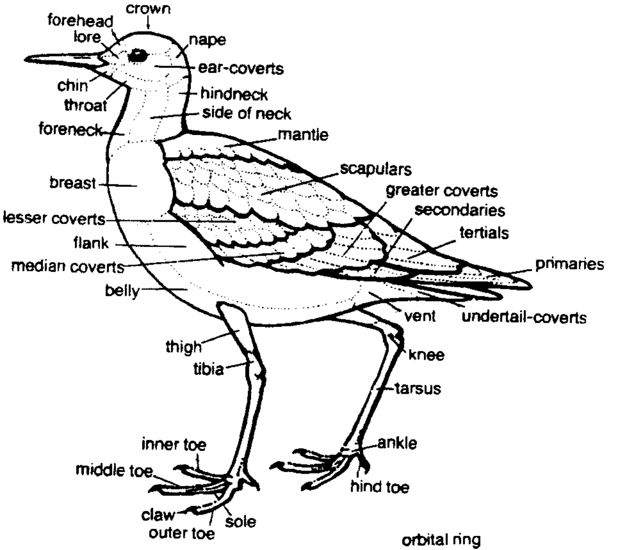
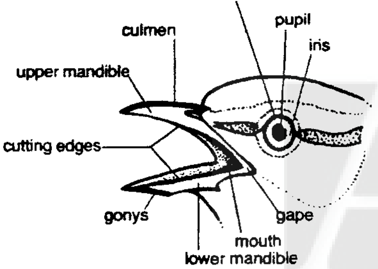
TOPOTYPE: term sometimes applied to a specimen, not forming part of the original type series, collected at the type locality of the species or subspecies concerned.

TOQ TOQ: *Foudia sechellarum* (for family see WEAVER).

TORPIDITY: a state of dormancy and lowered body temperature (hypothermia) that enables a bird to conserve energy during periods of energy shortage, and from which it can arouse by means of endogenous heat production. Birds of at least 3 orders (Apodiformes, Caprimulgiformes, and Coliiformes) can undergo daily cycles of torpidity, but prolonged dormancy of the type characteristic of mammalian hibernation has been demonstrated only in nightjars (Caprimulgidae) (see HEAT REGULATION; METABOLISM).

In the 18th century and earlier it was widely believed that swallows *Hirundo rustica* became torpid and passed the winter in hollow trees and crevices, or even in the mud at the bottom of ponds. When the actual





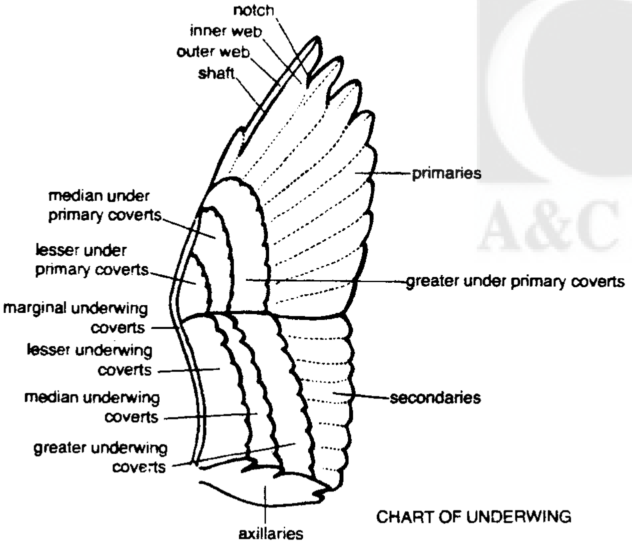


CHART OF UNDERWING

whereabouts of swallows during the winter became known, the hibernation theory was discarded as myth. The idea of avian hibernation was so completely discredited that the anecdotal accounts of the occurrence of dormancy in swifts and hummingbirds which were published during the first third of the 20th century by Hanna (1917) and by Chaplin (1933) attracted little interest. During a cold wave in January, 1913, in San Bernardino County, California, Hanna found a large number of dormant White-throated Swifts *Aeronautes saxatilis* in a rock crevice. He concluded that these birds might experience intermittent hibernation because they disappeared for many days in cold weather and during one such period he found them in substantial numbers among the rocks in a torpid state. Chaplin, in 1933, noted that in the 19th century Gould had observed torpidity in hummingbirds; he also reported that he had himself found *Chrysolampis mosquitus* and *Eupetomena macroura* torpid at ambient temperatures of 17–21°C. The birds sat on their perches with the head drawn down on to the shoulders, and 'showed to all appearances no spark of life.' Chaplin also observed that torpidity was not a direct response to cold because hummingbirds were often active at low temperatures. He suggested that swifts, nightjars, and colies might also experience torpidity. Six years later Huxley, Webb, and Best, apparently in ignorance of the literature, published similar although less detailed observations on hummingbirds.

In 1947 McAtee reviewed the literature on torpidity in birds and found few records, beyond those just mentioned, in which reliable witnesses reported first-hand observations. His review was published shortly before the remarkable discovery of a hibernating Poorwill *Phalaenoptilus nuttallii*, a caprimulgid which breeds in the arid and semi-arid parts of western North America. In December 1946 Jaeger (1949) found a Poorwill hibernating in a rock crevice in the Chuckwalla Mountains of the Colorado Desert in California. The bird was inert, its respiration and heart rate undetectable with the apparatus available in the field. The bird was ringed and in subsequent winters was found repeatedly in the same spot in a dormant condition with a body temperature of 18–20°C. Fewer than half a dozen torpid Poorwills have subsequently been found in nature but many aspects of the physiology of both normally alert and torpid Poorwills and other caprimulgids have been studied in captive birds (Withers 1977).

In torpid caprimulgids low body temperature, and a greatly reduced metabolic rate allow prolonged survival in a dormant state. Calculations indicate that normal fat deposits can easily sustain a torpid Poorwill for 100 days at a body temperature of 10°C. In captivity Poorwills have remained in torpor for as long as 4 days. However, the other kinds of birds which experience dormancy appear to remain dormant only overnight (hummingbirds) or at most for only a few days (swifts and colies).

The mass-specific energy metabolism of hummingbirds is extremely high, not only because of their small size, but because they characteristically feed on the wing and flight is energetically expensive. As long as hummingbirds maintain a high body temperature they are never more than a few hours from death by starvation. This would be a formidable hazard in periods of inclement weather or food shortage were it not for their capacity for becoming torpid at night during periods of energy shortage. They hold body temperature at a typical avian level (approximately 40°C) during daytime, but after going to roost at night they may allow it to fall to near ambient, which in some cases involves a decrease of more than 30°C. This pattern of heterothermy is central to the success of hummingbirds and has been extensively documented both ecologically and physiologically (see Bartholomew 1972; Calder 1974; Hainsworth and Wolf 1978).

At present two primary generalizations can be made about hummingbird torpidity. (1) Torpor occurs only when energy is in short supply. If food is readily available hummingbirds maintain normally high body temperatures. (2) Body temperature during torpor is in a regulated state; the level of hypothermia about which temperature is controlled varies from species to species, and appears to be related to the environment in which the birds live. This level is near 20°C in *Eulampis jugularis* which occurs in the lesser Antilles in mountainous areas where the altitude is generally less than 1,500 m. It is near 10°C in *Eugenes fulgens* which occurs on mountain slopes from Arizona to Panama, and near 7°C in *Oreotrochilus estella* which occurs at altitudes from 3,800 to 4,200 m in the Andes.

Torpidity occurs in the Apodidae but it has not been extensively studied either physiologically or ecologically. The nestlings of the Swift *Apus apus* become torpid during temporary food shortages. Adults of the White-throated Swift *Aeronautes saxatilis* will undergo torpor both in the laboratory and in the field and can spontaneously arouse from body temperatures near 20°C.

A nocturnal decline of body temperature of 10°C or more (usually not accompanied by complete torpor) has been reported in several sunbirds in the genera *Nectarinia* and *Anthreptes* kept in captivity at an altitude of 3,350 m in East Africa (Cheke 1970). Like hummingbirds, sunbirds feed on nectar and insects. A capacity for nocturnal hypothermia could afford them significant energy savings during periods of inclement weather.

Torpor also occurs in birds that do not depend primarily on nectar or insects for food. The Speckled Mousebird *Colius striatus* can enter into and arouse from a state of nocturnal torpor in which body temperature falls 15°C or more below normal levels. These birds, which belong to the Order Coliiformes, are widely distributed in Africa south of the Sahara. They weigh about 50 g and are almost exclusively vegetarian. Thus, they do not face the necessity of sustaining extremely high rates of mass-specific metabolism nor do they have to deal with the problem of temporary shortages of insect food during bad weather. Moreover, they readily maintain normal high body temperatures (about 39°C) at ambient temperatures near 0°C. Consequently, the precise ecological role of torpor in colies remains obscure.

It is of interest that a similar but less profound nocturnal hypothermia occurs in at least 2 species of tropical passerines which feed primarily on fruit, the Red-capped Manakin *Pipra mentalis* and the Golden-collared Manakin *Manacus vitellinus*. During periods of reduced food intake these manakins allow body temperature to fall to as low as 30°C at night and then gradually warm up to normal levels in the pre-dawn hours. However, they do not enter a completely dormant state. Similar but less extreme nocturnal hypothermia has been reported in the Willow Tit *Parus montanus* and Siberian Tit *P. cinctus* in northern Europe and in the Black-capped Chickadee *P. atricapillus* in north-eastern United States, but it apparently does not occur in Arctic populations of this species.

Avian torpidity and the associated condition of marked nocturnal hypothermia have so far been examined in only a few species. However, their occurrence may be much more widespread than currently documented. One can predict that they are most likely to be found in species that have unusually well sheltered roosting sites or live in warm regions. For example, in the lowland tropics where night time air temperatures rarely fall below 18–20°C, a nocturnal decline of body temperature of 10°C halves the difference between body and ambient temperatures. This reduces the rate of heat loss to the environment by 50% and results in a concomitant saving in metabolic energy which could be ecologically important during periods of reduced food availability such as occur during the dry season for both insectivorous and frugivorous species. TOTIPALMATE: having all 4 toes connected by webs (see LEG).

TOUCAN: substantive name of species of Ramphastidae (Piciformes, suborder Galbulae); in the plural, general term for the family. The name comes from 'tucano' in the language of the Tupi Indians of Brazil. The family consists of 6 genera and 42 species.

Characteristics. Toucans are middle-sized or large birds (34–66 cm long) confined to the tropical parts of the American continents. Wholly arboreal, they occur only in wooded regions, chiefly at low and middle altitudes. The outstanding feature of these ungraceful birds is the bill, which in all species is enormously enlarged, while in some it almost equals the body in length and bulk. Nearly always it is coloured with several bright and contrasting hues. Although in some species it appears almost too heavy for the bird to support, lightness combined with strength is obtained by a network of bony fibres ramifying through the space within the horny outer shell. Nevertheless, these bills are sometimes conspicuously broken; birds lacking half the mandible or maxilla often survive a long while in the free state. In size the toucan's bill compares with that of the hornbills of the Old World tropics, but it always lacks the dorsal out-growth or casque; the 2 families are not closely related.

Collared Araçari *Pteroglossus torquatus*. (*P.J.K.B.*).

The toucan's tongue is also remarkable. It is a long, narrow, horizontally flattened, thin lamina, which may attain a length of 15 cm in the largest species. Its distal part is on both sides obliquely notched by indentations that become progressively deeper toward the apex, where it has a bristly aspect. The wings are short and rounded; the tail tends to be long; the legs are strong and the feet zygodactylous. Each eye is surrounded by an area of bare skin that is usually brightly coloured.

Distribution and habitat. The largest toucans belong to the genus *Ramphastos*, which contains 12 species, up to 66 cm long. The Rainbow-billed or Keel-billed Toucan *R. sulfuratus* ranges through the forests from southern Mexico to northern South America. As in most toucans, the sexes are alike in coloration, but the males average larger than the females, with considerably longer bills. About 43–50 cm long, this stout bird is largely black, slightly glossed with green on the upper parts and washed with maroon on the hindneck. The upper tail coverts are white. The cheeks, throat, and foreneck are bright yellow, and the under tail coverts are bright poppy red. The coloration of the great, swollen bill varies somewhat with individuals and, with the exception of violet, all the colours of the rainbow are found on it. The tints blend rainbowlike into each other, and the basal margin of the bill is deep black. Other members of this genus have fewer but more strongly contrasting colours on their bills.

The genus *Pteroglossus* consists of 13 long-tailed, middle-sized or small toucans usually called araçaris. The Collared Araçari *P. torquatus* is a slender bird, about 42 cm long, which is found in wooded country at lower altitudes from southern Mexico to Colombia and Venezuela. In both sexes, the upper plumage is generally blackish, glossed with green on the back, with a bright red rump and upper tail coverts. The throat and foreneck are black, and the more posterior under plumage is largely yellow, with a band of black and red across the upper abdomen. The bill, less vividly coloured than in certain other araçaris, is whitish, grey, and black. The cutting edge of the maxilla has widely spaced, toothlike projections. The bright yellow eyes are surrounded by red bare skin. In this genus the curious Curl-crested Toucan *P. beauharnaesii* of the upper Amazon valley is sometimes placed. The feathers of its head consist largely of the broadly expanded horny shafts. Those on the pileum are curled forward and resemble shavings of glossy black horn.

The 7 toucanets of the genus *Aulacorhynchus* are largely green in plumage and reach higher altitudes than the 2 preceding genera, to about

3,000 m in the Andes and the highlands of Middle America. The Blue-throated Toucanet *A. prasinus caeruleogularis*, confined to the mountains of Costa Rica and western Panama, is about 30 cm long. In both sexes, the green plumage which covers most of the body lacks metallic lustre. The cheeks, chin, and throat are dark blue, and the under tail coverts are chestnut. The bill is yellow, white, red, and black, with yellow predominating. Toucanets perform vertical migrations, but other members of the family seem not to migrate.

Likewise found at high altitudes are the 4 species of the Andean genus *Andigena*, known as mountain toucans. The 56 cm long Black-billed Mountain Toucan *A. nigrirostris* is glossy black on crown and hindneck and olive-brown on back and wings. The rump is yellow, throat white, under tail coverts crimson, rest of under parts light blue, and thighs chestnut. The 5 small toucanets of the genus *Selenidera* have intricately patterned plumage and are the only members of the family in which the sexes differ in coloration. They inhabit warm forests of the Tropical Zone. The Saffron Toucanet *Baillonius bailloni* of south-eastern Brazil is the only member of its genus.

Food. Toucans eat many berries, arillate seeds, and other small fruits, and they vary their diet with such insects, spiders, small lizards, small snakes, and the like as they can catch, including slowly fluttering termites on evenings when the air is full of the winged sexual brood. Seizing the food in the tip of its great bill, the toucan tosses its head upward to throw the piece backward into its throat. Large items are first torn by the bill while held against the perch with a foot. The toucan that Humboldt and Bonpland carried on their historic canoe voyage up the Río Orinoco liked to fish in the river. Species of *Ramphastos, Pteroglossus, Aulacorhynchus*, and doubtless other genera, devour eggs and nestlings of small birds.

It is in connection with the toucans' feeding habits that their peculiar bills must be considered. The long bill enables these heavy, rather clumsy birds to reach fruits that grow at the slender tips of branches while they perch farther inward, where they find more adequate support. But to give a longer reach, the bill need be neither thick nor brightly coloured.

Behaviour. Toucans are sociable birds that are often found in small flocks of a few to more than a dozen individuals, yet they are almost devoid of group impulses. When they travel, one flies away and then another follows; and so they straggle on, one by one, until the whole flock has moved. The larger species fly with alternate flapping and gliding, tracing undulatory courses; but the flight of some of the smaller kinds is swift and direct. Toucans bathe in water that collects in hollows in crotches of trees or in the upper side of thick horizontal limbs, often high above the ground. They evince curiosity, and in remote forests they may look down with interest at the activities of a botanical collector or other human intruder. They are frolicsome birds, jumping about and sometimes playfully striking their great bills together in a sort of fencing, or grasping each other's bills and pushing, with no display of antagonism. Sometimes they preen one another's plumage with the tips of their bills. At least in *Ramphastos*, *Pteroglossus*, and *Aulacorhynchus*, one individual often passes food to another, doubtless its mate. Sometimes pair members feed each other reciprocally. Like other piciform birds, toucans scratch their heads by raising a foot outside the closed wing rather than over the drooped wing, as passerines commonly do.

The size and vividness of toucans' bills probably serve them well when they make predatory visits to the nests of other birds; they are so intimidating that even small hawks and the boldest of the American flycatchers (Tyrannidae) fear to attack a toucan perching beside its nest. But when the pirates are flying and cannot turn their heads to defend their backs, the outraged parents sometimes buffet them. Since the bills of conspecifics often differ more strikingly in coloration than their plumage, they probably serve for specific recognition among sympatric forms. The vivid bill may also enter into courtship, although little is known about toucans' nuptial displays. It has been suggested that the long bill may also help an incubating or brooding toucan to repel enemies from the doorway of its hole, but toucans hurry forth from their nests at the first hint of danger.

Sleeping. Araçaris roost throughout the year in holes of woodpeckers or other cavities, usually high in trees. Each flock seems to have a number of these lodgings; if their suspicions are aroused as they approach one, they may retire into another. Five or 6 adults may sleep in the same hole, folding their tails over their backs to save space in crowded quarters. In captivity, *Ramphastos* spp. roost with the bill laid among the plumage of the back and the tail folded forward over the bill, so that they become featureless balls of feathers. Bourne (1974) noticed 5 Red-billed Toucans *R. tucanus* sleeping side by side in close contact high in a tree in Guyana. As far as known, only *Pteroglossus* spp. and (at least occasionally) the Guianan Toucanet *Selenidera culik* sleep in holes when not nesting.

Voice. Toucans are poorly endowed vocally. Their monotonous calls have been compared to the croaking of frogs, the mewing of gulls, and the yelping of puppies. They produce rattling, castanetlike notes that seem to be mechanical but are actually vocal. Araçaris utter high, sharp notes, surprisingly weak for such large birds. The *dios te de, te de, te de* of the Chestnut-mandibled Toucan *Ramphastos swainsonii* is, however, not unmelodious as it floats down from distant treetops. These birds sing much at nightfall, swinging their heads up and down as they emit their notes.

Breeding. Toucans nest in trees, in hollows resulting from decay or, in the smaller species, in woodpeckers' holes, of which they may dispossess the makers. They may remove rotten wood from a hole, or enlarge the doorway if the surrounding wood is soft; but their occasional attempts to carve a nest cavity seem always to be ineffectual. *Ramphastos* spp. prefer living trees and may nest in the same cavity in successive years, but smaller toucans are often content with dead trees. Toucans' nests are often at a great height, but exceptionally they choose one near the ground. Rainbow-billed Toucans take a few green leaves into their holes and may carry them away after they wither. Otherwise, toucans take no lining into their nests; but the many large seeds which they regurgitate while they sit soon form a pebbly bed beneath the eggs. These number 2–4 in a clutch; they are broadly ovate, white or pinkish, and unmarked.

Incubation is performed by both parents, who are surprisingly restless for such large birds. They seldom sit for more than an hour at a stretch; and often they leave the eggs uncovered for up to an hour or more, while both attendants go off to forage. Even if, as in the araçaris, both parents had slept in the nest hole before laying began, only one stays with the eggs at night. A male Red-billed Toucan incubated by night and also brooded the young on most nights, but the female sometimes brooded through the night. However, only the female of a pair of Blue-throated Toucanets was seen to occupy a nest with eggs at night. Nocturnal incubation and brooding by the male is usual in the related woodpeckers and has also been found in puffbirds, but it is not invariable in the order Piciformes. The incubation period of the Red-billed Toucan is approximately 15.5 days; that of the Blue-throated Toucanet, 16 days.

Toucans are hatched perfectly naked, with no trace of down. Their eyes are tightly closed, and the mandible is both longer and broader than the maxilla. Their heels are equipped with prominent thickened pads, from which project a number of strong tubercles, arranged in a peripheral ring in species of *Ramphastos*. These heel pads, along with the abdomen, bear the nestling's weight; their function appears to be to prevent abrasion of the heel joint by the nest's rough floor. The nestling's uropygium is extraordinarily long and prominent and is often held with a strong upward tilt. Young toucans develop with extreme slowness. They are over 2 weeks old before their eyes begin to open, and at this age they are still naked.

Both parents brood and feed the young, nourishing them largely with fruits, insects especially while they are younger, and occasionally a lizard, small snake, or the nestling of some other bird. Much of the food is carried to the nest in the throat or stomach, but usually a final item is held prominently in the parent's bill and given to a nestling before the remainder of the load is brought forth. Waste material is removed from the nest in the parents' bills. In the Blue-throated Toucanet and species of *Ramphastos*, a single parent sleeps with the nestlings until a few days before their departure, but in the araçaris both parents pass the night with them. In Panama, 6 Collared Araçaris roosted in a very high hole that was afterward used for breeding. Only one parent slept in it while incubation was in progress, but after the eggs hatched 5 adults roosted in the nest hole each night. All 5 of them fed the nestlings, of which there were at least 3. The nestling period of this species is 43–46 days; that of the Blue-throated Toucanet, 43 days; and that of *Ramphastos* spp., about 47–49 days. Fledgling araçaris return to sleep in the nest hole with their parents, and the helpers when these are present; but apparently young of *Ramphastos* spp. and *Aulacorhynchus* spp. do not return. In the highlands, Blue-throated Toucanets rear 2 broods in a season, but the larger toucans of the lowlands apparently attempt only a single brood. A.F.S.

TOUCANET: substantive name of *Aulacorhynchus* spp. (see TOUCAN).

TOUCH: the 'sense of touch' is understood to mean the faculty to perceive mechanical deformation of the body surface (or internal structures) which can be caused by autogenic movements as well as by external influences. Exposed regions, like finger-tips or lips in man, are particularly touch-sensitive; the same is true of bill-rim, bill-tip, palate and tongue in birds. Tactile perception is, however, found distributed over the whole avian body as well, though it has but rarely been studied. Tactile perception, combined with temperature and pain sensitivity, constitutes in all vertebrates the so-called 'somato-sensory system'. In birds too, certain slow-adapting mechanoreceptors are at the same time strongly temperature sensitive; as in mammals, 'genuine' thermoreceptors are also found.

Receptors for tactile stimuli are, in most cases, the endings of sensory nerve fibres which are partially equipped with small organs and originate from the ganglia of the cranial nerves (trigeminal for bill, glossopharyngeal for tongue) and the spinal ganglia. Direct participation by elements of the sympathetic system in tactile perception is questionable, but the tactile corpuscles of birds also appear to receive additional sympathetic innervation. A great variety of sensory endings is known from the skin of mammals; in birds these concern free nerve-endings, Merkel and Grandry's corpuscles and also the lamellated Herbst's corpuscles (see SKIN). These contain, as the sensitive element, a central axon-process surrounded by several myelinated layers of Schwann cell derivatives and an outer capsule of connective tissue; they are essentially comparable to the somewhat larger mammalian Pacinian corpuscles but differ a little in enzymatic respect. Grandry's corpuscles are found only in birds, predominantly in the bill region of Anatidae. They may be understood as a higher development of the Merkel corpuscles also known in mammals, but are distinguished above all by the capsule and a larger number of 'tactile cells'; furthermore, they are positioned within somewhat deeper subepidermal layers. As in the Merkel corpuscles, flattened segments of afferent nerve fibres enter between at least two, frequently more cushion-like differentiated cells ('tactile cells'), the neurofibrils forming a dense plexus in the unmyelinated nerve segments. Synaptoid ultra-structures are found in the very narrow contact-zones with the 'tactile cells'. The interpretation of the latter as excitable secondary sense-cells is controversial.

Responsible, as a somato-sensory region for the processing in the central nervous system of sensory information from avian tactile receptors, is on the one hand an electro-physiologically detected region in the Neostriatum caudale adjoining the auditory region (Field L). On the other hand, anatomical studies have shown that not only the main sensory trigeminal nucleus but correspondingly also the frontal fore-brain region (Nucleus basalis) increases in size depending on the degree to which the bill is used as a tactile organ. The frontal fore-brain region is connected to the trigeminal nucleus by the Tractus quintofrontalis. From the size development of these two regions a functional order can be derived leading from *Merops* through *Strix*, *Aix*, *Melopsittacus* to *Capella* and *Ibis*. Finally, somato-sensory input is also clearly represented in the cerebellum, especially within folium V1.

Some insight into the functional importance of the touch-sensitive nerve-endings can be gained by considering their distribution over the avian body. Free nerve-endings are found in all regions but are apparently less densely distributed than in mammals. They alone can also enter epidermal cell layers. Merkel corpuscles have been found superficially beneath the epidermis and also the keratinized sections of tarsus and foot. Herbst's corpuscles occur at the base of the contour feathers, abundantly in the region of the bill-tip, e.g. in Scolopacidae and Anatidae (bill-tip organ), in the palate, and, with particular concentration, in the tongue-tip of woodpeckers; they are not found, however, on the plantar surface of the foot. In the especially well studied bill of ducks and geese (Anatidae), Herbst's corpuscles are somewhat more numerous and, importantly, they show a different distribution from that of Grandry's corpuscles. Overall, the supply with tactile endings of certain sections of the anatid bill considerably exceeds that of the human finger-tip. Larger numbers of Herbst's corpuscles occur furthermore on the metacarpus and between radius and ulna, attached to the remigial follicles. As on the bill-tip, alveolar isolating structures are formed around the corpuscles. A special 'cord' of numerous Herbst's corpuscles is protectively located between the tibia and fibula where it is exposed only towards the M. flexor-digitorum profundus. The distribution and special arrangement of the endings permit general conclusions to be drawn regarding the respective functions in the taking up and processing of food and also control of movements. Only a few experimental studies give direct information on receptor efficiency. According to these studies, the Herbst's corpuscles, like the more exactly known Pacinian corpuscles of mammals, may be numbered amongst the fast-adapting endings which are especially sensitive to dynamic tactile and vibratory stimuli. The fluid-filled cushion, enclosed in the capsule of connective tissue, functions as a low pass filter and, in accordance with their small size, the Herbst's corpuscles of birds react to slightly higher frequencies of vibratory stimuli than the mammalian Pacinian corpuscles. In the Bullfinch *Pyrrhula pyrrhula*, behavioural experiments have shown an optimal sensitivity to vibration (localized in the lower leg) lying between 400 and 800 Hz. Neurophysiological studies on ducks have demonstrated corresponding preferential frequencies. The threshold amplitude lies one order of magnitude below that of the human finger-tip. Vibrations of the remiges are presumed to be perceived in flight; air currents directed onto the breast feathers release reflex flight-movements.

The Grandry's corpuscles also belong to the fast-adapting 'phasic' receptors which are particularly suited to the processing of tactile stimuli. Here it is not amplitude or frequency but rather the speed of deformation which is decisive for stimulus efficiency. The Merkel corpuscles and free nerve-endings are employed as receptors for more persistent (tonic) pressure stimuli.

The behaviour of birds with widely differing ecological adaptations, well known from a great variety of ornithological observations, shows the slightly varying but always paramount importance of the bill in obtaining, tactilely investigating and dealing with food. This is true for the bill of snipe (Scolopacidae) which 'probe blindly' into the substrate, for dabbling ducks (*Anas* spp.), but also for the palate and tongue of granivorous birds in the 'shelling' of seeds. The function of the tongue-tip of woodpeckers becomes particularly clear when these birds explore insect tunnels in wood. The sensitivity of birds to vibrations, occasionally described as mysterious—e.g. swallows Hirundinidae leaving their nests in advance of earthquakes—can be explained by the efficiency of vibration receptors in the lower leg. Tactile sensations, translated by way of the feathers or the feet, are also involved in preening and in contact between eggs or chicks ready to hatch and the brooding parent. J.S.

TOURACO: see TURACO.

TOWHEE: substantive name of species of *Pipilo* (see BUNTING; also HYBRIDIZATION, ZONE OF SECONDARY).

TOXIC CHEMICALS: considered here as a hazard to birdlife. Any chemical can be toxic; whether it is depends on the dose. The term 'toxic chemicals' is used to describe those substances which are put into the environment by man on a scale and at concentrations which have or are likely to have deleterious effects on organisms. They include pesticides used in agriculture, forestry and public health, and industrial pollutants such as polychlorinated biphenyls (PCB) and heavy metals. Fertilizers can have profound effects on terrestrial and aquatic ecosystems and so may affect bird populations, but they are not usually classified as toxic chemicals, nor are oils (see OIL POLLUTION). The most important toxic chemicals from the ornithological point of view are pesticides, PCBs and mercury.

Pollution is principally a consequence of industrialization and has been a significant factor for many decades, but the extensive use of pesticides only began in the 1940s and 1950s. They became an integral part of farming throughout the developed world and much of the developing world in the 1960s. Growth in the use of pesticides in the United Kingdom is shown by the following: 15 chemicals were listed in the Ministry of Agriculture's List of Approved Products for Farmers and Growers in 1950, 47 in 1960, 163 in 1970 and 198 in 1980.

Thus, pesticides are a new and important ecological factor. They include herbicides, fungicides, insecticides, rodenticides and growth retardants. No pesticide is specific to a particular pest or weed, therefore their use always involves some risk to some other organism, though in practice it may often be ecologically negligible. Hazards to birds depend on the toxicity of the compound, its dose rate and on the way it is applied. Very dilute formulations of very toxic substances may be less dangerous than more concentrated formulations of less toxic substances. Less toxic substances which are very persistent (e.g. DDT) may be more dangerous than very toxic ones which break down quickly (e.g. several organophosphorus insecticides). If seed dressed with very toxic insecticides (e.g. aldrin, dieldrin and certain carbamates such as aldicarb) or fungicides (certain mercury compounds) is left exposed on the ground it can be particularly hazardous to birds since it acts as poison bait. The deliberate misuse of pesticides, notably mevinphos, α-chloralose and strychnine as poison baits has caused the deaths of numerous predatory birds in Great Britain.

Pesticides affect individual birds either directly by poisoning them, or indirectly by reducing their food supply or cover. The prediction of the effects of pesticides on bird populations is extremely difficult. First, because species vary considerably in their response to the same pesticide, for example, grey geese *Anser* are much more susceptible to the organophosphorus seed dressing carbophenothion than are Woodpigeons *Columba palumbus* or Canada Geese *Branta canadensis*. Secondly, because the interaction between lethal and sub-lethal toxic effects with environmental factors (which may include indirect effects of pesticides) are extremely complicated. Thus it is not yet possible to assess the impact of pesticides on most species of birds.

In the 1950s the use of dinitrocresol and the more toxic organophosphorus insecticides such as parathion, was responsible for the death of numerous birds in Great Britain, continental Europe and the USA. The deaths drew attention to the dangers of pesticides to wildlife and stimulated authorities to seek ways of reducing harmful side-effects of pesticides. The British Pesticides Safety Precaution Scheme was introduced in 1953. During the late 1950s and early 1960s attention was focussed on the persistent organochlorine insecticides. These vary in toxicity, aldrin, dieldrin and heptachlor being much more toxic than DDT and TDE. They or their metabolites are soluble in lipids and hence become stored in animal fats. This enables them to accumulate in animals and so to be transferred from prey to predator. Although the amounts of these chemicals in water are so small that they often cannot be detected, fish and molluscs can concentrate them through their gills and so can pass persistent pesticides on to fish-feeding birds such as pelicans, cormorants, herons and grebes. DDT breaks down extremely slowly below the surface layers of the soil. Thus, owing to their persistence, organochlorine insecticides can circulate within ecosystems for a long time. Much is now known about the amounts of organochlorine insecticides present in air, water, soils and organisms and about their transfer from one level or organ to another. Persistent organochlorine insecticides have numerous physiological effects, but the most significant is their effect on the central nervous system. Stress occasioned by migration, reproduction and starvation causes depletion of the fat reserves and so results in an increase of pesticide in the blood, which in turn affects the brain. DDE, the principal metabolite of DDT, causes EGGSHELL THINNING and dieldrin affects reproductive behaviour in birds.

Lethal and sub-lethal effects of persistent organochlorine insecticides on predatory and fish-feeding birds have been studied in the laboratory and in the field, notably in the British Isles, North America and in central and northern Europe. Pesticide residues can be considerable and yet little effect on populations can be discerned. For example, large residues and associated reproductive failure have been reported in the Heron *Ardea cinerea*, yet effects on the total English population of this species appear to have been negligible. Different pesticide practices have had different effects in different regions. The well documented declines in populations of Peregrines *Falco peregrinus*, Sparrowhawks *Accipiter nisus* and Kestrels *Falco tinnunculus* in the United Kingdom were primarily due to acute poisoning by dieldrin, as was the decline in the breeding success of the Golden Eagle *Aquila chrysaetos*. By contrast in the USA, the declines of the Peregrine Falcon, Osprey *Pandion haliaetus*, Bald Eagle *Haliaeetus leucocephalus* and Brown Pelican *Pelecanus occidentalis* and American White Pelican *P. erythrorhynchus* appear mainly to have been caused by DDT. The sub-lethal effects of DDE appear to have been more serious in the USA than in the United Kingdom.

Little is known about the indirect effects of pesticides on birds. However, the elimination of reeds from large areas of the English Fens through the use of dalapon must have affected the numbers of Reed Warblers *Acrocephalus scirpaceus* there, and there is some evidence that low numbers of Kestrels and Barn Owls *Tyto alba* may be due to lack of food caused by pesticides as well as to habitat loss. Extensive studies on the Grey Partridge *Perdix perdix* have shown that its decline in Great Britain is due primarily to a diminution of the insect food which is necessary for its chicks in summer. The decline of insects is due to herbicides which kill the weeds on which the insects depend, to insecticides and insecticidal fungicides applied to cereals, and to a decline in the practice of under-sowing. The great reduction in populations of many weed species by herbicides must have had profound effects on many other bird species but they have been little studied.

PCBs, which have numerous industrial uses, are like DDT in being fat-soluble and very persistent in the environment. Large residues of PCBs have been recorded in many birds, particularly sea-birds, in many parts of the world. Little is known about their effects on bird populations. They were probably a contributing factor in the sea-bird disaster in the Irish Sea in 1969 when many thousand Guillemots *Uria aalge* died.

Organic mercury compounds are used extensively as fungicides. Fungicides based on methyl mercury caused many farmland bird deaths and population declines in Sweden in the 1950s. Phenyl mercury was also used extensively in that country in order to preserve wood pulp. This compound is broken down into inorganic mercuric compounds but in bottom muds the latter can become converted into methyl mercury, which is commonly found in fish in Sweden. Little is known about the effects of secondary poisoning of fish-feeding birds by mercury in Sweden or elsewhere. It is often difficult to separate the effects of mercury from those of organochlorine insecticides since birds are frequently exposed to both types of chemical at the same time.

Demonstration of deleterious effects of pesticides on bird populations has resulted in restrictions or total bans on certain pesticides in developed countries and to a growing sophistication in the methods of controlling pesticide use. Large-scale mortality due to DDT, dieldrin, aldrin and methyl mercury ceased when restrictions were placed on these substances. As a result, British populations of Peregrines, Kestrels and Sparrowhawks have shown marked recoveries and reproduction in the Golden Eagle has returned to normal. Nevertheless, considerable DDE residues are still found in Sparrowhawks and the recovery of this species has been relatively slow. Elsewhere in Europe and in the USA recoveries of affected species have been slower or non-existent. Partly, this appears to be due to birds migrating in winter to areas where persistent organochlorine insecticides are still widely used. Restrictions on the use of the organophosphorus seed dressing carbophenothion in Scotland was agreed between industry and Government in the 1970s and removed a serious hazard to Greylag Geese *Anser anser* and Pinkfeet *A. brachyrhynchus* in that country.

Pesticides will continue to be used extensively in the developed world and their use in the developing world is likely to increase. Despite advances in their control they are likely to remain a significant factor in relation to bird populations in the years to come. N.W.M.

TRACHEA: the windpipe, an air passage leading from an opening (glottis) at the back of the mouth, running down the neck (ventrally to the oesophagus), and dividing into the two bronchi leading to the lungs (see RESPIRATORY SYSTEM). The anterior part, surrounded by the cricoid and other cartilages, is known as the larynx but is without vocal cords. At the posterior end and commonly also involving the bronchi (but wholly tracheal in some species, and wholly bronchial in some others) is the syrinx, an organ peculiar to birds (see SYRINX). The whole tube is reinforced by cartilaginous or bony rings, and dilatations or enlargements are found in some species, notably among ducks. In certain species, either in the males only or in both sexes, the tube is elongated by being coiled; different versions of this character are found in a wide diversity of birds, but its presence may not be constant even within a genus. In some swans and cranes the bone of the sternal carina is extensively excavated to accommodate the tracheal loops. (Fig. 1.)

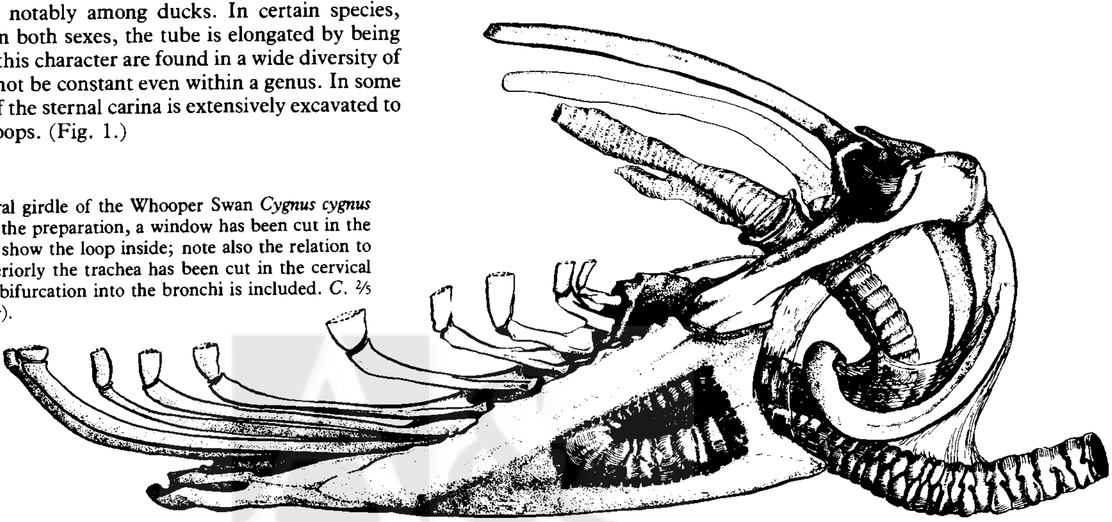

Fig. 1. Sternum and pectoral girdle of the Whooper Swan *Cygnus cygnus* showing looped trachea. In the preparation, a window has been cut in the side of the hollow carina to show the loop inside; note also the relation to the furcula (clavicles). Anteriorly the trachea has been cut in the cervical region, and posteriorly the bifurcation into the bronchi is included. *C.* ⅖ Natural size. (*Saida Symons*).

TRACHEOPHONAE: see under PASSERIFORMES.

TRACK: the path of a flying bird relative to the earth's surface; the resultant (allowing for speeds) of the bird's heading and the local wind (see MIGRATION, Flight performance).

TRACKS AND SIGNS: footmarks and other evidence of their presence left by birds. Foot and wing marks show on soft ground (mud, sand) and snow, and vary with the shape of foot, length of leg and gait (see LOCOMOTION, TERRESTRIAL). Signs include DROPPINGS, PELLETS, plucking places of birds-of-prey, food remains, shrikes' larders.

Ennion, E.A.R. & Tinbergen, N. 1967. Tracks. Oxford.
Urner, C.A. 1943. *In* Hickey, J.J. Guide to Bird Watching. London.

TRAGOPAN: substantive name of *Tragopan* spp. (see PHEASANT).

TRAIN: term sometimes applied to a long tail or tail-coverts e.g. of a Peacock *Pavo cristatus*, or by falconers to tail of a bird-of-prey (see TAIL).

TRAINBEARER: substantive name of *Lesbia* spp. (see HUMMINGBIRD); also formerly of several *Pharomachrus* spp. (see QUETZAL; TROGON).

TRANSECT: see BIOSTATISTICS; CENSUS.

TRANSIENT: perhaps the most precise term for a species or subspecies (on occasion applicable to individual birds) that appears on migration in the area under reference but neither breeds nor over-winters there; also 'passage migrant' (see MIGRATION, Time of year).

TRANSILIENT: term for a mode of moulting the primary feathers, proceeding by forward or backward leaps across one or more adjoining quills. The term was coined by Stresemann and Stresemann (1961) to describe the mode of primary moult of some cuckoos. Orderly transilient moult is apparently confined to some of the Old World parasitic members of the family (see MOULT).

Stresemann, V. & E. 1961. Die Handschwingen-Mauser der Kuckucke (Cuculidae). J. Orn. 102: 317–352.

TRAPPING: in the present context, the catching of wild birds for ringing and other study purposes. In the UK trapping is only permitted under licence (except for certain pest species by authorized persons); but no methods that might cause suffering are countenanced (e.g. bird-lime, stupefying baits, tethered decoys), and a special permit is required to use lights for catching birds at night. The position naturally varies from country to country, and in some the trapping of birds for food or caging is still practised on a large scale.

Static cage-type traps. The traditional method employed until the mid 1950s, when mist nets, rocket/cannon nets, and clapnets began to be widely used. Still utilized but now mainly in special circumstances e.g. Heligoland traps, duck traps, waders in the Baltic, corvids (see OBSERVATORY, BIRDS).

The Heligoland trap is a long permanent wire-netting cage, up to 4 m high at the mouth and 20 m wide between wings (Fig. 1), narrowing and beset by baffles as it gives access beyond a swing-to door to a 'lock-up', and finally to a windowed catching-box whence birds are removed through a sleeve. Migrants on Heligoland in the early part of the century were driven into such traps from low cover in the catching area ahead, or were attracted by water or bait provided. At the other extreme are the small Potter and Chardonneret traps used in suburban gardens, operating automatically on the tripped-door principle.

Intermediate types include aviary-sized crow-traps, where ingress is by wide-mouthed funnel from above and a tame crow used as 'bait'; garden house-traps, entered either through a drop-door worked by trip or pullstick or through little tunnels at ground level; duck-traps, straddling the water margin, with adjustable slit entrances let in on 3 sides, employed with excellent results for both ducks and waders (Charadrii) on reservoirs; floating duck-traps moored on endless cable, and sparrow-traps, both constructed on lobster-pot principles; and a variety of smaller automatic wire-netting traps with maze or creep-in funnel entrances, baited for finches (Fringillidae) etc., or set with low lead-in 'fences' between them on shores for pipits and waders—these have proved most successful on tideless rotting seaweed beds infested with shore-fly larvae in Scandinavia. For removal from these larger traps a catching-box (like the Heligoland's) is built-in, or a landing-net is used; in the smaller types, a flap opens to let the bird pass through a corresponding opening into an independent carrying-box.

Clap nets. Large double clap nets used formerly by bird catchers relied for their high efficiency on the tethered decoy—now illegal in Britain but still used extensively by ringers in the Netherlands (often in conjunction with a 'tape lure'—see later). A variety of smaller versions—some with elastic or spring aids to increase catching efficiency—are now used by ringers in Britain. A simple version, with net area up to 6 × 2.5 m (but often less) and thrown by a single pole, has been developed successfully for use on a wide variety of species—from waders on the tide

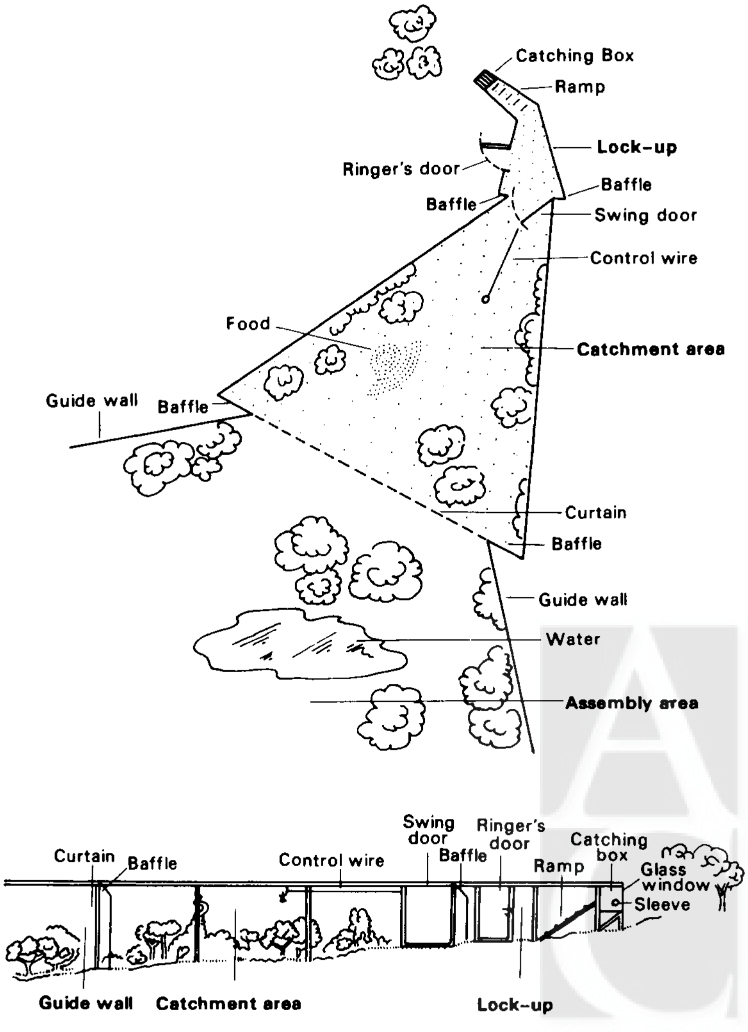

Fig. 1. Heligoland trap.

line to garden birds (baited to attract them to the catching area).

Small oval automatic spring-nets of soft netting string on stout wire frames, baited (e.g. with mealworms) and set like breakback mousetraps, will catch individual wheatears *Oenanthe*, shrikes etc. and—with care in expert hands—ground-nesting birds.

Rocket/cannon nets. Rocket nets—each measuring 60 × 20 m—were developed around 1950 by the Wildfowl Trust for catching geese *Anser* spp., with up to 400 being captured in a single throw. These have also been used to capture waders at large high tide roosts. However, since the mid-1960s cannon nets—typically 30 × 15 m and propelled by projectiles fired from 4 mortar-like barrels—have been more extensively used on waders, revolutionizing the study of this group. Catches average 200 per firing of the nets—but much larger catches have been made, including one of over 4,000 (3,500 Knot *Calidris canutus* and 600 Oystercatchers *Haematopus ostralegus*). Stuffed decoys may be used to lure birds into the catching area of cannon nets.

More recently cannon nets have been increasingly and successfully used on a wider range of species—ducks, coots, gulls (rubbish tip feeding areas as well as loafing and pre-roosting sites), corvids, passerines (including Snow Buntings *Plectrophenax nivalis*) in the UK; parrots, ibises in Australia and even vultures (Aegypiinae) in Africa.

A smaller, highly portable, net propelled by compressed air—a 'phut' net—has also been successfully developed in the 1970s for use on similar species.

Mist nets. The most important development in trapping techniques ever to take place was the invention of mist nets in Japan. These were first used in Britain in 1956 and very soon became the predominant method of capturing many species, especially passerines. These nets greatly increased the range of species which could be caught in significant numbers and provide the opportunity of ringing samples of birds in habitats/situations not previously possible (e.g. reed beds, roosts).

The fine nylon or polyester nets, hung upright between supporting poles, are almost invisible against a dark background, even in full daylight. The principle on which they work is very simple. On a rectangular 'framework' of 4–6 taut horizontal cords is threaded a significantly larger rectangle of netting. The surplus netting is apportioned vertically so that it hangs in folds, one beneath each horizontal 'shelf' string (other than the top one). A bird striking the wall of netting slithers down, to be pocketed in the surplus hanging beneath the nearest shelf string. A process of tethering maintains an even distribution of slack along the length of the net and permits catching in moderate winds. Strong winds greatly reduce the efficiency of mist nets.

Nets are normally 3 m high (divided into 3 to 5 panels) and 6–20 m long. Single panel nets (i.e. only 1 m high) are less visible and hence more effective in open conditions; alternatively, night-time mist netting is used on shores and marshes for waders etc.

Close supervision of nets needs to be maintained and, with birds being removed at regular intervals, catches in a single net rarely exceed 10–20 birds at a time. However, at hirundine roosts, where many birds may be caught over a short period, up to 100 have been captured at one time in a 20 m net. Tape recordings of bird calls, the so called 'tape lures', have been successfully used to attract birds into mist nets.

Other methods. Other traditional specialized methods for trapping birds now used for ringing include:

(i) For sea birds. The Fleyg, a long-handled outsize butterfly-Y-net is wielded by experts to intercept flying Fulmars *Fulmarus glacialis* and Puffins *Fratercula arctica*; wire crooks adjusted to their leg diameters are used to take Puffins, Kittiwakes *Rissa tridactyla*, etc. on the rock; 'stopped' snares to take Shags *Phalacrocorax aristotelis* and Gannets *Sula bassana* on their nests.

(ii) For ground feeding birds. Drop-nets of various patterns and dimensions worked by pull-cord and smaller drop-cages sprung automatically by trip-line or trigger.

(iii) For roosting birds. 'Bat-fowling' with tall folding nets clapped together to take birds as they fly out when disturbed from their roosts at night, or dropping nets over ground-roosting birds dazzled by strong light are other useful techniques, particularly at communal roosts of finches, gulls or Starlings *Sturnus vulgaris.*

(iv) For flightless wildfowl. Geese and swans during their 3–6 weeks flightless period can be rounded up and herded, generally with the aid of boats, into netting corrals erected on the surrounding shore. Catches of several hundred birds at a time have been made.

(v) For swans. A shepherd's crook on the end of a long (up to 6 m) pole can be most effective in catching individual swans, sometimes baited to attract the birds within range. The 'swan hook' is engaged round the bird's neck.

(vi) For birds of prey. A framework of foot snares on the outside of a small cage containing a live pigeon—known as a Bal chatri—has been used extensively for catching birds of prey in the Middle East and North America.

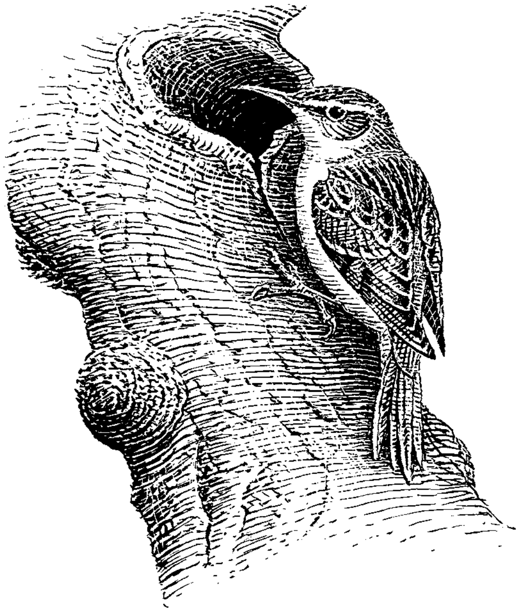
(vii) For birds breeding in nest boxes. A variety of devices attached to the entrance hole of nest boxes has been developed for catching the adult breeding birds. This technique has particularly been used on e.g. Pied Flycatchers *Ficedula hypoleuca* and tits (Paridae); see NEST-SITES, MAN-MADE. (E.A.R.E.) C.D.T.M.

Spencer, R. 1972. The Ringer's Manual (revised edn.). Tring.

TREAD: verb used, with the male as subject and the female as object, to signify the act of copulation in birds.

TREECREEPER (1): substantive name ('creeper' in American usage) of the species of Certhiidae (Passeriformes, suborder Oscines), all placed in the genus *Certhia*; in Britain commonly used without qualification for the sole native species; in the plural, general term for the family (see also under CREEPER and next entry below).

Characteristics. Mostly only 12–13 cm long (though *C. discolor* is 14–15.5 cm), treecreepers are small, brownish birds, streaked above and varying from almost white to grey-brown below, with slender decurved bills, long curved claws, and stiff pointed tails. They have short, rounded



Treecreeper *Certhia familiaris*. (*D.W.*).

wings and their flight is undulating, rather weak and usually only for short distances. They share with nuthatches and certain other families the habit of climbing about on trees, creeping up vertical trunks and along the undersides of branches; they will also move head downwards, but much more rarely than nuthatches. Unlike nuthatches, but like woodpeckers, they use their stiff tails as supports pressed against the bark.

Habitat. Treecreepers are birds of both broadleaved and coniferous forests, or well-timbered woods and parkland. Several species are restricted to mountain forests at 2,000–4,000 m.

Distribution and systematics. The family is confined to the Northern Hemisphere. There is confusion and disagreement over its taxonomy: some authorities recognize 6 species, and most 5, but the validity of 2 of these 5 as distinct species has also been questioned. All but one have restricted ranges in the Old World. The exception, *C. familiaris* ('Treecreeper' of Britain and Ireland, and 'Brown Creeper' of North America), is circumglobal between extremes of 70° and 15°N, if one accepts the concept of 5 species rather than 6, but the Brown Creeper is sometimes separated as *C. americana*. There is considerable variation in this species; a dozen or more races are recognized in a series of clines in Eurasia and another 10 or so in North and Central America. In different parts of its range it occurs in various types of woodland at all levels, but over much of continental Europe to the south of Britain and Scandinavia it overlaps with the very similar Short-toed Treecreeper *C. brachydactyla*, which also extends to north-west Africa (Morocco to Tunisia). In the area of overlap *C. brachydactyla* seems largely to have taken over the lowland broad-leaved niche and *C. familiaris* has become primarily a montane bird of dense conifer forest. Racial differences within both these birds cause much confusion in parts of their ranges, and it has even been suggested that *C. brachydactyla* should no longer be treated as a separate species. The other 3 species are all partly or exclusively Himalayan, and one of those also—the Rusty-flanked or Nepal Treecreeper *C. nipalensis*, found up to about 3,600 m from central Nepal to north-east Burma—may be only a high altitude race of *C. familiaris*. The larger Brown-throated or Sikkim Treecreeper *C. discolor* likewise occurs eastwards from Nepal, extending into semi-tropical montane regions of Thailand and Laos; and the Bar-tailed or Himalayan Treecreeper *C. himalayana*, which has a rather longer bill, breeds from Turkestan and Afghanistan to western China and Burma.

Movements. All treecreepers are largely non-migratory, although the northernmost populations tend to move south in winter and those nesting in high mountain regions descend to lower levels.

Food. Treecreepers are almost exclusively insectivorous, although they occasionally take tiny seeds, and their method of feeding is to work in a series of jerks up one tree and then fly diagonally down to the base of the next, to climb that in a similar manner.

Behaviour. Treecreepers are not gregarious, but outside the breeding season they may join parties of tits (Paridae). Also, while they generally roost alone behind the bark of trees, or excavate small cavities in soft bark or wood on the trunks of trees, they sometimes huddle together communally in very cold weather.

Voice. The calls and songs of most of the treecreepers tend to be thin and high-pitched, but, for example, *C. brachydactyla* utters a louder, shorter, more emphatic and slightly lower song than the initially hesitant but accelerating phrase of *C. familiaris*, while *C. discolor* sings a series of rather loud double notes with the emphasis on the second. Calls, singly or sometimes in series, vary from thin, plaintive and very faint, through soft, piping or shrill, to loud, explosive and penetrating.

Breeding. The nests are typically built behind loose bark or ivy stems or in deep cracks or crevices, but also occasionally in nest-boxes, wall crevices, or accumulations of dead leaves and twigs. They are untidy structures of twigs, roots, grasses, and mosses, but have a neat cup lined with feathers and bits of bark. The eggs are commonly 5–7 in number, but *C. familiaris* may have as few as 3 or as many as 9 in a clutch, while the Himalayan forms (especially *C. discolor*) apparently often produce only 3–4; they are white, marked with red-brown, varying between species from a zone of fine spots at the large end to a fairly even distribution of spots and blotches. Incubation commonly lasts 14–15 days and fledging usually 14–16, though the young of the Himalayan forms may apparently spend about 3 weeks in the nest. While the eggs are mainly or entirely incubated by the female, the young are fed by both parents; there is normally only one brood in the season. I.J.F.-L.

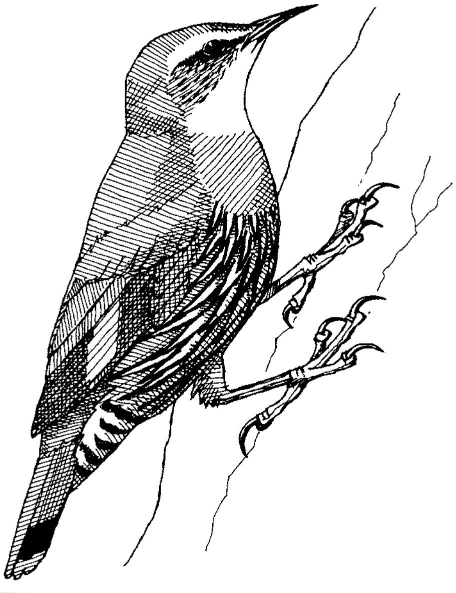
Vaurie, C. 1957. Systematic notes on Palearctic birds. No. 30. The Certhiidae. Amer. Mus. Novitates 1855: 1–14.

TREECREEPER (2): substantive name of the species of Climacteridae (Passeriformes, suborder Oscines); in the plural form 'Australian treecreepers', general term for the family. The single genus *Climacteris* contains 3 species groups (Keast 1957), typified by the Red-browed Treecreeper *C. erythrops*, the Brown Treecreeper *C. picumnus*, and the White-throated Treecreeper *C. leucophaea*, all of eastern Australia. The *leucophaea* species group has been placed in a separate genus *Cormobates*.

Classification and distribution. Seven of the 8 species recognized by Schodde (1975) are confined to Australia, with representatives in all of its recognized faunal subdivisions. The Papuan Treecreeper *C. placens* occurs in New Guinea, where 4 apparently relict subspecies are discontinuously distributed in mountain forests between 1,250 and 3,050 m.

Although *Climacteris* was formerly included in either the Certhiidae (see TREECREEPER (1)) or Sittidae (see NUTHATCH), its resemblance to other climbing birds is superficial. This association was questioned long



White-browed Treecreeper *Climacteris affinis*. (*N.W.C.*).

ago, and Mathews (1923–24) placed the genus in its own family. *Climacteris* possesses apparently unique features in its syringeal and limb musculatures (Orenstein 1977). Affinities have been proposed with the Acanthizidae (Mayr 1963; see WARBLER, AUSTRALIAN) and the Meliphagidae (Harrison 1969; see HONEYEATER). DNA–DNA hybridization studies support maintaining the Climacteridae as a separate family within a superfamily Menuroidea, allied to bowerbirds, lyrebirds and scrub-birds (Sibley *et al* 1984).

Characteristics. The Australian treecreepers are about 15 cm in total length, and have a fairly uniform dorsal coloration (grey-brown to rufous or blackish) with an off-white to rufous bar across the flight feathers. Most species have streaked underparts, and several have a pronounced superciliary line. The tail is rounded, with no stiffening of the rectrices. The bill is moderately long and somewhat decurved. The legs and toes are long, with the claws, especially that of the hallux, greatly developed and curved. There is some sexual plumage dimorphism, most noticeably in the Black-tailed Treecreeper *C. melanura*. Usually, reddish marks on the heads or breasts of females are blackish or absent in males.

Habitat. The several species frequent timbered country, and range from montane rain forest to dry savanna and semi-arid mulga *Acacia aneura* country in the interior.

Movements. Treecreepers are rather sedentary, although the White-throated Treecreeper may join mixed flocks of other species (Bell 1980).

Food. Treecreepers forage on the trunks and limbs of trees, on fallen logs, and, to varying degrees, on bare ground, with rare visits to leaves and flowers. Ants are the most important item in their diet. On trees, the birds normally start at the base of the trunk and climb upwards, following large limbs into the crown, before taking undulating flight to the base of another tree. When climbing, their legs are widely staggered, with one foot held well above the level of the other. The tail is not used for support. Treecreepers do not adopt the upside-down postures of nuthatches or sittellas (Neosittidae; see SITTELLA) (see Noske 1979).

Voice. The song of most species is a series of shrill, high-pitched whistles.

Breeding. Four species of treecreepers, the Red-browed, Black-tailed, Brown and Rufous *C. rufa*, are known to breed communally (Dow 1980; Noske 1980). One or more auxiliary birds, usually males, assist in feeding the incubating female and the nestlings. Of the other species, the White-throated Treecreeper apparently always breeds in simple pairs. Treecreeper nests are made of grasses, plant down, soft bark and animal fur, placed, often deep down, inside the hollow spout of a tree, or sometimes in a hollow log or other cavity. The clutch consists of 2–3 eggs (occasionally 1 or 4), which are white or of a pale flesh tint in ground colour, freely spotted with reddish-brown. Two broods may be raised in a season. (D.L.S.) TROCHLEA: pulley-shaped process at the distal end of each metatarsal element of the tarsometatarsus (see SKELETON, POST-CRANIAL).

TROGLODYTIDAE: a family of the PASSERIFORMES, suborder Oscines; WREN (1).

TROGON: substantive name of most species of the Trogonidae (sole family of the Trogoniformes); in the plural, general term for the family and order.

Characteristics. Trogons rank among the most beautiful birds. Considering their distribution in 3 widely separated tropical regions (America, Africa and Asia), they are surprisingly similar in colour pattern and shape. In all species adult males have the lower breast and abdomen bright red, pink, orange or yellow, usually contrasting with the colour of the chest and upper parts. The tail, rather long and graduated, tends to be carried closed so that it looks square-tipped and from below may show a specifically distinctive pattern of black and white. In the American and African species, adult males have most of the upper parts, and often the entire head and chest, brilliant metallic green (sometimes with a golden or bronzy gloss) or metallic blue or violet. The Asian species generally lack metallic colour, but males may have red or pink on the head, rump, chest or tail. Females are considerably duller, with metallic colour reduced or absent; but in many species (including all American and African ones) they have much the same bright carotenoid tints on the lower underparts as the males. In size they range from medium to large for arboreal birds (length 23–33 cm). The bill is short, broad at base, with a curved culmen. The tarsus is short; the weak feet have 2 toes directed forward and 2 backward, an arrangement unique in that the first and second digits are directed backwards (see LEG). The skin of trogons is delicate and easily torn; in museum specimens the bright red or orange colours tend to fade, and feathers drop off readily.

Most systematists are uncertain as to the closest relatives of the trogons, but alliance with the kingfisher group of the Coraciiformes has support. Fossil bones from southern France, believed to date from the Upper Eocene or the Oligocene, have been attributed to the Trogonidae.

Narina's Trogon *Apaloderma narina*. (*N.A.*).

Habitat. Trogons are primarily inhabitants of forest or woodland, but a few favour secondary growth, or clearings and coffee plantations. While almost restricted to tropical latitudes, they are not confined to the warm lowlands; some species occur only in cool mountains, even reaching elevations of 3,500 m, and a few extend into temperate latitudes.

Distribution. In America, where the family is best represented (5 genera usually recognized), they are all breeders in the Neotropical Region from Mexico to northern Argentina, and the Greater Antilles (2 monotypic genera), although one subspecies of the Middle American *Trogon elegans* does nest north to southern Arizona. The 3 African species (2 genera) are found south of the Sahara; one being widespread in evergreen forests of various kinds, one confined to humid equatorial forest and one to montane forest above *c.* 1,500 m. In Asia the sole genus, with 11 species, breeds from western India to south-eastern China, the Indo-Malayan Peninsula, many Indonesian islands, the Philippines and Sri Lanka. From 35 to 40 species of Trogonidae are recognized—the number varying according to taxonomic opinion. Because of similarity in appearance between some species and our ignorance as to details of distribution and behaviour, defining specific limits is hard in the American genera *Trogon* and *Pharomachrus*. The latter (whose members were formerly called 'trainbearers' because of greatly elongated upper tail-coverts) includes the Resplendent Quetzal *P. mocinno*, sacred to the ancient Mayas and Aztecs, which ranges in mountain forest from southern Mexico to western Panama.

Movements. Most trogons appear to be sedentary, although it is probable that younger individuals wander until they establish a breeding territory. Species or populations nesting in temperate latitudes, such as the Coppery-tailed Trogon *Trogon elegans* in Arizona, evidently may be partly migratory.

Food. Insects and other arthropods form the main part of their diet, mixed with small fruits (at least among American species). The Resplendent Quetzal is notably fond of the fruits of *Ocotea* spp., wild relatives of the avocado, which it swallows whole, regurgitating the large seed; it also takes arboreal snails, insects, small frogs, and lizards. The characteristic trogon way of feeding is aerial; the bird darts out and, fluttering vertically before a twig or leaf, or tree bark, picks off the prey (in Africa often a caterpillar); some insects are taken in flight.

Behaviour. Trogons are usually seen alone, in pairs, or in small family groups, perched on a horizontal branch or liana, well below the top of the tree canopy, often staying in the same spot for long periods. They sit rather erect, with tail hanging almost vertically. In some species a number of males gather during the courtship season, calling loudly within sight, or at least within sound, of each other. Displays have been recorded for only a few species.

Voice. Vocalizations, while often resonant and rhythmic, are simple in structure. What seems to function as 'song', recorded for many American and African species, may be described as a series of hollow whistles, hoots, caws or coos, varying, according to species, in pitch, timbre, loudness, rhythm, speed, and number of notes. Some species also have chirring, squeaky, or guttural notes. The tail may be raised or lowered slowly when calling, perhaps an indication that the bird is apprehensive. In some species the female has been reported to give vocalizations much like those of the male.

Breeding. Nests are in cavities, usually of a tree or decayed stump; some excavate holes in occupied arboreal nests of termites or wasps, or use the hollows formed by epiphytes. Both sexes share in nest-building, incubation, brooding and feeding the young. The clutch is usually 2 or 3, sometimes 4; eggs are immaculate white, cream, buff, brown, pale blue, or pale green. Incubation periods (reported for only a few American species) have ranged between 17 and 19 days. Young hatch naked, and are altricial and nidicolous. Fledglings resemble females, but usually lack bright abdominal colour and show some spotting on the wings. E.E.

TROGONIDAE: see below.

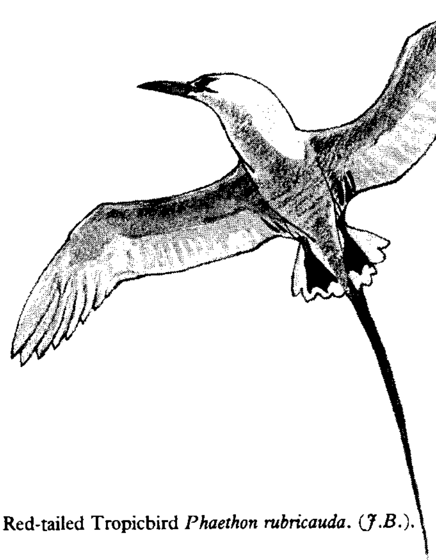
TROGONIFORMES: order comprising only the Trogonidae (see TROGON).

TROPICBIRD: substantive name of the species of Phaethontidae (Pelecaniformes, suborder Phaethontes); in the plural, general term for the family. The one genus *Phaethon* has 3 species.

Characteristics. Tropicbirds (lengths 25–45 cm) are typically white with a black bar across the eyes and solid black markings on some or all of the flight feathers. The plumage may, however, be flushed with delicate or richer roseate pink, and one subspecies, *P. lepturus fulvus*, is distinguished by plumage of strong apricot or orange-pink. The bill, which is stout and slightly decurved, is orange red, crimson or yellow according to species. The long central tail feathers (which may exceed the length of the body) give tropicbirds an unmistakable flight outline, and have prompted such vernacular names as 'marlin spike', 'paille-en-cul' and 'paille-en-queue'. First-year juveniles of all species lack the elongated central tail feathers and are more or less heavily barred and speckled with black on head, back, wings and tail. Barred plumage occurs also in adult Red-billed Tropicbirds *P. aethereus*. The short legs are set far back and cannot support the weight of the body on land. The webbed feet are used for paddling, for shuffling over the ground, and in digging the shallow nest scrape.

Habitat. Tropicbirds range over warm tropical and sub-tropical waters, nesting mainly on oceanic and off-shore islands and wandering far from land between breeding seasons.

Distribution and characteristics. Three species of tropicbirds are currently distinguished. The Red-tailed Tropicbird *P. rubricauda*, with several doubtful subspecies listed, is known from the south tropical Indian Ocean and the tropical Pacific. Largest of all the tropicbirds, this species may reach a length of 46 cm (excluding the central tail feathers) with wing-span of 88–100 cm. The narrow vanes of the 2 central rectrices are red, and the plumage of newly-moulted adults may be flushed with pale roseate pink. The bill is generally orange-yellow or red. Red-billed Tropicbirds, slightly smaller (length *c.* 35 cm), are distinguished by their barred adult plumage and coral-red bill. This species extends from Tower I (Genovesa) in the Galapagos group through the Caribbean Sea and tropical Atlantic Ocean, and into the Red Sea and northern Indian Ocean. The Indian Ocean and Gulf of Aden birds are slightly smaller than those of the Atlantic, and by some authorities are regarded as a separate species *P. indicus*. Yellow-billed (or White-tailed) Tropicbirds *P. lepturus* range through the Caribbean Sea, Atlantic and Indian Oceans, and south-western Pacific Ocean. This is the smallest species, about 25 cm long. The adult plumage is generally clear white or tinted but never barred; among the birds of Ascension Island, some of which are



Red-tailed Tropicbird *Phaethon rubricauda*. (*J.B.*).

flushed with salmon-pink, males tend to be more strongly tinted than females. In the subspecies *P. l. fulvus* of Christmas Island (Indian Ocean) both sexes are vividly coloured.

Studies of all 3 species of tropicbirds, especially breeding studies, have been made at several island sites. The 2 larger species tend toward annual breeding; the smaller Yellow-billed Tropicbirds are more likely to breed less-than-annually at intervals of 6 to 9 months, though climatic fluctuations and the amount of inter- and intra-specific competition (which is often high) may exert over-riding influences.

Behaviour and food. Tropicbirds may be numerous about the breeding grounds, where groups of 6 to 12 birds are often seen together in noisy courtship flight. At sea they fly alone or in silent pairs, swooping low over the water and plunging for small fish and squid.

Voice. The name 'bo'sun bird', common among British seafarers, may be derived from the shrill, trilling calls of the larger species, which strongly resemble the calls of a boatswain's pipe.

Breeding. Tropicbirds usually nest high on steep cliffs or in similar places from which they can take-off without walking or springing. The nests are hidden in cavities or under overhanging rocks, in sites that afford shade and can readily be defended against intruders.

Tropicbirds are gregarious in courtship, flying in excited groups along the cliff-faces, swooping, circling and calling in close line-astern formation. The tail-streamers are undulated during courtship flight. Pairing may involve fights, lasting several days, over nest-sites and partners, especially at the peak of the breeding season when many pairs are nesting at the same time. The birds grip each other with their bills and, with feet and wings spread to gain anchorage, strive to eject each other from the chosen site. Many adults bear scars and gashes about the head and neck. Coition occurs in the nest. A single egg is laid, and is incubated by both parents in watches of 2–5 days. The eggs are oval, varying in shade between pale and deep purple-brown and usually becoming paler in the course of incubation as the surface pigment rubs off. Incubation lasts from 41 days in the smaller, to 44–45 days in the larger species. Newly-hatched tropicbird chicks are covered with heavy grey or fawn down between 1 and 3 cm thick. They are left alone at the nest shortly after hatching while both parents are away foraging. In breeding colonies in which the laying season is spread over many months the small chicks are vulnerable to attack by adults of the same or a related species in search of nest sites, and many are killed by intruders during their first week of growth. Juvenile plumage starts to appear about the 10th or 12th day. The chicks grow slowly and leave the nest as fully-fledged juveniles some 11–15 weeks after hatching. B.S.

TROPISM: in the most general sense, a tendency (at the simplest level) to react in a certain way to a particular kind of stimulus—compare TAXIS.

TROUPIAL: *Icterus icterus*; in the plural, sometimes used in place of 'oriole' as a group name for the genus, or even the family (see ORIOLE (2)).

TRUMPET-BIRD: *Phonygammus keraudrenii*, a BIRD-OF-PARADISE so named because of its loud trumpet-like calls.

TRUMPETER: substantive name of the 3 species of Psophiidae (Gruiformes); in the plural, general term for the family, which is purely Neotropical; the name is given on account of the trumpeting call note.

Characteristics and distribution. Trumpeters are about the size of a domestic fowl (45–52 cm in length), with a rather long neck and long legs, a small rounded head, and a stout and short, somewhat curved bill. The tail is short and the wings rounded. The plumage is largely velvety black with purplish gloss on the foreneck. The sexes are alike. They have a somewhat hump-backed appearance especially when calling, so the local name in Surinam, 'Kamikami' (camel back), is well chosen.

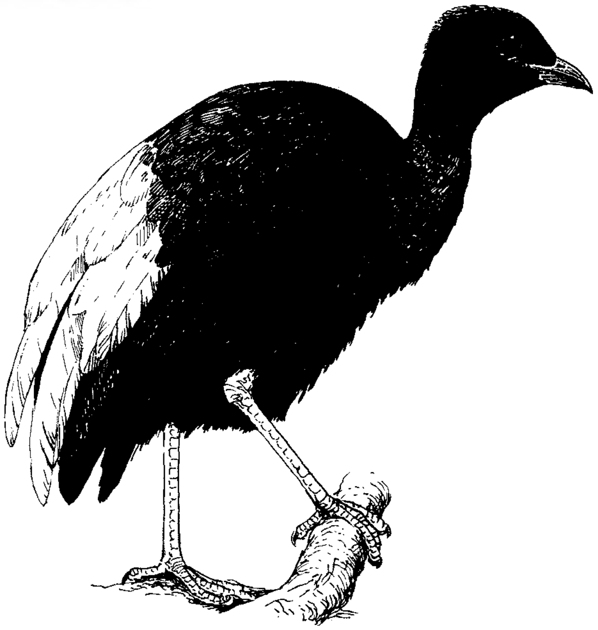
The single genus, *Psophia*, contains 3 species which replace one another geographically. All are mainly black, and of about the same size (weights of the Common Trumpeter *P. crepitans* from Surinam: 1 male, 1,019 g; 4 females, 1,000–1,500 g, average 1160 g). In the Common Trumpeter the secondaries and the tertials are ash grey. This species is found in northern South America east of the Andes south to the Amazon river. The White-winged Trumpeter *P. leucoptera* has white or ochraceous inner secondaries. It inhabits eastern Peru, eastern Bolivia, and north-western Brazil. The Green-winged Trumpeter *P. viridis* has the mantle and the secondaries green or brownish olive and lives in northern Brazil, south of the Amazon river.

Habitat. Trumpeters live on the ground of dense tropical rain-forests in South America.

Food. Their food is partly vegetable (berries and other fruits) but also includes many insects—Formicidae (Hymenoptera) and Tabanidae (Diptera) are recorded for *Psophia crepitans*.

Behaviour and voice. Trumpeters are gregarious, living in flocks on the ground. They run fast, fly laboriously and seldom, and roost in trees. They like bathing in shallow water, after which they sink down on the ground with widely spread wings to dry their feathers in the rays of the sun.

The ordinary call of *P. crepitans* when in a group is a long drawn-out *uh uh uh uh ooooo ooooo oooo*, the *uh*s in quick tempo, followed by 2 or 3 long-drawn *ooooo*s. When the bird is uttering this call, the feathers on the back are somewhat raised and the bill is opened and shut with each note. The birds are easily lured (and shot) by imitating this call. A loud trumpeting call is given with the wings widely spread, when birds



Common Trumpeter *Psophia crepitans*. (*C.J.F.C.*).

threaten other members of the flock; a soft *wheet wheet* is heard when they are at ease.

Breeding. Very little is known about their life in the wild and most of our knowledge comes from captive *P. crepitans*. In Guyana C.A. Lloyd found a nest of this species with 7 eggs in a large hole in a tree, and there is a reliable record from Surinam of a sitting bird in a large tree hole. The eggs are dirty white with a rather rough shell; in shape they resemble, in miniature, the eggs of the Ostrich *Struthio camelus*. The average dimensions of 5 eggs of *P. crepitans* laid in Surinam in captivity on 9, 10 and 12 December and again on 25 and 27 May were 58.5 × 47.55 mm. These eggs were incubated by the female alone. The incubation period is not known. According to Beebe (1917) the nestlings of this species are nidifugous. In Guyana, H. Whitely found downy nestlings on 10, 11 and 12 February, and Beebe on 21 April. The downy plumage was rufous with grey streaks on head and back. F.H.

TUBENOSES: general term for the Procellariiformes (Tubinares) (see PETREL).

TUBINARES: see PROCELLARIIFORMES.

TUFTEDCHEEK: substantive name of *Pseudocolaptes* spp. (for family see OVENBIRD (1)).

TUI: *Prosthemadura novaeseelandiae* (see HONEYEATER).

TURACO: substantive name of most species of Musophagidae (Cuculiformes, suborder Musophagi); in the plural, general term for the family. The word has been spelt Touraco or Tauraco, and the names Loerie (in South Africa), Go-away Bird (one genus), and Plantain-eater have been used for some species.

The turacos are endemic to the Afrotropical region and have been considered by most authors to be closely related to Cuculiformes. Others have linked them to gallinaceous birds through similarities of their Mallophaga, and they have been raised to a distinct order Musophagiformes. Recent work on their egg white proteins shows that the turacos Musophagi are related to the cuckoos Cuculi and should be placed in the same order Cuculiformes (see Sibley and Ahlquist 1972 for details and historical review). In this article the groupings and nomenclature of Snow, Clancey and Read (Snow 1978) are adopted. They recognize 22 species in 5 genera: *Corythaeola* (1 species); *Crinifer* (2); *Corythaixoides* (3); *Musophaga* (2) and *Tauraco* (14). To highlight the distribution of the family and possible relationships, a number of superspecies are identified by Snow *et al*; one each for *Crinifer*, *Corythaixoides* and *Musophaga*, and 4 for 12 species of *Tauraco*.

Systematic characteristics. Apart from the Giant (or Great Blue) Turaco *Corythaeola cristata* (size about 76 cm), all turacos are medium sized birds of length in the range 35–51 cm. Throughout the family the sexes are alike. Turacos have rather long tails (10 rectrices), and most of them have short rounded wings. Their flight is weak but they move easily and with great agility along branches and through vegetation. Bills are strong and decurved often with a 'keel'. A peculiar feature of the family is the exceptional variability of the position of the nostril and its shape (anything from circular to slit shaped). In 2 species which are difficult to distinguish in the field the nostrils are circular (Red-crested Turaco *Tauraco erythrolophus*) and slit-shaped (Bannerman's Turaco *T. bannermani*). The adaptive basis of these differences is unknown.

Another unusual feature is that in most species the feathers of the head and breast are largely deficient in barbules, so that they seem hairy. Their feet are also unusual; the outer toe is most often approximately at right angles to the main axis of the foot, but it may be moved further back or directly forward (semi-zygodactyl). In addition, the claws are short and abruptly curved. The family is also unique in the chemistry of the green and/or red pigments which occur in *Tauraco* and *Musophaga* species. Whereas green is in most birds produced by a combination of melanin and yellow carotenoid, in turacos it is due to turacoverdin. The red colour is due to turacin which contains copper, a pigment unique in the whole Animal Kingdom. Turacoverdin exists in several species of turaco that do not have turacin, but the reverse does not hold. The amount of green pigment is directly correlated with the luxuriance of the habitat, being most developed in the species of evergreen forest and least or absent in those living in deciduous woodland, especially thornbush.

Field characteristics, habitat and distribution. The Giant Turaco is blue above and green and brown below. It is found throughout the forests of western and west-central Africa and also in secondary growth and gallery forest in savanna that adjoins the main forest block.

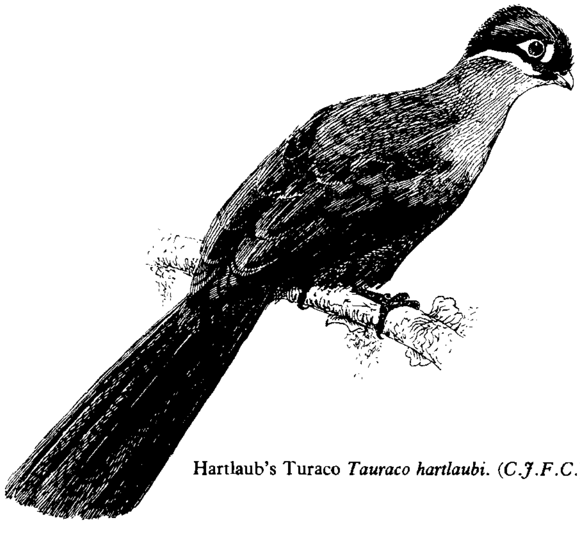
The remaining turacos divide into 2 groups; those mainly green-plumaged (*Tauraco*) or violet-plumaged (*Musophaga*) species which inhabit more or less thick woodland; and those mainly grey-plumaged birds (*Crinifer* and *Corythaixoides* species) inhabiting drier and more open vegetation. The Grey Plantain-eater *Crinifer piscator* occurs in the savanna of western and north-central Africa and its place in the savanna of central and north-eastern Africa is taken by the Eastern Grey Plantain-eater *C. zonurus*. They are predominantly grey but are streaked below; the most conspicuous difference between them is the presence of a white tail bar in *zonurus* which is absent in *piscator*.

The 3 species of *Corythaixoides* are grey-plumaged but they do not have streaked underparts and the position of their crests is different from the *Crinifer* species. Their distribution in acacia savanna ranges from north-east and central Africa (White-bellied Turaco *Corythaixoides leucogaster* and Bare-faced Turaco *C. personata*) to southern Africa (Grey Loerie *C. concolor*). The Bare-faced Turaco is of interest, as there are 2 populations separated by a gap of 1,000 km in northern Uganda and Kenya. In the northern population the foreparts of the neck and undersides of the wings and tail are pale yellow-green and the partially feathered throat brown; in the southern population the green is deeper in shade and restricted to a pectoral patch, and the throat is blacker.

The 5 species of *Tauraco* forming the superspecies *Tauraco persa* mainly differ from each other in their head ornamentation. The Guinea Turaco *Tauraco persa* has a green pointed crest which lacks white tips, the body plumage has a violet gloss and the bill is red. It is found at low altitudes from Gambia to Cameroun and south to northern Angola. A black-billed version, the Black-billed Turaco *T. schuetti* occurs in the Congo basin and eastwards to southern Sudan and the northern side of Lake Victoria. In contrast to these and others in this group Fischer's Turaco *T. fischeri*, the common turaco of the evergreen forests of the coastal zone of north-east Africa, has a red crest tipped with white, and a red bill. Another of this group, the Knysna Turaco *T. corythaix*, has a mainly coastal distribution in South Africa.

Three species of *Tauraco*, forming the superspecies *Tauraco hartlaubi*, inhabit montane evergreen forest in north-east Africa. Two of them have a larger patch of white on the face than other species in *Tauraco* but the third, Prince Ruspoli's Turaco *Tauraco ruspolii*, has a strikingly different head colouring of grey, green and pink. It also has a very restricted range in the southern Ethiopian highlands.

There are 2 isolated species of *Tauraco*. One, the White-crested Turaco *T. leucolophus*, has a mainly white head, and is found in gallery forest north of the Congo forest. The other, the Black-tip Crested Turaco



Hartlaub's Turaco *Tauraco hartlaubi*. (*C.J.F.C.*).

T. macrorhynchus, has a green crest and inhabits heavy forest in Upper Guinea and western parts of the lower Guinea forest. It is of interest as its range is split by the dry Dahomey gap; the western form has a black tip to its crest and the eastern form a red tip.

The *Musophaga* species differ from the other turacos in having an enlarged frontal plate. Except for the red area in the wings and a red crown, the plumage is mainly deep glossy violet produced by melanin which swamps the green turacoverdin. The Violet Plantain-eater *Musophaga violacea* is found in lightly wooded areas throughout western Africa. Its place in eastern and south-central Africa is taken by Lady Ross's Turaco *Tauraco rossae*. They differ mainly in beak shape and head ornamentation; the Violet Plantain-eater has no crest whereas Lady Ross's Turaco has a conspicuous erectile crest.

Movements. All species, as far as is known, are sedentary or make only short-distance movements which may be governed by the availability of food.

Food. Turacos are almost exclusively vegetarian, feeding mainly on fruits and to a lesser extent on foliage, flowers and buds. Some are known to eat snails (Chapin 1963). Although the English name plaintain-eater is used for several species, neither plantains nor bananas are part of their diet.

Behaviour. The whole family is more or less gregarious, usually met in pairs (breeding season) or small parties, often involved in feeding or associated with roosts at certain seasons. The Giant Turaco appears to be gregarious throughout the year. Often when one turaco calls, others in a group reply until all turacos in earshot are calling; this is particularly so in the forest species. As they are difficult to observe, little is known of their habits. Nuptial displays appear to vary much within the family. In the Grey Plantain-eater one bird of a pair (the male?) makes a noisy vertical ascent and dive just before perching near the other. A somewhat similar display occurs in *Corythaixoides* species. In others, displays involve raising of the crest, bowing and flirting of the tail and wing, which reveals the brilliant red patches.

Little is known of their breeding behaviour. They breed in pairs, as far as is known. Courtship feeding has been observed in the Blue-crested Plaintain-eater *Tauraco hartlaubi* and its young are fed on regurgitated fruit pulp; in the nest their faeces are swallowed by the parents.

Voice. One of the sounds associated with the African forest is the loud resounding chorus of calls of turacos. The most haunting and memorable are those of a party of Giant Plantain-eaters in which the chorus may last several minutes. It begins with a series of plaintive *oo-ers*, changing to a rapid series of staccato notes *kok-kok-kok-kok* . . . and ending with a series of vibrating *kurruk-kurruk-kurruk* notes. All species in *Musophaga* and *Tauraco* utter a series of hoarse grunting notes, *kraw-kraw-kraw*, often combined with repeated *coos* and barking calls. The savanna species also have loud calls but are not as resonant as those of the forest species. The Eastern Grey Plantain-eater is said to have considerable powers of mimicry. The calls of *Corythaixoides* species are onomatopoeic, hence the English name Go-away Bird.

Breeding. All members of the family build flat and often flimsy nests made of twigs, like those of pigeons, placed in trees or low bushes between 5–20 m above ground. The clutch size is 2–3 for species of *Crinifer* and *Corythaixoides* and 2 for the remaining species of turaco. The rounded eggs vary in colour from white or greyish-white to cream, glossy blue or bluish-white or even pale ivory-green. Incubation lasts about 18–20 days but exact data are few. The young on hatching are covered in thick down and the wing claw is well developed at least in some species. They are fledged after about a month, but they frequently move out of the nest and clamber about the nest tree long before they are able to fly. The breeding season of the forest species normally coincides with the rainy season, whereas the savanna species may be found breeding in all months of the year, in both dry and wet seasons. TURBINAL CARTILAGE: in each nasal cavity (see SKULL).

TURCO: substantive name of *Pteroptochos* spp. (see TAPACULO).

TURDIDAE; TURDINAE: family and subfamily of PASSERIFORMES, suborder Oscines (see THRUSH).

TURKEY: substantive name of 2 species of Phasianidae (Galliformes, subfamily Meleagridinae), *Meleagris gallopavo* and *M. ocellata* (formerly classified as a separate genus *Agriocharis*); in the plural, general term for the genus. Historically the name turkey has been used in reference to cranes (*Grus* spp.), vultures (*Cathartes* spp.), Capercaillie (*Tetrao urogallus*) and various Phasianidae.

Characteristics. *Meleagris gallopavo* is among the largest North American birds. Wild males may be *c.* 110 cm long and weigh 10 kg; females average 90 cm and 4 kg. While plumage of domesticated turkeys is white, red or brown, that of wild birds is primarily dark brown and black. Colours of the rump feathers and the terminal band on the rectrices vary from chestnut to cream. Birds of more arid environments tend to be lighter coloured. Males are generally darker in colour and feathers are more iridescent than in females. Males (and 5–10% of the females) possess a tuft of long, pendulous, bristle-like feathers on the breast called the 'beard'. The head and neck of the female are more fully feathered. Turkeys undergo 2 moults each year, a partial prenuptial moult in late winter and a complete postnuptial moult in late summer. There is no flightless period. Seven subspecies of *gallopavo* are recognized: *M. g. gallopavo, intermedia, merriami, mexicana, silvestris, oneusta* and *osceola*. Distinctions are based primarily on plumage characteristics and geographic location. Domestic varieties were derived from *M. g. gallopavo*.

M. ocellata is similar to *gallopavo* except that it is generally smaller (males average 4 kg; females, 2 kg), the plumage and head of males are more colourful, and males lack a beard.

Habitat. Turkeys are general in their habitat requirements and inhabit temperate, subtropical and tropical forests and prairie brushland. *M. gallopavo* is closely associated with mature forests that include oaks *Quercus* spp. or pines *Pinus* spp. Areas containing an interspersion of forest and open fields are preferred and high population densities occur in areas of 50–80% forest cover. Forests provide protection, night roosting sites and feeding areas. Open fields provide important feeding sites, especially for broods. Agricultural fields are used extensively in some regions. Edge areas along forest and field borders appear to be important for nesting.

Distribution. Turkeys are indigenous to North America, probably originating in Mexico, and are known as far back as the upper Pliocene. Pre-Columbian populations were distributed across the south-eastern third of the North American continent. The distribution and abundance of *M. gallopavo* declined during 1800–1950 from an estimated 10 million individuals to remnant populations totalling 300,000. Changes in land-use patterns during the period 1950–1980 allowed for the development of extensive areas of suitable habitat. Active management efforts, including live-trapping and transfer of wild birds, hunting regulation and modification of forestry practices have resulted in the restoration of the species to many portions of its original range and establishment in many areas beyond. At present, populations occur in nearly all of the American states and several Canadian provinces. Attempts to introduce the species to Europe have met with only limited success. The species is estimated to number approximately 1.8 million individuals. As with *gallopavo*, populations of *ocellata* declined because of habitat destruction and over-hunting. Present populations are patchily distributed from Peten, Guatemala and adjacent Belize, north through the Yucatan Peninsula and west into eastern Chiapas.

Populations. The number of females hatched per female in the population varies greatly. The maximum average documented for *gallopavo* is 3.8 females hatched per year. Annual survival is also variable but averages 30% and 50% for juvenile and adult birds, respectively. Natural (non-hunting) mortality is heaviest during the first few weeks after hatching and during the breeding season. Mortality is often high during the winter months in northern regions when deep snow persists more than 6 weeks. Survival beyond 7 years is uncommon in the wild. The maximum finite rate of growth (λ) reported for the species is 2.15 in an introduced population. Population densities of 4–8 birds/km^2 are common and 27 birds/km^2 has been reported. Population statistics for *ocellata* are generally unknown although rough estimates suggest densities are 1 bird/km^2 in Peten, Guatemala.

Movement. Turkeys are not long distance migrants; altitudinal migrations occur in mountainous regions. Movement patterns are marked by intensive use of relatively small areas with periodic shifts to other areas. The annual range of *gallopavo* includes 200–2,000 ha. Movement is most extensive in the spring and, in southern regions, during the winter. In northern regions, deep snow may limit winter home range sizes to less than 10 ha. Summer movements of females with broods may cover 100–400 ha. Dispersal occurs in early spring when young birds are 9 months old. These birds may move 1–50 km from their natal areas; females tend to disperse farther than males. Annual movements of *ocellata* have not been investigated.

Food. Turkeys are omnivorous; the diet appears to be limited primarily by size of food items. The diet during the first 8 weeks after hatching is approximately 80% insects. Adults feed primarily on fruits, seeds, succulent vegetation and invertebrates. Mast, such as acorns (*Quercus* spp.) and waste grains (e.g. *Zea mays*), is especially important during fall and winter months.

Behaviour. Turkeys are diurnally active, cursorial birds. Nocturnal periods are spent off the ground, roosting in trees (or sometimes on man-made structures). Flock members roost together and, in areas where roost habitat is limited, several flocks may roost in close proximity. The bird is gregarious and spends most of the year in flocks. Females with broods begin to aggregate at midsummer and flocks may include as many as 100 individuals. These flocks generally remain intact through the winter. Adult males are not usually associated with the brood flocks and move in segregated flocks of 4–20 individuals. Within the flock a social hierarchy exists, though it is not always linear; larger individuals tend to be dominant. Brood flocks disintegrate in spring and male flocks split into small groups thought to be composed of siblings. The breeding system is best described as harem polygyny (see POLYGYNY). Males are non-territorial and movements during the breeding season cover 150–2,000 ha. Females associate with the males for brief periods of time. The breeding display of the male, called 'strutting', is characterized by tail-fanning and wing-dragging typical of other galliforms. The body is inflated, the body contour feathers erected, and the head is drawn in against the back. The frontal caruncle is distended and chromatophores in the head and neck are activated making the head appear white, blue and red. Associated with this visual display are several short range sounds.

Voice. Turkeys begin vocalizing immediately following hatching. The repertoire of young birds includes 3 calls; adults possess approximately 15 calls. Calls are graded, with information content dependent upon pitch, number and spacing of call elements. When in flocks, birds vocalize very frequently. Calls commonly given by birds of either sex include *kyelps*, *putts* and *purrs*. The breeding vocalizations, given only by the male, include the 'gobble', a long range call, and the barely audible 'pulmonic puff'.

Breeding. The age of first reproduction is variable: where population densities are low or habitat conditions are unusually good, female *gallopavo* will breed in their first year. Male *gallopavo* may reach maturity in their first year but are apparently inhibited from breeding by older males. This pattern is thought to occur in *ocellata* as well. Copulation occurs in early spring. Female *gallopavo* begin nesting in February in southern regions and April in northern areas; nesting for *ocellata* begins in April. The nest consists of a simple scrape on the ground. The average clutch size for both *gallopavo* and *ocellata* is approximately 11 eggs (range 7–18). Eggs weigh approximately 65 g. Sex ratios in clutches approximate unity. Incubation requires 26–28 days and hatching rates exceed 90%. Renesting occurs commonly following unsuccessful nesting attempts. PARTHENOGENESIS is known to occur among *gallopavo*, producing males only. The young are nidifugous. W.F.P.

TURNAGRIDAE: see EXTINCT BIRDS; THRUSH, NEW ZEALAND.

TURNICES; TURNICIDAE: see under GRUIFORMES; BUTTON-QUAIL.

TURNING DOWN: releasing captive-bred birds into the wild.

TURNOVER RATIO: the species present in a particular habitat (for example a woodland, an island or a nature reserve), are rarely identical from one year to the next. Each year some species may be expected to disappear and others to colonize. Over several years an individual species may enter and disappear from a community several times, particularly if its total population, when present, is small (one or two pairs) and/or the habitat is marginally suitable or near the edge of the species' geographic range. The 'turnover ratio' is defined as the number of species entering and leaving a community over some specified time period (e.g. one year), divided by the total number of species present at the start of that time period. For example, turnover ratios for birds on islands vary between 0.2 and 20% per year of the species initially present, for islands ranging in size from 400 to 0.4 km^2.

TURNSTONE: substantive name of the 2 species of *Arenaria*; used without qualification, in Britain, for *A. interpres* (see SANDPIPER). See photo FEEDING HABITS.

TURUMTEE: name applied in India to *Falco chicquera* (see FALCON).

TWIN-SPOT: substantive name of some *Clytospiza* spp. and *Hypargos* spp. (see ESTRILDID FINCH).

TWITE: *Carduelis flavirostris* (see FINCH).

TYPE: general term embracing TYPE GENUS, TYPE SPECIES, and TYPE SPECIMEN; used without qualification for any of these, in appropriate context, but especially the last mentioned—for the concept see NOMENCLATURE.

TYPE GENUS: the nominal genus that is the type of a taxon in the family group and that provides the stem of the name of such taxon (or taxa of different ranks within the group). The mere naming of the higher taxa after the included genus selects the latter as the type. The names of the higher taxa are not affected by subsequent disuse of the generic name as such, whether by reason of the nominal genus being merged in another for taxonomic purposes or (after 1960) by rejection of the generic name as a junior synonym; new names given to higher taxa before 1961 for the second reason are to be retained if they have meanwhile been generally accepted. The rejection of a generic name as a junior homonym invalidates names based upon it for family-group taxa. See FAMILY GROUP; NOMENCLATURE.

TYPE LOCALITY: that from which a species or subspecies was described by the author of its name, or—failing that in the case of early names—one subsequently designated; where applicable, that at which the type specimen was collected. The type locality of a nominate subspecies is that of the species. A type locality may be changed if the original geographical attribution is definitely shown to have been erroneous; and where a type locality was too vaguely defined (e.g. only the country being named), a subsequent author may determine a 'restricted type locality'. See NOMENCLATURE; TYPE SPECIMEN.

TYPE SERIES: see TYPE SPECIMEN.

TYPE SPECIES: the nominal species that is the type of a genus or a subgenus (or of both in the case of a nominate subgenus). The term 'genotype' (also 'generitype', 'generotype') is inadmissible as an equivalent, and has in fact quite a different meaning. The 'fixation' of a type species is obligatory, and the author of a generic or subgeneric name proposed after 1930 must himself designate a type.

In the case of older generic names there may likewise be a 'type by original designation'; but failing this there may be a 'type by indication', and the latter may take various forms. If the author established the genus with a single nominal species, that species becomes the 'type by monotypy'; if he established it with an included species having its specific name or a subspecific name the same as the generic name, that species becomes the 'type by absolute tautonymy'; if he established it with only one of its species having in its synonymy a pre-1758 name (single word) identical with the generic name, that species becomes the 'type by Linnean tautonymy'. In the absence of original designation or indication, it is necessary to fix a 'type by subsequent designation'; any zoologist may do so, in accordance with rules contained in the International Code (see NOMENCLATURE).

It may be noted that a species with a tautonymous name is not necessarily the type of its genus. It may have been ineligible as a type by indication through not being expressly included in the nominal genus when that was established; or some other species might conceivably have been designated in preference.

TYPE SPECIMEN: the single specimen that is the 'type' of a nominal species or subspecies, or of both in the case of a nominotypical subspecies (see NOMENCLATURE). If the specimen was expressly designated at the outset by the author of the name (the recommended course) it is a 'holotype'; if it was designated later, from an original 'type series', it is a 'lectotype'; if it was designated later in special circumstances to replace a holotype or lectotype that, with all other members of any original type series, had been lost or destroyed, it is a 'neotype'.

If there was an original type series on which the author of the name based his description, all of them are 'syntypes' unless one has been expressly designated. If a holotype or lectotype has been designated, the remainder are 'paratypes' or 'paralectotypes' as the case may be. The term 'cotype' is no longer recognized.

As type specimens are of particular and permanent value as standards of reference in nomenclature, they should be regarded as 'the property of science'. A special responsibility rests on museums for the custody and proper labelling of type specimens, and for the publication of a catalogue of all type specimens held by them.

A type specimen, however, is no longer regarded as necessarily typical in any but a nomenclatural sense; it may in fact happen to be unrepresentative of the norm of the population from which it was drawn. The old type concept in biological thought has given way to a population concept, in which mean values and range of variation are what have real, as opposed to conventional, significance.

TYPICAL: apart from the ordinary meaning of the word, an adjective relating to TYPE; see also under NOMENCLATURE. Sometimes inappropriately used in the sense of NOMINOTYPICAL.

TYPICAL INTENSITY: see DISPLACEMENT ACTIVITY.

TYRANNI: see PASSERIFORMES.

TYRANNIDAE; TYRANNINAE: family and subfamily of PASSERIFORMES, suborder Deutero-Oscines; FLYCATCHER (2).

TYRANNULET: substantive name of small tyrant-flycatchers in *Camptostoma, Tyrannulus*, and other genera (see FLYCATCHER (2)).

TYRANT: substantive name (alone or in compounds such as 'ground-tyrant' and 'water-tyrant') of species in many genera of tyrant-flycatchers (Tyrannidae). Many other members of the family have 'flycatcher' as substantive name (the two names being also to some extent interchangeable), still others having various special names (see FLYCATCHER (2)).

TYSTIE: alternative substantive name of the guillemots of the genus *Cepphus* (see AUK).

TYTONIDAE: see under STRIGIFORMES; OWL.

U

ULNA: a bone of the forelimb (see SKELETON, POST-CRANIAL; WING).

ULNARE: one of the proximal carpal bones (see WING).

ULTIMATE: applied to factors that are remotely causative but do not lead immediately to the effect—contrasted with PROXIMATE.

ULTRASOUND: sounds of a frequency too high for the human ear to detect; above about 15–20 kHz (1,000 waves per second). Such sounds can be detected by most other mammals and by many insects. They have short wavelengths, which endow the echolocation systems of bats and dolphins with a high resolution. It seems unlikely that birds can hear 15 kHz so that the echolocation of swiftlets and oilbirds can only give a 'coarse-grained picture' of their surroundings. (See ECHOLOCATION; INFRASOUND).

UMBILICAL CORD: connection between the embryo and transitory structures within the egg.

UMBILICUS: term applied to each of the two ('inferior' and 'superior') openings in the shaft of a feather (see FEATHER, Contour feathers).

UMBRELLA-BIRD: substantive name of *Cephalopterus* spp. (see COTINGA).

UNCINATE PROCESS: a projection found on most of the ribs (see SKELETON, POST-CRANIAL).

UNDER TAIL-COVERTS: see TOPOGRAPHY.

UNDER WING-COVERTS: see TOPOGRAPHY.

UNGUAL: term applied adjectivally to the terminal phalanx of a digit, bearing the claw if any.

UPENDING: immersing the forepart of the body, head downwards, in the water, this causing the hind part to stick up into the air. This position is maintained by paddling movements of the feet.

See photo FEEDING HABITS.

UPPER TAIL-COVERTS: see TOPOGRAPHY.

UPPER WING-COVERTS: see TOPOGRAPHY.

UPUPIDAE: see CORACIIFORMES; HOOPOE.

URBANIZATION: with reference to birds, adaptation to an urban environment. As an area becomes increasingly urbanized, the process of adaptation by birds to the new environment can be observed. The process is usually spontaneous, starting from temporary invasions and leading to the establishment of permanent breeding populations. This is the most advanced stage of the birds' 'synanthropy'.

Conditions in city centres are continually changing under human impact, causing rapid changes in the composition and structure of urban bird communities. These contain fewer species than elsewhere, but total bird density may be up to three times higher than in forests (Tomiałojć and Profus 1977), and a dozen or more times higher than in grassland or desert, whereas single species can reach densities several hundred times higher than elsewhere. The degree of isolation between urban and 'natural' populations of a species is usually low but variable, depending both on the species and on the size and structure of the urban areas. These areas contain a higher proportion of 'adaptable' forms than the surrounding 'natural' habitats.

No essentially new qualities emerge in the course of urbanization, but differences do develop: there is greater tameness in relation to humans; diurnal and annual activity patterns change somewhat; prolonged breeding occurs and there is an inclination to adopt resident status; there may be deviation from traditional nest-sites and partial reliance on new types of food as well as increased overlap in diet with other species; territories are smaller and breeding densities higher. These are mostly the opportunistic consequences of abatement of the pressures of natural selection.

In cities interspecific interactions are less marked, as a result of fewer competing and fewer predatory species, a feature common to insular, man-made or other simple ecosystems.

According to most authorities, superabundance of food is the main reason for the invasion of cities by wild birds, which is especially true in winter. During the breeding season, however, very few species visit cities merely in search of food, though the Black-headed Gull *Larus ridibundus* is one example. At least for birds capable of long feeding flights—swifts *Apus*, some raptors, Rooks *Corvus frugilegus*, Jackdaws *C. monedula*, Woodpigeons *Columba palumbus*, American nighthawks *Chordeiles minor* and, in smaller habitations, many finches *Carduelis*, swallows and martins (Hirundinidae), owls and White Storks *Ciconia alba*—the crucial advantage of human settlements seems to be their greater safety for adults and young. Released from predation pressure, for example, Woodpigeons from Silesian urban parks produce yearly 4 times as many fledgelings per pair as in the country, in spite of relying on the same food sources, though this is apparently not so in London. In most species both extra food and better security under the protective influence of human presence are responsible for high densities in urban areas. These are achieved through a prolonged breeding season, despite smaller clutch-sizes, by lower mortality in the nest, and a longer adult life-span.

There are three types of response by a species to increasing urbanization.

Retreat from the urban area. Some species occur on the periphery of cities as relict remnants of the previous fauna. These include most ground- or bush-nesting species, e.g. buntings, pipits, some warblers (Sylviidae), Skylarks *Alauda arvensis*, some water birds and most large, shy and hunted birds. They will continue to retreat because even if they could adapt to the general conditions, there will be an increasing lack of nest-sites.

Adaptability to thrive equally well in cities as in natural habitats. These urban populations form integral parts of 'natural' populations of the same species. They are usually upper canopy forest dwellers and are able to penetrate urban areas easily. They include nuthatches *Sitta*, treecreepers *Certhia*, tits *Parus* and kinglets *Regulus*.

Re-entering urban areas after initial retreat. These are originally dwellers in the lower forest layers, nesting low down and feeding on the ground. At first it seems they retreat, but later on form a new truly urban population, though only in some parts of the breeding range; two more or less distinct populations, urban and 'natural', differing in several respects can be recognized. Pigeons (Columbidae), thrushes (Turdidae) and starlings (Sturnidae) furnish examples. Sometimes such urban populations extend their existing breeding range and invade new areas, e.g. Collared Dove *Streptopelia decaocto*, House Sparrow *Passer domesticus*, Black Redstart *Phoenicurus ochruros*, as well as European species introduced into other continents.

An intriguing aspect of bird urbanization lies in the changes which occur as the invading population develops into the urban one. For Mallard *Anas platyrhynchos* and Woodpigeon there is some indirect evidence of secondary tameness acquired by learning (Tomiałojć 1976). In the case of the Blackbird *Turdus merula*, some authors suggest that the reduced shyness of urban birds is inherited, although their experiments are open to doubt (Graczyk 1963, 1974).

Historical aspect of bird urbanization. Analysis leads to the conclusion that the sequence in which species enter urban areas reflects both the form urbanization takes in cities and changes in human attitudes to birds. The first urbanized birds were small passerines or scavengers tolerated by man. The latest species to invade cities represent birds once persecuted by man; but as urban man no longer behaves as a predator, except to superabundant species or individual birds causing a nuisance, it is likely that cities in future will accommodate more species, including some which now avoid them.

Geographical aspect of bird urbanization. This can be exemplified by the most advanced adaptations to urban life which have occurred recently in the north-western parts of Europe, as a result partly of the greater new urbanization in this region and partly of the more positive attitude there of humans to birds. A further factor is that large populations of first-year birds winter in the area traditionally, and have attached themselves to the urban environment. The early and almost total deforestation of the region forced these birds to adapt themselves to an agricultural landscape, including villages, from which it was only a small step to adapt further to the towns. All these reasons have presumably contributed to the apparent eastward expansion of some urban bird populations, e.g. of Blackbird and Woodpigeon. It is far from sure, however, that this has been a real expansion of West European populations as opposed to expansion due to the whole complex of reasons causing urbanization: the second possibility does not exclude the first. The exchange of avifauna between cities is possible, especially when they are not separated from each other by long distances of open country and ecological barriers such as vast forests or mountains.

As a rule, an urbanized population first occurs in an area with a dense natural population of the species involved. This initial high density can be either primeval and general, as in dense parts of the quantitative centre of the species' natural breeding range, or it may be secondary and local, as in areas where human activity has driven the species to concentrate in remnants of natural habitat. Only exceptionally does a species start to colonize urban areas on the periphery of its range. Even wide-ranging but sparse species like the Rock Sparrow *Petronia petronia*, Snow Finch *Montifringilla nivalis* and Blue Rock Thrush *Monticola solitarius*, have urban populations, but only where they were relatively common in natural habitats turned urban. Some species are more urbanized in north-eastern Europe: the Redwing *Turdus iliacus*, Fieldfare *T. pilaris*, Pied Flycatcher *Ficedula hypoleuca*, Linnet *Carduelis cannabina* and White Wagtail *Motacilla alba*.

Geographical data suggest, therefore, that, for the occupation of an urban area, local abundance of species in their natural habitats is essential, assuring the existence of surplus individuals which may frequently intrude into the cities until successful breeding status is achieved. L.T.

UTILIZATION BY MAN: human exploitation of wild birds as one of the world's natural resources; for other than wild birds see DOMESTICATION. Wild birds and their eggs have been taken for human food from the earliest times. While they represent important sources of food for some small human groups, they form only a tiny and decreasing proportion of world food consumption. Much the commonest bird in the world is the domestic fowl, which does provide a not insignificant proportion of the human food supply. Its greater productivity, accessibility and standardized taste has led the domestic fowl steadily to replace wild birds for the table. The manipulation and 'farming' of wild or near-wild colonies of large species for human food have increasingly become curiosities, as with the surviving medieval swannery of Mute Swans *Cygnus olor* at Abbotsbury, Dorset, and the sizeable number of ancient dovecotes, now mostly empty, in which feral doves *Columba livia* were induced to nest so that the surplus of their young (squabs) and eggs might be removed, the birds themselves flying free to live off the grain of farmers for km around. Much of the utilization of wild birds is of scant economic but immense anthropological or sociological significance for the societies engaged in it. This applies particularly to shooting for sport and the continued use of feathers for ornamentation. The 'take' by man is of very uneven significance for avian populations and species survival.

The use of bird droppings as agricultural fertilizer has been significant since the 19th century (see CAVE, GUANO; GUANO).

Flesh. The flesh of a majority of species of birds is probably palatable, even highly palatable, to man (see PALATABILITY OF BIRDS AND EGGS). Wild species are still killed for food in many parts of the world. D.L. Serventy's estimate is that approximately 500,000 Short-tailed Shearwaters ('mutton birds') *Puffinus tenuirostris* are taken annually in Australia. In other developed countries the taking of birds for food, other than incidentally in sport as discussed below, was widely practised in the past. By recent centuries, however, larger species of notable palatability were reserved as game birds and it was small passerine species that were being trapped or lured as food, e.g. Wheatear *Oenanthe oenanthe* and Skylark *Alauda arvensis*, and then mainly as delicacies. This use persists in the western world only in certain countries, Italy being a notable example. House Sparrows *Passer domesticus* were taken in clap-nets at roosts in Britain into the 20th century, and Rooks *Corvus frugilegus* were shot as young about to fly, in both instances partly for food, partly as a form of pest control. The taking of wild birds for food in the less-developed countries varies with the opportunity cost of the activity—the alternative value of the time if spent in farming or other directly productive employments. No estimate of the total numbers killed is available. The practice thus depends on a complex of the species present and the levels of economic and cultural development. Modern weapons have not much increased the 'take' for the market and the pot, since trapping birds *en masse* remains more effective and cheaper than cartridges.

The taking of birds on a large scale requires that they be concentrated, either as colonial nesters or in large flocks on passage. Seafowl colonies are a prime example of the first category. Such colonies furnished mariners during the era of sailing ships with regular ships' provisions, on the spot or smoke-dried or salted, as well as acting as emergency stores. The Great Auk *Pinguinus impennis* of Funk Island was routinely driven on board ships over spread sails, to be killed and preserved. More generally, seabirds were netted on their nesting grounds and in much lesser degree while flying low over these grounds. Young were taken while still flightless. Similar catching equipment was in use in north-west Greenland, the Scottish islands and Faroes, the Aleutians, Japan and the Pelew islands.

Gregarious migratory species, especially when fat and numerous in the late summer and autumn, are both rewarding and comparatively easy to catch. Tired and less wary after long flights, they have often been netted or trapped in abundance. The Heligoland trap employed to capture migrants for scientific ringing originated from a device used by fowlers for catching thrushes *Turdus* spp. and other birds. Japanese mist-nets also used for research TRAPPING were originally employed to trap for the table. The netting of Quails *Coturnix coturnix* has long been carried on in the Mediterranean basin. Nearly 2,000,000 were exported from Egypt alone in 1913 but this trade has now been curtailed. Bird-lime smeared on twigs is another means used to catch small perching birds. Artificially-shaped ponds with netted pipes and traps (see DECOY) were also used historically to take ducks (Anatidae) for the market on a large scale. Flight nets were employed in some places.

The effects of hunting for the pot on the reduction and extinction of species are unavoidably hard to disentangle from the influences of hunting for sport, habitat destruction, the introduction of predators, and natural extinctions. Hunting extinctions since the beginning of the 17th century are however thought to include the Broad-billed Mauritian Parrot *Lophopsittacus mauritanus*, Great Elephant Bird *Aepyornis maximus* of Madagascar, Dodo *Raphus cucullatus* of Mauritius, Flightless Blue Rail *Aphanapteryx leguati* of Rodriguez, Spectacled Cormorant *Phalacrocorax perspicillatus* of Bering Island, Labrador Duck *Camptorynchus labradorius* of eastern North America, and the Wake Island Rail *Gallirallus wakensis*, this last having probably been hunted to extinction as food for the Japanese garrison as recently as 1945 (see EXTINCT BIRDS).

Eggs. The use of the eggs of wild birds for human food was systematically reviewed by Cott (1953–1954). More recent work in this detail is not available, but in the interim the importance of the food source has been diminished by the depletion of some species, the protection of others, and the substitution of agricultural foods. At that time as well as today the species providing large supplies of eggs for human consumption were usually in the orders Charadriiformes, Sphenisciformes, Procellariiformes, and Anseriformes. The Sooty Tern *Sterna fuscata* then yielded probably over 1,000,000 eggs annually. A further 11 species each yielded probably over 100,000 eggs annually. It is noteworthy that these 12 high yielders tended to be exploited in islands of the Southern Hemisphere and in the North Atlantic-North-western European region. Only the Moorhen *Gallinula chloropus* and Junglefowl *Gallus gallus* were extensively exploited for their eggs in Asia where the largest and densest low income human populations are to be found. The significance of commercial egging is greatest for marginal island populations with access to colonial nests of large species with highly palatable eggs. Jealously-guarded property rights in the sites of nesting colonies have ensured the 'farming' only of eggs inessential to the replacement of populations, as opposed to opportunistic gathering.

Sport. Firearm development since the 16th century has evolved 'shooting flying' instead of shooting birds when perched or on the ground, and has been employed to devise highly stylized sports. These occur over much of the world, often introduced to outlying parts of the former British empire. The species typically shot are to be found mostly among the pheasants and partridges, ducks and geese, plovers (Charadriidae), woodcock and snipe (Scolopacidae), sandgrouse and pigeons. Such species tend to be especially palatable and relatively large but not easy targets. It is in Britain that the ritualized, seasonal, socially-exclusive killing of pheasants, partridges and grouse has become most intensive. These shoots require expensive equipment, staff, the abridgement or alteration of farming activities, and they are run as profit-making, or at any rate loss-minimizing, businesses. Sporting rights may locally be a considerable element in land values. Since game species are often artificially protected, fed and reared, the effect of sporting uses has been to sustain or increase their numbers. Adverse effects on ornithological variety have come about through the extermination of their predators and the futile killing of species that are scarcely predators on game birds at all, such as owls. There is an even greater slaughter of non-game species in countries where access to land is more open and mass participants in hunting do not restrict themselves to conventional 'game' bird categories. The damaging side-effects of shooting are hard to eradicate in that legal systems do not adequately recognize or enforce public property rights in wild birds. Shooting geese and ducks is less conventionalized and in developed countries is nowadays organized in co-operation with conservation bodies or managed by government agencies so as to yield a wild surplus for sport.

An alternative sport involving wild birds even more intimately is falconry. Various raptorial species are taken from the wild and trained to hunt other birds on the wing and also some ground mammals. In Europe Great Grey Shrikes *Lanius excubitor* are kept as sentinels since they remark the presence and direction of hawks at great distances. Falconry is surrounded by medieval ritual and terminology; in the middle ages gifts of hawks and falcons, notably white specimens of the Greenland Falcon *Falco rusticolus candicans*, were important in diplomatic exchanges (see FALCONRY).

Feathers. Ornamental uses have been found for feathers of many species, especially those with plumes or bright colours. Such feathers were for a long time trade items, notably those of kingfishers, while feathers of the OSTRICH *Struthio camelus* were sufficiently valuable for the species to be farmed instead of merely being hunted. Demand for plumes for women's hats gave rise to a destructive trade during the late 19th and 20th century, the peak of western man's direct impact on wild birds, as opposed to the impact through habitat destruction. Opposition to this trade in turn inspired the early conservation movement (see CONSERVATION; ORNAMENTATION, BIRDS IN HUMAN). Some species remain threatened by the feather (and egg) trades, e.g. Andean Flamingo *Phoenicoparrus andinus*. Feathers were also used for several purposes—to stuff mattresses, quills for writing, to trim the flight of arrows and shuttlecocks, for making the artificial 'flies' used by anglers—for which substitute materials or feathers from domesticated varieties are now mostly available. A significant continuing use is of the down plucked from their bodies by certain ducks as nest-lining for filling duvets and quilted clothing. Colonies of Eider *Somateria mollissima* in Iceland are still exploited for that purpose.

Captivity. Wild birds of diverse species are kept in captivity for aesthetic, educational, utilitarian and scientific purposes (see AVICULTURE; CAGE BIRDS). European seamen of the Age of Discovery were astonished at the number of pet birds kept in warm latitudes, such as the West Indies. They imported many species to Europe, such as the Canary *Serinus canaria*. Finches (Fringillidae) native to Europe were also made captive as cage birds and singing contests are still covertly held in public houses in dockland areas of London. Zoological gardens continue to keep and breed a great variety of species. In addition there is a sizeable and very destructive smuggling trade in ornamental rarities from Asia and Australia, said to pass through south-east Asian entrepôts *en route* to the New York market. Dead specimens of shot or trapped wild species form the collections on which taxonomic work is based (see TAXONOMY). Stuffed specimens in collections made for ornamental or status reasons enjoyed a great vogue, especially in the 19th century, as did collections of blown eggshells. Making private collections undoubtedly endangered the populations of several species in return for a vanishingly small scientific contribution (see OOLOGY).

More utilitarian purposes have been served by captive birds. Oriental fishermen keep Cormorants *Phalacrocorax* spp. and retain a portion of the birds' catch (see CORMORANT). This usage also occurred in 17th century Britain. Wild birds have often been cited as navigational indicators. Frigatebirds *Fregata* spp. have been used to carry messages between Pacific islands. Canaries *Serinus canaria* have been used to test the oxygen available in mines and wells. The Sacred Ibis *Threskiornis aethiopica* was reared in captivity in ancient Egypt and sold for the purpose of mummification in pots placed next to burial chambers. While debatably utilitarian, this was a trade for the suppliers of specimens; and, according to Gooders (1975), many pots excavated were 'adulterated' with bones of other species.

Biological control. Man has manipulated the populations of several species (e.g. Swallow *Hirundo rustica* and Purple Martin *Progne subis*) in the hope of controlling pests, by providing artificial nest sites about farmsteads where there are cattle bothered by insects. Certain species (e.g. Cattle Egret *Bubulcus ibis* and Common Mynah *Acridotheres tristis*) have been introduced well away from their indigenous range in attempts to control insect pests of field crops. Several such introductions have in turn become, or been accused of becoming, pests themselves (Long 1981).

Miscellaneous. Minor uses of wild species are scarcely classifiable. Birds have been used in augury (see OMENS, BIRDS AS). The gelatinous salival nests of the Edible-nest Swiftlet *Aerodramus fuciphaga* have long been a luxury food and trade item in east Asia. The first and successive repeat nests are knocked down with long bamboo poles (see EDIBLE NESTS). The sealing industry in the southern oceans routinely burned the dried carcasses of penguins as fuel on treeless islands, to 'try' out the oil from seal blubber. E.L.J.

V

VACUUM ACTIVITY: see OVERFLOW ACTIVITY.

VAGRANT: a wanderer outside the normal migration range of the species or subspecies, so far as that can be judged.

VAGUS: the tenth cranial nerve on each side (see NERVOUS SYSTEM).

VALIDITY: for that of scientific names, see NOMENCLATURE.

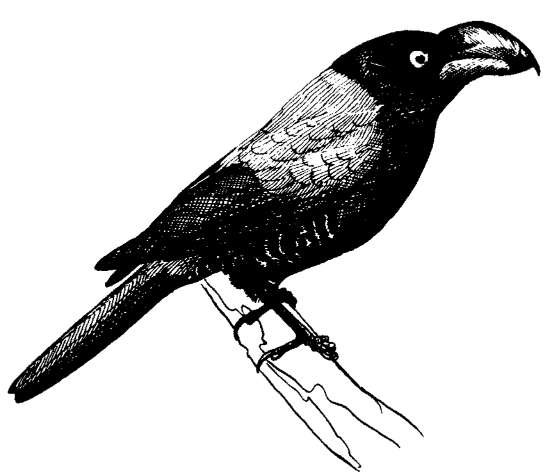
VANE: alternatively 'vexillum', the more or less coherent series of barbs on each side of the rachis of a typical feather (see FEATHER).

VANGA: the name used for 14 species in 11 genera, perhaps forming a single family, the Vangidae (order Passeriformes, suborder Oscines).

Excepting the occurrence of *Cyanolanius madagascarinus* in the Comoros, the family is endemic to Madagascar. In the scutellation of the tarsus, certain genera resemble the helmet-shrikes Prionopidae, of Africa. Maybe the Vangidae have resulted from a single invasion of Madagascar by a prionopid ancestor. If so, then the degree of radiation within a single land mass has been remarkable.

Characteristics. Vangas vary from 12.5–30 cm in length. They are boldly patterned in black and white, or blue and white, or with blacks, rufous browns and greys. Some are sexually dimorphic. The bill is usually heavy, often hooked; the feet moderately strong; the wings rather long, the tail moderately so. In the hand, some species recall bush-shrikes Malaconotinae (see SHRIKE) or even wood-swallows Artamidae. The White-headed Vanga *Leptopterus viridis* has a white head and underparts, and a glossy black back; Chabert's Vanga *L. chabert* is glossy black above, white below; the Blue Vanga *Cyanolanius madagascarinus* is blue above, white below (it has colonized Moheli, in the Comoros); the Rufous Vanga *Schetba rufa* has the whole head black in the male, with rufous back and white underparts; Bernier's Vanga *Oriolia bernieri* is usually black in the male, rufous in the female; and the Hook-billed Vanga *Vanga curvirostris* mainly black above, white below. The 3 species of *Xenopirostris* have the bill high and laterally compressed, the head black, back grey and underparts white. They provide a good example of a superspecies. The Helmetbird *Euryceros prevostii* has a long, much inflated bill, and plumage black and rufous. The Sicklebill *Falculea palliata* has a long, curved bill (for probing holes), with head and underparts white, and black back. The Tylas-vanga *Tylas eduardi*, formerly placed in the bulbuls (Pycnonotidae), lives alongside *Xenopirostris polleni* in the humid east, and is strikingly similar in colour, but with a much finer bill. The 2 smallest species are the Red-tailed Vanga *Calicalicus madagascariensis* and the Coral-billed Nuthatch-vanga *Hypositta corallirostris*. The former has a short bill, and rufous, grey and white plumage, the male with a black throat-patch. The latter was formerly placed in its own special family, but may be a specialized vanga, with (for climbing) elongated feet and claws, particularly the hindclaw. The male is wholly dull blue, the female brownish below.

Habitat and distribution. All the species are arboreal, habitat preferences linked with geographical distribution. *Oriolia bernieri*, *Xenopirostris polleni*, *Euryceros prevostii* and *Hypositta corallirostris* are confined to evergreen forest in the humid east. *Cyanolanius madagascarinus*, *Schetba rufa*, *Vanga curvirostris*, *Calicalicus madagascariensis* and (very rarely) *Tylas eduardi* also extend into more thickly wooded areas in the western savanna. The 2 *Leptopterus* spp. are even more adaptable, occurring also in the sub-desert scrub of the south-west. *Falculea palliata* is essentially only a western savanna form (in well-wooded areas), found but rarely in the sub-desert. *Xenopirostris damii* is similar in habitat, but is replaced in the sub-desert by *X. xenopirostris*. Some species are very restricted. *Xenopirostris damii* is known only from two localities in the north-west, *Euryceros prevostii* only from the north of the humid east.



Helmetbird *Euryceros prevostii*. (*C.E.T.K.*).

Populations. *Xenopirostris damii* and *polleni* are considered endangered, due to habitat destruction. Little is known about the status of *Oriolia bernieri*, but for the same reason it too could be endangered. Indeed, the numbers of all 14 species are probably everywhere dwindling.

Movement. All forms are probably strictly sedentary.

Food. All are insectivorous, but *Vanga curvirostris* and *Euryceros prevostii* may also regularly take tree frogs and small arboricolous reptiles. Most glean food while moving in loose flocks. However, *Xenopirostris xenopirostris* can raise bark with its strong bill to prey on underlying larvae. Furthermore, *Hypositta corallirostris* would appear to be the local ecological equivalent of creepers (Certhiidae) or nuthatches (Sittidae); while *Falculea palliata* is the only true hole-prober in Madagascar, the equivalent of wood-hoopoes (Phoeniculidae) in Africa.

Behaviour. Most species are strongly gregarious (as are Prionopidae). Thus *F. palliata* occurs in flocks of 25 or more. Most also occur in mixed parties with various passerines.

Voice. Some are noisy, giving whistling or chattering notes. One of the calls of *F. palliata* sounds like the cry of a child at play: hence the local name 'voronzaza' (bird baby').

Breeding. What little is known (the nests of only 8 of the species have been found) indicates the nest as a cup of twigs in a tree; the clutch-size as 3 or 4, the eggs whitish or greenish, spotted with brown and lilac. Possibly in all species, both parents share duties at every stage. In *Leptopterus chabert* the parents may be assisted by other individuals of the species, as in Prionopidae. (A.L.R.) C.W.B.

VANGIDAE: a family of PASSERIFORMES, suborder Oscines; VANGA.

VANISHING BIRDS: see ENDANGERED SPECIES.

VARIABLE: a statistical term for any attribute in respect of which individual birds (eggs, nest, etc.) may differ, e.g. weight, wing length, sex, colour (see BIOSTATISTICS).

VARIANCE: see BIOSTATISTICS (Measures of dispersion).

VARIATION: see EVOLUTION; GENETICS; NATURAL SELECTION; PLUMAGE; POLYMORPHISM; SPECIATION; SUBSPECIES.

VARIATION, COEFFICIENT OF: see BIOSTATISTICS (Measures of dispersion).

VARIETY: a variant form within a population that is in the main homogeneous; used also for a breed under DOMESTICATION. 'Varietas' was the lowest of the taxonomic categories of Linnaeus, but the modern recognition of the polytypic nature of many species has rendered it obsolete in his sense; see also under SPECIES; SUBSPECIES; and POLYMORPHISM.

VASCULAR SYSTEM:

Arteries

Vessels of lungs. Intrapulmonary branches of the pulmonary arteries (see HEART) yield the interparabronchial aa. that provide the microvascular network for the parabronchi, the tubules which make up the exchange tissue of the lungs. The pulmonary capillary bed is drained by the interparabronchial vv., tributaries of the pulmonary veins that conduct blood back to the left heart. The terminal trachea, syrinx, and the larger bronchi are served by branches of the common carotid aa.

Ascending aorta. The definitive avian aorta is derived from the foetal right dorsal aorta (the left in mammals). The coronary aa. arise near the aortic valve; both brachiocephalic aa. spring from the left side of the ascending aorta (Fig. 1). In strong flyers (e.g. pigeons) each brachiocephalic a. is greater in diameter than the aortic arch; in poor flyers such as *Gallus* the brachiocephalic a. is half the diameter of the arch. These differences reflect the enormous demand for blood by the pectoral muscles in the birds adapted for sustained flight. Each brachiocephalic a. divides into common carotid and subclavian aa., carrying blood to the head and thoracic limb.

Arteries of neck (Fig. 2). Each short common carotid divides in the thoracic inlet into its terminal branches: internal carotid a., vagus a. and vertebral a. The ascending branch of the vertebral courses headward through transverse foramina of the neck vertebrae, supplying vertebral muscles and spinal cord. The internal carotids ascend the neck side-by-side in an osseomuscular canal ventral to the vertebral column. This adaptation allows extremes of neck movements without stretching the carotids. The bicarotid condition is the most prevalent. In unicarotid birds, the left carotid usually persists (e.g. passerines); in some birds the single carotid represents fused left and right carotids. Cranially the internal carotids diverge and give off the external carotids, continuing into the skull as the cerebral carotid aa. (Fig. 2).

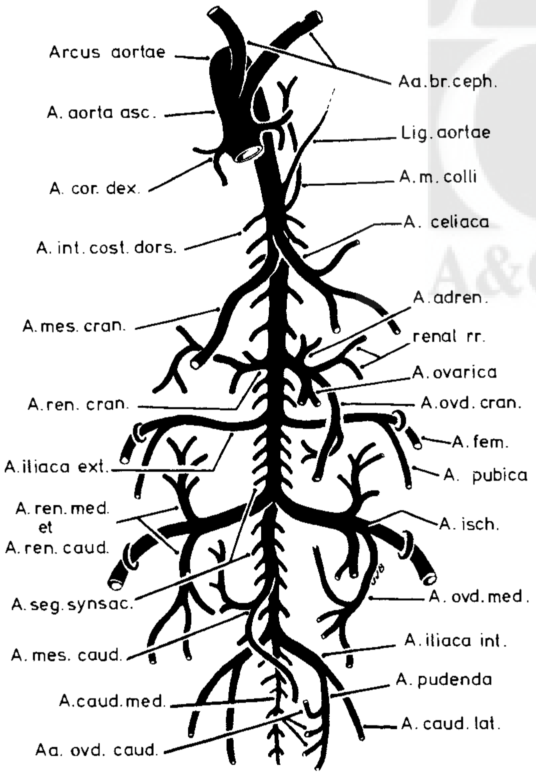

Fig. 1. Main branches of aorta; *Gallus*, female. Ventral view. Note on left side of specimen the prominent unilateral ovarian and oviductal arteries.

Abbreviations: adren. = adrenalis; asc. = ascendens; br. ceph. = brachiocephalicae; caud. = caudalis; cor. = coronary; cran. = cranialis; dex. = dextra; fem. = femoralis; intercost. = intercostalis; Lig. = ligamentum; med. = mediana; mes. = mesenterica; m. = musculorum; ovd. = oviductalis; ren. = renalis; r.r. = rami; seg. = segmentalis; synsac. = synsacralis. (From Baumel 1979).

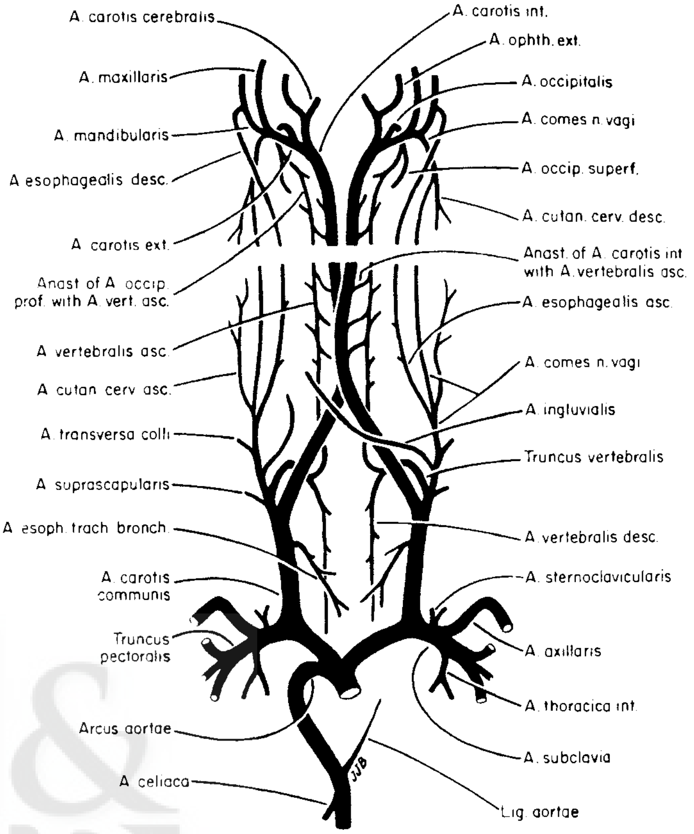

Fig. 2. Main branches of brachiocephalic arteries to head, neck and thoracic limb, *Columba livia*. Ventral view; foreshortening indicated by white transverse band across figure. Note that the common carotid artery consists of a short trunk; its main branch is the internal carotid. The external carotid is a branch of the cranial end of the internal carotid in adult birds. (From Baumel 1979).

Abbreviations: A.c.n. X. = A. comes nervi vagi; Anast. = anastomosis; asc. = ascendens; ax. = axillaris; car. = carotis; cerv. = cervicalis; comm. = communis; crb. = cerebralis; cutan. = cutanea; desc. = descendens; esoph. = esophagealis; esoph.trach. bronch. = esophagotracheobronchialia; ingluv. = ingluvialis; mand. = mandibularis; max. = maxillaris; occip. = occipitalis; oph. = ophthalmica; pect. = pectoralis, sup. scap. = suprascapularis; transv. = transversa; vert. = vertebralis.

Intracranial arteries. The cerebral carotid aa. are the primary sources of blood to the brain and meninges; the vertebral aa. contribute little or none. The external ophthalmic aa. (Fig. 2) may furnish blood to the brain in birds such as pelicans via communications with the cerebral carotids. Near the hypophyseal fossa the two cerebral carotid aa. of most birds anastomose with one another (exceptions: passerines of the suborder Tyranni). The intercarotid anastomosis is functionally equivalent to the cerebral arterial circle (of Willis) of mammals. In the cranial cavity each cerebral carotid releases middle, rostral, and caudal cerebral aa. The caudal cerebral a. in many birds is asymmetrical; the artery of one side supplies both telencephalic hemispheres and/or both sides of the cerebellum. The unpaired a. is formed by fusion of the two caudal rami of the carotids in certain birds, in others by the caudal ramus of one side only.

Extracranial arteries. The definitive external carotid a. (vagus a. is the foetal external carotid) arises from the internal carotid near the caudal end of the mandible. Its descending branches (Fig. 2) pass to the upper cervical viscera, muscles, and integument. Its ascending branches serve the jaws, jaw muscles, tongue, nasal cavity, and palate. The mucous membrane of the nasal, oral, and pharyngeal cavities and the unfeathered skin of the head contain rich microvascular networks, concerned in part with thermoregulation, e.g. gular flutter, panting (see HEAT REGULATION). The external ophthalmic (stapedial) a. leaves the internal carotid and passes through its own canal over the tympanic cavity. In the orbit it breaks up into small plexiform arteries that mesh with a similar venous plexus, the Rete mirabile ophthalmicum, which probably functions as a countercurrent heat exchanger. The external ophthalmic supplies the eye and orbit.

Descending aorta (Fig. 1). The paired segmental branches of the aorta supply the body wall (e.g. intercostal aa.) as well as the vertebral column, spinal cord, pelvic limb, tail, cloaca and vent. Paired visceral branches of the aorta supply the urinary and genital organs. Unpaired visceral branches are distributed to parts of the alimentary canal.

Arteries of digestive organs. The first of the three unpaired visceral branches is the coeliac a., branches of which supply the glandular and muscular parts of the stomach, duodenum, pancreas, liver, and spleen. The hepatic aa. accompany branches of the hepatic portal vv. in the liver. The cranial mesenteric a. serves the postduodenal small intestine as far distally as the ileorectal junction. A chain of anastomoses (marginal intestinal a.) connects rami of the cranial mesenteric a. with those of the coeliac and caudal mesenteric aa. The caudal mesenteric a. arises from the reduced segment of the aorta (median sacral a.) just distal to origins of the ischiadic aa. The branches of the caudal mesenteric a. run near the rectum with the huge caudal mesenteric vein. Its caudal branch extends to the terminal rectum, cloacal bursa, and the cloaca.

Arteries of urogenital organs (Fig. 1). The kidneys receive blood from several sources. The versatile cranial renal aa. arise from the aorta near the cranial mesenteric a. and supply the cranial divisions of the kidneys and adrenal glands. Cranial oviductal and ovarian arteries stem from the left cranial renal a. only; in the male each cranial renal a. yields testicular aa. The caudal renal aa. arise from the ischiadic aa. and serve the middle and caudal divisions of the kidneys. The usually single (left) oviduct is supplied by three arteries of the left side: cranial, middle, and caudal oviductal aa. from the left cranial renal, ischiadic and pudendal aa. Ovarian and oviductal aa. become hypertrophied in laying birds. The cloaca and, in the male, its parts specialized for copulation are supplied by the pudendal a.

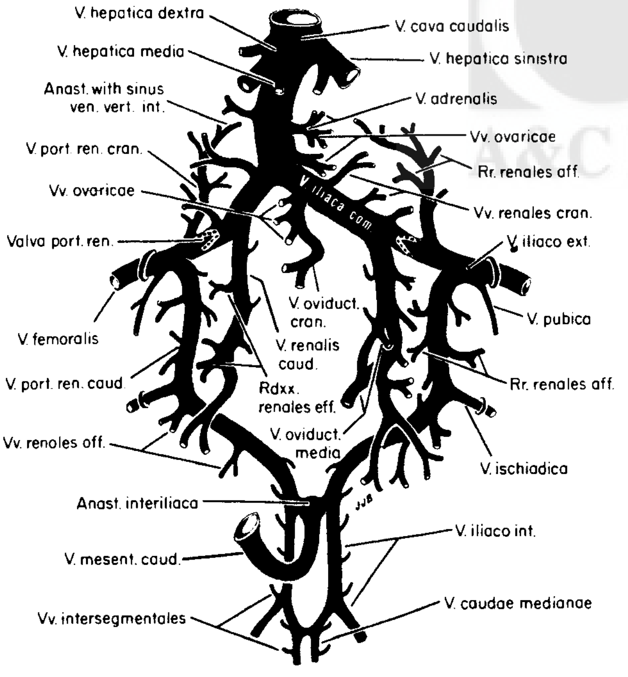

Fig. 3. Caudal vena cava and renal portal system of veins; *Gallus*. Ventral view. (From Baumel 1979).

Abbreviations: aff. = afferentes; caud. = caudalis; cran. = cranialis; dex. = dextra; eff. = efferentes; ext. = externa; fem. = femoralis; hep. = hepatica; int. = interna; med. = media or medianae; mes. = mesenterica; ovd. = oviductalis(es); port. = portalis; ren. = renalis(es); seg. = segmentales; sin. = sinistra.

Arteries of pelvic limb. In most birds the major pelvic limb artery is the ischiadic a.; however, in some species of Tyranni the femoral a. is dominant; the ischiadic is reduced in the Sphenisci; and in the cuculid *Centropus* sp. the ischiadic is completely absent. The Rete tibiotarsale is a vascular network of collateral branches of the distal part of the cranial tibial a. intermingled with satellite veins. The contact between the warm core arterial blood and the cooler venous blood from the periphery, conserves heat loss from the exposed feet (see HEAT REGULATION).

Terminal aorta (Fig. 1). The paired internal iliac aa. arise from the median sacral a. near the caudal mesenteric a. The internal iliacs divide into the pudendal a. and the lateral caudal a. (to muscles and integument of the tail region). The lateral caudal a. contributes to the incubation (brood) patch which is mainly served by the pectoral a. The median caudal a., the slender prolongation of the aorta, supplies the dorsal tail, bulb of the tail feathers, and uropygial gland.

Veins. Among the features of the avian venous system are the presence of: (1) a functional renal portal system; (2) bilateral hepatic portal veins; (3) usual dominance of the right jugular vein; (4) interjugular anastomosis near base of the skull; (5) interiliac anastomosis near the base of the tail (Fig. 3); (6) extensive communication between visceral and somatic veins via the caudal mesenteric (coccygeomesenteric) vein; and (7) the internal vertebral sinus which carries toward the heart much of the drainage from segmental veins. On account of their more dense innervation, avian veins are believed to be more active in distribution of blood and in venous return than veins of mammals.

Cranial vena cava. Each cranial caval v. receives blood from head and neck and the thoracic limb via the two jugular vv. and the internal vertebral sinus. The veins of the brain empty into sinuses which leave the skull through the foramen magnum, flowing into the caudal cerebral vv. and the internal vertebral sinus. Most extracranial veins are tributaries of the rostral cerebral vv. The jugular v. is formed by confluence of the rostral and caudal cephalic vv. The interjugular anastomosis connects the two jugular systems just dorsal to the pharynx. The jugulars receive veins from the skin and viscera of the neck; near their terminations the jugulars are joined by the vertebral vv. and communicating veins from the internal vertebral sinus. Generally, the right jugular is larger than the left. The left jugular is atrophied and nonfunctional in several passerine species.

Internal vertebral venous sinus. The vertebral sinus which is situated within the vertebral canal communicates directly with the intracranial dural sinuses. Segmental veins of the neck and trunk flow *into* the anterior segment of the vertebral sinus, then toward the base of the neck where the sinus empties into the jugulars. Blood in the posterior segment of the sinus flows *away* from the sinus into the internal iliac vv.

Caudal vena cava (Fig. 3). This largest vein in the body drains blood from the body wall posterior to the lungs, the pelvic limb, tail region, the liver and urogenital organs. In laying females the enormous ovary displaces the vein to the right. The caudal caval v. is partially embedded in the liver; it does not directly receive intercostal or other segmental body wall veins (see *Internal vertebral sinus*). Its main tributaries are the common iliac and hepatic vv.

Hepatic portal system. Venous blood from the alimentary tract and other organs served by the coeliac and mesenteric arteries is collected by the large right and smaller left hepatic portal vv. which enter the liver, ultimately dividing into a network of sinusoids between sheets of liver cells. The sinusoids, where exchange of substances occur between liver cells and blood, also receive arterial blood from rami of the hepatic arteries. The sinusoids re-form into radicles of the hepatic vv. that empty into the terminal part of the caudal vena cava.

Genital veins (Fig. 3). The ovarian and oviductal veins are hypertrophied in laying birds; therefore the veins of the left side are conspicuously larger than on the right. Testicular and ovarian vv. drain into the caudal caval v. The three groups of oviductal vv. empty into the left common iliac v., left caudal renal v., and further caudally, into the left pudendal v.

Renal portal system (Fig. 3). Birds possess another functional portal system other than that of the liver. Part of the venous blood from the pelvic limb and tail region may be diverted into the kidney via the renal portal vv. where it mixes with arterial blood in the peritubular network of capillary sinuses, then back into the caudal caval v. for delivery to the heart. The interiliac anastomosis unites the two internal iliac vv. near the caudal poles of the kidneys. The rear end of the caudal mesenteric v. communicates with the anastomosis, thus this vein can conduct blood from the gut into or away from the renal portal system. The renal portal valve is in the common iliac v.; when the valve is open blood from the external iliac and renal portal vv. can progress directly into the caudal caval system. When the valve is closed, blood from the limb passes through the kidney circulation, then back to the caval system via the renal vv. Or the blood may merely flow through the portal veins, by-passing the intrarenal circulation, draining either into the caudal mesenteric v. or into the internal vertebral sinus.

Veins of pelvic limb. In most birds an oblique ischiadic–femoral anastomosis shunts most of the blood from the distal part of the ischiadic v. to the femoral v. in front of the hip joint. The femoral v. becomes the principal vein of the limb. The reduced ischiadic v. continues into the pelvis with its artery and nerve, terminating in the caudal renal portal v. (E.T.B.F.) J.J.B.

For references see HEART.

VAS DEFERENS: (plural 'vasa deferentia')—see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

VECTOR: an animal that is a carrier of parasites or infections to another species; sometimes the vector species is an intermediate host in which the parasite necessarily accomplishes a part of its life-cycle—and in that case is termed a 'biological vector', as contrasted with a 'mechanical' one (see DISEASE; ECTOPARASITE; ENDOPARASITE).

VEERY: *Catharus* (*'Hylocichla'*) *fuscescens* (see THRUSH).

VEGETATION: see HABITAT.

VEINS: see HEART; VASCULAR SYSTEM.

VELVETBREAST: *Lafresnaya lafresnayi* (for family see HUMMINGBIRD).

VENA CAVA: see HEART; VASCULAR SYSTEM.

VENOUS SYSTEM: see HEART; VASCULAR SYSTEM.

VENT: the CLOACA.

VENTRAL: pertaining to the abdominal aspect or, more generally, the lower surface of the body; opposite of DORSAL.

VENTRICLE: a hollow space within an organ, especially the heart or the forebrain (see HEART; NERVOUS SYSTEM).

VENTRICULUS: the gizzard (see ALIMENTARY SYSTEM).

VERDIN: *Auriparus flaviceps* (see PENDULINE TIT).

VERMICULATED: covered with a dense pattern of fine wavy lines.

VERNACULAR NAME: see NAME, VERNACULAR.

VERTEBRAL COLUMN: the backbone (see SKELETON, POSTCRANIAL).

VERTEBRATES: see ANIMAL KINGDOM.

VERTICAL CLASSIFICATION: see HORIZONTAL AND VERTICAL CLASSIFICATION.

VESTIBULE: anatomically, a cavity leading into another; used especially of the cavity of the ear-labyrinth (see HEARING AND BALANCE).

VEXILLUM: the vane of a feather (see FEATHER; VANE).

VIBRISSA: a modified feather, like a bristle (see PLUMAGE).

VICE-COUNTY: a biogeographical subdivision of an administrative county, in Britain, used—primarily by botanists—as a unit area in distributional studies.

VIDUIDAE: a family of PASSERIFORMES, suborder Oscines; WHYDAH (1).

VILLI: (plural of 'villus'), internal processes of the ileum and caeca (see ALIMENTARY SYSTEM).

VINACEOUS or **VINOUS:** wine coloured.

VINCULUM: a fibrous band such as sometimes unites two or more tendons (see under MUSCULATURE).

VIOLETEAR: substantive name of *Colibri* spp. (for family see HUMMINGBIRD).

VIREO: substantive name (from the Latin *virere* 'to be green') for 25 species of *Vireo*, which with 13 species of *Hylophilus* (greenlets) constitute the subfamily Vireoninae and in turn make up the greater part of the New World family Vireonidae (Passeriformes, suborder Oscines). For the other constituent subfamilies, see PEPPER-SHRIKE, SHRIKE-VIREO. Vireos are thought to be of New World origin, but recent biochemical evidence indicates that they have affinities with a predominantly Old World group including crows, cuckoo-shrikes, drongos, monarch flycatchers and shrikes. Thus, vireos may not be closely related to New World nine-primaried oscines.

Characteristics. Vireos are from 10–17 cm long and weigh from 9 g (Black-capped Vireo *Vireo atricapillus*) to 24 g (Black-whiskered Vireo *V. altiloquus grandior*). The beak, characteristically notched near the tip of the maxilla, is heavier than that of New World warblers (Parulidae). Plumage is grey, greenish or brown dorsally and whitish or yellowish ventrally. Three subgenera distinguished both by appearance and behaviour are recognized: *Vireosylva* (e.g., *V. altiloquus*) has a pale superciliary stripe and lacks wing bars; *Lanivireo* (e.g., Solitary Vireo *V. solitarius*) and *Vireo* (e.g., *V. atricapillus*) have pale lores and eye rings and one or two wing bars. Plumage dimorphism is found only in *V. atricapillus* in which the crown is black in males and grey in females. Vireos lack pronounced seasonal differences in plumage.

Habitat. Vireos inhabit broad-leaved or mixed coniferous/broad-leaved scrub and forest. Sympatric species are separated ecologically either by foraging in different strata or by favouring different positions along a gradient of vegetation density or composition, e.g., in mixed forest of western North America, Solitary Vireos *V. solitarius* predominantly use conifers and Warbling Vireos *V. gilvus* occur mainly in broad-leaved riparian growth. North American migratory species winter in habitat resembling that of the breeding grounds.

Distribution. In summer, races of the widespread vireosylvid *V. olivaceus* occur from 65°N in Canada to 34°S in Argentina. The only other vireo breeding in South America is another vireosylvid, *V. gilvus*, which is restricted to the mountains of the northwest. Vireos have successfully colonized Bermuda (White-eyed Vireo *V. griseus*) and the West Indies, where 6 vocally distinct and sedentary species of the scrub-dwelling *V. 'griseus'* complex occur eastward to Puerto Rico. The vireosylvid *V. altiloquus*, often sympatric with West Indian scrub vireos throughout their island range, is even more widespread than the latter in the West Indian region, occupying coastal Florida, the Bahamas and the Greater and Lesser Antilles. On Grand Cayman Island only, *V. altiloquus* is replaced by a race of the closely related Yucatan Vireo *V. magister*. On Jamaica a third species, the Blue Mountain Vireo *V. osburni*, occurs in the mountains. On the mainland the sedentary Yellow-winged Vireo *V. carmioli* (*Lanivireo*), of the mountains of western Panama and the Mangrove Vireo *V. pallens* (*Vireo*), reaching north-western Costa Rica, are the southernmost representatives of their subgenera which in summer have breeding species southward from 62°N in Canada and 47°N in the United States respectively. The highest breeding diversity, 7 summering species, is found in the Conchos River Valley in west Texas.

Populations. Most species of vireos are common to abundant throughout their range, with the Red-eyed Vireo *Vireo olivaceus* regarded as the commonest native forest-dwelling passerine in eastern North America. Only the Slaty Vireo *V. brevipennis* of central Mexico and *V. osburni* of Jamaica are truly rare, the latter occurring in a 1:10 ratio with *V. altiloquus* in montane forest. Numbers of *V. atricapillus* and Bell's Vireo

V. bellii are declining in the south-western United States and north-western Mexico in part because of habitat destruction and cowbird (*Molothrus* spp.) nest parasitism.

Movements. Ten of the 11 species of vireos breeding in North America or the West Indies are migratory. Only the Hutton Vireo *V. huttoni* ranging from British Columbia to Guatemala is sedentary. The Yellow-green Vireo *V. olivaceus flavoviridis* is one of 2 New World passerines that is an intra-tropical migrant—breeding in Mexico and Central America and wintering in the Amazon Basin. Migration distances vary from *c.* 4,800 (northern population of *V. olivaceus* migrating to Amazonia) to 160 km (southern breeding population of the Grey Vireo *V. vicinior* in west Texas).

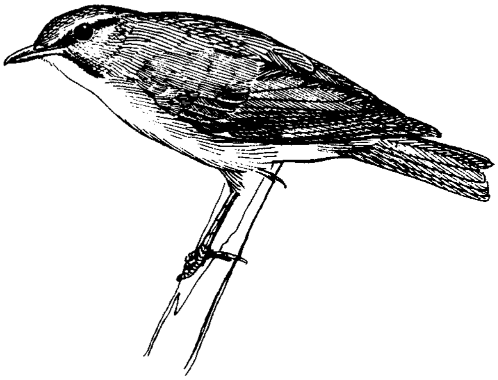
Food. Vireos are to varying degrees insectivorous and frugivorous depending in part on the season. In late summer, primarily insectivorous temperate zone vireos become increasingly frugivorous as migration (late August to October) approaches. Migratory races of *V. altiloquus* and *V. olivaceus* are exclusively frugivorous on the Amazonian wintering grounds and fruit comprises up to 50% of the diet of resident, tropical species. Vireos forage at a more deliberate pace than parulid warblers, taking prey while hopping among foliage and branches or, less often, while hovering at leaf clusters. All vireos also catch some prey by flycatching. Only *V. vicinior* forages regularly on the ground (*c.* 5% of all feeding bouts) but it is not exclusively insectivorous.

Behaviour. Vireos use song to defend territories ranging from 0.2–0.9 ha (*V. bellii*) to *c.* 20 ha (*V. vicinior*). Aggressive displays encompass head forward threat, and ruffling of body and crown feathers. Adults of the migratory species generally remain for a time on territory after breeding is concluded, but defence then is minimal. Prior to migration, young wander in family groups or in mixed flocks with other small birds. Winter territoriality occurs in *V. vicinior* and is suspected in *V. solitarius*, the Yellow-throated Vireo *V. flavifrons* and *V. griseus*. In winter the non-migratory *V. huttoni* forms small flocks or joins mixed flocks of other small species. Tropical vireos generally remain on territories all year.

Voice. Vireos utter tonally pure or frequency modulated notes organized in loud, persistent song of two basic kinds: (1) a 'chattering' repetition (2–30 times) of a single note constituting a single bout of song that in turn may be repeated up to 100 times before switching to a song comprising a different single note; (2) repeated bouts of song that involve 2–20 different notes in each bout. Species with monosyllabic 'chatter' song are mainly subtropical to tropical in distribution (e.g., Cozumel Vireo *Vireo bairdi*). The 'song' of *V. osburni* is unusual in consisting of trills (each *c.* 1.5–2 sec. long and comprising 10–25 notes) given from 1 to 10 times. In addition to song, trills resembling that of *V. osburni* are uttered by *V. vicinior*, *V. solitarius*, *V. flavifrons* and the Philadelphia Vireo *V. philadelphicus*. All vireos have 5 (*V. osburni*) to 15 (*V. gilvus*) calls varying from a simple *tic* to a structurally complex *myaah* given in breeding, aggressive and general maintenance contexts. Song of most scrub dwelling species is somewhat ventriloquial.

Breeding. Vireos breed from mid-April (or mid-November south of the Equator) to early August (early March) throughout their range. Males (arriving a few days in advance of females in migratory species) establish all-purpose territories by fighting and song. Males court females using several ritualized displays, including swaying of the body and/or wing and tail movements. Courting and copulation accompany nest-building (completed 5–15 days) which is shared by the sexes (except that only females build in most *Vireosylva*). Egg-laying follows within 1–2 days of nest-completion and incubation, performed only by females in *V. olivaceus*, *V. magister* and *V. altiloquus*, begins with the second egg and lasts from 11–13 days. Males of most species sing while on the nest. In all species both parents contribute to the care of the young both during the nestling period, which averages 12 days, and after fledging for an additional 20–30 days.

Nests are pensile, suspended from a small forked branch in vegetation from 0.5 m (*V. bellii*) to 25 m (*V. flavifrons*) above the ground. Clutch-size varies from 2 to 5, decreasing southward to the tropics. Eggs are white, ranging from immaculate in *V. atricapillus* to heavily spotted in the Thick-billed Vireo *V. crassirostris*.



Black-whiskered Vireo *Vireo altiloquus*. (*C.E.T.K.*).

Greenlets. Greenlets occur from southern Mexico to northern Argentina but only 3 out of 13 species (Grey-headed *Hylophilus decurtatus*, Tawny-crowned *H. ochraceiceps* and Scrub *H. flavipes* Greenlets) are found north of Panama. Greenlets are uniform in size and appearance and they lack the notch at the tip of the maxilla typical of *Vireo* spp. Song varies among species, from 'chatter' (*H. flavipes*) to songs resembling *Vireo* species (e.g., *H. decurtatus* sounds like *V. philadelphicus*) to distinctive whistled songs (*H. ochraceiceps*).

Greenlets are forest (e.g., *H. decurtatus*) or scrub dwellers (*H. flavipes*), mainly taking arthropods from near ground level (*H. ochraceiceps*, which follows ant swarms) to high in rainforest trees (*H. decurtatus*).

Breeding occurs between January and September in the species of greenlets in which it has been seen (*H. decurtatus*, Ashy-headed Greenlet *H. pectoralis*, *H. ochraceiceps*). Nests are pensile, suspended by the rim from a small fork in a tree or shrub 2–6 m up (in *H. ochraceiceps*), and are built by both sexes. Clutch-size is 2 in these 3 species and the eggs are whitish with small blackish spots. Both sexes incubate and feed the nestlings. The incubation period is 16 days for eggs of *H. decurtatus*; fledging occurs at 12 days in *H. decurtatus* and 14 days in *H. ochraceiceps*. Males of *H. decurtatus* and *H. pectoralis* sing while sitting on eggs.

VIREO, ANT-: see ANTVIREO; ANTBIRD.

VIREONIDAE: a family of the PASSERIFORMES, suborder Oscines, treated here as comprising the Vireoninae—the true vireos, including greenlets (see VIREO); the Vireolaniinae (see SHRIKE-VIREO); and the Cyclarhinae (see PEPPER-SHRIKE). It may be doubted whether it is necessary to recognize 3 subfamilies, the second and third including only 1 genus apiece, but they have in the past been treated even as separate families, and the groups are given separate articles in this work.

VIREOLANIINAE: see VIREO-SHRIKE.

VIROLOGY: see DISEASE.

VIRUS: see DISEASE.

VISCERA: the soft internal parts (entrails).

VISIBLE MIGRATION: the section of the stream of birds passing over an area on MIGRATION which can actually be seen from the ground.

VISION: the dominant sense of almost all birds which, with few exceptions, have extremely well developed and efficient eyes. Birds are completely dependent on their eyes while flying and rely heavily on vision for finding food, for recognizing mates or conspecifics (see PLUMAGE), and for detecting predators. Unlike mammals, birds have remained largely diurnal throughout their evolutionary history, and as a result, the eyes of birds are much more highly developed for vision in daylight.

Size and shape of eyes. The paramount importance of the visual sense is reflected in the relatively enormous eyes characteristic of birds; some hawks and owls, for instance, have eyes as large or larger than those of man. In many birds the two eyes together weigh nearly as much as the entire brain and are often as big as the head can accommodate. If the eyes are particularly lateral in their orientation, they will almost touch one another with only a thin, even translucent, bony septum between them. The large size of the bird eye is generally not apparent on superficial observation of the head because of its unusual shape; the cornea, which is usually small in comparison with the rest of the eye, is the only part of the eye externally visible between the lids. In fact, the bird eye is not spherical, as in mammals, but consists of two hemispheres of different radii of curvature joined at the ora serrata. The concavity at the cornea saves space and weight while at the same time achieving a larger retina and retinal image. Bird eyes apparently do not have the natural structural stability of a sphere, and for this reason a ring of cartilaginous plates, i.e. the scleral ossicles, is located at the ora serrata around the base of the cornea to support the eye and provide a firm origin for the intraocular muscles (Figs 1 and 4).

Eye movement. The large eyes of most birds are so tightly enclosed in their orbits that there is little room for the well-developed extraocular muscles found in most mammals. The aspheric shape of the eye may also make large eye movements difficult for structural reasons. In general, eye movements are relatively limited in birds, but there is considerable variation in the range of eye movements in different species. With the exception of many owls, all birds seem capable of some convergence of the eyes toward the beak with amplitudes of 10° to 25°. In the absence of binocular stimulation, the movements of the two eyes are independent. When the head is tilted, birds also show small counter-rotations of the eyes to compensate for the head movement. A few species of birds are reported to have large, easily observable eye movements. Although most of these birds are marine species, including gulls, penguins and cormorants, a recent quantitative study suggests that the domestic chicken also has large eye movements of 50° or more. Eye movements in most birds, however, are small and limited to the horizontal direction. This restricted range of eye movement in birds is compensated for by an extremely flexible neck; even casual observation of birds reveals a heavy dependence on head movements while foraging for food or keeping watch for predators. In owls and in many other species, the head can be turned nearly 180° in either direction.

Nictitating membrane. Like many other vertebrates, birds have a nictitating membrane or third lid which lies under the lids on the nasal side. In diurnal birds this is usually somewhat transparent and can be drawn horizontally across the cornea to clean or moisten it without completely shutting out the light. The nictitating membrane may also be used to protect the eye from physical injury during visually guided behaviour. For example, while foraging for food on the ground, granivorous birds such as the Woodpigeon *Columba palumbus* will often close their nictitating membranes during each peck just as the head nears the ground. The extent to which the nictitating membrane interferes with a bird's vision is unknown. Birds are reported to blink or draw their nictitating membrane across their eyes more frequently while moving their heads than when they are still, possibly in order to block out the blurred images that result from rapid head movements. Alternatively, the nictitating membrane is used to clean and moisten the cornea when normal vision is prevented or impaired by such head movements. Some diving birds that use their eyes underwater, e.g. diving ducks, divers, and auks, have an especially clear central window in their nictitating membranes which would facilitate their vision through the membrane. Contrary to earlier suggestions, however, the membrane in these birds has the same refractive index as the cornea and will not compensate for the loss of corneal refraction underwater.

General structure of the eye. The basic structure of the avian eye follows the general pattern of all vertebrate eyes (Fig. 1). This consists roughly of an optical system made up of the cornea, lens, and vitreous body, which casts an inverted image of external objects on the light-sensitive retina (for connection with the brain, see under NERVOUS SYSTEM). Birds' eyes fall roughly into three groups, of which examples are shown in Fig. 2. The first, from the Mute Swan *Cygnus olor*, is relatively flat and characteristic of most diurnal birds; the second, from the Golden Eagle *Aquila chrysaetos*, is more globose and typical of diurnal birds with especially good vision; and the third, from the Eagle Owl *Bubo bubo*, is a somewhat tubular eye adapted for useful nocturnal vision.

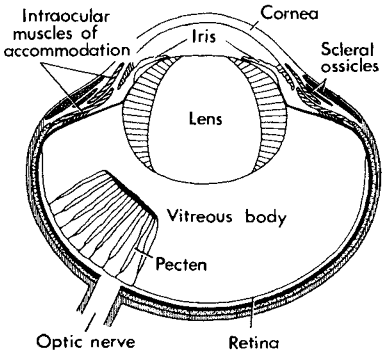

Fig. 1. Diagram of the avian eye. (After Duke-Elder).

Pupil reactions. The amount of light entering the eye depends on the reactions of the pupil. This is the aperture in the centre of the iris, a circular pigmented tissue situated over the anterior surface of the lens (Fig. 1) and giving colour to the eye (see IRIS COLORATION). The iris contains both radial and circular muscles which regulate the size of the pupil. In most vertebrates, these are smooth muscles under involuntary nervous control but, in birds as well as reptiles, both sets of muscles are striated. The fact that the iris muscles are striated suggested to some authorities that the pupil is under voluntary control in birds, but there is no evidence to support this view. Changes in pupil diameter are strikingly rapid and extensive in birds; the pupil of the pigeon, for example, is capable of about a ninefold reduction in area. The striated muscles may simply facilitate more rapid constrictions of the pupil; in some birds the pupil reacts at least twice as fast as the human pupil in response to an increase in illumination. The accommodation reflex that causes the human pupil to constrict for near vision has not yet been conclusively demonstrated in birds. The pupil in most birds is approximately round when fully dilated but may become somewhat more elliptical when constricted. As compared with humans, many diurnal birds have large pupils relative to the size of the eye; for the same illumination, the amount of light striking the retina will be correspondingly greater. It is unclear how the bird's retina withstands these higher light intensities but, under bright light conditions, the black epithelial pigment underlying the retina is reported to move forward to protect the highly sensitive receptor cells, particularly the rods. The sensitivity of the pupillary response appears to vary in different species, but only the pigeon has been studied. In general, the pupils of diving and nocturnal birds are considered more responsive to light; vision underwater requires a higher light sensitivity, and in many diving species the retina approaches the nocturnal type. Such a retina, adapted for low light levels, presumably needs extra protection in full daylight. In some animals, when only one eye is exposed to bright light, the pupils of both eyes will constrict. This consensual pupillary reflex is common in mammals but apparently does not occur in birds, with the possible exception of the owls. Occasional reports of such a reflex are probably due to the fact that the two eyes nearly touch in the heads of many birds; light may pass through the back of one eye and hit the retina of the other eye.

Pecten. One striking feature peculiar to the avian eye is the pecten. This is a pigmented, highly vascularized structure, usually pleated but sometimes with vanes, attached to the optic nerve along its base and standing up in the posterior chamber of the eye supported by the highly viscous vitreous body. When light enters the eye through the pupil, the pecten's shadow falls on its own base, the optic disc, which is a blind spot in the retina. The pecten is composed almost entirely of blood vessels and extravascular pigmented stromal (i.e. connective) cells enclosed in a thin membrane; no muscular or nervous tissue is present. Comparative studies indicate that the size of the pecten and the number of its pleats both increase with the importance of vision in a bird's behaviour but not necessarily with the size of the eye. Thus, the pecten is smallest in nocturnal birds, larger in seed-eating species, larger still in insectivores and largest of all in the diurnal predators such as hawks and eagles. Many theories about the visual function of the pecten have been proposed.

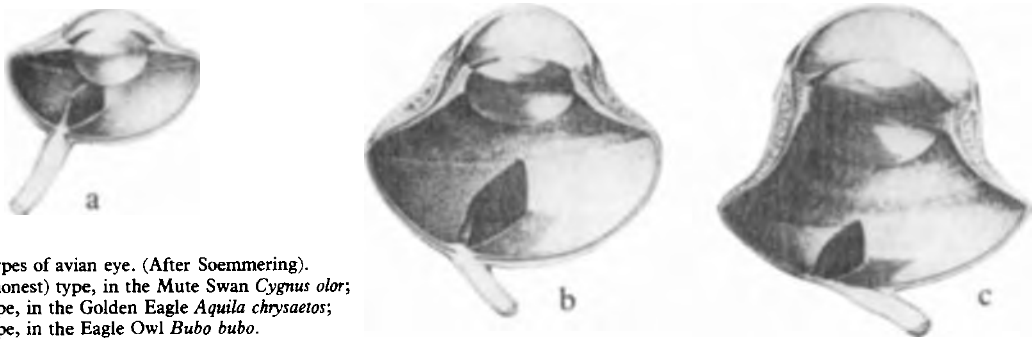

Fig. 2. Three types of avian eye. (After Soemmering).
(a) 'Flat' (commonest) type, in the Mute Swan *Cygnus olor*;
(b) 'Globose' type, in the Golden Eagle *Aquila chrysaetos*;
(c) 'Tubular' type, in the Eagle Owl *Bubo bubo*.

They include suggestions that the pecten acts as an intraocular visor against the sun's glare, that the flicker of an image across its pleats enhances movement sensitivity, or that the pecten's shadow has a sextant-like function in navigation. However, current evidence indicates that the pecten, by means of its enormous vascular surface, supplies nutrients and oxygen to the retina through osmosis and may be involved in the regulation of intraocular pressure. Neither birds nor reptiles have any blood vessels in the retina, although as in all vertebrates there is a blood supply through the choroid beneath the photoreceptors. Retinal blood vessels are believed to interfere with vision and, in primates, are displaced from the fovea, the region with highest acuity. Perhaps the pecten represents a similar adaptation for achieving higher visual acuity throughout the retina in birds.

Retinal structure. The avian retina is unusually thick and well developed, especially in diurnal birds, with many complex interconnections. The actual visual receptors of birds, as of all vertebrates, are of two kinds: rods and cones. The former are generally associated with good sensitivity to low illumination, relatively poor acuity, and imperfect or no colour vision. Nocturnal birds have a great preponderance of rods in their retinae. Cones are associated with good visual acuity at high light levels and with colour vision, but with a low light sensitivity—in other words, with poor dark adaptation. Diurnal birds have retinae in which cones account for up to 80% of the photoreceptors; in different species larger or smaller areas contain only cones, according to their visual requirements. In contrast to mammals, all cones contain a coloured oil droplet through which light must pass before reaching the sensitive outer segment. Moreover, at least two morphologically distinct classes of cone have been identified in the bird retina: single cones and double cones. The double cone consists of a normal cone that partially surrounds an 'accessory' cone, which often lacks an oil droplet. The nervous impulses from the light-stimulated photoreceptors pass through several layers of nerve cells and are eventually transmitted to the visual centres of the brain along the optic nerve. Although the density of photoreceptors in the bird eye remains relatively uniform compared to that in the human eye, the numbers of cells in each of the other neural layers vary considerably across the retina, especially in the inner nuclear layer. In fact, the cell density in the inner nuclear layer is disproportionately high in most birds, suggesting that correspondingly more complex levels of sensory processing occur in the avian retina. In all vertebrate eyes, particularly thick retinal regions, called areas, contain the highest density of cells and are believed to be the sites of best visual acuity. Mammals, as well as birds and reptiles, usually have one such area near the centre of each eye, but in most birds, which have more laterally oriented eyes, the retina also contains a second visual area for looking forward. These two areas are sometimes joined by a ribbon-like area, or 'visual streak', that runs along the horizontal axis of the eye.

Refraction and accommodation. In the avian eye, as in the eyes of all other terrestrial vertebrates, the major structure of refraction is the cornea; the greatest change in index of refraction occurs at the cornea as light passes from the air into the eye. The lens plays a much smaller role in refraction but serves as the primary means for changing the refractive state of the eye during accommodation. Earlier reports suggested that birds with laterally directed eyes were farsighted in the central visual field on either side of the head and nearsighted in the frontal field. More recent studies on the refractive state of the eye in several species (e.g. pigeon, chicken, ducks, owls) have demonstrated that the bird eye is in fact emmetropic, i.e., shows no refractive error, in either the central or frontal horizontal visual fields. In the pigeon, as in the lateral-eyed rabbit, the eye shows both no refractive error and substantial correction for astigmatism for more than 90° along the horizontal axis of the visual field. Such remarkable wide-field corrections are consistent with the idea that lateral eyes represent an adaptation for acute panoramic vision, which is used to watch the horizon for predators. Myopia in the frontal horizontal field would be an obvious disadvantage when flying, but some evidence has been found for nearsightedness in the pigeon's 'pecking field', which is located in front of the head but at least 30° below the beak; this lower part of the frontal visual field corresponds to a second visual area in the pigeon retina, i.e., the 'Red Area', which has an especially high density of photoreceptors.

All fast-flying birds would need an efficient means of quickly altering the focus of the eye, but the power and range of accommodation in birds appears to have been overestimated by early workers; the eyes of pigeons and some ducks, for instance, are only capable of the maximum accommodation of an adult human (5–8 Diopters), not two to three times this range as originally claimed. The ability of pigeons and other birds to examine objects from very short distances may result from the built-in nearsightedness of the frontal field rather than particularly high powers of accommodation. As in other vertebrates, this accommodation is achieved by direct effects of the ciliary muscle on the shape of the lens. In human accommodation, however, the normal sideways pull on the lens is released so that it can take its natural, more highly curved shape, whereas in birds the lens is apparently squeezed into a more convex form (see also MUSCULATURE). Birds' lenses are softer than human ones, and the intraocular muscles concerned with accommodation are more highly developed. These muscles are attached to the ring of scleral ossicles, which support the eye and keep it rigid against their pull.

Adaptations to aquatic habitat. In the air a large part of the refractive power of the eye is produced by the curved surface of the cornea, and the effect of this is lost underwater. The eye may be an efficient organ in the air and virtually useless underwater, and this seems to be true of such plunging birds as terns or pelicans which spot their fish from above, dive blind, and often miss. On the other hand, many birds—penguins, cormorants, diving ducks, divers and auks—have truly amphibious vision. Adaptations for aquatic vision vary in different species. In the Adélie Penguin *Pygoscelis adeliae*, the refractive effect of moving from air into water is minimized by the existence of a relatively flat cornea. Cormorants, dippers, and diving ducks compensate for the refractive loss of the cornea by means of a very large accommodative ability (at least 50 Diopters). Apparently the lens in these species is especially soft, and the contraction of the ciliary muscle pushes the malleable lens through the constricted iris disc (Fig. 4); the central anterior surface of the lens actually bulges through the pupil, resulting in a marked increase in its curvature (and refractive power).

Visual acuity. Visual acuity (the ability to distinguish fine details) should not be confused with visual sensitivity, which is the ability to distinguish small quantities of light as such and is highly developed in all nocturnal birds. The two faculties require rather differently constructed eyes and retinae, and it is rare for an eye to have both well developed. Visual acuity is a property first of the optical apparatus of the eye and secondly of the retinal structure. These can be usefully compared to the lens and film of a camera, the former determining the accuracy of the image and the 'grain' of the latter the fidelity with which the image can be

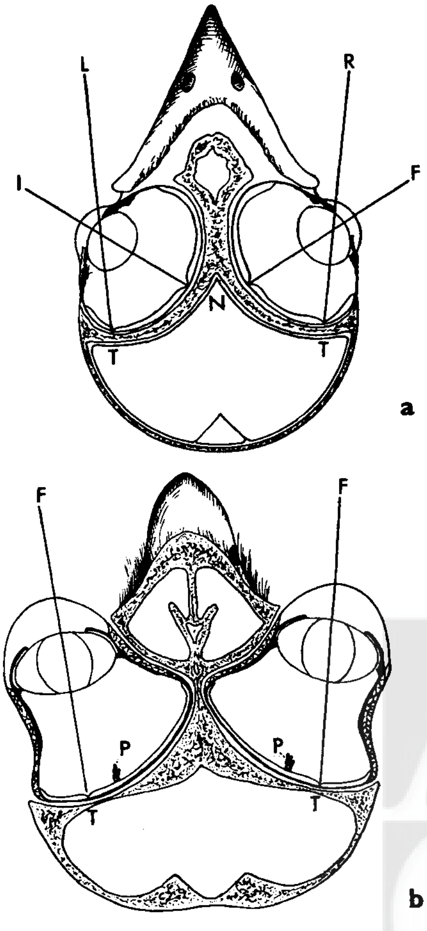

Fig. 3. Bird foveae.

reproduced. In birds the optical system is very well developed indeed; those birds needing a high resolution at great distances (wing-feeding insectivorous forms, predators in general, and such birds as crows) have eyes as large as possible and a somewhat flattened lens at a greater distance from the retina (Fig. 2b). This arrangement provides a larger image on the retina, while the highly curved cornea and large pupil ensure that plenty of light will enter the eye. At the same time, the retinal structure is specially well adapted for acute vision. All diurnal birds have a predominance of cones over the whole retina, and all have a central visual area from which rods are entirely absent. In addition, most have a small sharply defined pit in the central retina known as the fovea. Although they are not found in the lower mammals, appearing only in the primates and man, foveas are a common feature of the eyes of such sharp-sighted animals as lizards and some teleost fishes. However, the avian fovea is the most highly developed of all, with the possible exception of the lizards, and only a very few species (e.g. domestic chicken) do not appear to have one. At the fovea the retina contains many extremely fine, tightly packed cones; the correspondingly high density of ganglion cells (whose axons form the optic nerve) around the fovea suggests that each cone may be connected, via the overlying retinal nerve cells, to its own fibre of the optic nerve. Such an organization of connections is well designed for acute vision, since each cone can send an independent message to the brain, so making possible the appreciation of very fine detail within the retinal image. Some authorities think that the actual shape of the pit produces a slight magnification of the image in this region, thus further increasing visual acuity; others believe that it aids in the perception of moving objects. Most likely, the foveal pit results from the need to remove the especially thick overlying layers of retina that would otherwise degrade the optical quality of the image at the photoreceptors. Most birds have their eyes placed laterally in the head. Because the fovea is located near the centre of the retina, this lateral orientation of the eye (and the small range of eye movements in many birds) means that the most acute vision is usually to the sides; the two foveas can not be used for looking straight ahead. However, many birds—hawks, eagles, hummingbirds, bitterns, kingfishers and various passerine species including swallows—that are especially well equipped visually, and particularly those that hunt on the wing and need a good distance judgement, have a second fovea placed in a posterior temporal visual area; this can apparently be used in conjunction with the other eye for binocular vision (Fig. 3).

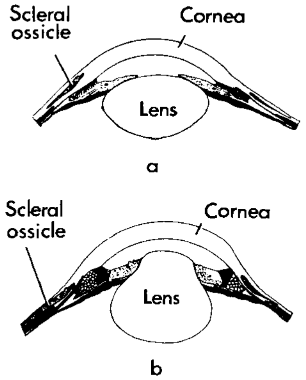

Fig. 4. Accommodation in the Cormorant *Phalacrocorax carbo*.
(a) Unaccommodated;
(b) Accommodated. Note the change in shape of the lens. (After von Hess).

Some birds have, in addition to a central fovea, a ribbon-like central area running across the retina in a roughly horizontal direction. Careful studies of 5 species (Lapwing *Vanellus vanellus*, Oystercatcher *Haematopus ostralegus*, Coot *Fulica atra*, Snipe *Gallinago gallinago*, and Herring Gull *Larus argentatus*) have shown that although the orientation of the bill is very variable between these species when the head is carried in its normal position, this central retinal area, as well as one of the semicircular canals in the ear labyrinth, is always horizontal. The ribbon-like area (known as a 'visual streak' in mammals) consists of an especially high density of photoreceptors and other cells and presumably is designed to improve the acuity of panoramic vision; possibly this retinal structure also gives a plane of reference in relation to the horizon. Such a ribbon-like area has never been found in forest-dwelling species or in birds of prey, but mainly in birds of the open spaces, such as seabirds.

Even casual observation of birds in their natural environment strongly suggests that many granivorous birds as well as predatory species have exceptionally high visual acuity. Indeed, physiological optics studies have revealed that the visual acuity of hawks and falcons could be as much as three times higher than man's, a prediction recently confirmed by behavioural measurements of visual acuity in the American Kestrel *Falco sparverius*. On the other hand, many behavioural studies indicate that the visual acuity of granivorous birds, such as the pigeons, may even be lower than that of man. This evidence has led some workers to take issue with the generally held belief that the visual acuity of birds is very much greater than that of other animals, but it is important to remember that laboratory tests do not necessarily yield an accurate assessment of an animal's best visual capabilities. Biological constraints on learning, specifically those concerned with the location of stimuli in the visual field, may be involved rather than visual acuity *per se*. However, maximum visual acuity is at least partly limited by the absolute size of the eye, so perhaps some smaller birds will turn out to have lower acuities than primates such as man with considerably larger eyes. The other constraint on acuity is the density of photoreceptors (especially cones) and other retinal cells, and many birds appear to have compensated for their smaller eyes by having exceptionally high cell densities. That these densities remain high throughout a larger part of the retina than is true in most mammals has led to the suggestion that visual acuity in birds is greater over a larger part of the visual field; perhaps this facilitates a more rapid assimilation of detail in the visual world.

Adaptations to nocturnal habitat. The majority of birds are predominantly diurnal and become inactive at night. There are, however, great variations in the apparent ability of different species to see at low illuminations; some roost much earlier in the evening than others, which go hunting well into dusk. The retina of a bird active both by day and night, the Manx Shearwater *Puffinus puffinus*, has been compared with that of a purely diurnal petrel, the Fulmar *Fulmarus glacialis*, and has been found, not unexpectedly, to have an increased number of rods. Even such diurnal birds as the pigeon and domestic fowl have powers of dark adaptation about as good as man, although the process is slow, taking nearly an hour or more to manifest itself in the pigeon as opposed to 10 minutes in man. In the Starling *Sturnus vulgaris*, Buzzard *Buteo buteo*, and Kestrel *Falco tinnunculus* the process is slower still, but when it is complete, these birds appear to have useful night vision. In all these species, however, the relatively low density of rods in the retina means that their acuity at dim light levels will be poor.

The birds that have made the most successful visual adaptation to nocturnal living are, of course, the owls. In these the whole eye has become elongated (Fig. 2c) by the development of an enormously enlarged cornea, pupil and lens. By this means the amount of light entering the eye is increased so that a brighter image falls on the retina. Such an optical arrangement entails a relative decrease in the size of the retinal image, but the large absolute size of the eye helps to minimize this disadvantage. In addition, the frontal position of the eyes, which provides better and more extensive binocular vision than is usual in birds, not only provides the basis for good perception of distance but probably also improves sensitivity through binocular summation of the light coming from the environment. (Frontal eyes are often present in nocturnal animals and in abyssal fishes.) Such owls as have been examined have a great predominance of rods in their retinae, and the outer segments are especially long. These retinal features increase both the owls' visual acuity at low light levels and their sensitivity to light. Not surprisingly, all owls have excellent powers of dark adaptation. Although some owls (e.g. Tawny Owl *Strix aluco*) are seldom seen during the day, others such as the Pygmy Owl *Glaucidium brasilianum* and the Burrowing Owl *Athene cunicularia* can hunt quite successfully in the daylight. Still other species (e.g. Hawk Owl *Surnia ulula*) are largely diurnal but also will hunt on the wing at night; they have silent flight and very good hearing and may rely more on this sense than on vision.

Retinal pigments and oil droplets. The outer segments of the photoreceptors (rods and cones) contain the visual pigments that are responsible for the absorption of light incident upon the retina. With the development of microspectrophotometry, it has recently become possible to determine with precision the absorbance spectrum of the visual pigment in a single isolated photoreceptor cell. From studies on a number of species—e.g. chicken, pigeon, Rook *Corvus frugilegus*, Laughing Gull *Larus atricilla* and Tawny Owl—one rod and three classes of cone visual pigments have been identified in birds. The three cone pigments, which are sensitive to red, green and blue light respectively, provide the basis for trichromatic colour vision similar to that in man and other primates. Behavioural evidence in the pigeon, however, further implies the existence of a fourth cone visual pigment that is sensitive to near ultraviolet light, suggesting that birds may in fact be tetrachromatic.

Brightly coloured oil droplets, contained within most cones but not within rods, are a striking feature of the retina of diurnal birds. High concentrations of carotenoids are responsible for the colour of these oil droplets, which are situated just above the outer segment of the cone. Depending on the specific types and amounts of different carotenoids in the oil droplet, only light above a particular 'cut-off' wavelength is able to reach the visual pigment in the outer segment. Oil droplets in birds are highly variable in colour, size and location within the retina. Using microspectrophotometry, at least 5 types of oil droplets, characterized by the cut-off wavelength, have been found. Different combinations of visual pigments and oil droplets will obviously result in many cone types, which are distinguishable by their spectral sensitivities. In many birds, the distribution of different oil droplets, and therefore cone types, is not uniform. The dorsal temporal part of the pigeon retina, for instance, is dominated by single cones with red and orange droplets; this 'Red Area' is clearly distinct from the remainder of the retina, i.e. the 'Yellow Field', which contains mostly double cones with yellow oil droplets. The visual functions of oil droplets are believed to include the reduction of chromatic aberration, a role normally played by the lens in other vertebrates, and the fine-tuning of colour vision by the selective filtering out of shorter wavelengths. Behavioural studies of the pigeon have shown that the Red and Yellow areas of the retina have significantly different spectral, i.e. colour, sensitivities. Such differences in colour vision are probably related to the visual tasks performed by these two retinal areas, which view different regions of the visual field.

Colour vision. All diurnal birds appear to possess colour vision, although it is thought that most nocturnal ones do not. This is reflected in the gaudy plumage of many diurnal species and the drab appearance and lack of colour in the plumage of many nocturnal birds. In view of the many different types of visual pigment and coloured oil droplets found in the retina, the colour vision of diurnal birds may well be more complex than in all other vertebrates, including man. Numerous behavioural studies have demonstrated that pigeons and chickens, at least, have colour vision; that is, these birds are able to distinguish stimuli on the basis of their wavelength content. Although early evidence indicated that a bird's ability to distinguish one hue from another was similar to that in man, more recent work using electrophysiological as well as behavioural techniques strongly suggests that colour vision in birds may be based on as many as four or five primary colours rather than the three found in man. The potential for such complexity lies in the different combinations of four visual pigments and five coloured oil droplets; at least six types of cone have been identified on the basis of their spectral sensitivity. Another important consideration is that the pure 'colours' perceived by the pigeon, and presumably by other diurnal birds, do not necessarily coincide in terms of wavelength with the basic colours visible to the human eye. For example, two of the peak wavelength sensitivities in the pigeon correspond to colour mixtures, i.e. blue-green and greenish-yellow, in the human spectrum. Moreover, depending on the relative frequencies of various cone types in different areas of the retina, colour vision is correspondingly altered for different parts of the visual field. In fact, the predominance of certain oil droplet colours in the eyes of various species of birds has been correlated with the background colour of the environment or the need to make difficult discriminations between similarly coloured food types. The greater complexity and sensitivity of avian colour vision suggests that the birds' view of the world may be considerably different from our own.

Ultraviolet and polarized light. Human colour vision is limited to a narrower range of the wavelength spectrum (400–750 nanometers) than the total range available for vision (300–800 nanometers). Limits on spectral sensitivity are determined by both the visual pigments and the parts of the eye and retina through which incident light must pass before reaching the pigments. Although in man the yellowish lens filters out near ultraviolet (UV) and violet light to reduce chromatic aberration, the lens in birds is transparent to these same wavelengths; the coloured oil droplets apparently serve to minimize chromatic aberration at the retinal level. Behavioural studies have confirmed that the pigeon and several species of hummingbirds do indeed see UV light (325–360 nanometers). Other evidence also suggests that there is a fourth UV-sensitive pigment in the avian retina; cones with this pigment possess a clear oil droplet that presumably allows UV light to reach the pigment. The adaptive significance of this sensitivity to UV light is unknown. Many flowers and leaves are known to have UV-specific colour patterns; although clearly relevant to hummingbirds, the advantage of UV colour vision is less obvious in other birds.

Very recently, sensitivity to polarized light has also been demonstrated in the pigeon. Apparently this ability not only involves the detection of changing axes of polarization but also the discrimination of (and orientation to) a fixed axis of polarization. The pattern of polarization in the sky varies during the day strictly in accordance with the position of the sun, and many migrating birds, as well as homing pigeons, are known to use the sun's position as a compass in navigation. Perhaps the ability to detect polarized light eliminates the need directly to visualize the sun when determining its location in the sky. Interestingly, pigeons can only discriminate the axis of polarized light when the lighted area is large and located in the upper visual field, which normally contains the sky. The inferior Yellow Field of the pigeon retina views this part of the field and is dominated by double cones, suggesting a role for this special type of receptor in polarized light vision.

Visual fields, binocular vision, and stereopsis. Birds (including even the owls) have eyes that to a greater or lesser extent are laterally oriented in the head (Fig. 3). Yet the obvious need to see straight ahead while flying appears to have resulted in at least some overlap between the visual fields of the two eyes in all species. The size of this binocular field is very small in most granivorous birds (10°–30°), larger in insectivores, hawks

Short-eared Owl *Asio flammeus* showing binocular vision. (*Photo: E.J. Hosking*)

and other predatory birds (35°–50°) and, of course, most extensive in the owls (60°–70°). The lateral orientation of the eyes and the limited range of eye movements necessarily means that the avian central fovea is restricted to a monocular view of the world. Even birds-of-prey are primarily monocular in terms of the relative sizes of their monocular and binocular visual fields; in fact, recent behavioural tests of visual acuity in the American Kestrel suggested that these birds usually turn their head to one side and use one central fovea, rather than both temporal (i.e. binocular) foveas, when making a difficult discrimination. Although the two temporal foveas found in the eyes of some insectivores and predatory birds are probably used for binocular vision, the second visual area in the eyes of other birds is not necessarily used in the same way. For example, the region of the Red Area of the pigeon that contains the highest density of cells views an inferior portion of the visual field that lies as much as 30° to the side (i.e. outside the binocular field); the Red Area is thus well adapted for examining the ground for food when the head is held in its normal position.

Birds must be capable of precise judgements of distance when flying and landing. While this is especially true for birds-of-prey that dive at high speeds for prey on the ground, judging distance may also be important for granivorous birds when pecking for food. In man the most accurate method of judging distance and solidity is by means of stereoscopic vision. This depends on the simultaneous appreciation of the slightly, but not too widely, dissimilar images from corresponding points on the two retinas. For this to be possible, it is obviously essential to have binocular vision, i.e. the faculty of viewing an object with both eyes simultaneously. Stereopsis, the perception of the two somewhat disparate retinal images as a single 'fused' image, involves the integration of the binocular inputs by visual centres in the brain. Unlike many mammals, the two optic nerves of birds are completely crossed at the chiasm; each side of the brain receives inputs from only one eye. Recent anatomical studies of the Burrowing Owl *Athene cunicularia*, however, have revealed that binocular integration of visual inputs from the two eyes does occur at a still higher level of the brain in a telencephalic structure called the visual Wulst. The organization of the Wulst appears to be very similar to that of the striate cortex, which mediates stereo vision in mammals. Electrophysiological studies of the Barn Owl *Tyto alba* have identified in the Wulst a large population of neurons selective for binocular disparity, a necessary prerequisite for stereopsis, and stereoscopic depth perception has recently been demonstrated behaviourally in the American Kestrel. Although found in the brain of all birds, the Wulst varies considerably in size. Indeed, comparative studies indicate that the relative size of the visual Wulst is directly proportional to the extent of the binocular visual field. The fact that binocular neurons are also present in the smaller Wulst of the pigeon strongly suggests that even birds with a small binocular field are capable of some degree of stereoscopic depth perception. Preliminary behavioural evidence that pigeons use binocular cues in judging distance has been reported.

The variation in size of the binocular field appears to correlate with the need for better and more extensive stereopsis. Yet the more common lateral orientation of the eyes in birds indicates that there is a countervailing selection pressure for maximizing the total extent of the visual field in the absence of head or eye movements. Presumably the resulting panoramic view of the world facilitates the detection of predators while foraging for food; aerodynamic constraints on the shape and size of the head may also play a role in determining the orientation as well as the general structure of bird eyes.

For birds that have limited binocular vision and appear to be very dependent on monocular information, a number of monocular cues are available for judging distances—such as size, overlapping contours, and parallax. Moreover, other animals, such as chameleons and toads, are known to determine the distance to an object of interest monocularly by using the precise accommodative efforts required to bring its image into focus; camera lenses or rangefinders use exactly the same principle. The extent to which birds use any or all of these cues is unknown. Some workers have pointed out that the conspicuous head bobbing, shown by many birds when they walk, may provide the basis for a kind of monocular 'stereopsis'. Whereas in binocular stereopsis two slightly different images are received by the brain simultaneously, the two disparate views seen by the same eye before and after a head bob might be integrated sequentially to yield a fused image of an object. Much work on avian vision remains to be done, however, before we have an adequate understanding of the bird's eye view of the world.

Visual behaviour. A thorough knowledge of the vision of a particular animal often makes possible a more complete understanding of its behaviour. Moreover, a detailed comparison of visual systems in a variety of species may provide insights into specific behavioural differences between groups of animals.

Head-bobbing is a striking behaviour of many birds. When walking, pigeons, chickens and numerous other common birds thrust the head forward in a rapid movement, hold it stationary while the body catches up and then thrust it forward again. The head appears to 'bob' because it moves backward and forward with respect to the body, but in reality, it moves only forward in the environment. Contrary to earlier suggestions that head bobbing is mechanically driven by the stepping movements of the legs and may aid balance, more recent work has demonstrated that this peculiar behaviour is totally under visual control. Movement of the visual world alone will cause the bird to bob its head.

When a man walks forward, the frontal placement of his eyes ensures that the visual world remains relatively still. Most birds, however, have laterally oriented eyes, so as they walk forward, much of the visual world moves backwards. Experimental evidence suggests that the stationary phase of the head 'bob' is an adaptation to allow a motionless view (with the central fovea) of the bird's surroundings; the forward thrust is especially rapid in order to maximize the duration of this fixed view. While flying, birds presumably use their frontal vision, which will operate similarly to man's and/or take advantage of the fact that the visual world will move more slowly because it is more distant.

Another curious but characteristic behaviour of many birds is called 'rapid peering', i.e. the side-to-side motion of the head while viewing an object or foraging for food. In many mammals, each eye sends information to both sides of the brain, whereas in birds, each eye projects only to half of the brain. Indeed, behavioural studies indicate that when a pigeon is trained to make a visual discrimination with one eye only and then forced to use the other eye, the bird often behaves as if it has never 'seen' the problem before. Perhaps rapid peering simply results from the need for a bird to see an object with each eye so as to store the necessary information in both halves of its brain.

VISITOR: alternatively 'visitant', meaning present in the area under reference only at certain times of year, the term being applied to a species, subspecies, population, or individual bird as the context requires. Thus, there are 'summer visitors', 'winter visitors', 'visitors on migration' (='transients'), and 'occasional visitors'; but these terms indicate merely local status and are meaningless except in relation to a stated area, a summer visitor in one place being necessarily a winter visitor somewhere else (see MIGRATION; also VAGRANT).

VISORBEARER: substantive name of *Augastes* spp. (for family see HUMMINGBIRD).

VITAMIN REQUIREMENTS: see NUTRITION.

VITELLUS: the egg-yolk (see EGG).

VITREOUS BODY: part of the eye (see VISION).

VOCALIZATION: sound produced by the special vocal apparatus, which in birds is the SYRINX. Vocalizations are traditionally divided into calls and songs, and although there are considerable difficulties in exactly defining the two terms, the distinction still remains in common use. Generally, calls are short, simple and produced by both sexes at any time, whereas songs are long, complex and produced only by males in the breeding season. There is also a phylogenetic trend, in that songs are more common and complex amongst the most recently evolved group of birds, the passerines, and in one sub-group in particular, the Oscine songbirds. The scientific study of vocalizations has been revolutionized by the advent of light, portable tape recorders used in conjunction with parabolic reflectors or sensitive gun microphones. A major breakthrough in analytical techniques was the application of the sonagraph pioneered by W.H. Thorpe. By plotting frequency (in kiloHertz) against time (in seconds) a clear picture of an individual sound could be displayed as a sonagram (Fig. 1). Sonagrams have since become the standard method of both analyzing and illustrating vocalizations in scientific ornithology. The sonagraph has to a certain extent been replaced by a new generation of more modern frequency spectrum analysers, which display sonagrams instantaneously on a Visual Display Unit screen before printing out on a hard copier. The tremendous saving in time means that hundreds of songs can be quickly examined, or whole populations screened for particular song types.

Calls and their functions. Calls are often given in quite specific contexts, such as fighting or courtship, which makes their functional interpretation relatively easy. The call itself may affect the behaviour of the receiving individual, again throwing some light upon its probable function. Calls can be thought of as expressing a tendency to behave in a certain way, and transmitting that information to other individuals who may modify their own behaviour accordingly. By studying different calls in relation to behaviour it is possible to build up a vocabulary of calls for a species. Passerines seem to have a vocabulary of up to 20 different calls, whereas gulls have about half that. There are calls for threat, courtship, flight, alarm, begging and so on, to cover most aspects of social behaviour.

Some species have calls which serve more specialized or unusual functions. Cave-dwelling birds such as the Oilbird *Steatornis caripensis* and the Cave Swiftlet *Aerodramus vanikorensis* produce a series of clicks when flying in the dark. These are special echolocating calls and the birds have developed a form of sonar similar to that possessed by bats. Unlike bats, the bird calls are not ultrasonic, but produced at normal frequencies and so can be clearly heard by humans. Another very special call is that produced by the African Honeyguide *Indicator indicator*. The calling birds lead larger animals to nests of wild honeybees. The nests are broken open by the large animal, and the honeyguides can then feed on any small pieces of honeycomb left. This symbiotic relationship appears to have developed originally between the birds and honey-eating Ratels *Mellivora capensis*. African tribesmen later learned that the persistent calling birds would lead them to honey (see HONEYGUIDE).

A more widespread kind of call which has been the subject of considerable study is the alarm call given by many passerines when a predator such as a hawk flies over. It was Marler (1981) who noticed that calls given by many different species shared the same basic design (Fig. 1). He reasoned that although it may be advantageous for a bird to warn his mate or offspring of impending danger, it was also dangerous for the calling bird to give away his position. The conflict has been resolved by the evolution of special flying predator calls which can be clearly heard, but which transmit a minimum of directional information and are difficult to locate. Birds and humans are thought to locate sounds by binaural comparisons of phase, intensity and time differences. Phase differences are more effective at low frequencies, as the information becomes ambiguous when wavelength is less than twice the distance between the two receiving ears. Conversely, intensity differences are more effective at high frequencies, because the sound shadow formed by the head of the listening bird only operates when the head dimension exceeds sound wavelength. Time differences are effective throughout the frequency range, but are enhanced by interruption, repetition and modulation. The further apart the ears of the listening bird, the more obvious time differences will become. Rough calculations suggest that for a medium-sized bird of prey, a call pitched at about 7 kHz would be too high for detectable phase differences, and too low for an appreciable sound shadow intensity effect. As Fig. 1 shows, this is just the frequency range of the special alarm calls many passerines produce when a real or experimental hawk flies over. Any possibility of binaural time differences are minimized by the almost imperceptible gradual start and finish, modulations are minimal and the calls are not repeated close together. Although these calls are theoretically extremely difficult to locate, recent research has shown that at least some birds of prey can orientate towards their source under experimental conditions (see Lewis and Cole 1980).

Although calls are relatively short and simple, there is now considerable evidence from a number of species that they contain enough information to transmit the identity of a particular individual. Many observers have noted the apparent ease with which parents returning to a densely packed seabird colony manage to locate their own young. Thorpe

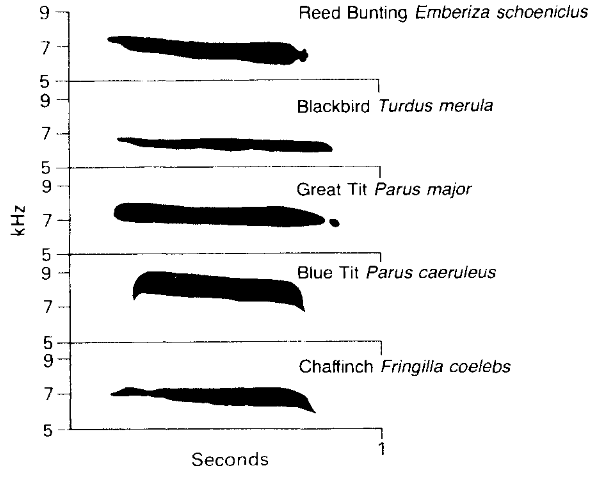

Fig. 1. Calls given by 5 different species when a hawk flies over.

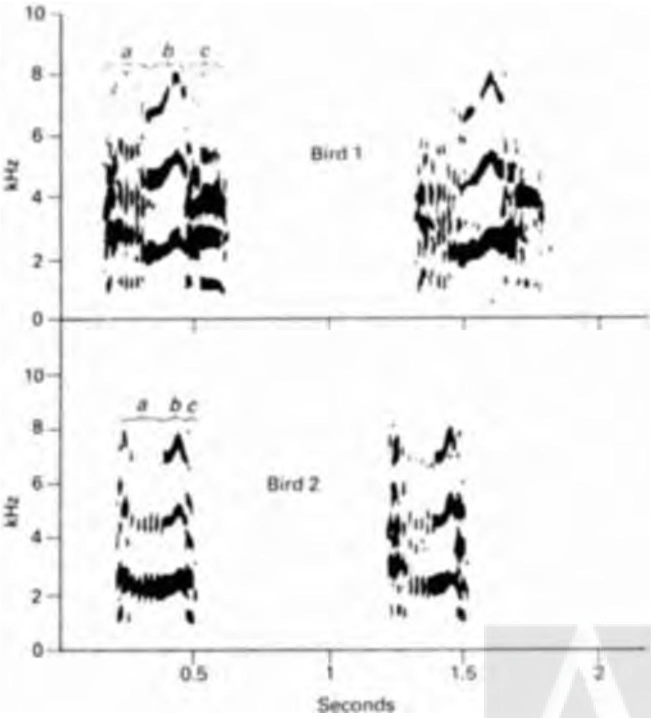

Fig. 2. Individual distinctiveness in successive calls from 2 Sandwich Terns *Sterna sandvicensis.*

and his fellow workers found that in species such as the Sandwich Tern *Sterna sandvicensis* each bird had its own distinctive version of a call. The calls can be divided into three separate segments (a, b and c) which vary consistently in frequency and duration between individuals (Fig. 2). In playback experiments, the young in the nest only reacted to their own parents' call. Similar results were obtained in recognition experiments with mated pairs of Gannets *Sula bassana* and several other species of colonial seabird.

Songs and their functions. The additional length and complexity of songs provides even more potential for information transfer between individual birds. The most obvious function is that of species recognition. Ornithologists use songs to identify a species and it would be surprising if the birds themselves were incapable of similar powers of discrimination. Many experimental studies have confirmed that whilst songs do act as specific signals, the cues which listening birds use for recognition are not necessarily the same as we use. J.-C. Brémond studied species recognition in the European Robin *Erithacus rubecula* by playing back tapes of modified Robin songs to territorial males. Males reacted strongly to normal control songs by approaching the speaker. Normal Robin songs are extremely complex and composed of alternating high and low phrases. Brémond constructed artificial songs consisting of either all high or all low phrases (Fig. 3), and obtained a much weaker response. Even a completely synthetic song constructed of high and low phrases produced from a sound generator achieved a good response. Clearly the basic syntactical rule of high-low-high-low is more important than the actual structure of the notes or syllables themselves. But other species seem to have quite different cues to which they respond. In Bonelli's Warbler *Phylloscopus bonelli*, the actual structure of the syllables themselves is more important, and any tampering with their fine structure renders an experimental song very ineffective. In the Indigo Bunting *Passerina cyanea* the very opposite applies, and individual syllables in songs can be completely reversed without any effect at all. In this species timing seems to be the most important factor, and if intervals between the syllables are lengthened or shortened, a very weak response is obtained during playback. It seems quite clear that there are no general rules of song structure for species recognition, but instead considerable variation from species to species.

Just as each species has a distinctive song, in many cases there is considerable intraspecific variation. For example each male Yellowhammer *Emberiza citrinella* has at least one version of the species song which appears to be individually distinct (Fig. 4). There is some evidence from playback experiments that territorial males learn both the identity and positions of their neighbours from their individual songs and respond very quickly to a strange new bird or a neighbour shifting his territory boundary.

Assuming that male songs carry both specific and individual information, there is still the question of what function or functions the songs may serve. One clue comes from the normal context in which song production occurs, by the unmated male in territory. This suggests the possibility that song has a dual function, as a territorial proclamation directed at other males, and as a sexual attractant directed at females. Much debate concerning the functions of song has centred upon the relative importance of these two aspects in individual species. Considerable evidence for a territorial function comes from a variety of experimental studies. One method is to trap territorial males and mute them by operation, thus stopping normal song production when the males are released back in their territories. In Red-winged Blackbirds *Agelaius phoeniceus* this resulted in the territories of mute males being constantly invaded by their rivals. Another more difficult method is to remove territorial males completely, and replace them with a system of

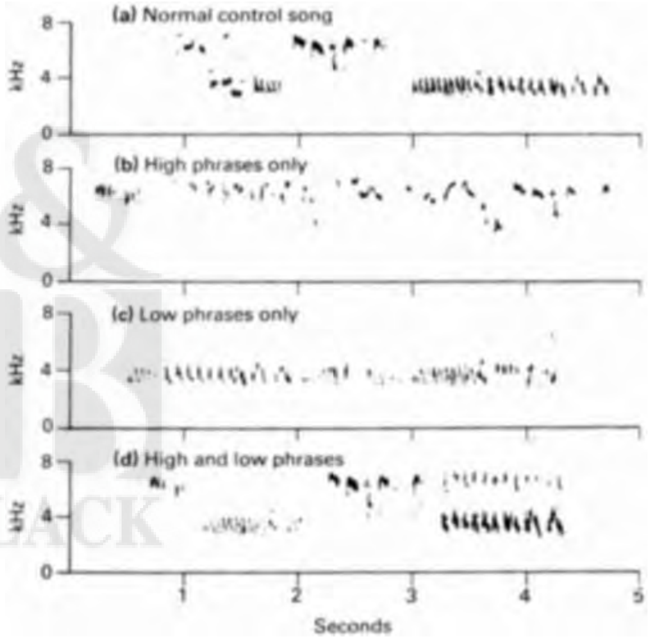

Fig. 3. Normal and artificial Robin *Erithacus rubecula* songs.

Robin *Erithacus rubecula* singing. (*Photo: J.B. & S. Bottomley*).

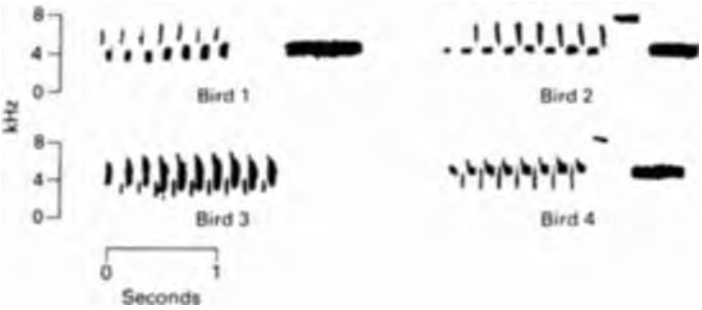

Fig. 4. Individually distinct songs of 4 male Yellowhammers *Emberiza citrinella*.

speakers which broadcast songs or control noises. In the Great Tit *Parus major*, prospecting males re-occupied the control areas several hours before the areas with broadcast song. Both these experiments suggest that song is an important first line of defence and does have some aversive effect upon rival males searching for a territory. But Great Tits like many species have more than one version of the species song, a repertoire of different song types. Each song type is repeated several times before switching to another, and so on. J.R. Krebs has suggested that Great Tits may be practising a subtle form of deceit; by singing in this way the impression is created that there are many more males present in a given area. Listening prospecting males may well decide to try their luck in a less crowded area. Krebs has tested his Beau Geste theory by using a similar speaker replacement technique as before. This time he broadcast a repertoire of song types in one area, and found that it was re-occupied later than an area broadcasting just one song type. It does seem that a repertoire is a more effective territorial proclamation, but there may be a variety of reasons. Switching song types may just prevent habituation, which has also been shown in the Great Tit. Having a large repertoire of song types may permit a resident to match the song of an intruder, indicating to the latter that his challenge is being answered.

Evidence that sexual attraction is the main function of song has been more difficult to obtain. Female songbirds seem to be far too elusive and reticent for field experiments. Much of the evidence is of an indirect nature such as the effect of females upon song production in the male. After the attraction of a female, song production decreases or in rare cases, such as the Sedge Warbler *Acrocephalus schoenobaenus*, ceases altogether. Normal territorial behaviour is continued by visual threat displays and fighting, but the male never sings again. The song structure of the Sedge Warbler also provides a clue in that it is unusually long and complicated. Songs can be up to a minute long and are composed of a variety of syllable types (Fig. 5). Instead of one or several song types, no two songs are alike, each being composed from a repertoire of up to 50 syllable types. C.K. Catchpole has suggested that such complexity is the acoustic equivalent of the Peacock's train, an extravagance whose only possible function could be to influence female choice. This was tested in the field by recording all the males in a population and estimating their repertoire size. It was found that the males with the most complicated songs obtained females before their rivals with less complicated songs. Similar results were obtained for another species well known for its song complexity, the Mockingbird *Mimus polyglottus*. There is also some evidence that more complicated songs of male Canaries *Serinus canaria* are more effective in stimulating the reproductive physiology and behaviour of females.

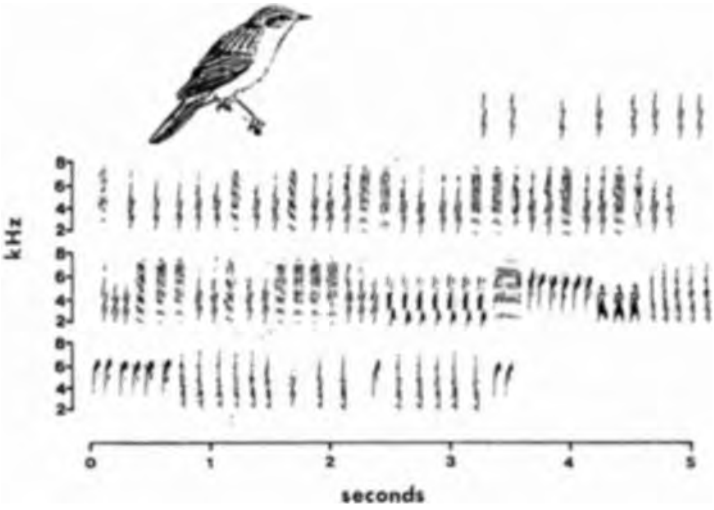

Fig. 5. The complex structure of one male Sedge Warbler *Acrocephalus schoenobaenus* song.

Grasshopper Warbler *Locustella naevia* singing on exposed perch. (*Photo: K. Carlson*).

An important point is that sexual and territorial functions are not mutually exclusive, and for many species a duality of function may well be built into their song structure. However, clues to function are more likely to be found either in species at one extreme of the functional spectrum, or by comparative studies on closely related species with differing song structures. The Sedge Warbler is a case in point, where the long, complex song and its use in sexual attraction seem linked. Catchpole then investigated song structures in other *Acrocephalus* species, and found major differences. The 4 monogamous species (including the Sedge Warbler) all have long complex songs for mate attraction, as females appear to select their mates directly on aspects of male quality including song complexity. The 2 polygynous species defend much larger territories, and as the female is likely to be left feeding the young alone, she selects her mate indirectly through territory quality. As a result the polygynous species have developed songs for territorial defence, and they are much shorter and simpler. One of these 2 species, the Great Reed Warbler *Acrocephalus arundinaceus*, is a partial polygynist, and this is also reflected in song structure. The unmated male has a longer version of his song which he uses to attract females. When he is paired, he detaches this longer and more elaborate section, and is left with a short, simple song which playback experiments have confirmed is more aversive to rival males. How far these findings can be related to other groups is not yet clear, but it does seem that long complex and variable songs are more likely to function in sexual attraction, and short, simple and stereotyped songs are more likely to have a territorial function.

Duetting. Duetting seems to be another case where the complexity of a song is increased by including contributions from two individuals, usually a mated pair. The songs produced are generally quite stereotyped and the two contributions so well co-ordinated that to the listener it seems to be produced by only one bird. Duetting has been found particularly in groups of tropical birds such as African shrikes of the genus *Laniarius*. In some species such as *L. erythrogaster*, the male produces one syllable and the female adds another in a simple alternating system called antiphonal song. In other cases, such as *L. funebris*, syllables are combined in a more complex sequence as shown in Fig. 6. The precise timing of the different contributions to within hundredths of a second is a striking feature of duetting between mated pairs. The functions of duetting remain obscure, but there are a number of clues

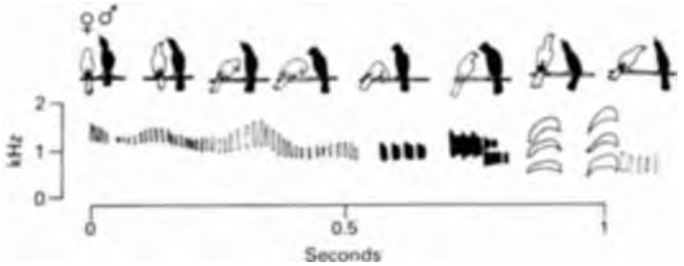

Fig. 6. Duet produced by a pair of African shrikes *Laniarius*.

from the distribution, ecology and behaviour of duetting birds. They are often tropical birds who live in dense vegetation and have high mate and territory fidelity. Perhaps duetting has developed to maintain contact between the mated pair under such conditions. However, in some species the mated pair sit close together and direct their loud duets as territorial proclamations to other neighbouring pairs.

Song development. It was Thorpe (1961) who pioneered the scientific study of song development in his classic work on the Chaffinch *Fringilla coelebs*. Until then, it had often been assumed that birds inherited their complex song structures. Thorpe was able to show the importance of early learning by raising nestlings in sound-proof chambers where they were deprived of external auditory feedback. The simple isolated song the birds eventually produced was nothing like the complex structure of normal adult song. How Chaffinches normally develop their song structure was also studied with captive birds. After fledging, a rather loose, rambling kind of quiet song, called early subsong, appears (Fig. 7a). It ceases in winter, but reappears in spring as a more complex version called late subsong (Fig. 7b). When the young male takes up territory and is exposed to the songs of nearby males the song structure becomes more recognizable as a Chaffinch song divided into three distinct phrases with a terminal flourish. At this stage it may still be changed and is called plastic song (Fig. 7c). When changes no longer occur and the structure becomes quite stereotyped it is called full song (Fig. 7d). In the Chaffinch and many other species the song will now remain unaltered for life.

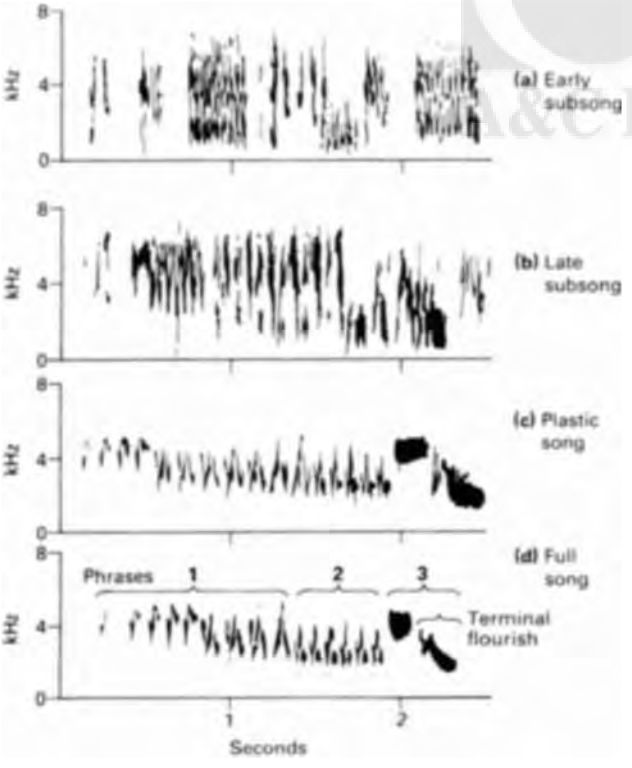

Fig. 7. Normal song development in the Chaffinch *Fringilla coelebs*.

By isolating his birds, Thorpe had prevented them from learning any detailed structure from other birds throughout this important first year. When he raised nestlings in groups, they tended to develop slightly more complex songs as they were able to copy a few more elements from each other's impoverished songs. Young males taken from the wild in autumn and then isolated subsequently developed almost normal songs in the spring, suggesting that learning starts at a very early stage. Later work established that just hearing playback of recorded songs at this early sensitive stage is enough to enable later development of full song. Another interesting point is that the bird is capable of storing some sort of model of full song structure as a neural template for several months before starting to sing in the following spring. The importance of auditory feedback was confirmed when F. Nottebohm carried out deafening experiments on Chaffinches at various stages. The difference is that this particular technique removes any auditory feedback the bird receives from his own songs, however inadequate they may be. Nestlings deafened at an early stage produced noises less structured than Thorpe's isolated but intact birds. When adult birds were deafened, however, they were able to retain their full song structure for several years. The basic concept of an early sensitive period of song learning in the first year, and then no further significant changes is now well established, but there are some exceptions. It is claimed, for example, that Canaries and Red-winged Blackbirds are both capable of adding to their repertoire in later years. There is obviously considerable interspecific variation in the length of the sensitive period for early learning. Even in the Chaffinch, the end of the sensitive period may not be just age-dependent. If a juvenile male is castrated before coming into song, then the ending of the sensitive period is delayed for another year as it is largely under hormonal control. When and where a young bird actually learns its song may be controlled by a number of factors which confer considerable flexibility in the final composition of a song type repertoire. For example, species or individuals which hatch early and are relatively sedentary will end up with songs learned from parents or neighbours in the natal area. Those which hatch late may be too late to hear local songs, and if they disperse to other areas will inevitably copy the songs of their new neighbours.

Hazel Grouse *Bonasa bonasia* male on song perch. Note feathered legs. (*Photo: A. V. Andreev*).

Finally, there remains the question of constraints and selectivity in song learning. If birds merely learned any acoustic stimulus then there would be no such thing as a species song. Most species have therefore evolved song-learning mechanisms which have built-in constraints imposing some control upon what can and cannot be learned. This selective learning was also revealed by Thorpe during his Chaffinch experiments. Having used recordings to tutor young birds during the critical period with normal Chaffinch song, he also tried using a number of artificial and alien songs as well. However, these were only successful if their characteristics were similar to those in Chaffinch song. For example, the Tree Pipit *Anthus trivialis* has a song which sometimes resembles that of the Chaffinch and young birds tutored on this eventually produced quite a reasonable imitation. Real Chaffinch songs re-articulated so that the terminal flourish appeared in the middle instead of the end were also used, and the young birds were able to learn these extremely well.

Marler (1981) and his group have investigated in some detail the basis of selective learning in Song *Zonotrichia melodia* and the Swamp Sparrows *Z. georgiana*. The songs of the 2 species differ particularly in temporal organization. Swamp Sparrows have a fairly regular, slow trill, whereas Song Sparrows have a more complex pattern of different fast and slow sections. Marler anticipated that these differences in temporal patterning might form the basis for any selective learning and to test the hypothesis constructed a series of artificial songs with which to tutor young Swamp Sparrows. These included Swamp Sparrow-like patterns, which were sequences of identical elements at a steady rate, and Song Sparrow-like patterns which had the more complicated structure of at least two different fast and slow parts. The young males were tutored with the various songs twice a day between the 20th and 50th day after hatching, within the critical period for this species. When they eventually came into song several months later, only Swamp Sparrow songs had been learned. The young Swamp Sparrows had rejected Song Sparrow elements even when presented in Swamp Sparrow-like patterns, and the selective learning was clearly based upon the specific structure of the elements, not their temporal patterning as first thought. By fostering Swamp Sparrow eggs into Canary nests, Marler also demonstrated that this early disposition for selective learning occurred without the possibility of earlier auditory experience. The experiments were repeated with these more thorough isolates who had no opportunity to hear their species song even as embryos. A similar pattern of results confirmed what appears to be an inherited basis for selective learning in this species.

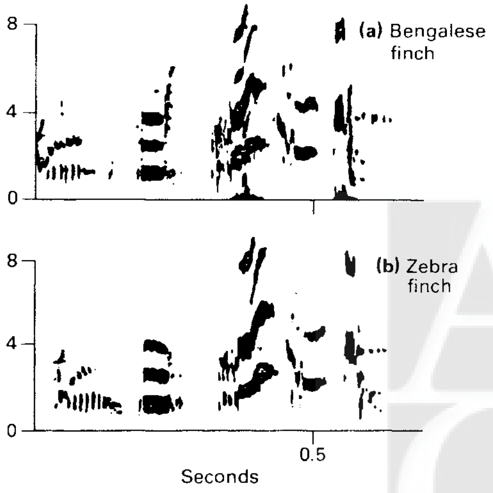

Fig. 8. Song of a Bengalese Finch *Lonchura striata* foster father and the young Zebra Finch *Poephila guttata* it raised.

However, not all species are subject to the same type of constraints, as shown by K. Immelmann in his work on tropical grassfinches such as the Zebra Finch *Poephila guttata*. The advantage of working with Zebra Finches is that in captivity they can be readily fostered upon other closely related species such as the Bengalese Finch *Lonchura striata*. Single eggs of one species were added to the clutch of another species and the brood reared in a sound-proof cage. At various stages the fostered young were then isolated in other sound-proof cages until their song developed. Young males separated after 80 days invariably developed the song of their foster-father even though he was a quite different species. Just how complete and accurate the copying is can be seen from the song of a young Zebra Finch raised with a Bengalese Finch foster father (Fig. 8). Such individuals can then be housed with fellow Zebra Finches singing normal songs, but they still persist in singing Bengalese Finch songs. Even though the critical period is shorter and the song of another species learned, once the process is complete it appears to be irreversible, as with other species. Why Zebra Finches are not so selective in the types of songs they will learn may be explicable in terms of their ecology and breeding behaviour. Unlike passerines in temperate latitudes they sing and breed throughout the year, often in colonial conditions and frequently near other species of grassfinch too. Under these conditions, the best strategy for song development might well be to learn the species song quickly from the father before going off to feed in mixed-species flocks where the risk of contamination would be high. The constraints here are applied through social bonding and a quick end to the critical period, rather than through an inherited preference for learning a specific song as in most other passerines.

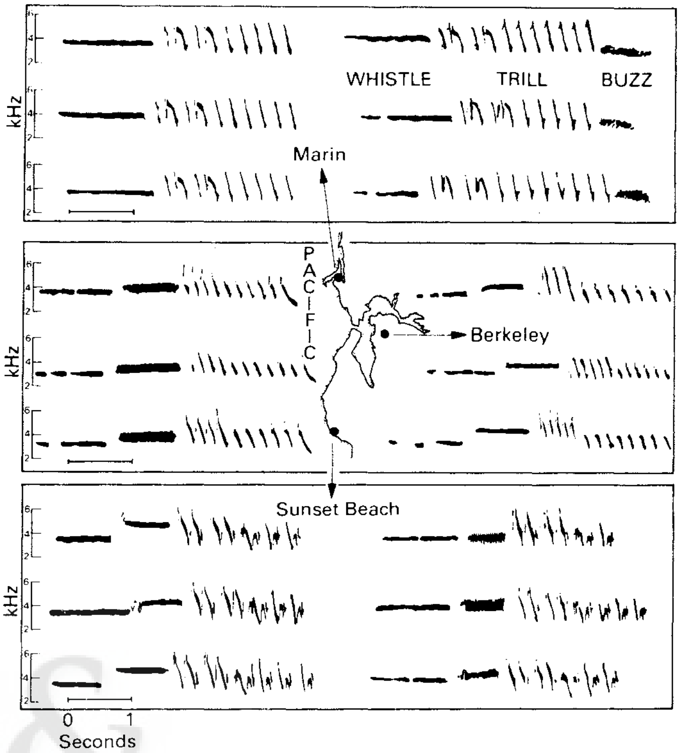

Fig. 9. Three different dialects shown by White-crowned Sparrows *Zonotrichia leucophrys* around San Francisco Bay.

Song dialects. Local dialects occur when the songs within one population share certain structural characteristics which are different from other populations nearby. It is usual to separate such microgeographical variation from geographical variation which occurs over much longer distances. Although local variations have been reported for many species, the most studied is the White-crowned Sparrow *Zonotrichia leucophrys*. Originally working around the San Francisco Bay area Marler and his group obtained sonagraphic evidence of clear dialects based upon variations in the pattern of introductory whistles, the fine structure of the trill, and the position of the buzz (Fig. 9). The population at Berkeley, for example, has three or more ascending introductory whistles, that at Marin has one or two with a terminal buzz, and that at Sunset Beach has two ascending or two followed by a buzz. There are other consistent differences in the fine structure of the trill which make this an excellent example of how individuals within each population conform to the dialect for their particular area. The question arises as to how this conformity comes about, and the answer lies in what is already known about the development of song. Marler took nestlings as well as young birds from the wild at up to 100 days old and raised both groups in acoustic isolation. The nestlings eventually produced abnormal songs which bore no relation to their home dialect, whereas the older wild trapped birds produced good copies of their dialect. This suggests that the special features of dialects are not inherited but learned with the general features of the species song. Marler confirmed this by tutoring young birds during the critical period and showed that they could learn their own or even a 'foreign' dialect at this time. Whilst the neural template rejects the songs of closely related species as a model, it is clearly flexible enough to accept different varieties of the species song. With the critical period in the White-crowned Sparrow ending as soon as 50 days, it seems highly likely that the model will be either the song of the father, or a neighbouring

Curlew *Numenius arquata* calling in flight. (*Photo: J.B. & S. Bottomley*).

male, and thus the local dialect is preserved and passed on by a form of cultural transmission.

The question which remains to be answered is, are dialects merely a functionless by-product of song learning, or do they have some additional role to play in communication? There are many theories concerning the significance of dialects, but perhaps the most interesting to emerge is that they may be involved in reducing gene flow between populations. Dialects are sometimes associated with different habitats and it has been suggested that dialects might attract only those females which are best adapted to breed in local conditions. Several predictions follow from such a theory: local populations are genetically different, there is reduced gene flow between populations, and females select males which sing their own dialect. In the White-crowned Sparrow there is some evidence from playback experiments that both males and females show a stronger response to their own dialect. Electrophoretic analysis of proteins from presumptive genetic loci demonstrate that there are greater genetic differences between populations of White-crowned Sparrows which also have dialects, and that gene flow appears to be reduced between them. However, when females were taken from mated pairs in the wild, and injected with testosterone to make them sing, most produced songs of a different dialect to their mate. It seems that some females disperse and select a mate from a different dialect area to their own. Clearly, more research is needed before the significance of dialects is fully understood.

That dialects are the result of song learning confers a degree of flexibility in the evolution of song structures. Cultural transmission may be an efficient way of passing on complex structures, but it is also prone to errors. Chaffinches normally copy their songs extremely accurately from other birds or tape recordings, but occasionally an element may be missed out or one added on. Such changes may be passed on through learning and can spread rapidly through wild populations in only a few years. After 10 or 20 years, the songs in a population may have changed beyond all recognition. This enormous potential for generating new variety is one of the reasons why bird songs are so remarkably complex and diverse in their structure. C.K.C.

VULTURE (1): the Old World vultures are a group of specialized carnivorous birds, which are usually classified in the family Accipitridae (order Accipitriformes). They are the most distinct group within the order and, although their relationship to other members is not clear, they may be related to the fish eagles *Haliaeetus* and snake eagles *Circaetus*. They have a long fossil history dating to the Lower Miocene, over 20 million years ago. Fossil species of these vultures have been recorded in both the New and the Old World, but the group is now extinct in the Americas, where their role has been replaced by the more recent cathartid vultures (see VULTURE 2). The 15 modern species of Old World vultures are now confined to Africa, Asia and southern Europe.

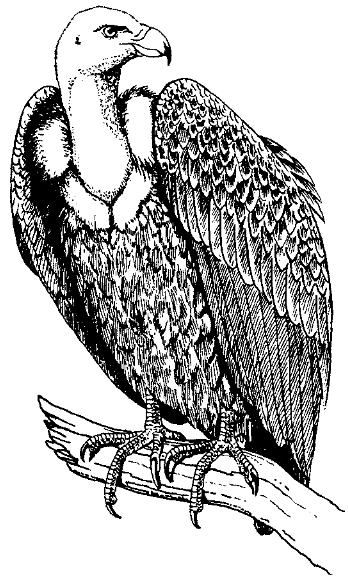
Characteristics. These birds (lengths varying from 40–100 cm) have a number of features which distinguish them from the other members of the Accipitridae (see HAWK). Most species of vulture feed almost exclusively by scavenging and they rarely or never kill their prey, but rely on finding dead animals. They depend on soaring flight to a greater extent than most other birds of prey, and the larger species are incapable of sustaining a flapping flight for more than a few seconds. The birds are, therefore, dependent on finding rising air in order to gain altitude. In flat country they use thermal upcurrents, and vultures cannot fly early in the morning until the heat of the sun has started to generate thermals. But in hilly or mountainous regions the birds chiefly fly by slope soaring, and can then be airborne at first light. Most species show no sexual dimorphism, so that the sexes of all the species are indistinguishable in the field; exceptions are the White-headed *Trigonoceps* and possibly the Indian Black *Sarcogyps*. The density at which some species of vultures can occur, in areas with a suitable food supply, is far greater than that of any other kind of carnivorous bird. Some species can congregate in groups of several hundred individuals at a food site. Like all birds of prey, the vultures have powerful bills with hooked tips, but their feet and claws are alleged to be comparatively weak (a fact which is not always apparent to those who have handled them). Most species have bare areas of skin on the head and neck, and these patches are most extensive in the larger species: they may reduce the fouling of the plumage when the birds are feeding, and may also be important in heat regulation because these areas are heavily supplied with blood vessels. Many of these features of the Old World vultures are shared by the New World vultures (Cathartiformes). But the 2 groups of vultures are not at all closely related and their superficial similarities are due to convergent evolution.

Habitat and distribution. The distribution of the Old World vultures is confined to more of less open country, and they are widespread in savanna, grassland and desert areas. None of the species are found in areas of dense forest. They are often associated with tropical climates, but they can also be found in cool regions, such as the Tibetan plateau, and until a few hundred years ago there were several species which were found commonly in Europe as far north as central Germany. Their distribution is governed as much by suitable food supplies as by climatic conditions: most species feed chiefly from the carcasses of antelope or other large grazing mammals, and they are generally abundant in areas which have large herds of grassland ungulates, and are notably absent from regions where such mammals do not occur such as Australia, Madagascar or Sri Lanka.

Griffon vultures. The 7 species of griffon vultures, belonging to the genus *Gyps*, feed almost exclusively from the carcasses of large mammals, and these species are usually the most numerous type of vulture in any region. They include the largest species of vulture, the Himalayan Griffon *Gyps himalayensis*, perhaps weighing up to 12 kg with a wing span of about 2.8 m. All members of the genus have long and flexible necks which enable them to penetrate far into carcasses to remove muscles and viscera. The bill has sharp edges for slicing through meat, and the tongue is serrated so that they can swallow their slippery food rapidly. They can be delicate in their feeding, and can detach virtually all soft tissues from even complicated bones. Most species have capacious crops, which can store about a quarter of the bird's body weight in food. Vultures are clean birds who will usually bathe and preen thoroughly when they have finished feeding. Griffon vultures can collect in groups of up to several hundred individuals at a large supply of food. When present in such numbers they are extremely efficient in their feeding, and can remove all the soft tissues from a large antelope in about half-an-hour. The birds are aggressive in their feeding, and all the species have developed a complex and ritualized series of threat displays and calls which are used to intimidate their colleagues (although vultures have few other displays or vocalizations). The various species have separate distributions and, although there is some overlap, the 2 smaller white-backed species, *Gyps africanus* and *Gyps bengalensis* (formerly in the genus *Pseudogyps*) are largely confined to flat savannas, while the larger species occupy mountainous or hilly terrain. Griffon vultures feed chiefly by locating animals which die from disease, starvation or accidents. They regularly travel great distances in their food searching, and may be partial migrants in many parts of their range. They do not search in groups, but they do depend heavily on watching the activities of their neighbours in order to locate food. Griffon vultures have no sense of smell—like all the Old World vulture species (and unlike some of the New World vultures). Birds sometimes forage at comparatively high altitudes (up to 1,500 m) and each individual is usually within sight of several other searching birds. When one bird sees a carcass it starts to descend rapidly. Other birds who see this descent will then drop to the ground, to be followed in turn by still more distant individuals, and so a chain reaction quickly radiates out from a source of food. Birds can congregate in this way from a radius of 50 km or more. The bigger griffon species sometimes roost in large numbers, and also nest colonially on cliff ledges. Some colonies contain only a few nests, but colonies may contain several thousand pairs. The smaller white-backed griffons are tree nesters and may congregate in loose colonies or nest solitarily.

Nest construction varies greatly between individuals, as well as between species. Some cliff-nesting birds lay on a ledge containing only a few twigs, while other individuals may have a nest site which has been in use for many years and which contains a construction of twigs a metre or more in depth and width. Most individuals line the nest with a few green branches before egg-laying. All species are probably monogamous, lay a single egg (as do most other vulture species) and have an incubation period of about 55 days. Both sexes share in the nesting duties and the birds have comparatively long fledging periods of up to 150 days.

Other vultures. The Lappet-faced Vulture *Torgos tracheliotus* (mass 7–8 kg, wing span 2.5 m) and the European Black Vulture *Aegypius monachus* (mass 7–10 kg, wing span 2.5–3 m) are very closely related and should perhaps be considered congeneric. They congregate at large ungulate carcasses, together with griffon vultures, although usually there are only 2 or 3 individuals at each feeding group. They are aggressive in their feeding, have intimidating threat displays and can usually drive off a group of griffon vultures. The birds chiefly take skin, tendons and other coarse pieces of tissue which they tear off with their powerful bills, and they do not usually eat large amounts of muscle tissue. They do not forage widely, but probably remain in a fixed feeding range throughout most of the year. When ungulate carcasses are not freely available the birds also feed on much smaller food items, such as hares, young antelope or game birds. It is very likely that they kill some of these animals.



Griffon Vulture *Gyps fulvus*. (*K.J.W.*).

The Indian Black Vulture *Sarcogyps calvus* (mass 4.5 kg, wing span 2 m) and the African White-headed Vulture *Trigonoceps occipitalis* (mass 4–4.5 kg, wing span 2.2 m) are probably closely related. Despite some accounts in the literature, they are quite unlike other large vultures. They do not usually feed in mixed groups. Both species are timid and retiring in their behaviour and, if they do come to a large carcass, they often confine their activities to isolated bones at the outside of the main feeding groups of griffon vultures. It is unusual to see more than 2 or 3 individuals at a feeding site and they appear to occupy fixed territories in which a pair and their young remain throughout the year. They probably feed chiefly from small carcasses which the other species do not locate, and they probably kill a proportion of their food.

The Hooded Vulture *Necrosyrtes monachus* and the Egyptian Vulture *Neophron percnopterus* are very similar in their feeding habits, but they are probably not closely related (the Egyptian Vulture shares a number of characteristics with the Lammergeier *Gypaetus barbatus*). Both are small species (mass 1.5–2 kg, wing span 1.5–2 m) with catholic feeding habits. They can collect in considerable numbers at the carcasses of large mammals, and peck at small scraps of meat dropped by the larger birds. But they also feed on insects, small reptiles, birds' eggs, young nestlings and even the dung of carnivores. The Egyptian Vulture is one of the few birds which uses tools while feeding (see TOOLS, USE OF). It regularly feeds on birds' eggs. Small eggs are picked up in the bill and dropped on to the ground to break them open, but to crack larger eggs the birds pick up stones which are then hurled on to the shell.

The Lammergeier (mass 5 kg, wing span 2–2.5 m) is a solitary and uncommon bird over most of its range, although feeding groups are commonly seen in Ethiopia. It is confined to precipitous mountain regions, where it feeds from the carcasses of large mammals such as sheep and goats. It carries large bones and tortoises high into the air and drops them on to rocks to break them open, and then sweeps down to feed on the contents.

The least typical of this group of birds is the Palm-nut Vulture *Gypohierax angolensis* (mass 1.5 kg), which rather resembles a sea eagle. It feeds on stranded fish and carrion, but its main food is the fruit of the oil palm and its distribution closely matches that of the palm plantations.

Most of this group of vultures are specialized for feeding on the carcasses of large ungulates and, because of their gliding flight, can travel great distances each day in search of food. They can therefore exploit the food supply which is available for scavenging animals far more successfully than any mammalian scavengers, and the total food consumption by the various vulture species makes them important members of many tropical communities. VULTURE (2): substantive name for 5 of the 7 species of Cathartidae (Cathartiformes). The remaining 2 species, differentiated by their larger size, are known as condors. These 7 species are collectively known as 'New World vultures', but perhaps are better described as cathartid vultures, since the fossil record for the group includes 'Old World' forms.

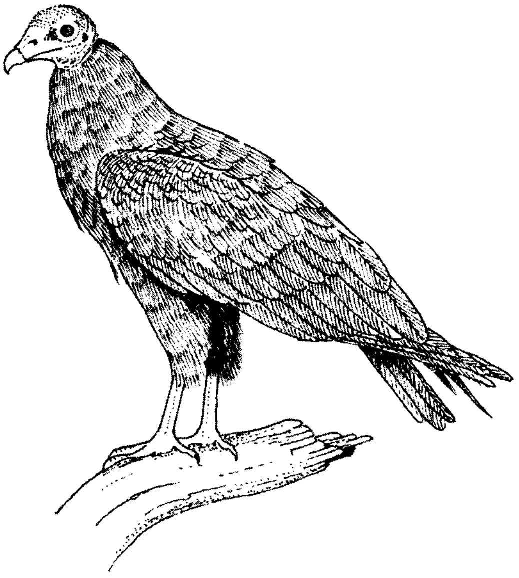
Characteristics. The cathartid vultures are large (60–100 cm long), soaring birds, generally black or dark brown in colour with patches of white or greyish white on the wings. The one exception is the King Vulture *Sarcorhamphus papa* which has a white plumage with black on the tail, rump and wings. The condors possess a feathered ruff around the neck, consisting of white down on the Andean Condor *Vultur gryphus* and black, lance-shaped feathers on the California Condor *Gymnogyps californianus*. All species have essentially unfeathered heads and necks and, with the exception of the Black Vulture *Coragyps atratus*, the bare skin is principally red, orange or yellow. In size, they range from the relatively small Black Vulture with a 1.5 m wing span to the immense Andean Condor with a span up to 3.2 m. Sexes are similar in size and colour except for a tendency for male condors to be slightly larger, and the presence of a large, comb-like caruncle on the head of the male Andean Condor. Cathartid vultures differ from Old World vultures primarily on anatomical characters, most notably by their perforated nostrils.

Distribution and habitat. Cathartid vultures range from southern Canada to the southern tip of South America, with the greatest number of species and abundance of individuals in tropical and subtropical regions between Mexico and northern Argentina. Two species, the Andean Condor and Greater Yellow-headed Vulture *Cathartes melambrotus* occur only in South America, while the severely endangered California Condor is restricted to approximately 5 million ha in southern California; only an estimated 30 birds remained by 1980. The Turkey Vulture *Cathartes aura* and Black Vulture are the 2 most widespread and conspicuous species in most regions, and have correspondingly broad habitat tolerances. Greater Yellow-headed and King Vultures are often associated with forested regions, while the Lesser Yellow-headed Vulture *Cathartes burrovianus* is a bird of humid savannas and marshes, and the 2 condors occur in rugged, mountainous regions.

Movements. Turkey Vultures from western North America are highly migratory with large flocks passing through Central America into northern South America each fall. The other species are generally non-migratory, although south-bound flocks of Black Vultures have been observed during the fall in Costa Rica and Panama.

Food. Cathartid vultures are carrion feeders, although Black Vultures occasionally, and Turkey Vultures rarely, kill new-born or defenceless animals. Black Vultures also congregate in large numbers at garbage dumps, primarily at the edges of tropical towns. Vultures may routinely soar tens of kilometres from roosting or nesting sites when searching for food. Apparently most species locate food by sight or by keying in on other vultures already feeding, but Turkey Vultures also locate food by smell.



Turkey Vulture *Cathartes aura*. (*K.J.W.*).

Behaviour and breeding. Most vultures and condors are colonial in the formation of roosts, and various numbers may congregate at a carcass. The Black Vulture is the most colonial, and is the only one that may also nest in loose colonies. The exception is the King Vulture which is usually seen singly or in pairs. No species constructs a nest. Condors lay a single egg on an overhung ledge or in a small cave on a rocky cliff. Pairs of condors may remain mated for several years, and apparently do not breed annually, presumably due to the prolonged nesting cycle and period of dependence by the fledged chick. The King Vulture lays a single egg, and the Black and Turkey Vultures lay 2-egg clutches. Vultures nest in a variety of locations, including a patch of bare ground in a dense tangle of vegetation, in an upright or fallen, hollow log, between jumbles of boulders or in caves. Incubation (32–58 days) and brooding and feeding of nestlings are performed by both adults. A Black Vulture chick may make the first short flight at 10 weeks of age, while a California Condor chick first flies at 22–25 weeks. Cathartid vultures are generally silent except for low hissing or grunting sounds heard from nestlings or adults.

W

WADER: in the plural, general term commonly used in the British Isles for members of the suborder Charadrii of the Charadriiformes. 'Shorebirds' has a similar meaning in North America, where 'waders' tends to be applied to the Ciconiiformes.

WADING: see LEG.

WAGTAIL: substantive name of some species in the family Motacillidae (Passeriformes, suborder Oscines), which also includes the pipits and longclaws, all of which will be covered in this article.

Characteristics. Small (lengths *c.* 14–17 cm), slender-bodied ground birds with long tails that are often wagged up and down. The legs and toes are long and these birds either walk with a rather deliberate gait or run at great speed over the ground. The hind-toe is elongated in most species and may reach 4 cm in length in some longclaws. The bill is slender and pointed. There are 11 species of wagtails (*Motacilla*) all strikingly coloured with black, white, grey, yellow or green plumage. The 35 species of pipits (*Anthus*) are duller and cryptic in coloration, often with heavily streaked brown plumage. Many species look alike and they are often difficult to identify. The longclaws (*Macronyx*), of which there are 8 species, are more robust in build and rather lark-like in appearance; they are often brightly coloured.

Habitat and distribution. All species inhabit open country from rocky shores (Rock Pipit *Anthus spinoletta*) to wet meadows and grasslands (many pipits, e.g. Meadow Pipit *A. pratensis*), arid and sandy regions (Tawny Pipit *A. campestris*), streams (Grey Wagtail *Motacilla cinerea*) and mountain tops (Hodgson's Pipit *A. roseatus*, which occurs up to 4,000 m in the Himalayas). The Pied Wagtail *M. alba* is common on farmland and also near human habitation, often running after insect prey on roads and roof-tops.

The wagtails occur throughout the Old World but they are only rare visitors to Australia. A geographical race of the Yellow Wagtail *M. flava* is the only wagtail to breed in the Western Hemisphere, nesting in the arctic tundra of western Alaska. The pipits are among the most widely distributed song birds in the world; they breed in all continents from the arctic tundra, through the South American pampas and African desert to the antarctic, where one species (*Anthus antarcticus*) breeds on the island of South Georgia. The Rock Pipit *A. spinoletta* has a wide distribution, inhabiting rocky shores in northern Europe, high mountain valleys throughout the Palearctic (where it is known as the Water Pipit) and alpine meadows and tundra in north America. The Tree Pipit *A. trivialis* inhabits open woodland and regularly perches on tall trees. Richard's Pipit *A. novaeseelandiae* extends throughout the Palearctic to Australia where it is the only pipit.

The longclaws are African; the Yellow-throated Longclaw *Macronyx croceus* is extremely similar in appearance to the Meadow Lark *Sturnella neglecta*, a New World ecological equivalent; both these unrelated species have cryptic upperparts and bright yellow underparts with a dark band round the breast, a striking example of plumage convergence, presumably under similar selective pressures on the two continents.

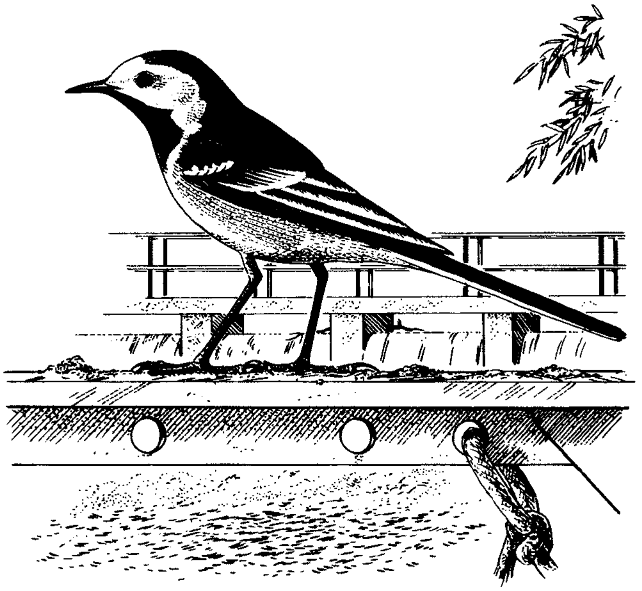
Populations and movements. The Palearctic wagtails and pipits are migratory, many moving to tropical Africa and Asia for the winter. In African winter quarters the Tawny Pipit inhabits dry country, the Tree Pipit open ground where there are well spaced trees and the Red-throated Pipit *Anthus cervinus* open wet country. Populations of the Pied Wagtail that breed in northern Britain migrate to southern Britain in the winter and, if the weather is harsh, they may move further south to France and Spain. The continental race, often referred to as the White Wagtail, migrates to the Middle East and northern tropical Africa. Ringing recoveries have shown that the Icelandic population winters in Senegal. In winter, the White Wagtail may come into competition with the similar African Pied Wagtail *M. aguimp* which some authorities have regarded as conspecific. Both occur round human settlements, especially villages and rice-fields, but most of the White Wagtails probably occur further north than the African Pied.

The Yellow Wagtail *M. flava* is famous for its geographical variation in plumage and there has been considerable argument about the designation of populations as subspecies. As many as 8 subspecies winter in Africa, from the truly yellow *M.f. flavissima* that breeds in Britain to the black-headed *M.f. feldegg* from the Balkans and the Black Sea. Several subspecies join together in winter quarters to feed and roost in large flocks. At the end of the winter the different subspecies leave successively for their breeding grounds, those breeding furthest south migrating first (e.g. *M.f. iberiae*) and the northernmost subspecies departing last of all (e.g. *M.f. flava*).

Food. Mainly insects, both adult and larvae collected by picking from the ground or, in wagtails, also by fly-catching in mid-air. The frequency of fly-catching in the British wagtails is related to tail length, the Grey Wagtail, which has the longest tail, doing the most and the Yellow Wagtail the least, with the Pied Wagtail intermediate. It seems likely that the tail assists in the control of aerial manoeuvres during the capture of flying insects. Adult Diptera (especially Scatophagidae, Tipulidae and Chironomidae) are common in the diet, also grasshoppers, spiders, worms, molluscs and crustaceans. Seeds are occasionally eaten and in winter wagtails often congregate at artificial food sources on rubbish dumps.

In mid-winter, when there may be only 8.5 hours daylight for feeding in southern Britain, both the Pied Wagtail and the Rock Pipit feed for about 90–95% of the time, collecting one prey item every 3 or 4 seconds throughout the day. Rock Pipits that winter on rocky shores may eat *Littorina neritoides* (a small periwinkle) at an average rate of 33 per minute and Chironomid midge larvae at 35 per minute. They also eat isopod crustacea (*Idotea*) and amphipods (Talitridae). In winter, Pied Wagtails regularly feed on small adult insects and their larvae at a rate of 20 per minute. Even with these prodigious rates of feeding, calculations show that both these birds only just manage to find enough food to maintain their energy balance on a winter's day.

Behaviour. In summer, wagtails and pipits space their nests out and defend breeding territories. In favourable habitats there may be up to 5 pairs of Rock Pipits per km of coastline. In winter some species usually feed in flocks (Meadow Pipit, Pied Wagtail), and exploit large patches of abundant food. Pied Wagtails also roost communally in reed beds, low trees and bushes, and near human activity such as sewage farms, factories and greenhouses. In mid-winter the roosts may build up to several hundred or even 2,000 individuals. Extensive colour ringing studies have shown that most birds feed within 12 km of the roost. In the early morning, the flocks leaving the roost depart towards good feeding sites. One advantage of roosting communally, therefore, may be that it allows



Pied Wagtail *Motacilla alba*. (*A.H.*).

information transfer in the population about the location of food. Roosts may also provide warm, sheltered sites safe from predators.

Some species defend territories in winter. Rock Pipits defend stretches of the coast, and some Pied Wagtails also defend winter feeding territories and individuals may return to the same territory in successive winters. Territory boundaries are vigorously defended with displays involving head bobbing and short jumps into the air. Observations in Japan, Israel and Britain have shown that winter territories are often occupied by single birds but sometimes 'winter pairs' form, usually involving a male and a female, or a male and a bird in juvenile plumage. The pair defends the territory together, but the male is the dominant partner and the other bird continually appeases it with special postures. Sometimes, when food is scarce, the male evicts his 'mate' from the territory. These pairs are apparently not related to breeding and seem to be just concerned with winter survival.

The social organization of Pied Wagtails in winter is related to the food supply. Sometimes individuals may be defending territories and, nearby, other conspecifics are feeding in large flocks on locally abundant foods. Social behaviour can be changed experimentally by altering the pattern of food distribution. On small piles of food, individuals will defend territories. If the food in these same piles is then spread out and dispersed evenly, flocks of wagtails will form to exploit the food. This is presumably because it is uneconomical to defend widely scattered food supplies.

Voice. The pipits are well known for their spectacular song flights (e.g. Meadow Pipit, Tree Pipit) in which the song is delivered from high in the air as the bird parachutes slowly back down to the ground or a tree perch. Both the wagtails and the pipits often give flight calls and in the pipits these calls are one of the best ways of identifying species in the field. The Pied Wagtail has a territorial call that is only given by territory owners. The call (*chee-wee*) dissuades intruders from landing on the territory. If tape-recordings of the territorial call are broadcast on an occupied winter territory, the owner reacts violently and flutters within a metre or so of the loudspeaker, as if it thinks there is another owner present!

Breeding. Pipits nest on the ground, amongst grass. Wagtails also nest on the ground (Yellow Wagtail) or in crevices in rocks, walls, under bridges, haystacks etc. (Pied Wagtail). Nests are neatly built of grass and moss and lined with hair. The eggs are white or buff, speckled brown or grey. Incubation, usually by female only, is from 12–16 days. Both parents usually care for the young, which fledge in *c.* 14 days. Pied Wagtails finish breeding during July and then moult, the primary moult taking about 57 days. Almost all the population has finished the moult by the end of September.

WAGTAIL-TYRANT: substantive name of the 2 tyrant-flycatchers of the genus *Stigmatura* (see FLYCATCHER (2)).

WAGTAIL, WILLY: misnomer applied to the ground-feeding *Rhipidura leucophrys* of the Australasian Region (see FANTAIL).

WALDRAPP: alternative name of the Bald Ibis *Geronticus eremita* (see IBIS).

WALKING: see LEG; LOCOMOTION, TERRESTRIAL (and photo).

WALLACEA: the geographical area east of Wallace's Line (q.v.), which runs up the Sunda Shelf, between Bali and Lombok (only *c.* 30 km apart), Borneo and Sulawesi (*c.* 100 km apart) and south of a line between the Philippines and Sulawesi. At this line a marked faunal change takes place, very many families, genera and species of the Oriental Region penetrating no further east than this line. The eastern boundary of Wallacea is the Sahul Shelf, on which lie New Guinea and Australia (the Australasian Region). A similar marked faunal discontinuity is repeated here between Australia and Timor, the Southwest Islands and Tanimbar and between New Guinea and Kai, Seram and the northern Moluccas. Wallacea is a mosaic of oceanic islands falling outside the continental faunal regions. (*See* C.M.N. White and M.D. Bruce, The Birds of Wallacea. In press 1985, British Ornithologists' Union.)

WALLACE'S LINE: see above and ORIENTAL REGION; also AUSTRALASIAN REGION.

WALLCREEPER: substantive name of the Old World family Tichodromadidae (Passeriformes, suborder Oscines). The Wallcreeper *Tichodroma muraria* is put in a family of its own as its former inclusion with the Certhiidae, later Sittidae, was not based on any firmly established relationship. Only 2 subspecies are recognized.

Characteristics. The Wallcreeper is 135–165 mm long, and its weight at 17–19 g corresponds to that of the Great Tit *Parus major*, but the wings measure 98–116 mm, those of the Great Tit only 70–78 mm. Apart from the red and white marks on the wings, the blue-grey plumage is like that of the Nuthatch *Sitta europaea*. The bill is slender and curved, like the treecreeper's *Certhia*. The feet are noticeably weak. In breeding plumage the male has a black throat and breast; in the female the breast is either whitish-grey or there is a grey or black mark of varying size. After the breeding season, both sexes moult into winter plumage with whitish-grey underparts. In the spring plumage only breast, throat and head are moulted. The wings are often used as an aid in climbing, being constantly flicked, showing the white and red markings. The tail is not used as a support when climbing.

Habitat. The Wallcreeper is found among the rocky areas of mountains where it climbs by hopping from one projection to another. Flowing water, in the form of mountain streams or small waterfalls, is a characteristic feature of most nesting areas. Wallcreepers also nest readily in gorges where there is an alternating pattern of sun and shade.

Distribution. Wallcreepers are found in the highest mountain ranges of Europe and Asia from the Cantabrians and Pyrenees in the west, through the Alps, the Carpathians, Balkan peninsula, Asia Minor, to the Caucasus, Iran and the Himalayas, where they live as high as 5,000 m. In the Alps they breed mostly between 1,000 and 2,500 m; but in Switzerland nesting places are known at only 350 and 550 m.

Wallcreeper *Tichodroma muraria*. (*D.W.*).

Movements. In the autumn Wallcreepers leave the high mountains and move down to lower rocky areas or ruins; there they may defend a winter territory against all others of their kind.

Food. Both in summer and winter the food consists of insects and spiders, which are extracted from their hiding places with the thin bill, or seized directly.

Behaviour. Except in the breeding season, Wallcreepers lead a solitary life and will attack any conspecific from October onwards. In addition to flicking the wings, the male flutters round the female, who may shiver her wings. They bend their heads upwards till their bills are almost upright and crossed.

Voice. Wallcreepers have a few quiet calls which are seldom heard. Both sexes sing short melodious phrases while climbing.

Breeding. The nest, built by the female alone, is situated in a crevice or hole in a wall or rock face, and consists of moss, roots, grass, feathers and wool. The eggs are white, sparsely freckled with fine reddish-brown. The clutch of 3–5 eggs is incubated by the female alone for 18–19 days. She is fed regularly by the male. The young fledge at 28–29 days old.

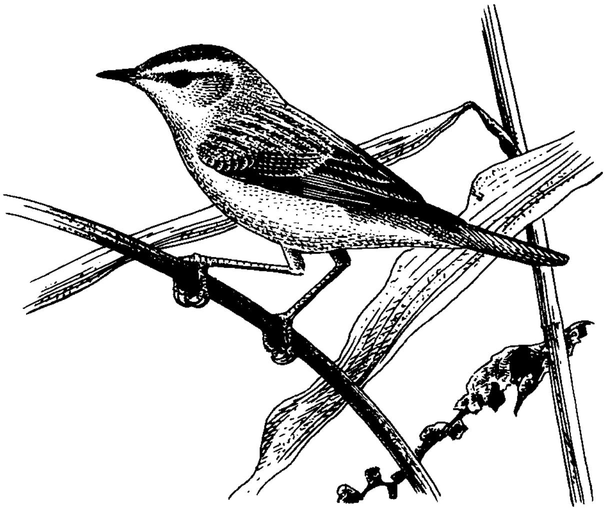
WARBLER (1): substantive name of many species of the family Sylviidae (Passeriformes, sub-order Oscines); in the plural a general term for the family. The Sylviidae are commonly known as Old World warblers, having 10 primaries, as opposed to the New World warblers (Parulidae) of the 9 primaried group (see WARBLER (2)). The family encompasses about 350 species in 63 genera, nearly half of which are monotypic (Morony *et al* 1975). Many warblers are of uncertain affinity. Here the family is taken to include the genera *Chloropeta*, *Hyliota* and *Parisoma* (sometimes regarded as flycatchers Muscicapidae), the longbills (genus *Macrosphenus*, sometimes included with the babblers Timaliidae or the bulbuls Pycnonotidae), the Fernbird (genus *Bowdleria*) and the kinglets (sometimes considered a separate family Regulidae) but not the Australian Maluridae (see WREN (2)) and Acanthizidae (see WARBLER, AUSTRALIAN). With the exception of the gnatcatchers (Polioptilinae, see GNATCATCHER) the warblers form a single subfamily, Sylviinae.

Characteristics. Warblers are typically small or tiny (from 9cm), with fine, narrowly-pointed bills. They are mostly insectivorous, capturing prey mainly by foliage-gleaning, and many are arboreal. Plumage colours are generally unobtrusive, greenish, brownish or grey, although some tropical species are brightly coloured. In most the sexes are alike in plumage although there are exceptions as in *Regulus* and some species of other genera including *Sylvia*, *Apalis* and *Orthotomus*. The juvenile plumage is unspotted, in common with that of the babblers but distinguishing the warblers from 2 other families, the flycatchers and the thrushes (Turdidae), to which they are also closely related.

The variety of warblers. The differences between genera are often more obvious to the field observer, familiar with habitat preferences, voice and behaviour, than to the museum worker since inter-generic distinctions in morphology tend to be vague, involving such characters as relative bill size, size of the first primary, presence and length of rictal bristles and relative tail length and shape. Morphological distinctions between closely-related species may also be slight and identification accordingly can require examination in the hand for small structural differences, as in wing formulae or primary emarginations. Description of so diverse a family is facilitated by dividing it into a number of groups, principally on grounds of broad similarities in ecology and habitat preferences, without necessarily implying taxonomic relatedness.

Reed and bush warblers. Several warbler genera are well represented in marshes, reed-beds, swamps and rank vegetation, although each has members in less humid habitats. The largest genus *Acrocephalus* has some 28 species spread throughout Eurasia, Africa and Australia. The genus is a very successful colonizer of oceanic islands, particularly in the Pacific. They are robustly-built warblers, with prominent bills and large feet, able to clamber about in reeds and other vertically-growing marsh vegetation. Most are a uniform brown colour but the harsh, chattering songs are species-distinctive. The mainly Asian genus *Cettia* consists of secretive, plain-coloured birds with rounded, sometimes long, tails of only 10 rectrices. They inhabit reed-beds, dense forest undergrowth and lush vegetation some, notably the Large Bush Warbler *C. major*, ranging to 4,000 metres in the Himalayas in rhododendron and bamboo thickets. Cetti's Warbler *C. cetti* is a marshland species which extends into southern Europe, from where it has recently expanded northwest as far as southern Britain. Members of this genus have surprisingly loud, melodious voices. The *Bradypterus* warblers of Africa and Asia are similarly brown, skulking birds with distinctive voices. They are known as bush-warblers or scrub-warblers but the 18 species are spread through a variety of habitats from swamps to damp forest undergrowth. The genus *Locustella* is characteristic of dense low vegetation in Eurasia. The whirring songs of some species resemble the stridulations of Orthoptera, hence the familiar name grasshopper warblers. One species, the Taiga Grasshopper Warbler (*L. fasciolata*), has a loud, bell-like song. *Locustella* warblers are morphologically distinctive, with long undertail coverts, very narrow beaks lacking rictal bristles, and large feet. They are chiefly terrestrial, creeping readily on the ground under and through the densest vegetation.



Sedge Warbler *Acrocephalus schoenobaenus*. (*A.H.*).

Scrub and woodland warblers. Many genera are represented in scrub but in Europe the term scrub-warblers refers to the genus *Sylvia*, some 20 species of which breed chiefly in the west Palearctic. They are found in a broad range of vegetation types from very low scrub (e.g. the Desert Warbler *S. nana*) to mature, deciduous woodland (e.g. the Blackcap *S. atricapilla*) but are particularly characteristic of dense evergreen scrub (maquis) in the Mediterranean region. Most are distinctively patterned; black or grey above with contrasting pale or rufous underparts and characteristically the sexes differ in plumage. Another typically Palearctic genus is *Hippolais*. These may be close to *Acrocephalus* and like them have large bills (although relatively wider and flattened) and harsh, varied songs. The tails of *Hippolais* are square-ended, not graduated as in reed warblers, and, although the species are largely plainly coloured, some are bright yellow. The latter include the Icterine Warbler *H. icterina*, a characteristic bird of European parks where the generic tendency to place nests well up in shrubs enables it to survive even in the absence of much ground cover.

Leaf warblers. The monograph by Ticehurst (1938) remains the authoritative guide to the genus *Phylloscopus*, a confusing assemblage of some 40 species of small, short-billed warblers which breed throughout the Palearctic and in the tropical African forests. The various species look remarkably alike, mostly coloured olive or yellowish-green, but have distinctive songs. Most are arboreal in broad-leaved trees, but some also frequent the canopy of coniferous forests (e.g. the Pallas's Leaf Warbler *P. proregulus*). *Phylloscopus* is largely replaced in the tropical Asian forests by the genera *Seicercus* and *Abroscopus*, which have stouter bills and brighter plumage, including rufous or grey head markings. The 2 latter genera are called flycatcher-warblers and indeed they and some species of *Phylloscopus* are active foragers which employ flycatching methods more frequently than most other sylviids.

Grass warblers. The 40 species of *Cisticola* (all but 6 described by Lynes 1930) are characteristic of grassy habitats in Africa from where one species, the Fan-tailed Warbler *C. juncidis*, has spread into Europe and Asia and as far as Japan and Australia. Another species, the Golden Cisticola *C. exilis* of India, south-east Asia and Australia, is the only one unrepresented inside Africa and its continental islands. Within Africa it is evident that evolution has resulted in greater interspecific differences in voice and habitat specialization than in morphological distinctions. *Cisticola* warblers range through a variety of lowland and montane grassy habitats including marshes (e.g. the Great Black-backed Cisticola *C. galactotes*) and woodland clearings (e.g. the Rattling Cisticola *C. chiniana*). Most are tiny, short-tailed birds, with the morphological distinctions in many species of having longer tails during than outside the breeding season, a double annual moult and strong size dimorphism between the sexes, the males being larger than the females. Many warblers of low vegetation have aerial displays but those of some *Cisticola* warblers are especially noteworthy, the cloudscrapers (e.g. the Crackling Cloud Cisticola *C. ayresii*) having particularly dramatic performances with wing-snapping and song delivered from a great height. The wren-warblers *Prinia* are typical of African and Asian grasslands and scrubby habitats. They are dull-coloured birds with long, graduated tails. They are partly terrestrial, foraging through low vegetation, and are often found in small parties. Grassy habitats also house a number of very large distinctive warblers among which may be mentioned the canegrass warblers *Megalurus* of south-east Asia and Australia, the Broad-tailed Warbler *Schoenicola platyura* which has separate populations in Africa and southern India and the Large Grass Warbler *Graminicola bengalensis* of India and south-east Asia. Three large warblers in the genus *Sphenoeacus* (each formerly in a monotypic genus) form a superspecies of the African grasslands although one species, the Damara Rockjumper *S. pycnopygius*, is associated with rocky areas.

African tree warblers. The genus *Apalis* is typical of the evergreen forest canopy, although the Yellow-breasted Apalis (*A. flavida*) occurs in a wide variety of bushy habitats, from light forest to acacia steppe. Conspicuous tail movements, which serve to emphasize the tail pattern in some species, may be important in species-recognition. Some (e.g. the Masked Apalis *A. binotata*) have well differentiated montane and lowland forms and the status of these as subspecies or species is problematical. The Bar-breasted Apalis *A. thoracica* has 16 well-marked geographical races (Hall and Moreau 1970) and provides a striking example of geographical differentiation in the African avifauna. Some of its subspecies are isolated in montane forests and others have clearly been isolated in the past but have since come together and intergrade. Some of the genus (e.g. the White-winged Apalis *A. chariessa*) are brightly coloured and have striking patterns. The genus *Eremomela* includes principally arboreal warblers inhabiting dry scrub and woodlands and secondary forest. Different species tend to be segregated by habitat and this has also been claimed for some species of *Camaroptera*, *Sylvietta* and *Apalis*. The *Eremomela* warblers are greyish or green above, some with contrasting head markings. The crombecs *Sylvietta* are short-tailed, typically-arboreal warblers, soberly-coloured in buff, green or grey. They frequent various habitats from arid scrub to evergreen forest. Some, notably the Crombec *S. brachyura*, forage on tree trunks and branches, probing in crevices with their long bills, a habit which has earned them the name nuthatch-warblers. The genus *Camaroptera* inhabits dense undergrowth, scrub and lowland evergreen forest. They are an inconspicuous green or brownish in colour but some have distinctive calls. On this account *C. brachyura* is frequently known as the Bleating Bush Warbler. Some species sew leaves together when nest-building, suggesting a taxonomic relationship with the tailorbirds *Orthotomus*, to which they also show some resemblance in voice and morphology. The Cinnamon-breasted Warbler *Euryptila subcinnamomea* is believed to be allied to *Camaroptera* on morphological grounds but is distinct ecologically, frequenting boulder-strewn hillsides in south-west Africa. The longbills or bush-creepers *Macrosphenus* are aberrant warblers, having long bills sharply hooked at the tip, and long, loose feathers on the flanks which are used by at least one species (Kemp's Longbill *M. kempi*) in display. They occur in dense undergrowth, typically in evergreen forest.

Tailorbirds. The tailorbirds *Orthotomus* are so called for their habit of sewing a large leaf or several leaves together to form a cone in which the nest proper is built, using plant wool. The leaf-stitching involves passing vegetable fibres or cobwebs through holes punctured in the margins with the bills. Tailorbirds are familiar inhabitants of gardens in India and south-east Asia, otherwise occurring in forest and scrub. One montane forest species occurs outside Asia, the African Tailorbird *O. metopias*. Tailorbirds have long, decurved bills, short wings and graduated tails, the latter held characteristically cocked-upwards. Males have longer tails than females and more striking, frequently rufous, head-markings.

Kinglets. The kinglets *Regulus* are tiny birds which typically inhabit the canopy of coniferous forest, although the Firecrest *R. ignicapillus* occurs in European deciduous woodlands also. Two other species occur in the Old World, the Goldcrest *R. regulus*, with various subspecies ranging between the Azores and Europe and Japan, and the Formosan Kinglet *R. goodfellowi* restricted to Taiwan. The Ruby-crowned Kinglet *R. calendula* and the Golden-crowned Kinglet *R. satrapa* occur in North America, the former extending south to northern Mexico. Kinglets resemble some leaf warblers *Phylloscopus* in coloration but have dense, soft plumage and red or orange central crown markings which can be erected in display. The Ruby-crowned Kinglet has a melodious voice but the others have thin, high-pitched songs and calls. Kinglets are active birds, frequently hovering as they forage through the forest canopy, often in flocks with other kinglets and tits (Paridae). The tit-warblers *Leptopoecile* resemble the kinglets in their gregariousness and in having soft, copious plumage but they may not be closely related. They inhabit fir forests and juniper scrub in Central Asia and western China. Both they and the kinglets have formerly been considered aberrant members of the tit family.

Other warblers. The archipelagoes of the Pacific and Indian Oceans, Madagascar and the forests of the African and Asian mainland contain a variety of aberrant warblers, many in monotypic genera. Among these may be mentioned 3 African genera (*Chloropeta*, *Parisoma* and *Hyliota*) which are sometimes regarded as flycatchers. *Chloropeta* may be closely related to *Acrocephalus* and indeed one of the 3 species, the Yellow Swamp Warbler *C. gracilirostris* is a marshland bird, the other 2 frequenting bushy woodland and forest edges. The tit-flycatchers *Parisoma* resemble *Sylvia* warblers in coloration and in nest structure. They frequent acacia savanna, their foraging activities also suggesting that they are warblers. The 3 species of *Hyliota* are dark above and pale below, with white wing patches. They forage in typical warbler fashion in the canopy of woodland or forest. The genus *Tesia* (including *Oligura*) contains several active, tiny, almost tail-less warblers which occur in the forests of south-east Asia. They are called ground-warblers, being largely terrestrial. *Hemitesia* of Africa may be a close relative. The unusual warblers of Madagascar include the 2 species of emu-tails (*Dromaeocercus*). They are secretive birds of swamps or forest undergrowth, unusual in having only 8 rectrices, these consisting of feathers in which the barbs are not all joined together. The tail-feathers of the Fernbird *Bowdleria punctata* are of a similarly unusual structure, the barbs being disconnected so that the rectrices have a spike-like appearance. The Fernbird, an inhabitant of swamps and adjacent undergrowth, is the sole sylviid of New Zealand. The morphological resemblance between the Fernbird and the emu-tails is presumably due to convergence; a similar tail structure also occurs in *Stipiturus* (see WREN (2)).

Habitat. The above accounts make it clear that warblers frequent all types of vegetation, although most are found in dense habitats. Ecological segregation of closely-related species may involve differences in habitat selection. For example, the 3 *Phylloscopus* species nesting in Britain are largely separated there by habitat, the highest densities of the Willow Warbler *P. trochilus* occurring in bushy scrub and open areas with scattered trees, the Chiffchaff *P. collybita* favouring bushy deciduous woodland and the Wood Warbler *P. sibilatrix* occurring in dense deciduous woodland, often beech, with little or no bushy understorey. The warblers also provide examples of different species exhibiting vertical stratification within the same habitat. For example, the Long-billed Crombec *Sylvietta rufescens* and the Red-faced Crombec *S. whytii* are sibling species which are separated by foraging height in the limited area where their ranges overlap in Zimbabwe, the former foraging in the undergrowth and the latter in the canopy.

Distribution. The Sylviidae reach their greatest diversity in tropical and southern Africa, where 160 of the approximately 350 known species breed. By contrast the Asian tropics have a smaller variety (about 84 species). The warblers of tropical Asia and Africa are joined during the northern winter by many of the 106 species which breed in the Palearctic. Mainland Australia has only 8 species, including the endemic genera *Cinclorhamphus* (2 species of song larks) and *Eremiornis* (Spinifex Bird), the family being largely replaced there by the native wren-warblers

(WREN (2)). The ecological equivalents of the Sylviidae in the Americas are the wood warblers (Parulidae, see WARBLER (2)) and in some ways also the vireos (Vireonidae, see VIREO) but the family is represented there by the gnatcatchers, 2 species of kinglets and also the Arctic Warbler *Phylloscopus borealis*. The latter has established breeding populations in western Alaska which nonetheless migrate to south-east Asia, in common with their Palearctic-breeding conspecifics.

Populations. Virtually nothing is known of the actual size of the populations of most species, although it is clear that many of the Palearctic migrant species especially are extremely abundant. The Willow Warbler has an autumn population which has been roughly estimated at 1,000 million birds (Moreau 1972), making it the most numerous of the Palearctic passerines which winter in Africa. Palearctic warblers wintering in the African Sahel zone were badly affected by drought in 1968 and subsequently. The decline of the western populations of the Whitethroat *Sylvia communis* was particularly severe; the British population decreased by over 75%, with only a slow recovery evident a decade later. A few warbler species, especially island endemics, have tiny populations and so are vulnerable to extinction. For example, the Aldabran Brush Warbler *Nesillas aldabranus* was believed to number fewer than 11 individuals in 1983.

Movements. Like many insectivorous birds, most breeding warblers of the cold and temperate zones are strongly migratory. Some western Palearctic species winter in the Mediterranean area where resident warblers, mostly *Sylvia* spp., are joined by large numbers of Blackcaps and Chiffchaffs from central and northern Europe. Other Palearctic warblers winter chiefly in Africa or tropical Asia, some undertaking prodigious journeys. For example both Siberian Willow Warblers and north European Arctic Warblers make journeys of up to 12,000 km twice yearly to and from Africa and south-east Asia respectively. The available evidence is that most warblers of the Ethiopian and Oriental regions are sedentary or perform only local movements. Fidelity to both breeding and winter quarters has been found in a number of species, particularly of *Sylvia*, *Acrocephalus* and *Phylloscopus*, and may be widespread generally.

The requirements of migration have affected the morphology and physiology of migrant species. Such species tend to have long, pointed wings, as opposed to the short, rounded ones of other warblers, including resident congeners. Short-distance migrants (e.g. the Blackcap) may moult before their southward journey, but many warblers moult in winter quarters and others moult only the body plumage before departing in the fall. The Willow Warbler has two complete annual moults; post-breeding and after arrival in Africa. Endogenous rhythms underlying migration have been investigated in a number of species, notably *Sylvia* warblers. In the Garden Warbler *S. borin* endogenous timing processes have been shown to influence the directional changes performed during fall migration.

Food. Most warblers have a varied diet including a broad range of insects and other arthropods. Some take tiny items such as scale insects and insect eggs. Frugivory is common in some species, especially of *Sylvia*. Indeed the Blackcap and the Garden Warbler are among the very few Palearctic passerines that winter commonly in the African evergreen forests, where they eat many fruits (Moreau 1972). Other plant material is occasionally taken; the kinglets in particular seem to consume tiny seeds regularly. Nectarivory has been recorded in some species of *Apalis*, *Sylvietta*, *Eremomela*, *Cisticola* and *Prinia*, at aloes (*Aloe* spp.) in Africa and there are similar observations from Europe where in some localities Blackcaps, Sardinian Warblers *Sylvia melanocephala* and Chiffchaffs regularly take nectar from aloes and other flowers, both native and exotic. Nectarivory may be more widespread in the family than the available records suggest. Detailed comparative investigations of warbler diets are few but seem to suggest that, although large overlaps in diet may occur, different species may specialize on different prey species or sizes.

Behaviour. Most warblers are solitary birds although some (e.g. the kinglets and grass warblers *Prinia* spp.) forage in small parties outside the breeding season or join mixed-species flocks. Temperate zone species are highly territorial on their breeding grounds, the males establishing territories which they advertise by persistent song. In some species (e.g. the Reed Warbler *Acrocephalus scirpaceus*) territories are small and closely packed together in dense cover such as reed beds. They provide the nest site but birds forage widely outside their boundaries. In others (e.g. the Blackcap) large territories, up to a hectare in extent, are established and most of the food requirements of the resident pair and its progeny are obtained there. Some warblers defend territories not only against conspecific intruders but also against members of closely related species. Such interspecific territoriality has been studied in detail in the case of 2 European species-pairs, the Reed Warbler and Sedge Warbler *Acrocephalus schoenobaenus* and the Blackcap and Garden Warbler. In both cases, males react to each other's songs and interspecific fights are frequent. In the case of Blackcaps in Britain responses to song playback experiments with Blackcap song and with Garden Warbler song are equally strong and experiments involving the removal of territorial Blackcaps have shown that the species can prevent the establishment of Garden Warblers in the same area. Such studies show that in certain warblers segregation may be as much by behavioural as by ecological mechanisms.

Voice. The Sylviidae include some distinguished singers, such as the Blackcap and the Chinese Bush Warbler *Cettia diphone*, which are noteworthy for their varied, melodious voices. However, only a minority of warblers actually warble i.e. produce a continuous, gentle, trilling sound, and the range of vocalizations in the family is broad. Song is used to advertise the positions of territories particularly in temperate zone populations where breeding birds occur at high densities. In some (e.g. the Sedge Warbler) song output declines markedly or even ceases once the birds have attracted mates but in others (e.g. the Willow Warbler) song is obvious throughout the breeding season. Some temperate zone species sing in winter quarters and in at least some of these (e.g. the Great Reed Warbler *Acrocephalus arundinaceus*) the behaviour is known to be associated with maintenance of feeding territories.

The songs themselves are often distinctive between genera but considerable variation may occur even within a single genus. For example, in *Sylvia* warblers stereotyped, harsh songs are characteristic of species of dense low scrub (e.g. the Dartford Warbler *S. undata*) whereas those of woodlands (e.g. the Blackcap) have varied songs with a high proportion of pure notes. Habitat acoustics for both *Acrocephalus* and *Sylvia* warblers have been investigated and seem to have played an important part in the evolution of vocalizations intended for long distance communication. Many warblers are vocal when foraging or when disturbed at the nest and their various calls can also be distinctive, especially those of mainly tropical genera such as *Cisticola*.

Some warblers are excellent mimics of the vocalizations of other birds. The Blackcap and Icterine Warbler are good examples but the Marsh Warbler *Acrocephalus palustris* is arguably the outstanding example of avian vocal mimicry. Its song consists entirely of imitations of other species but arranged in a species-characteristic manner. Average repertoires of individual Marsh Warblers comprise imitations of some 80 species, over half of them African birds heard in the warbler's winter quarters.

Breeding. Most warblers are monogamous but occasional instances of polygamy have been reported for a number of species (e.g. Garden Warbler, Sedge Warbler and Chiffchaff). Warblers typically build elaborate, carefully-woven nests, which are spherical or domed structures with an entrance in the top or side. Such nests are characteristic of *Phylloscopus*, *Prinia*, *Cisticola* and *Apalis*, among others. The crombecs build a dangling pouch of soft grass, cobwebs and moss. The stitching of leaves together during nest building is seen not only in the tailorbirds and *Camaroptera* but also in 3 species of *Cisticola*, about 8 of *Prinia* and in the Red-winged Warbler *Heliolais erythroptera*. Open, cup-shaped nests are typical of the Polioptilinae and some Old World genera including *Eremomela*, *Acrocephalus*, *Hippolais* and *Sylvia*. Most nests are placed in low cover, on or near the ground or in bushes. Those of reed warblers are often slung between reed stems. Nest construction may involve the female alone (e.g. Chiffchaff), or more frequently both sexes with the male commencing construction. The eggs are usually darkly spotted or blotched on a pale ground colour. In the tropics clutch sizes are usually 2–4 but in temperate zones 3–7 eggs are usual. Incubation is by both sexes or sometimes the female alone (Chiffchaff). Incubation and fledging periods are approximately 12–14 and 11–15 days respectively, slightly longer in some tropical species. The nestlings have natal down in some genera (including *Phylloscopus*, *Cettia*, *Regulus* and *Locustella*) and are naked in others (including *Acrocephalus*, *Sylvia* and *Hippolais*). They may leave the nest before they can fly and are attended by the parents for some days thereafter.

WARBLER (2): substantive name of most species of Parulidae (Passeriformes, suborder Oscines); in the plural, often in the form 'wood-warblers' or 'American warblers', general term for the family. The wood-warblers belong to the great complex of New World 9-primaried songbirds that includes such groups as the tanagers (Thraupinae), cardinal-grosbeaks (Cardinalinae), buntings (Emberizinae), and troupials (Icteridae). Division of this complex into families and subfamilies is in some instances difficult, and various rearrangements at this level have been proposed in recent years. The honeycreepers, formerly segregated as a family (Coerebidae), are currently considered to be nectarivorous tanagers except for 2 genera, *Coereba* and *Conirostrum*. These 2 are of uncertain affinities. They may be related to the Parulidae, but are here treated as a separate family (see HONEYCREEPER; BANANAQUIT; CONEBILL). A few aberrant species generally placed in the Parulidae may ultimately be found to belong elsewhere.

Characteristics. The wood-warblers are small birds, lengths 10–16 cm, the largest being little larger than a House Sparrow *Passer domesticus*. Many are brightly coloured, with yellow, orange, black, and white among the most frequent colours. A few species have blue or red plumage, while others are greenish, dull brown, olive or grey. Sexual and seasonal colour dimorphism is frequent among northern species, but in many tropical wood-warblers the sexes are equally brightly coloured all the year round.

Habitat. Wood-warblers are widely distributed ecologically, inhabiting coniferous and deciduous woods, tropical rain-forests, swamps and marshes, old fields, shrubbery, and sparse desert vegetation.

Distribution. The family ranges throughout the New World, from Alaska and northern Canada to southern South America. Omitting those here placed in the Coerebidae, there are some 114 species; a number of these form closely related species-pairs or superspecies. There are some 27 genera (including those tentatively assigned to the Parulidae); attempts to reduce this number have not been based on adequate study, and a few of the widely recognized genera may be composites. Most of the genera (18) are predominantly North American or West Indian; 7 are primarily tropical, and 2 (*Parula*, *Geothlypis*) are widely distributed through both American continents.

Movements. Most northern species are highly migratory, and frequently travel in mixed flocks. The great migrating 'waves' of wood-warblers are among the most impressive features of the bird life of eastern North America. Some migratory species merely move to the southern part of the breeding range, but others winter as far south as Argentina.

Food. Most species are insectivorous, but some add berries and other vegetable matter to their diet.

Voice. Wood-warblers have well developed songs, typically of relatively short duration. Many have a complex pattern and are of rather low volume. Those of the more terrestrial species tend to be loud and ringing, often (as in the Ovenbird *Seiurus aurocapillus* and the White-browed Warbler *Basileuterus leucoblepharus*) of an uncomplicated series of notes. The well-studied species in the genera *Dendroica* and *Vermivora* have two distinct songs, used in separate contexts.

Breeding. Northern wood-warblers build their nests in a variety of sites—on the ground, in bushes and vines, or in trees. Two species, the Prothonotary Warbler *Protonotaria citrea* of the south-eastern and Lucy's Warbler *Vermivora luciae* of south-western United States, are hole nesters, the latter sometimes re-using the globular nests of the Verdin *Auriparus flaviceps* (see PENDULINE TIT). Members of the genus *Parula*, which constitute a single superspecies, nest in hanging bunches of 'Spanish moss', beard-lichen, or similar vegetation. Most tropical members of the family nest on the ground, or on ledges and banks. Eggs are usually white, more or less speckled with various colours; a few species lay immaculate white eggs. Clutches among tropical species usually range from 2–4, whereas northern wood-warblers lay 3–5 eggs, exceptionally 6. Incubation and fledging periods are usually 11–12 and 8–10 days, respectively, in North American species and distinctly longer, 13–17 and 12–15 days, in the few tropical species studied.

Distribution and systematic characteristics. The largest genus, with some 27 species, is *Dendroica*, a North American and West Indian group. The most widely distributed species is the Yellow Warbler *D. petechia*, the only member of the genus that breeds south to northern South America and the only wood-warbler in the Galápagos Islands. Predominantly yellow, the males of most races have chestnut streaks on the breast, and some have chestnut caps or hoods. Concealed white tail spots are typical of *Dendroica*; only in *D. petechia* are the spots yellow. The most frugivorous member of the family is the Yellow-rumped Warbler *D. coronata* of North America south in the mountains to Guatemala (with which Audubon's Warbler *D. auduboni* is now considered conspecific). It feeds extensively on berries in autumn and winter. The Cerulean and Black-throated Blue Warblers *D. cerulea* and *D. caerulescens*, also North American, are the only members of the family in which the males are conspicuously blue in colour. The large Kirtland's Warbler *D. kirtlandii* has one of the most restricted breeding ranges among non-insular birds. It nests only in an area of about 100 by 130 km in central Michigan, and within this range only in dense stands of pine about 1–6 m tall. In winter it is confined to the Bahamas and adjacent Turks and Caicos Islands.

Seven species of *Dendroica* are confined to the West Indies. Of these, 3 belong to superspecies with allospecies on continental North America. The other 4 comprise an endemic West Indian superspecies of uncertain affinities within the genus. These are *D. plumbea* of Dominica and Guadeloupe, *D. pharetra* of Jamaica, *D. angelae* of Puerto Rico, and *D. bishopi* of St Vincent (the latter often placed in a monotypic genus *Catharopeza*). The group differs from all other *Dendroica* in lacking sexual dimorphism in colour, but retaining a dull immature plumage for a full year.

Closely related to *Dendroica* are 2 North American species that have evolved morphological and behavioural adaptations to specialized feeding niches, and are placed in their own monotypic genera. The Black-and-white Warbler *Mniotilta varia* has become adapted to a tree-climbing, bark-foraging habit much like that of the treecreepers (Certhiidae), with corresponding development of toes and claws. The American Redstart *Setophaga ruticilla*, which has little in common with the redstarts (*Phoenicurus* spp.) of the Old World, has become adapted for the aerial capture of insects. It is a common and well-known species, breeding in the temperate portions of the United States and Canada and wintering south to northern South America. The male is glossy black with a white belly and patches of orange on tail, wings, and sides, while in the female the black and orange are replaced by grey and yellow. It is unique among the Parulidae in that first-year males, although capable of breeding, wear a female-like plumage.

Several other genera of wood-warblers share the flycatching habit; as is the case in other families in which this habit has evolved, the bills in these genera tend to be wider and flatter and the rictal bristles better developed than in most wood-warblers. About 11 brightly-coloured species of the tropical genus *Myioborus* are also called 'redstarts'; the northern-most, the Painted Redstart *M. pictus*, was formerly placed in *Setophaga* but agrees with *Myioborus* in nesting habits, song, plumage pattern, and lack of sexual dimorphism. Another flycatching group of wood-warblers is the genus *Wilsonia*, consisting of 3 North American species that are predominantly yellow in colour but with various striking black markings on face or head. In pine forests of Middle America live 3 species of flycatching warblers that are partly or predominantly bright red. The Red-faced Warbler *Cardellina rubrifrons* ranges north to the mountains of the south-western United States, whereas the Red Warbler *Ergaticus ruber* is exclusively Mexican and the Pink-headed Warbler *E. versicolor* is confined to Guatemala and adjacent parts of Mexico.

The 11 species currently placed in the genus *Vermivora* fall into three natural groups that may prove to be generically separable, having in common sharply pointed bills. These are a face-patterned group, a plain group, and a tropical group. One of the face-patterned group, Bachman's Warbler *V. bachmani* of south-eastern United States, is at the point of extinction but may persist deep in heavily wooded swamps. The 2 tropical species *V. gutturalis* and *V. superciliosa* show some resemblance to *Parula*.

The largest of the primarily tropical genera is *Basileuterus*, with 21 species ranging from northern Mexico to northern Argentina. Most species are predominantly yellow, some with brown or grey backs. Most have a sharply defined crown-patch or other conspicuous marks about the head. Typical of this group is the Golden-crowned Warbler *B. culicivorus*, a species whose range virtually coincides with that of the entire genus. Sometimes placed in *Basileuterus* are the 2 species of the genus *Phaeothlypis*, dull-coloured birds with no striking markings and more terrestrial in habits than typical *Basileuterus*.

The Wrenthrush *Zeledonia coronata* of the mountains of Costa Rica and Panama was long given its own monotypic family, generally placed adjacent to (or by a few authors included within) the Turdinae. Recent studies of egg-white proteins, syringeal and limb musculature, and general life-history all indicate that *Zeledonia* is a member of the New World 9-primaried group, nearest to the Parulidae and probably best placed in that family. Specifically, it bears strong anatomical and external resemblances to the tropical genus *Basileuterus*, but exhibits some major adaptive modifications, notably long legs and reduced flight mechanisms, for a largely terrestrial existence.

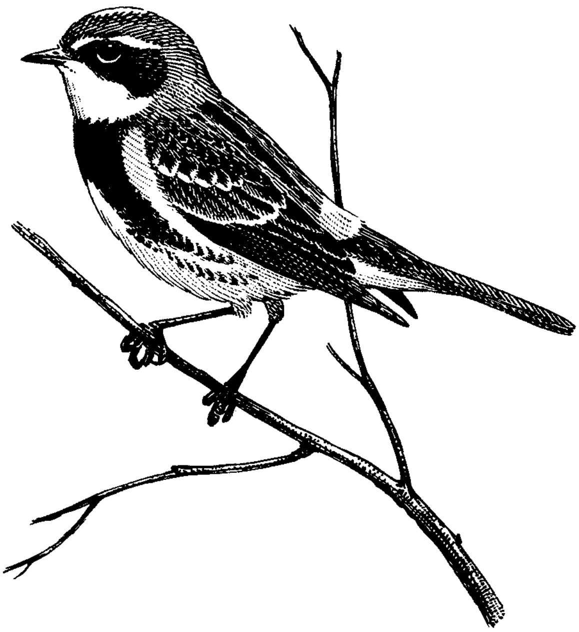
Also notably terrestrial in a predominantly arboreal family are the 3 members of the North American genus *Seiurus*. Best known and most widely distributed is the Ovenbird *S. aurocapillus*. Like its namesakes of the unrelated Neotropical family Furnariidae, the Ovenbird builds a dome-shaped nest, reminiscent of an old-fashioned outdoor oven, on the ground. It shares with the 2 species of waterthrushes *S. motacilla* and *S. noveboracensis* the habit of walking rather than hopping when on the ground. The waterthrushes, however, have a tail-bobbing motion much like that of wagtails (*Motacilla* spp.) and numerous other waterside birds.

The yellowthroats comprise a widespread group of closely related species of the genus *Geothlypis*. These are dwellers in marshes, meadows, and undergrowth, almost throughout the Americas. Most have greenish backs and yellow underparts, and males have a black facial mask of varying degrees of development. Rather similar (and considered congeneric by a few authors) are the 4 North American species comprising the genus *Oporornis*. Two of these, the Mourning Warbler *O. philadelphia* and Macgillivray's Warbler *O. tolmiei*, yellow-green birds with (in males) grey hoods and black throats, may prove to be conspecific.

The West Indies are the home of several somewhat aberrant wood-warblers, including 4 endemic genera. Semper's Warbler *Leucopeza semperi* of St Lucia, an exceedingly rare bird, is a nondescript grey. Two species of the genus *Teretistris*, grey-backed with yellow underparts, divide the island of Cuba between them. Two monotypic genera are found on Hispaniola: the Ground Warbler *Microligea palustris* and the White-winged Warbler *Xenoligea montana*. The latter strongly resembles certain West Indian tanagers (Thraupinae), and may possibly be misplaced as a wood-warbler.

Other species whose allocation to the Parulidae has been questioned include the largest of the wood-warblers, the Yellow-breasted Chat *Icteria virens*, a relatively heavy-bodied, stout-billed, long-tailed species that is coloured much like a yellowthroat (*Geothlypis*), but behaves and sounds more like a member of the unrelated family Mimidae (mocking-thrushes). It is a North American species, breeding south to the tableland of central Mexico. Also called 'chats' but very different in appearance are the 3 species of the genus *Granatellus*, tropical birds that are strongly sexually dimorphic (underparts rosy red in males, buff in females) and somewhat reminiscent of tanagers. Finally, the Olive Warbler *Peucedramus taeniatus*, which extends from south-western United States through Central America, has been thought to be related to *Dendroica*, but there is a substantial body of evidence to suggest that its affinities are closer to the 'Old World insect-eaters' (Muscicapidae in the wide sense) than to the New World 9-primaried group.

The Parulidae are notable for the number of hybrid combinations that have been reported. Hybrids are known between several species-pairs, especially the Blue-winged Warbler *Vermivora pinus* and the Golden-winged Warbler *V. chrysoptera*, which regularly hybridize where their breeding ranges overlap; 2 of the hybrid forms are so distinctive that they were originally described as species and are still known by the English names of 'Brewster's' and 'Lawrence's' Warblers. Few hybrid birds have been so thoroughly studied under field conditions, as the principal zone of interbreeding includes several of the major cities of the eastern United States. Intrageneric hybrids between sympatric species that are not species-pairs are very rare, even though (for example) 6 or more species of *Dendroica* may inhabit the same wood in north-eastern United States. On the other hand, at least 8 intergeneric hybrids of various parentage have been reported. This is not just a function of excessive generic splitting in the Parulidae, as the parent species in these combinations are often very different (see HYBRIDIZATION, ZONE OF SECONDARY). K.C.P.



Yellow-rumped Warbler *Dendroica coronata*. (*R.G.*).

Note: In the Checklist of North American Birds (6th edn) 1984, wood-warblers and troupials are placed as subfamilies (Parulinae and Icterinae) of an expanded family Emberizidae.

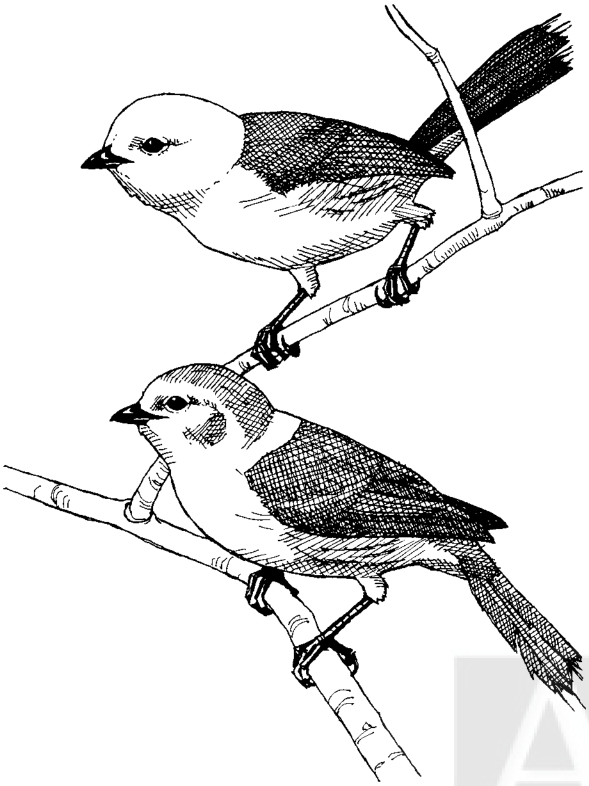
WARBLER (3): substantive name sometimes applied to species of Maluridae (see WREN (2)).

WARBLER, AUSTRALIAN: substantive name for species of Acanthizidae (Passeriformes, suborder Oscines); a family of 14 genera and about 65 species which includes scrubwrens, thornbills and allies. The largest genus, *Gerygone* (19 species) extends from the Malay Peninsula through Indonesia, New Guinea, Australia and New Zealand to the South-west Pacific. *Sericornis* (scrubwrens, 14 spp.) is shared almost equally between New Guinea and Australia. *Acanthiza* (thornbills, 13 spp.) has one species, *A. murina*, in New Guinea, the rest in Australia. The remaining 11 genera have no more than 3 species each and, with the exception of the New Guinean *Crateroscelis*, are confined to Australia. K.H. Voous regards the New Zealand genera *Mohoua* and *Finschia* as constituting a subfamily Mohouinae of the Acanthizidae. Keast (1977, Notornis 14: 50–58) however, has suggested that their affinities lie rather with the pachycephaline flycatchers.

Characteristics. Although recently separated from the Maluridae (see WREN (2)), the family Acanthizidae has yet to be rigorously defined, particularly in anatomical terms. It consists of small (*Smicrornis brevirostris*, Weebill, 9 cm) to medium-sized (*Dasyornis* spp., bristlebirds, 25 cm) songbirds of unexceptional proportions, mostly dull or cryptically coloured, with little or no obvious sexual dimorphism, semi-terrestrial to wholly arboreal and building domed nests. Some species have loud melodious songs. The tails of some species are regularly cocked, hence the name 'wrens'.



Whitehead *Mohoua albicilla*. (*N.W.C.*).

Habitat. Primary rain-forest (*Crateroscelis*, *Oreoscopus*, many *Sericornis* spp., several *Gerygone* spp.), second-growth, monsoon forest and mangroves (some *Sericornis* spp., many *Gerygone* spp.), to lower, dryer, more open habitats such as sclerophyll woodland, mallee-heath and acacia shrubland (many *Acanthiza* spp., *Hylacola*, *Pyrrholaemus*), tussock grassland (*Calamanthus fuliginosus*), and samphire flats (some populations of *Acanthiza iredalei*). The Rock Warbler *Origma solitaria* is remarkable in being restricted to the caves and boulders of sandstone and limestone districts of eastern New South Wales. The bristlebirds *Dasyornis* (3 spp.) inhabit extremely dense thickets in forests and on coastal dunes, in which they are more often heard than seen.

Movements. At least some (possibly most) rain-forest species are strongly sedentary. Woodland and mallee-heath species are generally resident with some local dispersal, whereas several arid-zone species are highly mobile, e.g. Slender-billed Thornbill *Acanthiza iredalei*, Chestnut-breasted Whiteface *Aphelocephala pectoralis*. A few species are known to be migratory; these include the Western Warbler *Gerygone fusca* and the White-throated Warbler *G. olivacea*.

Food. Chiefly small insects and vegetable matter: lacewings, bugs, ants, wasps, flies, beetles, orthopterans, caterpillars, seeds and berries. Whereas *Gerygone* spp. are more or less wholly insectivorous, most other species take a varying proportion of seeds and other plant matter as well as insects; the proportion of seeds is apparently highest in the thick-billed whitefaces *Aphelocephala* spp. Some ground-feeding species (e.g. Scrub Tit *Sericornis magnus*, White-browed Scrubwren *S. frontalis*) also take tiny snails and crustaceans, while a substantial part of the diet of the Pilotbird *Pycnoptilus floccosus* apparently consists of worms and tiny freshwater mussels. The Rufous Bristlebird *Dasyornis broadbenti*, on the other hand, takes in season large quantities of the small fleshy fruits of 'Native Currant' *Leucopogon parviflorus* (Epacridaceae) and a *Rhagodia* sp. (Chenopodiaceae).

Behaviour. Most aspects of behaviour are very poorly known, even for the commonest species. Many species breed in pairs, though co-operative breeding has now been reported for the Buff-rumped, Striated and Yellow-tailed Thornbills *Acanthiza reguloides*, *A. lineata* and *A. chrysorrhoa*, for the White-browed Scrubwren and the Weebill. Outside the breeding season, individuals of some species are mostly found singly (e.g. *Gerygone olivacea*, *G. fusca*), whereas in other species they occur in family parties or small flocks (e.g. *Acanthiza chrysorrhoa*, *Aphelocephala* spp.).

Voice. Many species have a loud, melodious and distinctive voice, and some are exceptionally fine songsters, e.g. *Crateroscelis murina* of New Guinea and *Hylacola pyrrhopygia*, *Calamanthus* spp. and *Pyrrholaemus brunneus* of Australia; *H. pyrrhopygia* and the Speckled Warbler *Chthonicola sagittata* are accomplished mimics. *Gerygone* spp. have high, thin songs, mostly uttered as plaintive repeated rising or falling strophes or staccato bursts of the same pitch. Others, including *Sericornis* and *Acanthiza* spp., utter mainly buzzing, rattling or trilling notes, though some of these species also possess short unobtrusive songs. The furtive, thicket-loving bristlebirds have loud, far-carrying whistling calls, usually the sole indication of their presence.

Breeding. Nests are globular or oval, with a side-entrance; made of pliant plant-material (grass, bark, stems, roots) sometimes decorated with moss, cocoons and spiders' silk and lined with plant down, fur and feathers; the nest of the Fern-wren *Oreoscopus gutturalis* is made almost entirely of moss, whereas that of the Banded Whiteface *Aphelocephala nigricincta* is constructed largely of twigs and, atypically for this family, has a spouted side-entrance. Nests may be supported from below, on or near the ground (e.g. *Dasyornis*, *Pycnoptilus*, *Hylacola*, *Calamanthus*, some *Acanthiza* spp., *Sericornis* except *S. citreogularis*), or be pendent in outer foliage (e.g. *Gerygone*, *Smicrornis*, some *Acanthiza* spp., *Sericornis citreogularis*). The Common Whiteface *Aphelocephala leucopsis* and at least 2 species of *Acanthiza* regularly nest in hollows in trees and fenceposts or under bark. The Rock Warbler suspends its nest by dense spiders' webbing from cave-ceilings and rock-overhangs.

Where details are known, the nest is built by the female or by both sexes; in *Acanthiza chrysorrhoa* both birds build the main nest, after which the male often builds one or more cup-shaped false nests on top of the main one.

The eggs of the scrubwren group (*Sericornis*, *Hylacola*, *Calamanthus*, etc) can be quite striking in coloration, having in most species a dark ground (grey, grey-brown or terra cotta) with or without darker spotting. Those of *Acanthiza* and *Gerygone*, on the other hand, are of a whitish or creamy-pink ground with spots and speckles of reds and lavender greys. The clutch is mainly 2 or 3, less often 4 or 5 (as sometimes in *Acanthiza* and *Aphelocephala*). Many species are favoured hosts to cuckoos.

Details of egg-laying, incubation and nestling periods are poorly known, but according to Courtney and Marchant (1971) some species may lay at intervals of 48 rather than 24 hours. S.A.P.

Yellow-tailed Thornbill *Acanthiza chrysorrhoa*. (*N.W.C.*).

WARBLER-FINCH: *Certhidea olivacea*, one of DARWIN'S FINCHES which superficially resembles a warbler and fills the ecological niche of the warblers in the Galapagos.

WARBLING-FINCH: substantive name of the species of *Poospiza*, a genus of South American finches (for family see FINCH).

WARM-BLOODEDNESS: see ENERGETICS; HEAT REGULATION.

WARNING: the approach of a predator may be announced by potential prey species either visually or aurally. Visual signals usually emphasize some striking feature of the plumage; for example, the tail-flirting of the Moorhen *Gallinula chloropus* when the white under tail-coverts are displayed prominently. Audible signals are loud or penetrating calls, sometimes specialized to denote the type of danger, for example, an aerial or a ground predator (see ALARM; VOCALIZATION).

WATERCOCK: *Gallicrex cinerea* (see RAIL).

WATERFOWL: vague term for aquatic (usually fresh-water) birds of wild species, especially of the Anatidae (see DUCK); in Britain applied more particularly to those kept for ornamental purposes, in some degree of captivity, on private lakes or artificial ponds (see AVICULTURE); in North America used in the sense (British) of WILDFOWL.

WATERHEN: alternative name (perhaps obsolescent) in Britain of the Moorhen *Gallinula chloropus*; also used as substantive name of *Amaurornis* spp. (see RAIL).

WATERTHRUSH: substantive name (now commonly written as one word) of 2 *Seiurus* spp. (see WARBLER (2)).

WATER-TYRANT: substantive name of tyrant-flycatchers of the genera *Fluvicola* and *Ochthornis* (see FLYCATCHER (2)).

WATTLE: see INTEGUMENTARY STRUCTURES.

WATTLEBIRD (1): substantive name of *Anthochaera* spp. (see HONEYEATER). This Australian usage is of uncertain priority in relation to the next below.

WATTLEBIRD (2): name introduced by George Forster in 1777 and used in the plural as general term for the Callaeidae (Passeriformes, suborder Oscines), of which all species have different substantive names. The family is restricted to New Zealand and comprises 3 monotypic genera (one extinct). Relationship of the Callaeidae to other families is uncertain; generally placed near the starlings (Sturnidae), they may be closer to the Corcoracidae, or to the bowerbirds and birds-of-paradise. They probably arose by adaptive radiation from a single immigrant stock that developed wattles; the resemblance of *Callaeas* to the Apostlebird *Struthidea* is thus probably in part convergent.

Characteristics. Wattlebirds are medium-sized (25–48 cm) birds of the primitive forest, arboreal but sometimes feeding on the ground. Their most conspicuous common characters are the paired fleshy wattles at the gape. They share certain skeletal characteristics and others such as extremely rounded wings with very long first primaries, long tails, somewhat arched in profile and section, with projecting feather shafts; powerful legs and feet with long hind claws. The wattles (orange except in one form) develop from the fold of skin at the angle of the nestling's gape, remain small in juveniles and are largest in adult males; their function is obscure. In *Callaeas* they are normally held close in to the throat, overlapping in adult males and meeting below the bill, and never pendulous (as often illustrated). The 3 species are the Saddleback *Philesturnus* (*Creadion*) *carunculatus*, the Kokako *Callaeas cinerea* and the extinct Huia *Heteralocha* ('*Neomorpha*') *acutirostris*.

Habitat and distribution. Inhabitants of the forest interior, the wattlebirds are now much localized. Kokako persist only in little modified and extensive remnants of original lowland forest. The Huia was recorded only from the southern part of the North Island. Saddlebacks are now restricted to a dozen islands, free of predatory mammals, off the North Island and Stewart Island, having been transferred to some by the New Zealand Wildlife Service.

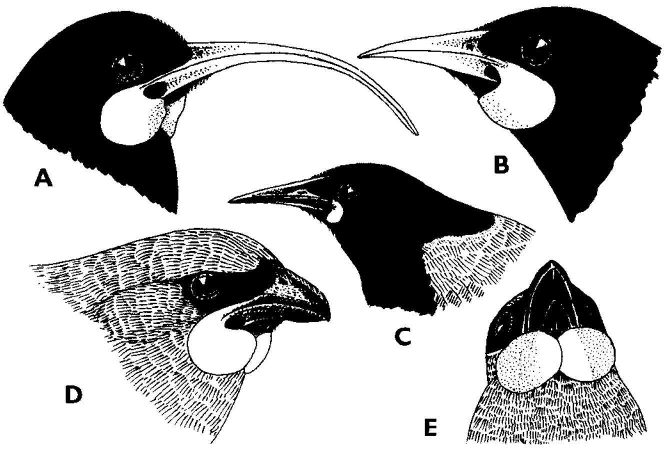

Fig. 1. Bills of New Zealand Callaeidae. **A** and **B**, female (left) and male Huia *Heteralocha acutirostris*; **C** Saddleback *Creadion carunculatus*; **D** and **E** Kokako *Callaeas cinerea*. (*C.F.*).

Food. The Saddleback feeds mainly on insects from decaying wood, bark and the forest floor, but also on fruits; the diet of the Huia was similar but the Kokako feeds mainly on young leaves and fruit, with some invertebrates. Food is occasionally grasped with a foot, parrot-fashion. The Saddleback (and formerly the male Huia) can prize open insect tunnels in wood by a 'gaping' technique, using specially adapted muscles.

Breeding. The nests are shallow, open, loosely built of rootlets, twigs and leaves, lined with moss and fern-scales, generally sheltered from above and placed in a hollow or ledge up to 10 m above ground. The 2–3 (sometimes 4) eggs are grey or brown, with purplish-grey or brown blotches. The incubation period of the Saddleback is 19–21 days; 20 days or more for the Kokako, which fledges in *c.* 27–28 days. Incubation and brooding are by the female only, but both sexes carry food. Nestling faeces are removed (Saddleback) or eaten (Kokako).

The Huia was notable for the extreme sexual differentiation of the bill, each sex using a different technique to obtain beetle larvae ('huhu') and wingless orthoptera ('weta') from decayed wood; the male chiselled out grubs while the female's long pliant bill probed borings; but there is no evidence that they cooperated in feeding. The sexes were otherwise alike, glossy black with a broad white band across the tip of the tail. The Maori wore the prized tail feathers in their hair as a mark of rank and traded them throughout the country. Extinction has been attributed to hunting by the Maori and by collectors during the 19th century (last recorded *c.* 1910).

The Saddlebacks are the best known wattlebirds; sedentary and long-lived, they pair for life and occupy territories that are maintained by the loud male songs of varying 'dialect', culturally transmitted (Jenkins, 1977). When excited, the male's wattles stand out and are curved to lie forward of the gape. Bill-touching, mutual preening and courtship-feeding maintain the pair-bond at all seasons. The display involves bowing to exhibit the chestnut saddle, tail fanning and stretching of the neck, and wing vibration by the female. Saddlebacks rarely undertake sustained flights, although they crossed water gaps of *c.* 200 m between the Chickens Islands.

Kokako resemble Saddlebacks in their sedentary habit, mating for life, maintenance of the pair-bond and displays. They use their strong legs to leap through the forest between the canopy, where they sing and display, and the understorey of shrubs and lianes where they feed. Formerly known as 'wattled crows', they are bluish-grey, with velvety black lores and short, stout, arched bills. The wattles are orange with bluish bases in *Callaeas c. cinerea* (South and Stewart Islands) and bright blue in the North Island *C.c. wilsoni*. The song, mellow and bell-like, has earned the bushman's names of 'organbird' and 'true bellbird'. The South Island subspecies is probably extinct; the North Island race has become a symbol for the conservation movement in New Zealand.

WATTLE-EYE: substantive name of *Platysteira* spp. and related forms (for family see FLYCATCHER (1)).

WAVEY: a name in North America for the Snow Goose *Anser caerulescens* (see under DUCK).

WAXBILL: substantive name of various *Estrilda* spp. etc.; in the plural, general term for the family Estrildidae (see ESTRILDID FINCH).

WAX, METABOLISM OF: see HONEYGUIDE.

WAXWING: substantive name of the 3 species of the subfamily Bombycillinae of the family Bombycillidae (Passeriformes, suborder Oscines), used without qualification in Britain for the only European species; in the plural, general term for the subfamily (for related forms, see under HYPOCOLIUS). The English name refers to the red, drop-shaped and wax-like tips of the secondary flight feathers, which are prolongations of the shafts. The phenomenon can be seen to a much lesser degree in the tail. Many individuals of all species lack these appendages, which are not correlated with age, sex or season: their exact function is unknown, but it may be that the decoration of the tail-wing-tip area distracts the attention of a predator.

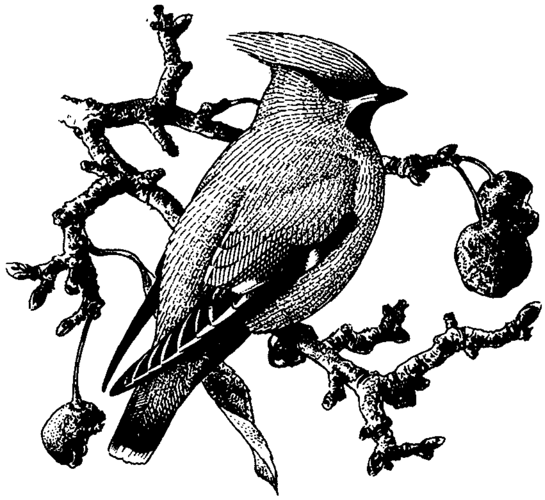
Characteristics. The 3 species are similar in size (*c.* 18 cm long) and colour, with characteristically soft, silky plumage, relatively long, pointed wings and slightly rounded tails. Their heads are crested and the vinaceous brown plumage shades into greyish-brown on the back and grey on the rump. The tails are black, tipped with lemon-yellow or red. The short bill is broad at the gape, slightly hooked and notched; feet and legs are short and stout. The sexes are similar, except that males as a rule have black throats. Juveniles of all species lack a throat patch.

Habitat. Outside the breeding season waxwings may be found wherever acceptable fruits are available, including gardens and even the centres of cities. The breeding habitat is coniferous forest, often near water but also on dry heaths.

Distribution. The one genus consists of the (in American usage) Bohemian Waxwing *Bombycilla garrulus* of Holarctic distribution, the so-called Japanese Waxwing *B. japonica*, native to eastern Siberia, and the Cedar Waxwing *B. cedrorum* of North America.

Movements. Their flight is strong and undulating and flocks make irregular movements in winter from their northern breeding areas to central Europe (in some years to Britain), central China, Japan and as far as Central America (see IRRUPTION).

Food. The highly nomadic waxwings are the only primarily frugivorous bird group in the North Temperate zone. They eat only the flesh of the berries and capture insects in the air during the breeding season.



Waxwing *Bombycilla garrulus*. (*A.H.*).

Display. Aggressiveness in *Bombycilla garrulus* is indicated when one bird perches upright near another, with all its feathers and its crest sleeked down, making it appear tall and thin. In the courtship display, however, the axis of the body is horizontal and the feathers erected rather than sleeked. The male hops towards the female, depresses his tail and erects the feathers of his lower back, rump and upper tail-coverts to form a smooth continuous hump. At the same time he raises the feathers on his belly and under tail-coverts, making him appear much larger and shorter-legged. As he erects his feathers, he pivots a little towards the female, at the same time turning his head slightly away. His crest is erected almost vertically. As he turns his head away, he bends his closed tail laterally towards the female. If she is responsive and shows signs of erecting her feathers in similar fashion, a 'gift-passing' ceremony follows, in which the pair perch near one another and may face in the same or opposite directions. The male has in his bill a small object which may be a morsel of food but may equally well be someting inedible which he has just picked up. He stretches his neck so that he is looking down at the female, who is crouching slightly, and deliberately places the object in her open bill. The two birds then hop apart and relax the plumage a little. They remain motionless, then a second or two later they move together again, take up the same posture, and the ceremony is repeated with the roles reversed. This silent passing backwards and forwards of the 'gift' may continue and has been seen to take place up to 14 times in succession. Copulation may occur after perhaps one display in 10.

Voice. A soft whistle, trill and chatter have been recorded, but no true song.

Breeding. Nests may be found singly or in small groups. They are usually in spruces but sometimes in pines or deciduous trees. They are made of twigs, beard moss, lichens and moss with a soft lining; the male may assist the female in building. Clutches of 3–7 (most commonly 5) eggs are laid late in May but usually in June. The ground colour is pale greyish blue, marked profusely with small black dots and fine irregular lines. Both sexes incubate for 15–18 days, the female being fed on the nest by her mate. The naked young are fed by regurgitation, fledge in from 19–22 days and accompany their parents for 3 weeks. E.P.

WEATHER AND BIRDS: the state of the atmosphere at a definite time and place with respect to heat or cold, wetness or dryness, calm or storm, clearness or cloudiness, and its bearing on the behaviour and life history of birds. Here, weather is taken to mean short-term, somewhat irregular changes in atmospheric factors within the seasonal climate of a given latitude and longitude.

General considerations. As homeotherms, birds possess a high, constant core body temperature. Weather conditions play a role in determining what proportion of their food birds must convert to heat energy to maintain their body temperature (see ENERGETICS). Within a certain range of ambient temperatures, called the thermoneutral zone, the cost of body temperature maintenance is minimal. In progressively lower air temperatures more energy must be spent in activities such as shivering to keep up body temperature. Conversely, in ambient temperatures above the thermoneutral zone, birds spend energy (and water) to keep down their internal temperatures by evaporative cooling of moist tissues (see HEAT REGULATION). Increasing solar radiation or relative humidity pushes the thermoneutral zone toward low temperatures. Higher wind velocities move the thermoneutral zone toward higher air temperatures. A major response of birds towards transient weather conditions is to adjust their behaviour, where possible, to minimize the metabolic cost of environments outside the range of thermoneutrality. When these behavioural adjustments fall short, we see damage to avian survival and reproduction. Birds as flying machines also are affected by weather, particularly by winds during migration. Weather can interfere with the sensory systems of birds and determine the location and activity of prey items, thereby indirectly affecting the birds themselves.

Food-finding. Evolution appears to have selected for behaviour which promotes the net energy intake of foraging birds. Because net energy equals energy found minus the cost of searching, one should expect birds to minimize the energetic cost of foraging whenever necessary and possible. Small songbirds of hot, dry regions must often look for food in temperatures well above their thermoneutral zone. As they also must conserve water, evaporative cooling cannot be used profligately. With increasing ambient temperature, many small birds seek insect prey in increasingly shaded areas. In one study, above 45°C the Verdin *Auriparus flaviceps* confined 70% of its foraging to deep shade near the trunks of trees.

In winter, many temperate zone birds are confronted with the opposite problem, how to conserve energy below the thermoneutral zone. One mixed-species flock of tits *Parus*, nuthatches *Sitta* and woodpeckers *Picoides* wintering in a deciduous wood used several techniques to husband energy. In response to either decreasing temperature or increasing wind velocity, the birds descended from the canopy layer into the decreased wind velocities lower down. In very harsh weather, they confined their food-searching to the ground. They also used windbreaks more, switching to larger-diameter branches and to the leeward sides of substrates. Additionally, the windward sides of woodlands were abandoned in proportion to wind speed. As a bird moves more rapidly, it effectively finds itself in higher wind velocities. Consequently, lower temperatures and higher ambient wind speeds caused these species to curtail their own movements to reduce energy expenditures. Over a range of 30°C, one tit *Parus carolinensis* quadrupled its foraging speed. As expected, solar radiation had an ameliorating influence. Under similar regimes of wind and temperature, birds foraged farther away from windbreaks, nearer the windward side of the wood and at faster rates in sunshine than under a heavy cloud layer.

Quite independently of its consequences for avian energetics, weather can influence food-finding by interfering with birds' ability to perceive their prey. The Osprey *Pandion haliaetus* was less successful at catching fish when the water surface became rippled by wind. Ospreys also caught fewer fish under cloud than in direct sunlight. Since the reduction in catch coincided with a reduced diving rate, the ripples and cloud cover evidently interfered with the birds' visual perception. Also, under conditions of reduced visibility Ospreys took a higher proportion of silvery, highly visible fish and fewer brownish-coloured species. Some sea terns show markedly reduced success when strong winds and a rough sea conspire to force prey deeper and disrupt diving accuracy. Completely calm conditions can also be detrimental, facilitating the prey's vision of the overhead predator.

We know little of how other sensory systems employed by hunting birds might be influenced by weather. Do winds riffling forest leaf litter interfere with owls' location of running mice by sound? Does high humidity which enhances the aerial transmission of chemical scents, aid the olfactory location of food by kiwis *Apteryx*, Turkey Vultures *Cathartes aura*, petrels (Hydrobatidae), shearwaters (Procellariidae) and, possibly, oilbirds *Steatornis*? Weather induced changes in the distribution and abundance of prey strongly affect aerial insectivores. On warm, still days David Lack found Common Swifts *Apus apus* collecting insects between 6 and 30 m above open fields. Whenever a fresh breeze appeared, the Swifts hunted on the upcurrent of air at the windward edge of tree belts where insects were blown and concentrated from nearby fields and meadows. Rain stopped the Swifts' hunting flights by grounding their prey, but Spotted Flycatchers *Muscicapa striata* continued to hawk for insects sheltering under umbrella-like tree canopies. In certain parts of their winter range, American Kestrels *Falco sparverius* hunt insects during thaws and rodents and birds during freezes.

Roosting and perching. Birds can adjust their roosting and perching habits to alleviate the energy demands of weather. Treecreepers *Certhia* and Tree Swallows *Iridoprocne bicolor* roost nightly in compact masses within tree cavities in severe weather. The reduction in exposed surface saves each bird maintenance costs. In the laboratory, 50% of the birds in a flock of House Sparrows *Passer domesticus* roosted in contact at −10°C, while only 10% did so at 0°C.

Where birds select to spend the night can depend on the weather. In one winter study, Starlings *Sturnus vulgaris* roosted in pine stands rather than deciduous woods, presumably in response to the reduced wind velocities found there. The assemblage of birds roosted homogeneously throughout a pine wood in fairly mild conditions. On harsher nights, they abandoned the windward side and descended to a low height in the remainder of the woods. This adjustment placed them in the least windy habitat available.

During the day, perching or standing birds can reduce metabolic costs in hot or cold weather by selecting more benign microclimates and adopting certain postures. On bright cold days in winter, small woodland birds stop to rest, sleep or preen behind windbreaks and fully exposed to solar radiation. On cool mornings perching vultures (Cathartidae) and Anhingas *Anhinga anhinga* spread their wings perpendicular to the sun's rays. Roadrunners *Geococcyx californianus* below the thermoneutral zone capitalize on solar radiation by erecting body plumage to expose highly absorbent patches of black skin. Above their thermoneutral zone Herring Gulls *Larus argentatus* have been seen rotating their bodies east, south and then west through the day so as to face the sun continuously. This behaviour kept to a minimum the birds' surface area exposed to direct solar radiation while presenting the highly-reflective white head and breast to the sun's rays. In hot weather, vultures intentionally defaecate on their legs and feet, apparently to cool themselves by evaporation.

Migration. The components of weather impinge on birds commuting between reproductive and non-breeding sites. As in food-finding, both the energy cost of the migration flight and the ability of sensory capacities to monitor the environment are determined by prevailing atmospheric conditions (see MIGRATION).

Tail winds increase the ground speed of a flyer, thereby reducing the energetic cost of covering a given distance. At the very least, one would not expect migration in headwinds greater than the birds' airspeed. Crosswinds tend to displace migrants from their normal route and to reduce the ground speed of individuals compensating for wind drift.

Cloud cover is of uncertain significance for small nocturnal migrants. While some appear able to maintain a heading while enveloped in heavy cloud, radar work has revealed disoriented birds under such conditions of drastically reduced visibility (see MIGRATION; NAVIGATION). At minimum, disorientation would increase flight time with concomitant heavier energy demands. It could also lead to peril if birds wrongly flew out to sea or over such unsuitable areas as deserts.

Air temperature during flight is apparently of secondary significance. The southerly winds preferred by spring migrants are usually warm, while autumn movements are greatest on northerly winds, even cold ones.

Intense precipitation may penetrate plumage and destroy its insulating properties. It also adds weight to be kept aloft. This dual drain on energy usually restrains migration during inclement weather. Nonetheless, migrants have been driven to the ground or into the sea by rain, snow, hail and icing.

Weather cues available to migrants. In North Temperate latitudes, alternating high and low pressure areas move from west to east. Winds at the ground and aloft flow clockwise around high pressure centres and counterclockwise around low pressure centres. Thus, between a low to the west and a high to the east prevailing weather is marked by southerly winds and warmer temperatures. Between an easterly high and westerly low, winds are from the northern quadrant and temperatures are colder. As a rule, small birds begin migrating in the spring just after a high pressure system has passed when warm tailwinds prevail. Some reports describe long-distance flyers in particular taking off in the light, variable winds within a high. This behaviour would put them into a warm tailwind hours later as the easterly-moving weather crosses their flight track. In the autumn, songbirds begin migration under the northerly wind flow between low pressure to the east and a high to the west. Apparently, in the autumn a tailwind is selected even though birds could fly in warmer temperatures if they waited for a low to the west when winds would be warmer, but head on. Variations on the above theme occur among species depending on flight distance and preferred migration direction.

Swifts and swallows are exceptional in that, particularly in autumn, their low-altitude migrations often point against the wind. The explanation might be that these birds, which remain near the ground to catch insects en route, would be in danger in a tailwind if they stalled when overtaken by a sudden gust. Recent evidence indicates that wind velocity, when separated from direction, does not significantly influence the tendencies for passerines to migrate or remain aloft. However, hawks and other large diurnal migrants are concentrated along leading lines (lake and ocean shores, mountain ranges) if crosswinds are strong (see below).

Changes in temperature, atmospheric pressure and relative humidity are joined in a predictable way. A low pressure cell following a high brings increasing temperature and relative humidity and decreasing atmospheric pressure. As one would expect, falling pressure and high or rising temperature almost always accompany spring migration; the reverse is true in autumn. Rather inexplicably, radar studies of nocturnal migrants have shown that peak migrations in both autumn and spring can occur when relative humidity is low.

Waterfowl and shorebirds are much faster flyers than songbirds and many species are a good bit larger. Although these migrants generally respond to weather as do passerines, they show more variability, curlews *Numenius* leaving Finland in thunderstorms, vagrant shorebirds pushed well outside the normal range by crosswinds, geese *Anser* flying on into snowstorms in the spring. Sightings of this sort may be explained by the very long non-stop flights these species undertake. Snow Geese *Anser caerulescens* reportedly journey from James Bay in Canada to the Gulf coast of the United States without respite. American Golden Plovers *Pluvialis dominica* overfly the Pacific non-stop from Alaska to the Hawaiian chain. Variation in weather during these long flights would be extensive and greater than on the shorter flight paths of most songbirds. Also, their large size and greater energy reserves make the larger shorebirds and waterfowl impervious to weather a songbird would not survive.

The large-winged buzzards *Buteo*, vultures (Cathartidae) and eagles *Aquila*, *Haliaeetus* are adapted for soaring and gliding (see FLIGHT). Their migration is diurnal and is heavily influenced by weather and localities promoting the thermal or deflected updrafts on which soaring depends. Weather and topography interact to promote a complex variety of warmer, rising air formations from doughnut-shapes under cumulus clouds to banded patterns oriented parallel to the prevailing wind. Conditions promoting thermals useful to migrants occur under clear skies and light to moderate winds. Hawk flights north in spring are greatest then, particularly when winds are southerly. Most autumn flights also take place in clear weather and, like the songbirds, hawks in autumn seem to prefer a cold tailwind to a warmer southerly headwind. The well-known concentrations of migrating hawks along shores upwind of large bodies of water occur when wind-pushed thermals carrying them along diminish in intensity over water.

Mountain ranges astride prevailing winds are important corridors for soaring and gliding migrants. The Appalachian Mountains of eastern North America extend south-west from eastern Canada almost to the Gulf of Mexico. When northerly to westerly air meets this barrier it is deflected upward, providing a long wafer of air in which hawks glide in straight lines for many kilometres between wing beats. As gliding costs only a fraction of the energy spent in powered flight, hawks in autumn capitalize on these updrafts; the vast bulk of birds following mountain ridges goes past in the interval between a low and the next high pressure system on winds from the north to west.

Reverse migration. Reverse migration, as applied to the Northern Hemisphere, refers to flights south in spring and north in autumn, tendencies contrary to prevailing movements. This phenomenon is a consistent, though minor, component of seasonal passages. Its causes remain obscure, but in spring reverse migration is usually accompanied by tailwinds from the north, air that would strike head on migrants pursuing the normal path. This fact suggests that birds may retreat southward temporarily when they meet harsh weather, or that birds use wind direction as a cue in determining flight direction, or that migrants backtrack on favourable winds to reach destinations recently overshot. Reverse migration of songbirds in autumn is also known. Warm southerly tailwinds usually accompany these excursions, but their significance and causation are poorly understood.

Reproductive behaviour. In general, reproductive activities of temperate-zone species are under the fundamental control of photoperiod-induced changes in hormone levels (see BREEDING SEASON; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM). Prevailing weather conditions can inhibit or advance the timing of breeding behaviour, and if severe enough they may prevent successful reproduction.

The impact of weather on territorial singing in passerines diminishes as the breeding period progresses. Song Sparrows *Zonotrichia melodia* of North America cease singing in late autumn and remain silent in December regardless of weather. In January, singing is heard only during unseasonably warm spells. Low temperature becomes less a deterrent as spring progresses. During March, males sing in temperatures which silence them in January. Windy and cloudy weather also inhibits singing in January, but not later on.

Nest building and egg laying in songbirds are delayed by colder and promoted by warmer than normal weather. The onset of egg-laying by larger birds such as waterfowl and raptors appears little affected by weather. In regions with long dry seasons, precipitation is an important trigger for reproduction. Many birds of African and Australian deserts begin courtship and nest building within hours of the first rain.

In small birds, which are tied more closely to weather, length of the periods off the nest is directly related to ambient temperature. Several species have been found to spend shorter periods both on and away from the eggs in cooler weather. An explanation might be that in cool air the incubating bird becomes hungry more often, but the same weather stimulates it to return and cover the cooling eggs promptly.

During the nestling period, weather's principal action is to regulate the rate at which parents find food. Particularly affected are aerial insectivores and birds that must commute long distances between foraging and nest sites. Rain and cold weather ground flying insects. In the American Purple Martin *Progne subis* rain lasting 3 or more hours or temperatures below 13°C substantially reduced food delivery to nestlings. Certain species that are particularly vulnerable to adverse weather have evolved the ability to reduce nestling growth rates under starvation conditions and to survive unusually long periods without food. Starving nestling swifts, shearwaters (Procellariidae) and storm petrels (Hydrobatidae) use up fat stored in good weather, slow down feather growth, and periodically allow their body temperature to fall almost to air temperature. These qualities allow nestlings to survive without food for several days or more, while passerine birds without these adaptations starve to death in a few hours. T.C.G.

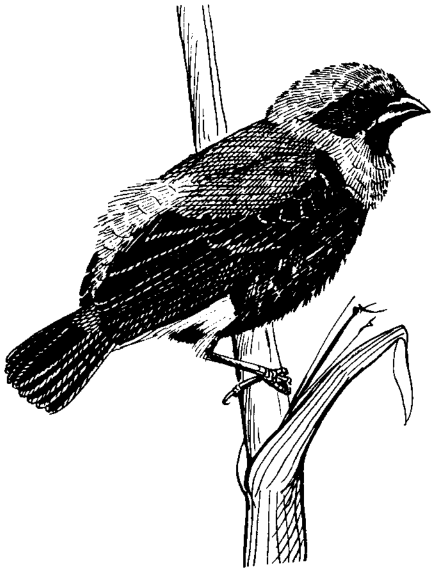
WEATHER MOVEMENT: see MIGRATION.

WEAVER: substantive name of many species of Ploceidae (Passeriformes, suborder Oscines). Most current authorities place the weaver-finches in a separate family Estrildidae (see ESTRILDID FINCH), and the sparrows in their own family Passeridae (see SPARROW), whereas formerly they were both considered subfamilies within Ploceidae. The viduine whydahs (alternatively indigo-birds, combassous, widow or widow-finch) have been considered a subfamily of Estrildidae by some, and of Ploceidae by others, and are treated separately (see WHYDAH (1)). A full review of the literature is given in Bentz (1979).

Here the weaver family is divided into the buffalo-weavers (Bubalornithinae), true weavers (Ploceinae), sparrow-weavers (Plocepasserinae) and scaly-weavers (Sporopipinae). The latter 2 subfamilies are the subject of a separate article (see SPARROW-WEAVER AND SCALY-WEAVER). The Ploceidae, an Old World and very largely African family, are finchlike birds 13–26 cm long, generally with rather short conical bills; they have rounded wings with 10 primaries (the outermost much reduced) and tail with 12 rectrices. All build roofed nests, and the tropical species breed mainly in the rainy season. Unlike the Estrildidae and Viduinae, the nestlings of Ploceidae do not have patterned mouth parts.

Within the true weavers, Moreau (1960) recognized 8 genera (number of species in parentheses): *Amblyospiza* (1), *Anomalospiza* (1), *Euplectes* (16), *Foudia* (6), *Malimbus* (10), *Neospiza* (1), *Ploceus* (57), and *Quelea* (3). Some of the species numbers have been modified and the São Tomé Grosbeak-weaver *Neospiza concolor* is possibly not a member of the Ploceidae. Nothing has been seen of it for many years and its life history is unknown. Within the large genus *Ploceus*, certain species groups can be recognized, some through similarities of nest structure, and some have been given generic status in the past. Eleven superspecies have been proposed within Africa by Hall and Moreau (1970). Insular isolation has not been important for speciation in Ploceinae, and the great rain forest that covers much of central Africa, from the Atlantic to Uganda, has



Black-winged Bishop *Euplectes hordeacea*. (*C.E.T.K.*).

acted as an efficient barrier to the spread of savanna species (see below).

In the buffalo-weavers 2 genera are recognized: *Bubalornis* (2 species) and *Dinemellia* (1 species).

Characteristics, distribution and habitat. Apart from 7 species in *Ploceus* and all species in *Foudia*, the true weavers are confined to the Afrotropical region, although one African species, Rüppell's Weaver *Ploceus galbula*, found in southern Sudan and northern Somalia, extends its range into western Arabia. Most of the *Ploceus* species of the drier areas of Africa, but not those of forest and wetter areas, have marked sexual dimorphism, with the females predominantly dull and streaky ('sparrowy') and the males, brilliant yellow in their plumage in the breeding season, assuming a similar dull plumage in the non-breeding season. As many species of *Ploceus* occur in Kenya and Uganda as occur in western and southern Africa combined. Of the 50 or so found in Africa, 8 have very restricted distributions and are rare. Most of the remainder inhabit savanna or fringing forest, the most widely distributed being the Village Weaver *Ploceus cucullatus* which also occurs in cultivation within the forest zone. The Giant Weaver *P. grandis* (22 cm), endemic to São Tomé, is considered to be derived from the Village Weaver (15 cm). Of the forest species, the Yellow-mantled Weaver *P. tricolor* is found in both the Upper and Lower Guinea forest blocks. It is strikingly coloured, black above except for a yellow patch on the mantle, and deep chestnut below except for a black throat. The Strange Weaver *P. alienus* is restricted to the middle canopy of montane forest above 1,600 m in eastern Zaire and Uganda. It is unusual in that the whole head of both sexes is black, the back, wings and tail are olive green, the upper breast deep chestnut and the rest of the underparts mustard yellow. The most distinctive feature is the long bill which is exceptionally broad at the tip and flattened on the culmen. The Black-necked Weaver *P. nigricollis* is found in evergreen forest in Zaire and West Africa but in savanna in southern Ethiopia, Kenya and Tanzania. A very distinctive forest group consists of 3 species, *P. insignis*, *P. preussi* and *P. dorsomaculatus*, which resemble each other in colour pattern (black wing and tail, yellow with black on the back, and underparts below the throat yellow), slender bill, and habit of foraging for insects on the bark of trees in the manner of a nuthatch.

The 5 Asian species in *Ploceus* are birds of paddy plains, open grasslands, cultivation and open woodland. They are all similarly coloured, with yellow and blackish heads and large areas of the body dull or streaky. The most widely distributed is the Baya Weaverbird *P. philippinus*, ranging throughout India, Sri Lanka, Bangladesh, south-west China, Burma, Sumatra and Java. There are 2 *Ploceus* species endemic to Madagascar, one, *P. sakalava*, inhabiting dry forest and the other, *P. nelicourvi*, inhabiting humid forest.

Except from the Red-headed Weaver *Malimbus rubriceps*, which inhabits woodland and acacia savanna, all the malimbes are found in evergreen forest in Upper and Lower Guinea. The sexes are generally unlike, and red and black are the predominant colours in all species.

The *Euplectes* group, the bishops and widow-birds (formerly *Coliuspasser*), live in open grassland and edges of swamps, often with several species occurring within a small area, but each ecologically separate. Thus the Red Bishop *E. orix* has largely the same range as the Yellow-crowned Bishop *E. afer*, but the latter appears more dependent on water. The bishop males, in breeding dress, look like brilliant coloured balls of either red or yellow and black as they display, and have short tails (50–70% of wing length). The widow-birds are less brilliantly coloured but have much longer tails. The largest of them is the Sakabula (Long-tailed Widow Bird) *E. progne* with a wing of about 14 cm and a black tail, some 50 cm long, that ripples behind the breeding male as he flies. The Yellow Bishop *E. capensis* is of interest as it is found in montane grassland throughout most of the northern part of its range but generally in lowland grassland elsewhere in East Africa, Zambia and Zimbabwe.

The queleas are birds of the savanna, the most numerous being the Red-billed Quelea *Q. quelea* (see QUELEA CONTROL) which occurs throughout the Afrotropical region but is more numerous in east and central Africa. In wetter parts of its range it is replaced by the Red-headed Quelea *Q. erythrops*. In breeding dress the males are quite distinct, the one having a red bill and black facial mask, the other having a black bill and the whole of the head and throat bright red.

Of the monotypic genera, the Grosbeak Weaver *Amblyospiza albifrons* (18 cm) is found in rank grass and swamps in west, central and southern Africa. The males are mainly black with chestnut heads with a white patch on the wing and usually one on the forehead. The females in contrast are white with heavy brown streaks below and mottled brown above. The Cuckoo Weaver *Anomalospiza imberbis* has a similar wide distribution, but prefers drier more open grassland. It looks like a canary, the males having yellow-green upper parts streaked with dark brown and bright yellow underparts.

The fodies (*Foudia*) are found on Madagascar, Comoro, Aldabra, Mauritius and other islands in this group. The most widely distributed, often through introduction, is the Madagascar Fody *Foudia madagascariensis*. On the islands it inhabits, it is found in open plantations and near habitation. The breeding male is bright red on the head and underparts, streaked with black on the mantle and its wings are dark. Females and non-breeding males have streaky brown, 'sparrowy' plumage.

The 2 *Bubalornis* buffalo-weavers are large birds (25 cm) for the family and wholly black unless the feathers are ruffled to show their white base. The main distinction between them is the colour of the bill: black in the Black Buffalo-weaver *B. albirostris*, becoming white or pinkish and greatly swollen in the breeding season; and red in the Red-billed Buffalo-weaver *B. niger*. The former is found in acacia country south of the Sahara and its range extends into southern Sudan and Uganda. *B. niger* has two separate populations, one in southern Africa the other in Tanzania and northwards to Ethiopia and Somaliland. The White-headed Buffalo-weaver *Dinemellia dinemelli* is unmistakable with its white head, neck and underparts. The rump, upper and lower tail-coverts, and bend of wings are orange-red, and the rest of the plumage dusky brown. It inhabits dry areas in north-eastern Africa.

Movements. The forest species within the family are all considered resident. Some savanna species are known to be migratory in some parts of their range but resident in other parts. Thus in Nigeria, Heuglin's Masked Weaver *Ploceus heuglini* moves southwards in the dry season after breeding in the north, and is locally migratory in eastern Africa; but on the Accra Plains in Ghana it is resident. The movements of the Red-billed Quelea in Nigeria have been unravelled by Ward (1965). The birds move south in the early part of the wet season to find food but then return northwards to breed in the Sahel after the grasses there have fruited. Complex migrations also occur in other parts of its range (Ward 1971). In the Himalayas, the bulk of the breeding population of Baya Weaverbirds migrate to lower levels in the non-breeding season.

Food. Most ploceine weavers of open country eat both grain and insects, some only grain, whilst the forest species are predominantly insectivorous. Some weavers are known to take nectar from flowers. The buffalo-weavers forage on the ground for seeds, fruits and insects. All members of the family feed their nestlings with insects but the savanna species use seeds as well.

Behaviour. Crook (1964) recognized three main types of courtship within the family. (1) The male sings and chases the female, and the nest is built during or after this courtship period. This behaviour is typical of all evergreen forest species which are monogamous, such as the malimbes, and the nests are generally dispersed and rarely advertised by the male. (2) The male builds a nest and then displays at it to attract a mate. This behaviour is typically found in all African savanna species of *Ploceus* that are colonial and polygynous. The entrances to nests are on the underside of the structure and males display by hanging upside down at the entrance, flapping their wings and calling. If a female accepts a nest, she proceeds to line it with grass heads and other soft material before laying eggs. The male defends a small territory within the colony and subsequently attempts to attract another female to a new nest. The Asian weavers do not have such elaborate displays at the nest and, in some species at least, the male leads the female to the nest after a sexual chase. The males of those species with side entrances to their nests (such as the Grosbeak Weaver and queleas) advertise them with a flapping display while perched upright on or near their nests. (3) The male builds a nest and then seeks to attract a mate by an aerial display and song flight, and only after he has done so does he lead her to it. This is typical of *Euplectes* species, in which the species-specific plumage of the males is prominently displayed during the slow flapping flight over their territory. A unique exception is the display of Jackson's Whydah *E. jacksoni* of East Africa. The males have communal dancing grounds in highland grassy areas. Each male calls and leaps repeatedly into the air (0.7 m or more) within a circular patch (0.8–1.2 m wide) which has a central tuft of grass with two cup-like recesses on each side of it. The grass tuft is possibly symbolic of a nest, as visiting females show much interest in it. Copulation takes place at the dancing grounds, but the nests are built by the female not the male, usually at the base of a tuft of grass.

The fodies are monogamous. The male Toq Toq *Foudia sechellarum* quivers his wings while approaching the female but this changes to an upright wing-beating display on closer approach. The male Madagascar Fody has a similar flapping display but the body is held less erect. The nest invitation display of the latter consists of a retarded flight to the nest, the slow wing-beats interspersed with glides.

The Cuckoo Weaver *Anomalospiza imberbis* congregates into large flocks in the non-breeding season but is very pugnacious in the breeding season, holding individual territories. The buffalo-weavers are gregarious throughout the year and are usually found in flocks of 10–12 birds foraging like starlings. The Red billed Quelea forms gigantic flocks and their roosts often number several millions of birds. Ward (1965) has proposed that the roost acts as an information centre for the large areas prospected by birds seeking food, and this may well be true for other weavers that roost gregariously.

Voice. During the courtship displays that have been described, the males are very vocal. The calls are in the main high-pitched and individually have little carrying power, but the cumulative noise of a large breeding colony, an incessant chattering, is deafening. The notes and calls are usually described as chirps, buzzes and wheezy whistles. Some weavers are said to have melodious and elaborate songs (such as Heuglin's Masked Weaver) but very few have been studied. The buffalo-weavers are noisy both in flight and on the ground when feeding, and utter a variety of chatterings at the nest. The calls of the White-headed Buffalo-weaver are described as parrot-like.

Breeding. The fodies, queleas, *Euplectes* species and *Amblyospiza* build a vertical oval shaped nest with a side entrance, and, except for the fodies, nest in grassland or marsh. The nests of the fodies are more spherical and untidy than those of *Euplectes* which have a very thin, woven outer shell and a thick non-woven inner lining. In all *Malimbus* and *Ploceus* species, other than the Asian, the nest chamber is elongated in the horizontal axis, and the entrance is from below and separated from the egg chamber by a ridge that prevents the eggs from rolling out. This nest type is usually placed in trees and shrubs, often at the tips of twigs and palm fronds. They are often sited over water or close to habitations of either wasps, large birds or human beings (see NESTING ASSOCIATION). In several species the entrance tubes are very delicately woven, reaching 1 m in length in Cassin's Malimbe *Malimbus cassini*. The whole nest takes over a week to build, and is woven from long strips torn from leaves or stems of palm trees. Blobs of mud, sometimes cow dung, are invariably used by the Asian Baya Weaver and Black-throated Weaver *Ploceus benghalensis*, and the latter sticks brightly coloured flowers into the wet mud.

The buffalo-weavers build large untidy domed nests, entered from the side, of thorny twigs, which are highly protective and distinguish them from nests of all other weavers. In both *Bubalornis* species, the adults and immature males work in parties to build the large communal nest. The individual egg chambers each have one opening and are lined by the female with either grass seeds, green leaves or rootlets. The Black Buffalo-weaver is polygynous and this may also be true of the other species. In contrast, the White-headed Buffalo-weaver builds single nests, on the boughs of a thorn tree, often low down, usually in a scattered colony but sometimes clustered together.

Of the species for which breeding data are known, males of most savanna species in *Ploceus* are polygynous and alone build the nest. The female lines the nest with grass heads and other softer materials, incubates the eggs, and feeds the young with little help from the male. In West Africa, male Village Weavers give no help to the female but in central and southern Africa they help feed the nestlings. In consequence the male of the west African race builds more nests on average and has more mates than his counterpart in other parts of its range.

Generally, forest weavers (*Ploceus* and *Malimbus*) are monogamous; both sexes construct the nest and feed the nestlings. In Cassin's Weaver, the adults are assisted by one or two subordinate males during nest construction but these are chased off by the dominant male when the nest is complete. The fodies are also monogamous, and both sexes help in nest construction (in most species) and feed the nestlings.

In general, the clutch-size of insectivorous forest species (average 2.1) is less than that of granivorous savanna species (average 2.6). In the buffalo-weavers the clutch-size is usually 3–4. The known incubation periods recorded for the various genera are as follows: *Euplectes* 11–16 days, *Foudia* 12–14 days, *Ploceus* 12–17 days, *Quelea* 12 days. The corresponding nestling periods are respectively: 13–16 days, 11–15 days, 15–20 days, and 12–14 days. Incubation in the Red-headed Weaver is 12–13 days.

Eggs of *Foudia* and some *Ploceus* species are either white or pale blue, but the majority of the family has blotched or spotted eggs. In contrast, those of a race of the Black-headed Weaver *P. melanocephalus* are among the most variable of any bird, being recorded as white, pink, terra-cotta, brown, or green, with or without brown, reddish or purplish spotting. In the Village Weaver, the female consistently lays one type of egg and will throw out any eggs that differ markedly from her own. As the Didric Cuckoo *Chrysococcyx caprius* is a common parasite, this may be a protective behaviour; the cuckoo lays eggs with a somewhat parallel range of variations in colour and pattern. *Quelea* eggs are pale blue (in one species heavily streaked), those of the malimbes are plain white, or else white profusely spotted and blotched with brown or grey. The eggs of buffalo-weavers are generally dull white or pale green, heavily spotted and streaked.

The Cuckoo (or Parasitic) Weaver *Anomalospiza imberbis* parasitizes various species of *Cisticola* and *Prinia*. The few data available suggest that the egg colour mimics to a large degree that of the host. Not infrequently, 2 young of the weaver are raised in one nest, but the host young normally disappear.

WEAVER-BIRD: synonymous with WEAVER, or with weaver and ESTRILDID FINCH (weaver-finch) combined.

WEAVER-FINCH: see ESTRILDID FINCH.

WEAVER, SPARROW: see SPARROW-WEAVER AND SCALY-WEAVER.

WEB: a fleshy membrane between two toes (see LEG; and SWIMMING AND DIVING); or the vane of a feather (see FEATHER; VANE).

WEBER'S LINE: see ORIENTAL REGION.

WEDGEBILL: name applied to several unrelated species: *Schistes geoffroyi* (for family see HUMMINGBIRD); *Glyphorhynchus spirurus* (see WOODCREEPER); *Sphenostoma cristatum* (see RAIL-BABBLER).

WEEBILL: *Smicrornis brevirostris* (see WARBLER, AUSTRALIAN).

WEIGHT: see SIZE.

WEIGHT RECESSION: a phenomenon in which young birds lose weight during their development, first attaining weight above adult level, but thereafter decreasing towards an adult weight achieved around the time of fledging. See also GROWTH.

WEKA: substantive name, alternatively 'weka rail', of *Gallirallus* spp. (see RAIL).

WHALE-BIRD: sailors' name for various species of petrel (Procellariidae); applied in the Antarctic to the Dove Prion *Pachyptila desolata*, and in Alaska to the Short-tailed Shearwater *Puffinus tenuirostris* (see PETREL).

WHAUP: popular name in Scotland for the Curlew *Numenius arquata* (see under SANDPIPER).

WHEATEAR: substantive name of various *Oenanthe* spp.; used without qualification, in Britain, for *O. oenanthe*—the white rump of which is the origin of the name (see CHAT; THRUSH).

WHIFFLING: rapid descent in flight involving fast side-slipping first one way and then the other.

WHIMBREL: *Numenius phaeopus*, a species of curlew (see under SANDPIPER). See photos EGG-TOOTH; HATCHING.

WHINCHAT: substantive name of some *Saxicola* spp.; used without qualification, in Britain, for *S. rubetra* (see CHAT; THRUSH).

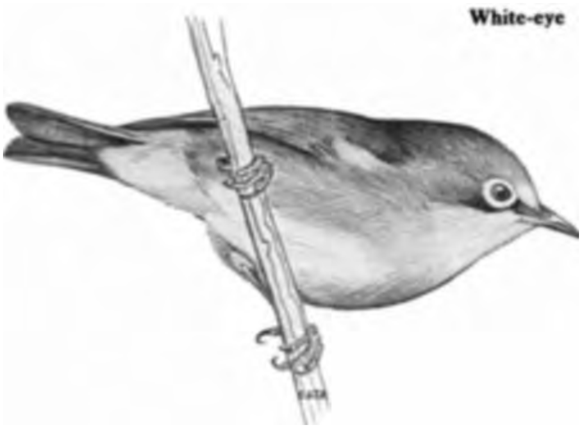
WHIPBIRD: substantive name of *Psophodes* spp. (see RAIL-BABBLER).

WHIP-POOR-WILL: *Caprimulgus vociferus* (see NIGHTJAR; also POOR-WILL).

WHISTLER: alternative substantive name for species of Pachycephalidae (see THICKHEAD).

WHITE-EYE (1): substantive name of most species of *Zosterops* comprising more than four-fifths of the Zosteropidae (Passeriformes, suborder Oscines); in the plural, general term for the family. Other names for species are 'silvereye', 'spectacle-bird' and 'zosterops'.

Characteristics. The white-eyes form a remarkable homogeneous Old World family of small birds (average length 12 cm) with generalized characters. They have slightly decurved, sharply pointed bills (short in nearly all the species), brush-tipped tongues, somewhat rounded wings with only 9 functional primaries and, in nearly all species, the white ring round each eye from which they take their name. This ring, often broken by black feathers of the lores, is formed of minute silky-white feathers, and it varies much in width. In a few species it hardly shows; at the other extreme, in certain of the African birds, it is enlarged to a big patch. Otherwise the plumage of the white-eyes is notably lacking in sharply defined pattern; most of them have the upper parts more or less green or yellow-green, the under parts grey or yellow, clouded with melanin—giving green or brownish on the sides. Yellow pigment has been lost in a number of insular populations, the entire plumage of some of them being reduced to greys and browns. The sexes are always alike; slight differences, if found in size (females smaller) or amounts of melanin or chromatin (female duller), are often overlapping within a local population and always masked by greater racial or clinal differences. There are no seasonal changes in plumage.



Green White-eye *Zosterops virens*. (*C.E.T.K.*).

Habitat. White-eyes are birds of forest edge and canopy, and frequent bushes in the gardens. They are found from sea level to the timber-line at about 3,500 m in tropical mountains, and from the acacias of south-western Africa to the mangroves of Australia and the edge of the richest tropical rain forest in south-east Asia. In the Great Barrier Reef they occur on wooded cays too small to support a breeding population of other passerines and may themselves reach very high densities (200 breeding pairs on 16 ha of Heron Island).

Systematics and distribution. There are about 85 species in the family Zosteropidae, the systematics of which are exceptionally difficult at the specific level though there is general agreement that most of them should be included in the genus *Zosterops*. This is because for the most part the genus *Zosterops* with well over 200 recognized forms varies only within narrow limits of plumage differences, and the populations found in different geographical regions may show striking resemblances as a result of convergence. For example, Madagascar and New Guinea *Zosterops*, *Z. lutea* of northern Australia and *Z. flavilateralis* of the East African lowlands, and *Z. griseovirescens* of Annobon in the Gulf of Guinea and *Z. natalis* of Christmas Island in the Indian Ocean are very much alike. Traditionally, the Zosteropidae of Africa and the neighbouring islands and those of the Indo-Pacific region have been treated separately, and the affinities within *Zosterops* of the two regions remain inscrutable. The most widespread and characteristic species are *Z. senegalensis* (range Senegal to Zululand) in the former and *Z. palpebrosa* (range Djalalabad in Afghanistan to Flores in Indonesia) in the latter region. The latest reviews recognize 4 highly polytypic species of *Zosterops* in Africa and 9 others in the islands on both sides of Africa, and 50 in the east from Pakistan to Samoa. *Z. japonica* has been introduced to Hawaii.

The family as a whole is distributed in the whole of the Ethiopian, Oriental and Australasian regions, and parts of the eastern Palearctic region, reaching their extremes of latitude in Ussuria on the Asian continent (*Z. erythropleura*) and Hokkaido in northern Japan (*Z. japonica*), and at the Cape of Good Hope (*Z. virens*) and Campbell Island south of New Zealand (*Z. lateralis*). On the continents of Africa, Asia and Australia, wide-ranging species follow Gloger's rule (melanin increasing with humidity) and Bergmann's rule (the cooler the climate the bigger the bird). In Africa the wing-length is known to increase with altitude irrespective of temperature.

Movements. White-eyes are highly mobile and have a strong tendency to migrate or disperse in flocks. The species breeding in the northern parts of Asia migrate to warmer parts in winter. Migration also occurs in eastern Australia where the individuals of the Tasmanian stock are found scattered between Tasmania and south-eastern Queensland in winter. White-eyes have established themselves on remote islands more widely than any other family of passerine birds. The most recent successful colonization is historical; in the 1850s Tasmanian birds of *Z. lateralis* crossed 1,200 miles of sea and reached New Zealand, where they have since become the commonest land bird.

In contrast with high mobility, some populations must have become profoundly sedentary as they exhibit high degrees of differentiation on oceanic islands and mountains, sometimes within sight of each other. Moreover, the speed of differentiation is remarkable in such isolated populations, which would account for high variability in insular birds. There are many examples of the double invasion of islands, and even of triple invasion (Norfolk Island), typically with one species differing much more than the other from the putative parental stock. Some, such as *Z. strenua*, a recently extinct Lord Howe Island endemic, and *Z.*

albogularis, a near extinct Norfolk Island endemic, have become 'giants'. *Z. modesta* of the Seychelles has lost its yellow pigment whereas *Z. cinerea* of the Caroline Islands and *Z. borbonica* of Mauritius and Reunion have lost both eye-ring and yellow pigment. Many combinations exist, of changes in size, in intensity of pigment, in shape of bill, and in eye-ring. Twenty-three species have been judged odd enough to be kept out of the genus *Zosterops*, and they are arranged in 11 small genera. Gigantism is found in *Speirops* in the Gulf of Guinea, *Woodfordia* at the south-eastern end of the Solomons, *Megazosterops* on the Palau Islands and *Hypocryptadius* on the mountains of Mindanao in the Philippines. The last mentioned, represented by a single species (*H. cinnamomeus*), is by far the largest, with wing-length reaching 9.5 cm and body-weight 31 g. *Chlorocharis emiliae* found on the mountains of Borneo has black eye-rings.

Food. They have a wide range of food—insects, spiders, nectar and fruit. Nectar and soft juicy fruit are obtained with the aid of the brush tongue; they are considered a pest by fruit growers. Although foliage gleaning is the commonest mode of feeding, they may also hawk, snapping the prey in the air, or may even scavenge on the ground. They often use their strong beak as a pivot to widen small crevices in clumps of leaves, bark, buds and old nests of other birds, in search of prey.

Behaviour. White-eyes are usually paired for life and breed in small territories. Most of them flock outside the breeding season and indulge in group activities of foraging, moving, bathing and resting, sometimes appearing in mixed species flocks. Flocking birds frequently perform mutual preening (allopreening) between pairs during the resting periods, and roost in clumps, huddling against each other on a perch. They have ritualized forms of aggression, the most common being wing fluttering and beak clattering. Courtship behaviour involves horizontal wing quivering and, at least in some species, motions of nest building without holding the material.

On the Mascarene Islands *Z. olivacea* (considered to have been derived from an earlier invasion) is specialized for feeding at flowers, and pairs remain territorial throughout the year, whereas *Z. borbonica* (considered to have been derived from a later invasion) is conspicuously social even during the breeding season and cases of communal feeding of young are known.

Voice. Most species seem to have a definite song at dawn throughout the breeding season. Some of them are kept in cages in Asian countries for their rich and melodious warbles. The courtship song is a soft warble.

The characteristic contact call is a high-pitched plaintive note, sometimes long-drawn and far-carrying. Soft contact notes are exchanged among members of foraging groups, and other distinct calls exist for alarm, aggression and distress.

Breeding. A cycle of breeding from nest building to fledging may be completed in as little as 3 weeks in some species, though post-fledging feeding may continue for up to 2 weeks. The nest is a deep cup of mixed plant material usually slung in a slender fork just below the canopy cover of vegetation, at any height above ground. The eggs, white or pale bluish, usually number 2 to 4. Both parents incubate, and feed the young. The incubation period and the nestling period are extremely short and similar in length (10–12 days). Young are fed with insects initially but by fledging their diet contains a significant portion of plant food.

WHITE-EYE (2): substantive name of certain pochards *Aythya* spp. (see DUCK).

WHITEFACE: substantive name of the species of *Aphelocephala*, a genus of Australian warblers (for family see WARBLER, AUSTRALIAN).

WHITEFRONT: colloquial short name for the White-fronted Goose *Anser albifrons* (see under DUCK).

WHITEHEAD: *Mohoua albicilla*, of New Zealand (for subfamily see WARBLER, AUSTRALIAN).

WHITETHROAT: substantive name of *Sylvia communis* and (Lesser) *S. curruca* (see WARBLER (1)).

WHITETIP: *Urosticte benjamini* (for family see HUMMINGBIRD).

WHOOPER: name sometimes used alone for the Whooper Swan *Cygnus cygnus* (see under DUCK).

WHYDAH (1): substantive name, alternatively 'widow' or 'widow-finch', of species of the genus *Vidua* (including '*Hypochera*', '*Tetraenura*' and '*Steganura*') Passeriformes, suborder Oscines. The name is also sometimes used in another sense; see WHYDAH (2). The name may have originated either because of the similarity of the long central tail feathers of some species to that of a widow's train, or from the locality Ouidah on the West African coast where they were found in the cage bird trade. The name indigo-bird (or the locally used alternatives combassou, indigo-finch or widow-finch) is used for the 6 species in the subgenus *Hypochera*. The name paradise whydah is used for the 4 species in the subgenus *Steganura*.

The viduine whydahs, a small group of about 14 species of African finches, all of them brood parasites of the Estrildidae, are of uncertain systematic affinities. They share some characteristics with the Ploceidae and others with the Estrildidae. Although some similarities between viduines and estrildids are due to mimicry, this does not preclude the possibility of a recent common ancestor as the primitive parasites may have originally parasitized a closely related species of estrildid. On the other hand, the egg white protein patterns of the viduines are perhaps closer to those of *Passer* than to those of the Ploceidae. A detailed systematic study of this group of finches is needed.

Characteristics, distribution and habitat. Viduines are birds of open woodlands, and occur in most terrestrial habitats in Africa except for the evergreen forests and the deserts.

The indigo-birds are all similar in appearance and size (10 cm long). The male in breeding dress is blackish with a metallic gloss of green, blue, or purple. The colour varies considerably within a species from area to area, and the variation has made it difficult to understand the species limits. The species also vary in colour of the wings, bill and feet. In the non-breeding season the male resembles the female in being streaked and brown. The tail is short throughout the year. The most widespread species is the Village Indigo-bird *Vidua chalybeata*, found throughout the drier areas of the Afrotropical region, including oases in the southern Sahara. The other species are the Variable Indigo-bird *V. funerea*, the Purple Indigo-bird *V. purpurascens*, Wilson's Indigo-bird *V. wilsoni*, the Barka Indigo-bird *V. larvaticola*, and the Jambandu Indigo-bird *V. raricola*.

The Shaft-tailed or Queen Whydah *V. regia* and the Straw-tailed Whydah *V. fischeri*, sometimes placed in a subgenus *Tetraenura*, have widely disjunct distributions, the former in southern Africa and the latter in north-east Africa. In the breeding season the males have red bills and the 4 central tail feathers are several times as long as the bird (total length 30–34 cm, female about 11 cm). The vane is nearly as narrow as the shaft but in *V. regia* it is flared at the tip.

In the paradise whydahs the tail of breeding males is extremely ornate, the central pair of long feathers being flattened and twisted into the vertical. In flight the males look like horizontal exclamation marks, the dot being the bird. The males are black except for a broad yellow or chestnut hind-collar, chestnut breast and buff abdomen. The most widespread is the Acacia Paradise Whydah *V. paradisaea* which occurs across the savanna belt from Senegal to Somalia and thence south along the eastern side of the continent to southern Africa. The West African races *orientalis* and *aucupum* are sometimes listed as distinct species. The Broad-tailed Paradise Whydah *V. obtusa* has a wide east-west distribution south of the Congo forest block, but does not reach southern Africa. The elongated rectrices are shorter, broader and untapered. The other 2 species *V. interjecta* and *V. togoensis* occur north of the forests, in central and western Africa.

In the 2 remaining species, the Pin-tailed Whydah *V. macroura* and Steel-blue Whydah *V. hypocherina*, the elongated rectrices of the breeding males are fairly narrow and taper to a point. The non breeding males and females are more heavily streaked than those of the paradise whydahs. The Pin-tailed Whydah is found throughout the Afrotropical region and even occurs in clearings within the forest zone which is exceptional for this family. The Steel-blue Whydah is confined to the arid areas of East Africa. The males in breeding dress differ markedly: the Pin-tailed is black and white, and the other wholly black with a high blue gloss above and below.

Movements. No long-distance migrations are known and in some areas the viduines are resident. However local movements occur in dry habitats. Marked Village Indigo-birds flock several km from their breeding areas, and some Variable Indigo-birds and Shaft-tailed Whydahs move more than 50 km from breeding season to dry season habitats.

Food. The viduines feed almost entirely on the small seeds of annual grasses. Seeds are taken on the ground, not from the seed heads still on the grasses. They uncover seeds in sand or dust with a quick kick of both feet. They occasionally take termites during emergences in the rains.

Behaviour. All members of the family gather into flocks during the non-breeding season. Social behaviour is best known for the Village Indigo-bird. Males space themselves several hundred metres apart and sing all day in traditional trees. Females visit several males in a day and are courted by each male in turn, in a bouncing aerial display. Females then return to one male and mate with him. The males also visit each other; the males who are unsuccessful at mating do most of the visiting and the most successful male has most of the visitors. There are usually 10–20 males in such a local breeding population, the most successful male being near the spatial centre of the population. The social organization resembles the dispersed lek of some other non-parental birds such as some birds-of-paradise. The most successful male in a local population usually gets more than half of all matings, involving perhaps 20 females in all. A few other males each account for the remaining matings. This highly polygynous mating system of the Village Indigo-bird was revealed by using colour ringed birds. Other viduines have not been studied in this way but it is likely that other indigo-birds, as well as the Shaft-tailed Whydah and the Straw-tailed Whydah, have similar social organizations, for they all have song dialects as does the Village Indigo-bird (see later).

The breeding behaviour of the Shaft-tailed Whydah and Straw-tailed Whydah is similar to the indigo-birds. The males mimic the songs of their host species and court females that fly to them on their call sites. In contrast, the male Pin-tailed Whydah and Steel-blue Whydah court their females on the ground and do not mimic songs, though the former then chases the female into a tree to continue the courtship display for many minutes. The paradise whydahs mimic the songs of their host species and some species have a conspicuous aerial display over their courtship area.

Voice. The songs of the viduines include the calls and songs of their host species, which they imitate from their foster parents, the only exceptions to this being the Pin-tailed Whydah and probably the Steel-blue Whydah. Wild hybrids (indigo-bird × paradise whydah) sing the same songs and calls as their local foster species and also the same songs and even alarm calls as the local paradise whydahs, indicating that they learned the songs both from their foster species and from the wild viduines that mimic the same foster species. The young viduines also mimic the begging calls of the host young, even when there are no host young in the nest; these mimetic begging calls are apparently innate. The host songs vary from place to place and these variations are faithfully reproduced by the local viduine population. Each male Village Indigo-bird mimics the songs of 3 or 4 different individual hosts (Red-billed Firefinch *Lagonosticta senegala*); the male may learn his foster father's song and then copy a few other firefinches or mimetic songs as sung by other male indigo-birds.

The viduines also have other alarm calls and chattery songs that are characteristic of their species groups and unlike those of the host species. In a local breeding population of Village Indigo-birds, the males share the same local variations of their own 22 song types with each other. These local dialects are apparently formed around the male who mates with most females, and his songs are copied by the other males around him. The adults sometimes switch songs when they move from one dialect neighbourhood to another.

Paradise Whydah *Vidua paradisaea*. (*M.W.*).

Breeding. All verified records indicate that most species of viduines are species-specific brood parasites. In all cases known the young of the parasite matches the young of the host species in the colour and pattern of the mouth. The mimicry involves the number and pattern of black spots on the palate, the colours (pink, lavender, blue, yellow) inside the mouth, and the colour of the highly reflective tubercles at the gape. These patterns differ among most species of estrildid finches, so each species of viduine is restricted to a single species of host. However, several species of waxbills (including Common Waxbill *Estrilda astrild*, Black-rumped Waxbill *E. troglodytes*, Fawn-breasted Waxbill *E. paludicola*, and Orange-cheeked Waxbill *E. melpoda*) all have the same pattern and all are parasitized by the Pin-tailed Whydah, whose young share this common pattern.

The parasite : host relationships that have been observed directly or that are known from song mimicry include the following: Village Indigo-bird and Red-billed Firefinch, Variable Indigo-bird and African Firefinch *Lagonosticta rubricata*, Purple Indigo-bird and Pink-backed Firefinch *L. rhodopareia*, Wilson's Indigo-bird and Bar-breasted Firefinch *L. rufopicta*, Barka Indigo-bird and Black-faced Firefinch *L. larvata*, Jambandu Indigo-bird and Black-bellied Firefinch *L. rara*, Shaft-tailed Whydah and Violet-eared Waxbill *Uraeginthus granatinus*, Straw-tailed Whydah and Purple Grenadier *U. ianthinogaster*, the Pin-tailed Whydah and several species of waxbills *Estrilda* (see above), Acacia Paradise Whydah and Melba Finch *Pytilia melba*, Broad-tailed Paradise Whydah and Orange-winged Pytilia *P. afra*, Exclamatory Paradise Whydah *Vidua interjecta* and Red-winged Pytilia *P. phoenicoptera*, Togo Paradise Whydah *V. togoensis* and Yellow-winged Pytilia *P. hypogrammica*. On distributional grounds alone, the Steel-blue Whydah probably parasitizes the Black-cheeked Waxbill *Estrilda erythronotos* (including *charmosyna*) in East Africa. This list accounts for all the known viduine species. Rarely, a viduine is raised in the nest of another host, perhaps as the result of an egg laid in the nearest estrildid nest when the usual host's nest is destroyed before the parasite has laid, and odd indigo-birds have been recorded singing the wrong host species' song, probably because their mother mislaid an egg.

Females, of all species, lay 3 or 4 eggs in a series or 'clutch', one a day, with an interval of several days between successive series. Sometimes only one egg and sometimes the entire series is laid in one nest. The eggs are white and slightly larger and rounder than the eggs of the host. The incubation period is 10 days in the Village Indigo-bird. Unlike most other brood-parasites, viduine nestlings make no attempt to evict the host's own offspring, and their close association with their foster-family may continue for an appreciable time after fledging. The nestling parasite grows faster than that of the host and sometimes crowds the host young. R.B.P.

WHYDAH (2): substantive name, alternatively 'widow-bird', of some species of Ploceidae in the genus *Euplectes* (see WEAVER).

WIDEAWAKE: alternative name of the Sooty Tern *Sterna fuscata* (see TERN).

WIDGEON: obsolescent alternative spelling of WIGEON.

WIDOW: alternatively 'widow-bird', same as 'whydah' (see WHYDAH (1); WHYDAH (2)).

WIGEON: substantive name (usually unchanged in plural; the spelling 'widgeon' is practically obsolete) of certain *Anas* spp.; used without qualification in Britain for *A. penelope* (see DUCK).

WILDFOWL: general term for quarry species of birds other than 'game birds'; in the most common present usage in Britain it is confined to species of the family Anatidae (see DUCK; also GAME-BIRDS) but sometimes extends to waders (Charadrii) and other edible birds associated with water. In North America 'waterfowl' is more commonly used in this sense. In Britain the term 'waterfowl' embraces a larger group of birds ecologically dependent on water, including members of several orders of birds. The term 'ornamental waterfowl' is used principally for live Anatidae kept in captivity.

'Wildfowling' is the practice or sport of taking wildfowl, and is conducted by a 'wildfowler'; in the past the terms embraced many forms of capture, often involving the use of nets, but it is now generally confined to the shooting of wildfowl with shot-guns. 'Duck-hunting' and 'duck-hunter' are equivalent terms in North America, where the sport is more strictly controlled by law than in European countries. In Europe, wildfowl are shot principally while 'flighting', either naturally at dawn or dusk or under the moon, or when disturbed from a resting or feeding place. This method (known there as 'pass shooting') is used to a lesser extent in North America, where most wildfowl are shot when coming in to artificial models or 'decoy' birds, made of wood ('blocks'), cardboard, rubber or plastic, the hunter being concealed nearby in a 'blind'. Although such decoys are still relatively unfashionable in Europe, the practice of feeding certain ponds regularly with grain to encourage a 'lead' of ducks is widespread and results in large bags. In North America, where this is known as 'baiting', it is illegal, although crops are specially grown in certain areas to lure wildfowl to feed there.

An arduous old-time branch of the sport known as 'punt-gunning' persists in Britain. In this a large-bore 'punt gun' is mounted on a special shallow-draught boat in which the wildfowler, lying prone, stalks the birds—usually on the open mudflats of an estuary. It is variously curtailed by law in most European countries and altogether prohibited in North America. Large-bore guns mounted in fixed emplacements overlooking small ponds are still used in France ('huttiers').

The sale of some wildfowl for food is limited to certain months in most of Europe, the period varying in different countries, but has long been outlawed in North America.

The wariness of ducks and geese is such that wildfowling has been held to be one of the most exacting and exciting of field sports. The subject has caught the imagination of writers and painters, who have portrayed the romance of the wild marshes and the elusive quarry which frequents them. M.O.

WILDNESS: see under TAMENESS.

WILLET: *Catoptrophorus semipalmatus* (see SANDPIPER).

WIND: see ANTARCTIC; FLIGHT; MIGRATION; OCEANIC BIRDS; WEATHER AND BIRDS.

WINDHOVER: alternative name of Kestrel *Falco tinnunculus* (see FALCON).

WINDOW: a pale patch on the outer primary feathers of the wings of certain gulls.

WINDPIPE: see TRACHEA.

WING: the paired forelimb of birds, specially modified for flight. It was doubtless originally 5-fingered, although in *Archaeopteryx* it had already acquired tridactyle form but with the wrist bones as yet unfused (see ARCHAEOPTERYX).

The wing has become secondarily modified for swimming in penguins, Simpson's (1946) work proving that penguins were evolved from flying ancestors and were freed from any restriction on the ratio of body weight to wing and tail area when they took to an aquatic life. Similarly, the 'ratite' orders of running birds are thought to be derived from flying ancestors, as evidenced by the fossil *Eleutherornis helveticus*, the wing becoming secondarily reduced in these and other non-flying species (see EARLY EVOLUTION OF BIRDS).

Functions. The main function of the avian forelimb is FLIGHT. It is also used solely for swimming by penguins, as formerly by the flightless Great Auk *Pinguinus impennis* (and earlier by flightless auks of the fossil genus *Mancalla*). Certain flying species also use their wings while diving, notably the auks of the Northern Hemisphere and the diving petrels of the Southern. In these, the feet are used merely as rudders, but in such diving ducks as the scoters *Melanitta* spp., eiders (Somateriini), and the Long-tailed Duck *Clangula hyemalis*, both the wings and the legs are used as paddles under water and the wings are kept folded, but away from the body with the alula held in hyperextension (see SWIMMING AND DIVING).

All birds make use of their wings for balancing, particularly when perched on a moving object in a strong wind. During courtship and breeding, when the males of many species become pugnacious towards one another, the wings are frequently used as weapons of combat, the bird in most cases seizing the opponent with the bill and buffeting him with the wings. Spur-winged Plovers *Vanellus* ('*Hoplopterus*') *spinosus* fight while in flight, turning and striking with the wing, which, as it carries a spur, is capable of inflicting mortal injury. Although little is known about the use of wing-spurs in other species, such as the Spur-winged Goose *Plectropterus gambensis*, there seems to be little doubt that these are also aggressive weapons.

Wings play an important part in the displays of many species, and during these they are widely spread and may be vibrated in front of the hen bird, as in the Silver Pheasant *Lophura nycthemera* and related species. Many birds are brightly coloured, such as the birds-of-paradise and Sun-bittern *Eurypyga helias*, but the use of the wings in courtship display is not confined to colourful species and occurs in such sombre birds as Savi's Warbler *Locustella luscinoides*, the Grasshopper Warbler *L. naevia*, and the Dunnock *Prunella modularis*. The wings are also displayed in courtship flight by many waders (Charadrii), the Roller *Coracias garrulus*, and the Golden Oriole *Oriolus oriolus*, to mention but a few examples.

As a further function, mention must be made of climbing, with special reference to the nestling Hoatzin *Opisthocomus hoazin* (see HOATZIN). This bird climbs around its nest and the nesting tree, using its feet and wings in true quadripedal fashion. The thumb and first fingers possess large claws, the manus is relatively large, and there is arrested development of

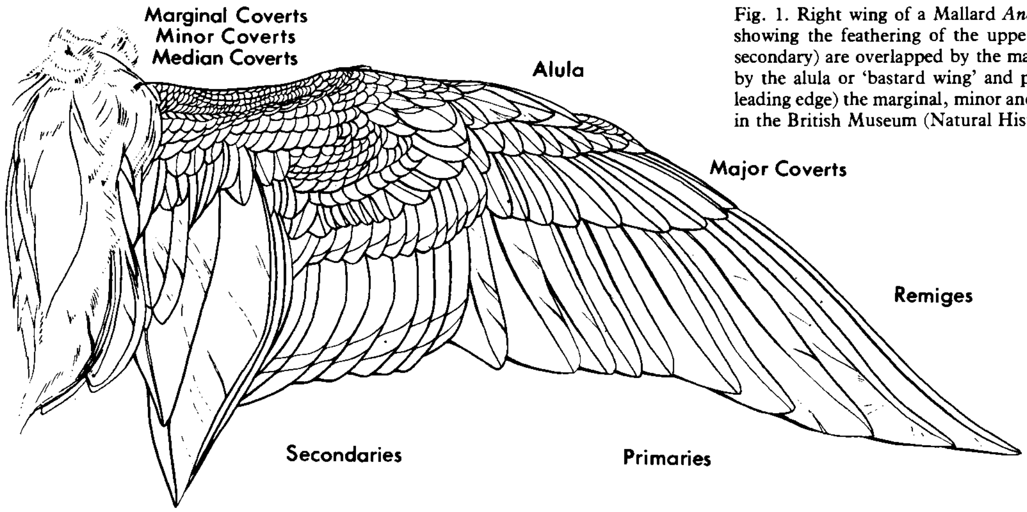

Fig. 1. Right wing of a Mallard *Anas platyrhynchos* in extended position, showing the feathering of the upper surface. The remiges (primary and secondary) are overlapped by the major coverts, and these in turn distally by the alula or 'bastard wing' and proximally by (in succession from the leading edge) the marginal, minor and median coverts. (From a preparation in the British Museum (Natural History)). (*M. Yule*).

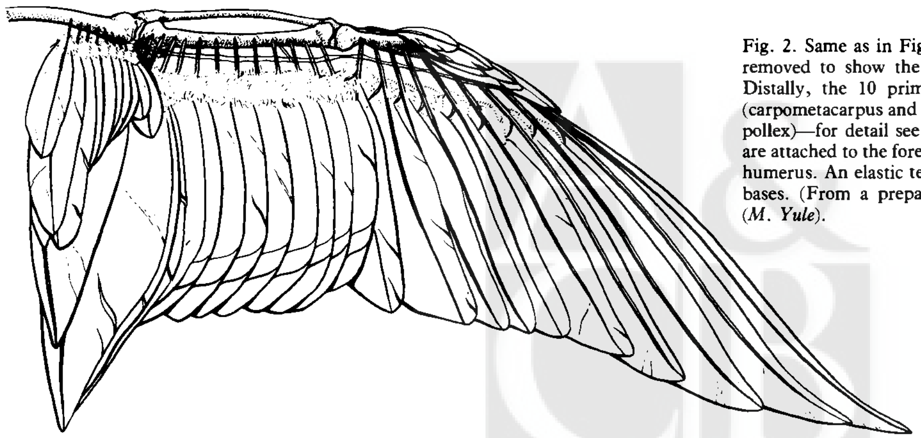

Fig. 2. Same as in Fig. 1, with soft tissues and covert feathers (tectrices) removed to show the relation of the main flight feathers to the bones. Distally, the 10 primary remiges are attached to the hand or manus (carpometacarpus and digital phalanges), which also bears the alula (on the pollex)—for detail see Fig. 3. Proximally to these, the secondary remiges are attached to the forearm (ulna), and the so-called 'tertiary' feathers to the humerus. An elastic tendon can be seen connecting the remiges near their bases. (From a preparation in the British Museum (Natural History)). (*M. Yule*).

the quill feathers of the thumb and fingers, thus enabling freer movement. The claws become absorbed in adult life and the manus assumes shorter proportions.

Structure. The wing consists of a light, variable vane for striking the air, the insertion of the wings being high up on the thorax, with the centre of gravity and the heavy internal organs well below the point of insertion.

The bones consist of the humerus, radius and ulna, and the bones of the hand or manus (see SKELETON, POST-CRANIAL). The latter are variable, owing to the loss of certain carpal bones and the fusion of others with the metacarpus. The radiale (or scapholunar) is present in all birds and the ulnare (or cuneiform) in many, exceptions being the emus and cassowaries and the kiwis. The 2nd and 3rd distal carpals are present in the young of most species, fusing in adult life with the metacarpal.

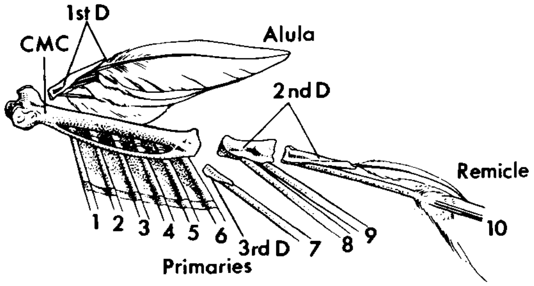

Fig. 3. As in Fig. 2, but left wing from below: detail of the manus area with the bones dissected apart. CMC = carpometacarpus; 1st D = digit or pollex (fused 1st and 2nd phalanges); 2nd D = second digit (1st phalanx and fused 2nd and 3rd phalanges); 3rd D = third digit. Feathers as marked. (From a preparation in the British Museum (Natural History)). (*M. Yule*).

Digits lost in the evolution of the typical avian manus are (on the most widely accepted view) V, IV, and the distal part of III. The second digit forms the major part of the manus in penguins, emus, cassowaries, and kiwis. The function of the hand, in general, has become largely subordinated to the provision of a firm basis for the primary feathers. The three parts of the wing—upper 'arm', forearm, and hand—can move only in one plane in relation to each other, a further adaptation towards stability.

The muscles present many problems in functional anatomy (see MUSCULATURE). Thus, the forearm and muscles of the manus are greatly reduced in kiwis, but in the Ostrich *Struthio camelus* there is little degeneration of musculature distal to the elbow. P.R. Lowe found that the only difference in the wings between the Flightless Cormorant *Nannopterum harrisi* (with almost no carina) and a flying cormorant *Phalacrocorax* sp. was in the general and relative proportions of wing to body; the Falkland Flightless Steamer Duck *Tachyeres brachypterus* has larger wings than the Flying Steamer Duck *T. patachonicus*, which is probably to be accounted for by their use under water when swimming. Penguins lack the biceps brachii muscle, but specialization of the pectoralis and tensor patagii longus takes over the function; other distal muscles of the wing are absent or reduced and the shoulder musculature is highly developed in response to the swimming action necessary.

The propatagium is a membranous fold of skin along the anterior margin of the wing, from shoulder to carpal joint; it contains flexor muscles and tendons. The metapatagium is a similar fold between the body and the posterior margin of the upper wing (see MUSCULATURE).

Feathering. The feathers of the wing (see PLUMAGE) have a definite arrangement as follows: the flight feathers or remiges are developed in the wing membrane (ala membrana) and point backwards, each feather partly overlapping the next. They are divided into the metacarpo–digitals or primaries, attached to the manus, and the cubitals or secondaries, attached to the ulna. There are typically 11 primaries, 6 attached to the metacarpus and 5 to the phalanges, but the outermost primary is often rudimentary ('remicle') or absent, while certain birds, notably the flamingos, grebes, and storks have 7 primaries attached to the metacarpus and 12 in all. The 5th secondary remex (numbered inwards from the carpal joint) was formerly thought to be absent in some species, but the modern view of this 'diastataxy' is that there is a gap between the 4th and 5th secondaries (see below and REMICLE).

In *Archaeopteryx* there were 9 primaries, as in a number of modern birds. The Ostrich has as many as 16, and the cassowaries have as few as 2 or 3. The primaries are best numbered outwards from the carpal joint, but as the opposite method is also practised it is necessary to specify which is being used (see PRIMARY).

The remainder of the wing is covered by three sets of wing coverts (tectrices) both on the upper surface and (constituting the 'lining') on the under surface, the major, minor, and marginales, the last in several rows covering the leading edge of the wing. Each major tectrix is attached in relation to one of the remiges, the bases of which are thus covered; the upper covert of the 1st metacarpal remex is generally rudimentary, as a requirement for folding the wing. The minor tectrices fill in the gap between the major and marginales feathers, overlapping the former and being overlapped by the latter. The shoulder region is covered by the humeral or tertiary feathers, and by the scapular feathers on the back and the axillaries underneath, thus ensuring a smooth feather contour at the junction of wing and body.

In the 'ratites', it is to be noted that the quills of the primaries are not fixed into grooves on the manus but lie loosely over the bones, their bases projecting beyond the bone margin. In penguins, the feathers have evolved a scale-like structure and there are no true primary feathers.

Alula or bastard wing. This, also called 'ala spuria', consists of a number of small quill feathers attached to the first digit. As mentioned, it is used in swimming by certain ducks; it is also used in flight, particularly by birds-of-prey, being of importance in the prevention of stalling (see FLIGHT). It is present in *Rhea*, providing further evidence of the flying ancestry of the 'ratites', as shown by de Beer (1956).

Claws. Three large digital claws were present in *Archaeopteryx*, and the presence of claws in modern birds must be regarded as primitive remnants, particularly as they are more commonly found in nestlings and are later absorbed. In structure, they are composed of horny epithelium, like other claws. They are found only on the 1st and 2nd digits, and persist in adult life on the 1st digit in the Secretary-bird *Sagittarius serpentarius*, the Black-necked (or Northern) Screamer *Chauna chavaria* and on all 3 species of finfoot (Heliornithidae); mention has already been made of the Hoatzin.

Spurs. These are used in combat. A spur consists of a conical bony core with an external horny sheath. They are invariably situated on the radial side of the carpus or metacarpus. The Spur-winged Goose *Plectropterus gambensis* is an example of a bird with a carpal spur arising from the scaphoid; the jacanas and the Spur-winged Plover *Vanella spinosus* have spurs arising from the first metacarpal, and the Black-necked Screamer has one on the 1st and the 2nd metacarpal. A carpal spur is present in sheathbills.

Ornamental plumes. These are occasionally present on the wing and are erected in display. Thus the Standard-wing *Semioptera wallacea* (Paradisaeidae) has 2 long plumes arising from the minor tectrices, near the distal end of the ulna. The remarkable 'sails' of the Mandarin Duck *Aix galericulata* are modified humeral feathers and are prominent in display. In some nightjars the innermost primary is greatly elongated, forming an ornamental train (with the second primary to a lesser extent) in the Pennant-winged Nightjar *Macrodipteryx vexillarius* and ending in a racket in the Standard-winged Nightjar *M. longipennis*. In cranes the innermost secondaries are elongated and incoherent plumes that, when the bird is at rest, droop over the hind end of the body. (For the wing plumes of male *Argusianus argus* see PHEASANT.)

Proportions. While one can point out certain principles in the shape and relative size of the wing, and correlate these with the mode of life of the bird, there are an enormous number of variations within these generalities.

Birds that spend most of their time in flight have evolved long, narrow wings (which tend to be pointed in sea birds but broader in land birds), with the primaries often separated to expose the 'slots' through which the air passes, thus reducing vortex formation over the wing tip. The relative lengthening of the wing has been brought about in the albatrosses (Diomedeidae) by the development of a humerus of great length with a short manus, whereas in the swifts the reverse is true and the primaries are relatively long; these are used in lateral steering and are, therefore, associated with the aerial insect-catching activities of swifts, whereas albatrosses simply glide in the air and feed off the water.

Slow fliers, and those that hunt in enclosed areas such as woodland, have relatively shorter and more rounded wings; excellent examples are the rounded wing of the Sparrowhawk *Accipiter nisus* compared with the pointed wings of the falcons (Falconidae), and the same applies respectively to the Jay *Garrulus glandarius* and the Rook *Corvus frugilegus*.

The frequency of the wing-beat increases as the size of the wing decreases, relative to body weight, reaching its maximum in the hummingbirds with up to 80 beats per second (see FLIGHT).

Diastataxis. This is an apparent absence of the fifth secondary remex in some groups of birds—also called 'aquintocubitalism'. In diastataxic wings every pair of major coverts except the fifth embraces a remex, and this effect is believed to be due to torsion of the feather papillae during embryonic life. Where the effect does not occur the condition is known as eutaxis.

The following are diastataxic: Gaviidae, Podicipedidae, Procellariiformes, Pelecaniformes (except *Nannopterum*), Ardeidae, Phoenicopteridae, Anhimidae, Accipitridae, Gruidae, Heliornithidae, Eurypygidae, Charadriiformes, Pteroclididae, Psittacidae, Strigidae, Caprimulgiformes, and Coraciidae.

Eutaxic forms include: Struthionidae, Galliformes (except Megapodiidae), Rhynochetidae, Cariamidae, Psophiidae, Cuculiformes, Meropidae, Momotidae, Todidae, Coliidae, Trogonidae, Piciformes, and Passeriformes. J.G.H.

WING BAR: a line across the wing contrasting in colour with the rest of it.

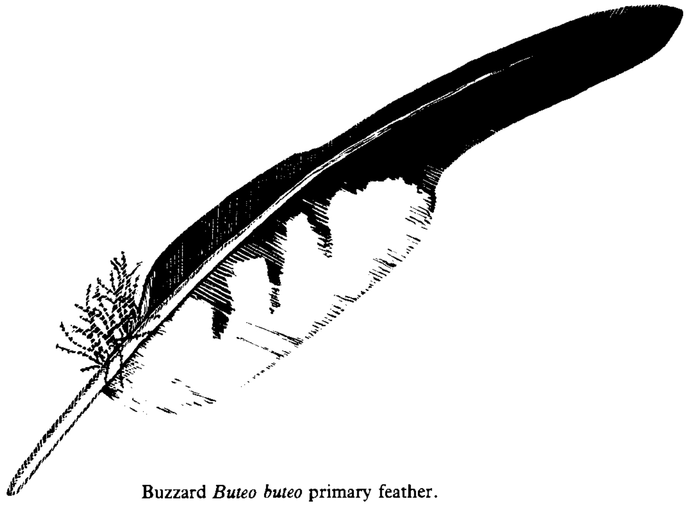
WING CLAPPING: raising the wings and striking them together to produce a loud crack (see MECHANICAL SOUNDS).

WING CLIP: see MARKING.

WING COVERTS: see TOPOGRAPHY.

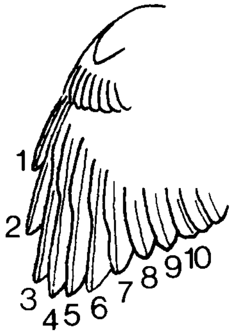
WINGED: wounded and unable to fly.

WING FORMULA: mainly mathematical representation of the shape of the distal part of a bird's wing. Wing formulae may be recorded from live or dead birds but may not be directly comparable through shrinkage of the dead bird's wing. Clear differences of wing formula exist between many closely related species whose plumage is very similar and, although there is considerable variation between individuals, such differences have also been demonstrated between races and populations of the same species (Busse 1967). Specific determination through wing formula characteristics is regularly used by bird-ringers to separate similar species, particularly among Sylviinae. In its fullest form the wing formula includes the distance (in millimetres) between the tip of the outermost primary and the longest primary covert and the distance between the tips of the rest of the primaries (and the longest secondary) and the wing point (tip of the longest primary). In addition the longer distal primaries may be notched or emarginated and this is noted. The emargination refers to the narrowing, which may affect either or both webs, towards the tip of the feather. On the outer web this may gradually slope outwards but on the inner web it may terminate abruptly at a notch. The example illustrated is a Buzzard *Buteo buteo* primary. The depth of such a notch may be measured, from the tip of the feather, and form an integral part of the overall wing formula. All relative measurements of feather length

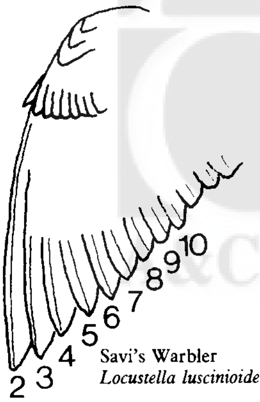


Buzzard *Buteo buteo* primary feather.

should be made on the closed wing because flexing causes alterations in the relative positions of the feathers as their points of attachment range along the metacarpals and phalanges. For the purposes of wing formula recording it is convenient and conventional to number the primaries from the outside inwards. In the example illustrated below slightly abbreviated wing formulae (measurements of some feathers are omitted) are given for two related species. The Cetti's Warbler *Cettia cetti* is predominantly a sedentary species and has a blunt, rounded wing but the Savi's Warbler *Locustella luscinioides* is a long-distance migrant with a sharp, pointed wing. In both illustrations the wings are shown partly opened but the measurements were taken from the naturally closed wings of museum specimens (Williamson 1968).



Cetti's Warbler *Cettia cetti*



Savi's Warbler *Locustella luscinioides*

Wing formula	*Cettia cetti*	*Locustella luscinioides*
1st primary	p.c. + 11 mm	p.c. − 1 mm
2nd	10 mm	Wing point
3rd	2½ mm	1½ mm
4th	Wing point	5 mm
5th	Wing point	7½ mm
6th	1 mm	10 mm
10th	9 mm	18 mm

Note that the first primary is measured in relation to the tip of the longest primary covert (p.c.), the other primaries in relation to the wing point or longest primary.

WING LOADING: see FLIGHT (Adaptations for soaring).

WINGS, COMPARATIVE ANATOMY OF: the structure of the wing in birds as compared with that in other flying animals. The power of true flight, as distinct from gliding or passive 'ballooning', has been acquired four separate times in the course of evolution. Each method involves the use of wings that are analogous in being organs used in actively striking the air. The wings of insects, however, are not homologous with the others, being outgrowths from the dorsolateral areas of the two posterior segments of the thorax. In the other three instances, all among animals conforming with the general vertebrate plan, the wings are forelimbs adapted to the purpose; but the several modifications differ widely in detail. The bird's wing is unique in having the surface area composed of feathers, borne on an arm in which the bony elements of the manus are much reduced. In the extinct pterodactyls (Order Pterosauria, Class Reptilia) and in the bats (Order Chiroptera, Class Mammalia) the surface area consists of a membranous fold of skin borne on the arm and hand, the latter extended by elongated digits. In pterodactyls, represented in the geological record from the lower Jurassic to the upper Cretaceous, the extension of the skin was carried on an extremely elongated outermost digit (usually reckoned the 5th). In bats the larger part of the membrane is extended by elongated metacarpals and phalanges of digits 2 to 5 (the pollex being free, and clawed); a smaller part is anterior to the anterior margin of the arm, beginning from the side of the neck. In bats the wing is in fact more than a forelimb, as the membrane stretches down the side of the body and has its relatively small posterior part extended by the hind leg and the tail.

WING SOUNDS: see MECHANICAL SOUNDS.

WING SPAN: measurement from wing-tip to wing-tip across bird with wings fully extended—see FLIGHT. Standard measurements of wing-length taken from carpal joint to tip of longest primary cannot be used to assess wing span. Long-winged birds have generally evolved elongated inner wing bones (*radius* and *ulna* plus *humerus*) with extra secondary wing feathers attached. The maximum wing span for extant species approaches 4 m in the Wandering Albatross *Diomedea exulans* and may exceed 3 m regularly in the Andean Condor *Vultur gryphus* and Marabou Stork *Leptoptilos crumeniferus*. The first has a long, narrow wing adapted for dynamic soaring over the oceans and the other two long, broad wings with fingered primaries adapted for soaring over land (see FLIGHT). Fossils of extinct relatives of condors have been found with wing spans approaching 5 m, of an albatross-like species at over 7 m (see FOSSIL BIRDS) and of a flying dinosaur (the pterodactyl *Pteranodon ingens*) at about 8 m. All these creatures were soaring or gliding species not likely to have been able to sustain flapping flight. The larger size of the extinct birds is thought to be evidence that the atmosphere was more dense in former times. A 70% increase in density would probably allow birds with a mass of up to 25 kg to fly: the present-day limit is 10–15 kg (see FLIGHT). The big swans (Whooper *Cygnus cygnus* and Mute *C. olor*) have the largest wing span of current species which sustain flight almost wholly through active flapping—the biggest individuals may just exceed a span of 2.5 m.

C.J.M.

WING TAGGING: see MARKING.

WINNOWING: rapid wing beating through a very shallow arc in swift flight.

WINTER VISITORS: see VISITOR.

WIRE-BIRD: alternative name for the St Helena Sand-plover *Charadrius pecuarius sanctaehelenae* (see PLOVER (1)).

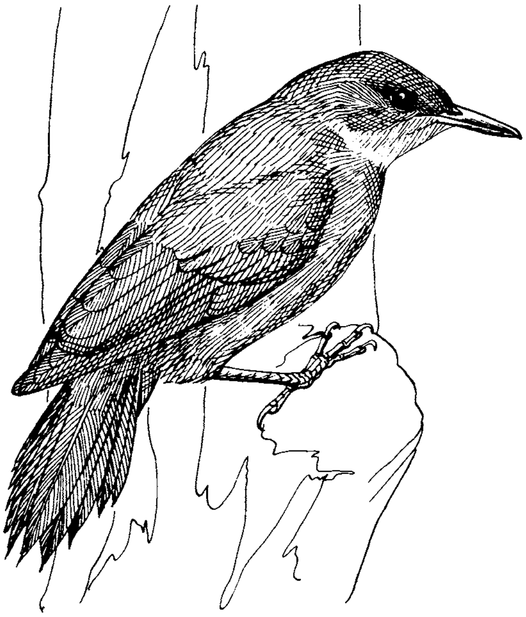
WIRETAIL: substantive name of *Sylviorthorhynchus desmursii*, a South American furnariid (for family see OVENBIRD (1)).

WISHBONE: the FURCULA; and see SKELETON, POST-CRANIAL.

WISP: see ASSEMBLY, NOUN OF.

WOODCHAT: name, alternatively 'Woodchat Shrike', of *Lanius senator* (see SHRIKE).

WOODCOCK: substantive name (commonly unchanged in the plural) of *Scolopax* spp. (see under SANDPIPER).



Ruddy Woodcreeper *Dendrocincla homochroa*. (*C.E.T.K.*).

WOODCREEPER: substantive name, alternatively 'woodhewer', of most species of Dendrocolaptidae (Passeriformes, infraorder Tyranni); in the plural, general term for the family. These birds are often treated as a subfamily Dendrocolaptinae of the ovenbird family Furnariidae from which they are derived. In size, plumage, and habits this Neotropical (primarily South American) family of nearly 50 species is rather uniform.

Characteristics. The majority of woodcreepers are between 20 and 37 cm in total length, the genera *Glyphorhynchus* (wedgebills) and *Sittasomus* being exceptions and averaging about 15 cm. Characteristically the plumage is olive, with rufous wings and tail, light or buff striations on the head, and similarly striated or barred under parts. A few, such as the Narrow-billed Woodcreeper *Lepidocolaptes angustirostris*, are almost white below; others, such as *Sittasomus* and *Dendrocincla* spp., lack striations but, although the latter retain the standard plumage colours of olive and rufous, the former are pure dark grey or yellowish below. The shafts of the rectrices are characteristically stiffened and the whole tail developed as in woodpeckers for a support in climbing trees. The legs are short, with powerful feet and long sharp claws. The bill is mostly stout and well developed, often rather compressed, long or moderately so, and more or less decurved. The extreme development is in the scythebills (or sicklebills) of the genus *Campylorhamphus*, which have long (*c.* 7 cm), scimitar-shaped bills, representing about a third or a quarter of the total length of the bird. On the other hand, the wedgebills have short, straight bills with an upturned lower mandible. There are 4 genera of woodcreepers that show some intermediacy in anatomical and plumage characters with the subfamily Philydorinae of the Furnariidae (ovenbirds); in sequence leading to typical woodcreeper morphology, these are, *Dendrocincla*, *Deconychura*, *Sittasomus*, and *Glyphorhynchus*. The other woodcreeper genera, *Drymornis*, *Nasica*, *Dendrexetastes*, *Hylexetastes*, *Xiphocolaptes*, *Dendrocolaptes*, *Xiphorhynchus*, *Lepidocolaptes* and *Campylorhamphus* may be termed the 'strong-billed' woodcreepers, and appear to form a tightly knit group morphologically.

Distribution. The family comprises 13 genera and 48 species, and ranges from Mexico (Sonora Province, in the north-west) to northern Argentina, east and central Bolivia, and Peru; it also reaches Trinidad and Tobago, but is not found in the Antilles. Thus, the range is closely similar to that of the antbirds (Formicariidae) and is essentially Neotropical, largely South American. Most species are sedentary but the Narrow-billed Woodcreeper *Lepidocolaptes angustirostris* is said to be a summer visitor to the area of Buenos Aires.

Habitat and food. The family is well adapted for an arboreal existence and the birds generally behave much like treecreepers (Certhiidae). Woodcreepers of the genus *Xiphorhynchus* are fairly typical of the family. Although primarily forest forms, they also occur in semi-open situations and forest borders. Some occur in mangroves. They forage, like most woodcreepers, by hitching up the trunks of trees or along branches. They use the stiff, spiny tail as a brace in climbing, and with the feet positioned well out laterally from the sides of the body, the birds are well away from the surface of the tree. They hitch straight up the trees or in spirals, searching for insects, other invertebrates, or small cold-blooded vertebrates (small frogs, salamanders and lizards), frequently stopping to peer under loose bark, and into moss clusters, vegetation clusters, or epiphytic plants, looking up into the cracks and crevices of these situations with one eye, then proceeding. Although peering is more typical foraging behaviour, there are many instances of woodcreepers probing, prying, and pecking at bark and small objects. After 'completing' a tree, they fly in a strong, undulating flight to or near the base of another tree to begin the cycle again. Some species are found high in the forest, while others forage primarily at the lower levels. Several species have been recorded feeding on the ground. They are usually seen singly or in couples, often accompanying mixed species foraging flocks, and some species (especially *Dendrocincla* spp.) often follow army ant swarms, taking insects that are disturbed by the ants off the bark of trees, or fly catching for them. The Great Rufous Woodcreeper *Xiphocolaptes major* and the Scimitar-billed Woodcreeper *Drymornis bridgesii* are adapted to feeding on the ground.

Voice. The voice varies considerably, being recorded as loud, musical, and melancholy for the Narrow-billed Woodcreeper *Lepidocolaptes angustirostris*; a loud *whee-whee-whee* as well as challenging notes for the Scimitar-billed Woodhewer *Drymornis bridgesii*; and a long-drawn-out trill for the Streak-headed Woodcreeper *Lepidocolaptes souleyetii*.

Breeding. The nests and eggs of very few species have been described, but so far as is known all build nests of leaves and vegetable materials in old woodpecker holes, hollow stumps, and trees, between the leaves of epiphytes or palm trees, and in other such enclosed places. The eggs are always white and more or less glossy, and the clutch size is usually 2 and rarely 3. The incubation period has been observed only in the Streak-headed Woodcreeper, as 15 days; and the nestling period in that species and in the Spot-crowned Woodcreeper *Lepidocolaptes affinis* as 19 days. WOODHAUNTER: *Hyloctistes subulatus* (for family see OVENBIRD (1)).

WOODHEN: alternative name for the wekas *Gallirallus* spp. (see RAIL).

WOODHEWER: see WOODCREEPER.

WOOD-HOOPOE: substantive name now generally used for all members of the Phoeniculidae (scimitar-bill being an alternative name for some); in the plural, general name for the family. From 6 to 9 species are recognized; they are now often placed in a single genus, *Phoeniculus*, but the forms with very curved bills (scimitar-bills) are sometimes separated (as here) as *Rhinopomastus*, and the single species with a nearly straight bill as *Scoptelus*.

Characteristics. This small group (lengths *c.* 21–43 cm), restricted to sub-Saharan Africa (though known from fossils in Europe), is morphologically homogeneous and very different in appearance and behaviour from the better known true Hoopoe *Upupa epops*. They have long graduated tails and (in most forms) long decurved bills. The tarsi are short, thick and scutellate, and toes 3 and 4 are fused at the base. Primaries and rectrices number 10. Plumage colour of all wood-hoopoes is primarily black, with or without a metallic green, purple or blue gloss. White, buff or brown also appear on some species. The feet and bill are red, orange, yellow or black, depending on the species or population; these characters often vary with age. Sexual size dimorphism is pronounced in some species. The uropygial gland produces a strongly odoriferous substance when the birds, either adults or older nestlings, are frightened in the roost or nest cavity (as is also the case in the hoopoes). On the ground wood-hoopoes hop (unlike the hoopoes, which walk).

Habitat and distribution. Wood-hoopoes are primarily arboreal and are found in thick forests (e.g. *Phoeniculus bollei*), open acacia savanna (e.g. *P. purpureus*, *Rhinopomastus cyanomelas*), and along tree-lined water courses in arid country (e.g. *R. minor*). One species or species complex, the Green Wood-hoopoe *P. purpureus*, has a very large range which includes virtually all the Afrotropical region except the equatorial rain-forest of West Africa.

Food. Wood-hoopoes feed mostly on insects and other arthropods, but some at least occasionally also take succulent fruits, including berries. Although most foraging occurs in trees, primarily by bark-probing, Green Wood-hoopoes in Kenya also feed on the ground, tearing open the droppings of large mammals to uncover the insect fauna therein. The Violet or Grant's Wood-hoopoe *P. granti* has been seen to take the eggs of the Speckle-fronted Weaver *Sporopipes frontalis*.

Voice. Wood-hoopoes proper (*P. purpureus* and *P. bollei*) are quite vocal, their calls generally being rather loud and frequent; scimitar bills *Rhinopomastus*, on the other hand, tend to vocalize less and their calls have comparatively little carrying power.

Behaviour. Social systems range from solitary pairs, as exhibited by the scimitar-bills, to co-operative breeding in stable flocks that number from 3 to 16 in Green Wood-hoopoes. Within such flocks there is only one breeding pair, with other flock members ('nest helpers') usually being related to one or both breeders. A spectacular feature of their behaviour is the frequent social cackling (whence the Afrikaans name 'Kakelaar'), accompanied by fast, exaggerated bowing and whipping up and down of the tail.

Breeding. The nest is placed in either a natural cavity or an old woodpecker hole and little or no nest material is used. The eggs (2–4 or 5) are coloured, unusual for cavity nesting species, blue, green or grey. In *P. purpureus* the breeding female alone incubates, and she is fed both by her mate and by other flock members. The helpers may provide most of the food received by the female breeder and later the nestlings. The incubation and fledging periods for *P. purpureus* are 17–18 and 28–30 days respectively. Nest sanitation is not practised, but the young birds typically place their droppings at one edge of the floor cavity. After the young wood-hoopoes fledge they continue for some time to be cared for by the flock members. Later, sometimes within a few months, these young serve as helpers at the next nest. (D.A.B.) Green Wood-hoopoe *Phoeniculus purpureus*. (*N.A.*).

WOOD-IBIS: former substantive name of *Mycteria* (*Ibis*) spp., now more correctly known as wood-storks (see STORK).

WOODLARK: *Lullula arborea* (see LARK).

WOODNYMPH: substantive name of *Thalurania* spp. and *Cyanophaia bicolor* (for family see HUMMINGBIRD).

WOOD-PARTRIDGE: substantive name of several species of woodland gamebirds (see PHEASANT).

WOODPECKER: substantive name of most species of Picidae (Piciformes, suborder Pici); in the plural, general term for this family of about 198 species. There are 3 subfamilies of woodpeckers, the wrynecks (Jynginae) with 2 species, the piculets (Picumninae) with 27 species, and the true woodpeckers (Picinae) with 169 species, based upon Short's (1982) monograph of the family.

Several woodpeckers bear other names such as 'flicker' and 'sapsucker'; the tiny woodpeckers that do not apply the tail to the bark as they cling to it are known as 'piculets'.

Characteristics. Woodpeckers generally are the most specialized of bark-foraging birds, being adapted to cling easily to the bark and to move readily over tree surfaces where they are able not only to glean, probe and pry, but to excavate into the bark and wood to obtain insects. Their tapping sounds as they feed and their characteristic appearance with strong, straight bill and tail braced against the bark render them widely known and attract interest in them. Most species are small to medium-sized (15–33 cm in length), but piculets and a few woodpeckers are tiny (to 8.5 cm) and some are larger (up to 58 cm). The predominant colours are black, white, green and brown with patches of red or yellow; one or two colours usually mark the body and the head is often distinctively striped. The sexes are alike in a few species, and are markedly different in only 2 or 3 species, the chief difference commonly being the presence of a red or yellow patch on the head of the male that the female lacks. Dorsal streaking and barring are frequent and the wings and tail usually bear spots or bars paler than the dominant colour. Ventrally many species are streaked or spotted. Most species have an undulating flight.

Habitat, distribution and movements. Naturally woodpeckers are associated with trees and occur in diverse forests, woodlands, savannas, and scrub deserts. A few species are adapted for life in treeless grasslands, where they nest in holes in the earth. Some woodpeckers, especially smaller species, frequent gardens, tree-lined streets, parks, orchards, and vineyards. Most are strictly resident and maintain territories year-round, but a few species (especially of genera *Jynx*, *Sphyrapicus*, *Colaptes*) migrate extensively and some show periodic movements associated with insect abundance, or slight southward (temperate species) or downslope (montane species) post-breeding shifts. Woodpeckers range from the tundra-edge to southernmost Africa and South America, occupying Eurasia, the Americas and Africa. They fail to reach oceanic islands, Australasia, Madagascar, and of course Antarctica, although regularly occurring on islands of the continental slopes. They approach Australasia as closely as the Philippines and Sulawesi. In mountainous regions some woodpeckers regularly reach the limit of trees and even higher seasonally in the Himalayas (*Picus squamatus*), and the terrestrial Andean Flicker *Colaptes rupicola* (35 cm) spends its life entirely above tree line. Coexisting species of woodpeckers tend to compete, and less botanically diverse woods have fewer species, richer forests have more (as many as 13 species of woodpeckers may live sympatrically in tropical Malaya and perhaps Peru).

The world's largest woodpecker, the Imperial Woodpecker *Campephilus imperialis* (58 cm) of Mexico, is probably extinct, and a few individuals of its near relative the Ivory-billed Woodpecker *C. principalis* (50 cm) perhaps still exist in Cuba. Widespread North American species include the ground-feeding Northern Flicker *Colaptes auratus* (33 cm), the garden-haunting Downy Woodpecker *Picoides pubescens* (16 cm) and its larger, shyer relative the Hairy Woodpecker *P. villosus* (24 cm), the Red-bellied Woodpecker *Melanerpes carolinus* (25 cm), the omnivorous Red-headed Woodpecker *M. erythrocephalus*, the migratory Yellow-bellied Sapsucker *Sphyrapicus varius* (22 cm), and the still common, large, crested Pileated Woodpecker *Dryocopus pileatus* (40–48 cm). Tropical Middle America and South America feature large, crested species of *Campephilus*, several of *Dryocopus* and *Colaptes*, 2 species of *Picoides*, numerous species of *Melanerpes*, most species of *Celeus*, and a number of species of the endemic *Piculus* and *Veniliornis*. Cuba is the home of the highly coloured, endemic *Xiphidiopicus percussus*.

In Europe (most extend into Asia as well) are a number of species of *Picoides* (*Dendrocopos*) including the common Great Spotted Woodpecker *Picoides major* (23 cm) and the smaller, shyer Lesser Spotted Woodpecker *P. minor* (14 cm) of parks, woodlands and gardens, and 2 species of ground-feeding *Picus*, the Green Woodpecker *P. viridis* (31 cm) and the Grey-headed Woodpecker *P. canus* (25 cm), which extends to China and Sumatra. The large Black Woodpecker *Dryocopus martius* (45 cm) is still common in forested central Europe and in mountains one can find the Three-toed Woodpecker *Picoides tridactylus* (22 cm) that reaches Asia and North America as well, and the White-backed Woodpecker *P. leucotos* (25 cm), which occurs east to Japan.

Food. Although specialists at woodpecking, many species feed opportunistically on the bark surface of trees for insects, fly-catch for winged termites and other flying insects, go to insect-bearing dead, fallen branches on the ground, and eat available fruits and nuts. Rarely a few species prey on other birds, seizing young from an open nest or enlarging nesting holes of other birds to get at their young. Sapsuckers (*Sphyrapicus*) and a few species of *Picoides* (*Dendrocopos*) regularly feed on sap at special pits excavated and maintained in certain trees at some seasons. Ants are a favourite food of many woodpeckers that pick them from the bark, excavate for them into trees or rotten stumps, or take them from tree-ant nests; the ground woodpeckers (*Geocolaptes*, *Colaptes*) and some species of *Picus* regularly feed on the ground, mainly on ants.

Behaviour. Only a few species are social; woodpeckers commonly are seen singly, or occasionally in pairs (but also in family parties for a period following nesting).

Acorn Woodpeckers *Melanerpes formicivorus* (24 cm) of south-western North and Middle America are highly social, living in groups of up to a dozen birds including a primary pair and usually their offspring of one or several years. These groups nest communally, sharing incubation and feeding of the young. The life of the Acorn Woodpecker is based largely upon two foraging strategies, the harvesting and storing of acorns of several species of oaks, and in spring and summer, when weather conditions are suitable, upon flycatching. Entire tree trunks may be covered with pit-like holes excavated by the woodpeckers, into which they force the acorns. As they are largely dependent upon these acorns for much of the autumn, winter and spring, the members of a group vigorously defend their 'storehouses' against other Acorn Woodpeckers and other species of birds, and mammals. The related *Melanerpes lewis*, *M. erythrocephalus* and *M. carolinus* also store acorns, but not to the same extent and less systematically than the more social Acorn Woodpecker.

Tropical woodpeckers tend to remain paired throughout the year, as do some woodpeckers of temperate regions, but most forage alone. Paired birds maintain vocal contact. Adults are aggressive in defence of their territory, which often is proclaimed by drumming signals or by a long series of notes. The sexes respond sex-for-sex in territorial encounters, which are marked by a variety of vocalizations, and displays involving bowing and swinging movements of the head and body, and wing and tail movements.

Voice. Some tropical species are relatively quiet but most woodpeckers characteristically use the bill to produce a 'drumming' sound by tapping it against an appropriate tree surface as a means of communication (see MECHANICAL SOUNDS). As many as 18 different vocalizations have been ascribed to various pied woodpeckers (*Picoides*, or *Dendrocopos*) and most woodpeckers have call notes and often ringing or scream-like calls.

Breeding. Birds excavate holes in which to roost at any time of the year but, as the breeding season approaches, one or both members of a pair will excavate the cavity to be used for nesting (in some species the male's roosting hole becomes the nesting cavity, and a few species may use the same hole for several years). The height and situation of the nest vary, as does the time required to excavate it, although under stress the nest can be completed within several days. Starlings, toucans, other hole-nesting birds, and mammals often compete successfully for the woodpeckers' newly excavated holes. A few woodpeckers nest socially with as many as 20 nests in a single tree (*Melanerpes striatus*) or earthen bank (*Colaptes rupicola*). Small species utilize very narrow broken or dead stubs and branchlets too small to be used by larger woodpeckers or other competitors.

Woodpeckers' nesting cavities are lined only by wood chips and splinters. From 2–9 glossy white eggs are laid and incubated by both sexes alternately during the day, but by the male alone at night in virtually all species. The incubation period is 11–17 days. The naked, blind hatchlings develop rapidly. Both adults feed the young, first entering the nest, and later feeding at the nest entrance when the young are able to climb to it. The fledging period for the larger species is 2½–3½ weeks.

Fledglings are fed by the parents, whom they tend to follow about. The period at which the young become independent is critical, for the adults may force them out of the territory and they then lack holes in which to roost. In some tropical species there is long association with the parents, even after independence, and the young may remain on the territory, sometimes excavating roosting holes near those of the parents (*Chrysocolaptes lucidus*). The nest of some piculets becomes a 'dormitory', the entire family roosting together at night in it for a long period of time.

Moult. Moult takes place annually, after breeding, but may be protracted. Usually the largest, strongest tail feathers, the central pair, are moulted after all others have moulted and the new ones come in, rendering the tail maximally effective as a brace throughout the moult. The initial juvenile plumage is replaced in the postjuvenile moult beginning in the nestling stage, usually with abbreviated juvenile first and second primaries being shed and adult feathers coming in by the late nestling stage. The postjuvenile moult is usually complete, but it is incomplete in piculets and the juvenile secondary coverts of some woodpeckers (*Picoides* or *Dendrocopos*) may not be moulted until the bird is a year old. The juvenile plumage generally is similar to that of the adult, but duller and often with greater streaking; the outermost (reduced) primary is broader and longer than in adults. Juvenile-plumaged females often show more male-like head colouring than adult females, and the sexes are nearly alike in the juvenile plumage of some species. Sapsuckers (*Sphyrapicus*) and Red-headed Woodpeckers *Melanerpes erythrocephalus* (24 cm) have a juvenile plumage differing greatly from that of adults, and the moult into adult plumage may last 6 months.

Special features. Woodpeckers differ from the related barbets (Capitonidae) and other members of the order Piciformes in their straight, often chisel-tipped bill, thick bony skull, long, extensible, barbed and often sticky-coated tongue (sublingual glands secrete sticky mucus, which with the barbs and long tongue enables the woodpecker to extract ants or other insects from their tunnels within the tree), arrangement of pelvic muscles, and bifurcate manubrium of the sternum. The co-ordinated structure of the bill, skull, head muscles, tongue and glands forms an effective and unique food-securing system. Most woodpeckers have 12 rectrices, forming a hard, fairly rigid tail. *Sasia africana* has but 8 rectrices and other species of *Sasia* and *Campephilus pollens* have 10. The outermost pair is usually much reduced, and lacking in those woodpeckers with fewer than 12 rectrices. The tail of piculets and wrynecks is more flexible and less hardened along the shafts, but woodpeckers show a gradation from fairly flexible in less specialized to rigid in very specialized woodpecking species. The central pair are longest and most rigid but in a few specialized woodpeckers (*Campephilus*, *Reinwardtipicus*, *Chrysocolaptes*), the two central pairs are equally rigid. Woodpeckers have a tough, thick skin that probably serves to minimize effects of insect bites and stings. The legs of woodpeckers are short and strong, with sharp nails. Although zygodactylous ('yoke-toed', 2 toes forward, 2 behind), woodpeckers often splay the toes apart and very specialized species splay 3 or even all 4 toes forward (i.e., upward on tree) when climbing. The first toe (hind toe of most birds, the hallux) has been lost in some species of several genera (*Sasia*, *Dinopium*, *Gecinulus*, *Picoides* or *Dendrocopos*), and *Dinopium shorii* may have or lack a tiny hallux.

The bill tends to be slightly curved along the culmen (dorsal ridge) and pointed at the tip in ant-feeding, generally less specialized woodpeckers (*Colaptes*, *Campethera*, *Meiglyptes*), and straighter and more chisel-tipped in more wood-pecking species. The most specialized excavating species (e.g., *Campephilus principalis*, *Picoides arcticus*) have a broad-based bill with a deep chisel-tip. The nostrils are partly or fully covered by feathering in most woodpeckers and often are elongated and slit-like in specialized woodpeckers, protecting the nasal chambers from wood particles scattered as the bird excavates.

Jynginae. The wrynecks are peculiarly coloured in a cryptic pattern of tans, browns, grey and black. The sexes are alike. Wrynecks do not excavate nests but use natural cavities. More often than woodpeckers they perch crosswise, infrequently clinging to the bark. Twisting movements of the head and neck in display and alarm are responsible for their name. The 2 closely related species are the migratory Northern Wryneck

Jynx torquilla (16 cm) of Eurasia and North Africa, and *J. ruficollis* of tropical Africa. They probably represent a modified offshoot of primitive woodpecker stock.

Picumninae. The tiny piculets are poorly known taxonomically and behaviourally. Although the short tail is not used as a brace, they tap, feed, and drum like true woodpeckers. Most are brown, grey or greenish above, sometimes barred or spotted, with pale underparts marked with streaks, spots or bars. One species of *Picumnus* and 2 of *Sasia* occupy Asia, *Sasia africana* occurs in central Africa, the remaining 22 species of *Picumnus* inhabit Middle and South America, and the distinctive, large *Nesoctites micromegas* is endemic on Hispaniola.

Picinae. The true woodpeckers are most numerous in tropical America and South-east Asia. Africa, surprisingly, has rather few and no large woodpeckers. The classification used here differs in a few ways from that of Voous used elsewhere in this volume, and particularly in the case of use of *Picoides* instead of *Dendrocopos* for reasons given in detail in publications by Short (1971, 1982) and by Winkler and Short (1978).

One species of *Picoides* (*P. obsoletus*) aside, the two dozen African woodpeckers represent the endemic genera *Campethera*, *Geocolaptes*, and *Dendropicos*. Few species occur in heavy forest—most are woodland and savanna species. *Campethera* species are unspecialized, largely feeding on ants. *Geocolaptes olivaceus* is the terrestrial African Ground Woodpecker of southern Africa. *Dendropicos* contains more specialized wood-pecking species allied to *Picoides*.

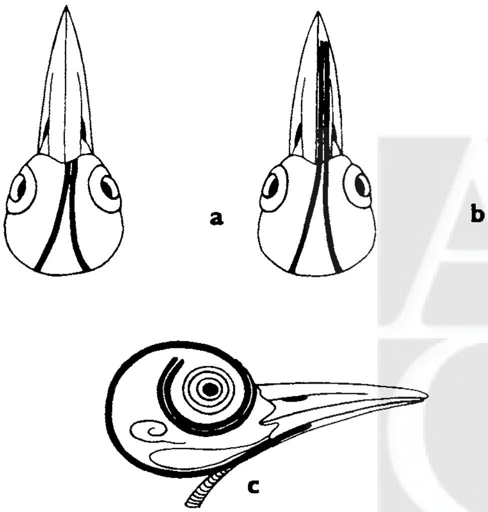

Fig. 1. Progressively different dispositions of the hyoid bones ('horns') in Picidae:
(a) the horns end at the base of the bill, as in *Reinwardtipicus validus*, *Chrysocolaptes* spp., *Picoides* spp. (including *Dendrocopos*), *Veniliornis olivinus*, *Picumnus* spp. etc.
(b) The horns end in the right cavity of the upper mandible, as in *Dinopium javanense*, *Colaptes* spp., *Picus puniceus*, etc.
(c) the horns end below, behind, or upon the right orbit, as in *Picoides villosus*, *Hemicircus concretus*, and *H. canente*. (*J. Steinbacher*).

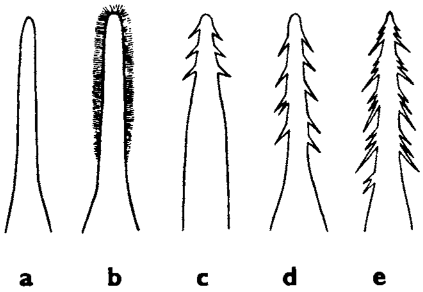

Fig. 2. Different forms of tongue-tips in Picidae:
(a) smooth, without any bristles (*Jynx*).
(b) brush-like (*Sphyrapicus varius*, *Melanerpes candidus*, *M. formicivorus*).
(c) with 2–3 barbs (*Colaptes melanochloros*).
(d) with 4–6 barbs (*Celeus flavescens*, *Veniliornis olivinus*, *Dryocopus lineatus*).
(e) with groups of barbs of different sizes (*Campephilus* spp. and *Melanerpes aurifrons*. (*J. Steinbacher*).

Powerful Woodpecker *Campephilus pollens*. (*P.J.K.B.*).

Tropical Asian woodpeckers are morphologically very diverse and include the endemic genera *Meiglyptes*, *Hemicircus*, *Mulleripicus*, *Blythipicus*, *Gecinulus*, *Dinopium*, *Chrysocolaptes*, and *Reinwardtipicus*, as well as numerous species of *Picoides* and *Picus*, one species of *Dryocopus* and a single species of *Celeus*. Of these some *Picoides*, *Dryocopus javensis*, *Hemicircus*, *Blythipicus*, *Chrysocolaptes* and *Reinwardtipicus* are most specialized for excavating. *Gecinulus grantia* feeds almost exclusively in bamboo. A distinctive, endangered woodpecker of Okinawa in the Ryukyu Islands, *Sapheopipo noguchii*, numbers about 200 birds.

WOOD-QUAIL: substantive name of *Odontophorus* spp. found in Neotropical woodlands (for family see PHEASANT).

WOOD-RAIL: in the plural, general term for certain genera of Rallidae (see RAIL).

WOOD-SHRIKE: name sometimes applied to species of Campephagidae or, in the plural, used generally for the family (see CUCKOO-SHRIKE); also, sometimes, similarly in respect of the Prionopinae (see HELMET-SHRIKE).

WOODSTAR: substantive name of *Chaetocercus jourdanii*, *Myrmia micrura*, *Myrtis fanny*, and *Philodice* spp. (for family see HUMMINGBIRD).

WOOD-STORK: *Mycteria americana*; also a general term for all four *Mycteria* spp., though the other three usually have 'stork' as the substantive name, e.g. Milky Stork *M. cinerea* (see STORK).

WOOD-SWALLOW: substantive name, alternatively 'swallow-shrike', of the species of Artamidae (Passeriformes, suborder Oscines); in the plural, in either form, general term for the family.

The family includes only the genus *Artamus*, which seems to have originated in Australia. As there is no recent monograph of the genus, the exact number of species can be given only as from 10 (Mayr 1962) to 15, of which 6 are wholly or partly Australian. The five purely Australian species share a number of features of plumage and behaviour not shown by those found partly or entirely outside it (Frith 1976). The latter perhaps represent a radiation in the Indo-Pacific region from an early ancestral stock of Australian origin. Their nearest relatives are uncertain, and they certainly are neither swallows (Hirundinidae) nor shrikes (Laniidae).

Characteristics. The wood-swallows are stoutly built birds up to 20 cm in length. The bill is stout, moderately long, slightly decurved, and pointed; it has a wide gape. The legs are short, the feet strong. The tail is blunt and rather short. The wings are long and pointed, reaching almost to the tip of the tail. The plumage colour of all species, except a partly chestnut Australian one, is a mixture of black, grey, and white. The sexes are alike or nearly so. They possess powder-down feathers, the tips of which break up into a kind of dusting powder, used by the birds in dressing the plumage; some of the Cotingidae have such feathers, but no other families among the passerines.

Wood-swallows may be identified from a long distance by their habit of huddling close together, 4 or 5 birds on a bare branch, and the tail is often waggled from side to side. The flight is exceedingly graceful, often interrupted by long periods of gliding, for which the wings are well adapted, and the larger species are able to soar on thermal up-currents. In some of the species the birds sleep in compact knots, one standing on another. They are very pugnacious, and will violently attack passing birds as large as crows or harriers (Circinae).

Habitat. Ranges from scrub, desert and agricultural land to clearings in montane forest according to species.

Distribution. The family is centred on Australia and the south-west Pacific. One species extends westwards to Malaysia, but without reaching the mainland of Asia; another is widespread in south-east Asia from eastern India and Sri Lanka, through Burma and Thailand, to western China.

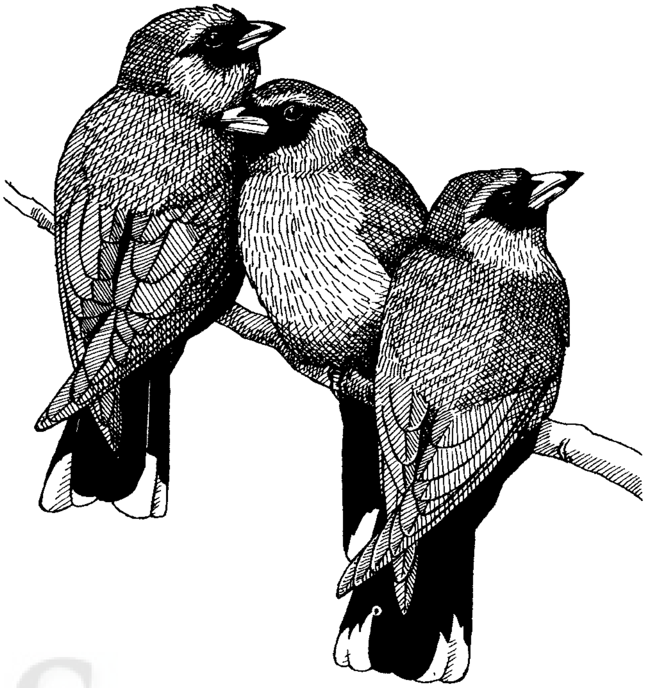
Movements. In South Australia, West Australia, and New South Wales, some species are migratory. Thus, the Masked Wood-swallow *A. personatus* described as invading the southern portion of West Australia on a large scale in some seasons, arrives in South Australia regularly in September in flocks, departing in January. The White-browed Wood-swallow *A. superciliosus* also arrives in South Australia in September. These two species form mixed feeding flocks and breeding colonies. Local movements of this type have been noticed in Northern Burma.

Food. Insects, from midges to large butterflies and beetles, usually captured in flight, though *A. cinereus* will take prey from open ground or foliage.

Voice. Harsh cries and twittering notes.

Breeding. Wood-swallows breed in colonies. The nest is usually placed on the top of a projecting stump or branch, occasionally in a hole; a favourite site is on a palm tree, either on the bases of the leaves or on the rough projections whence the leaves have fallen. The site is usually 10 m or more from the ground. Some Australian species, however, nest in shrubs or bushes within 3 m of the ground. The Little Wood-swallow *A. minor* haunts cliffs and broken country, where it nests in crevices among the rocks or on ledges in caverns.

The nest is a shallow, loose cup of fine grasses, roots, fibres, feathers, and similar materials, as a rule with no definite lining. The 2–4 eggs somewhat resemble those of shrikes, being spotted and blotched on a white to cream base. The nidicolous young are hatched with some down on the upper parts. Parental duties are shared by both sexes. Nestlings of the Greater Wood-swallow *A. maximus* have been observed being fed by 4 or 5 adults. B.E.S. and P.J.K.B.



Black-faced Wood-swallow *Artamus cinereus*. (*N.W.C.*).

WOOD-WARBLER: alternative general term for the American warblers or Parulidae (see WARBLER (2)); also, in Britain, the name of *Phylloscopus sibilatrix* in the family Sylviidae (see WARBLER (1)).

WORMS, PARASITIC: see ENDOPARASITE.

WRECK: an occasional disaster affecting pelagic species of birds, e.g. storm-petrels (Hydrobatidae) and Little Auk *Alle alle*, when these are swept ashore or inland in large numbers by persistent gales (see OCEANIC BIRDS).

WREN (1): general term for birds in the family Troglodytidae (Passeriformes, suborder Oscines). 'Wren' without qualification, is usually assumed to refer to the Holarctic species *Troglodytes troglodytes*, which is also called the European Wren, or the Winter Wren in North America.

The family Troglodytidae is considered to contain 12–14 genera and 60–65 species, including the Black-capped Donacobius *Donacobius atricapillus*, which was formerly placed in the Mimidae. Except for the Holarctic *T. troglodytes* it is an exclusively New World family, probably having its origin in Central America where the greatest variety of genera and species is found. Indeed, only one species, *T. troglodytes*, occurs in the Old World, although it does comprise a large number of subspecies that differ in size and plumage coloration. Some of the most distinctive races live on isolated islands off the Atlantic coast of Scotland (e.g. Fair Isle and St. Kilda).

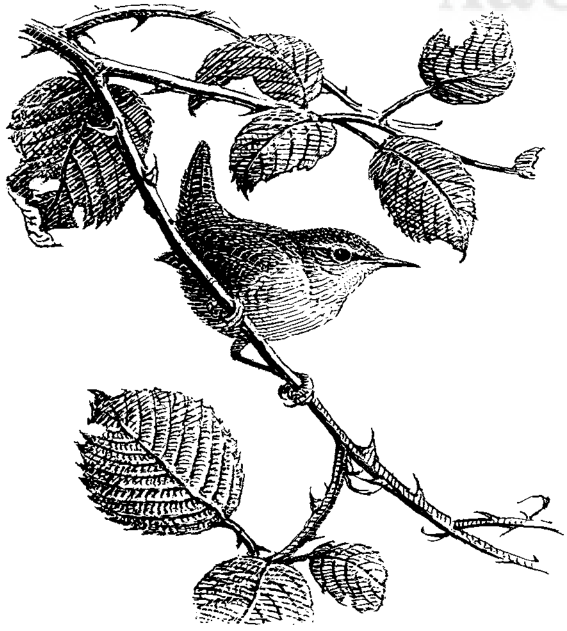
Characteristics. The wrens are mostly small (8–15 cm) with brown to rufous upper parts, a paler belly and, in many cases, a pale eye-stripe and a closely barred pattern on the flight and tail feathers. Their most distinctive characteristic, however, must be their tails, which are usually held erect to be moved vigorously back and forth in both territorial and mating displays. All wrens have rather short, blunt wings, making them poor fliers.

Habitat and distribution. Within their exceptionally wide New World range (from central Canada south to Tierra del Fuego) wrens of different species occupy almost every kind of habitat, though they are most characteristic of dense, low vegetation. Only a few species are found in lowland tropical forest, one of which, the Thrush-like Wren *Campylorhynchus turdinus*, is unusual in foraging among epiphytes high in the trees. At the other extreme such species as the Cactus Wren *Campylorhynchus brunneicapillus*, the Rock Wren *Salpinctes obsoletus* and the Canyon Wren *Catherpes mexicanus* live, as their names imply, in relatively dry and barren habitats, in the south-western United States. Typical farmland species in North America are the House Wren *Troglodytes aedon*, a common nest-box species, in the north, and Bewick's Wren *Thryomanes bewickii* in the south. The Marsh and Sedge Wrens, *Cistothorus palustris* and *C. platensis*, breed in reed marshes and sedge meadows respectively, the latter mainly in the north-eastern states. The Carolina Wren *Thryothorus ludovicianus* is particularly associated with dense understorey in forests.

Within the New World *Troglodytes troglodytes* breeds only along the north-western seaboard and in the area around the Great Lakes, where it almost always lives near dense shrubby cover on the forest floor. In Western Europe this is the type of ground it occupies at highest densities, but it also occurs in almost every other available habitat to some extent. Thus it is found breeding in disused buildings, drystone walls and broken cliff-faces in the west of Scotland, and in hedgerows, riverine scrub, urban gardens and all types of forest with appreciable understorey cover throughout the whole continent.

Food, populations and movements. Wrens, being small and almost exclusively reliant upon an invertebrate diet, are extremely susceptible to severe winter weather. Thus it is not surprising to find that many species undertake quite lengthy seasonal migrations in order to overwinter in milder conditions than are then found over some or all of their breeding range. In North America the House, Winter, Rock and Marsh Wrens show movements of this kind, which take the bulk of their populations either to the oceanic coastlines or to the southerly States for the winter.

In Northern Europe *Troglodytes troglodytes* may also move south for winter: exceptionally heavy birds, not thought to be members of the British breeding population, are sometimes caught in quite large numbers at ringing stations along the east coast of England during the autumn passage. The likelihood is that these birds breed in Scandinavia. In the south of England there are certainly local movements into especially productive habitats, such as reedbeds, for the winter.



Wren *Troglodytes troglodytes*. (*D.W.*).

The Wren in Europe has another habit which helps resident winter populations to survive periods of exceptionally inclement weather—communal ROOSTING for the night. As many as 50 birds may gather at dusk and cram themselves into a suitable cavity. They will often use Wren nests from the previous season, but also nest-boxes, hollow logs and eaves. Despite this special adaptation there are records of several dozen dead Wrens being found in and around roosting sites after a few days of continuous frost. Thus, Wren populations may undergo spectacular crashes over the course of severe winters (e.g. 1962–1963 in Britain) from which it takes them several years to recover.

Behaviour. The males of all the wren species so far studied in any detail are territorial during the breeding season, and perhaps for much of the rest of the year as well. In general only resident males confront vagrant or neighbouring males that trespass upon their ground. Fights are rare; most territorial disputes are settled conventionally, although precisely how is not known. Song is obviously involved because PLAYBACK of tape-recordings within occupied territories produces frenzied singing and overt aggression from resident males. Female and yearling Cactus Wrens join the male in the defence of their group territory.

Species living in or near the tropics are known or suspected of being monogamous in their breeding habits, but several Northern Temperate forms, including the House, European and Marsh Wrens, are known to be polygynous, quite frequently in productive habitats. The evolution of regular POLYGYNY has apparently resulted in some striking behavioural modifications to the presumed ancestral monogamous pattern.

First, at least in those northern species which have been well studied, the songs most characteristic of the polygynous species are long and complex, whilst those of the monogamists are simple, repetitive buzzing vocalizations (e.g. Cactus Wren). The European Wren produces an extraordinarily loud and long song for a bird of its small size. Each rendition usually lasts for more than 5 seconds and consists of several different types of high trill, which, together with other notes of great variety, make up a typical song of more than 100 notes in all. This wren and the next most frequent polygynist, the Marsh Wren, not only sing the longest, most complex songs in the family, but also sing for much more of the time, especially during the dawn chorus in Spring and Summer. At this season male European Wrens may sing for approximately one-third of the time for the first 3 hours after dawn. Neighbouring males can be heard answering one another for many minutes, whilst standing their territorial ground some 10–30 m apart.

Some tropical wrens have songs of outstanding beauty, especially those in the genera *Microcerculus* and *Cyphorhinus*. Thus the Nightingale Wren *M. marginatus* utters an extraordinarily slow sequence of pure flute-like tones, a complete song lasting for 30 seconds or more. Other tropical wrens habitually sing duets, the male and female of a pair singing either in unison or antiphonally.

Breeding. A second set of trends correlating with the variety of wrens' mating systems concern nest-building and the use to which the nests are put. The female Cactus Wren usually helps her monogamous mate to construct nests, but this has never been observed in either the European or the Marsh Wren. Cactus Wren nests are used as roosting sites throughout the year by the breeding pair and their offspring, as well as for housing the eggs and nestlings resulting from any breeding attempts. Male House, European and Marsh Wrens all build more nests in their territories than are ever used by breeding females. House Wren nests are usually in naturally occurring cavities in tree-trunks or buildings, and males quite frequently build 3 in a season. European Wren nests are domed and are also found at such sites, but they may also be bound to woody or herbaceous vegetation in forest understorey and other scrub. Males of this species quite frequently build 6, and sometimes as many as 12 nests in a single season. Some of these are used for breeding attempts by females, whilst others, which are sometimes referred to as COCK NESTS, are not. There is no obvious structural difference between these two types, at least to the human observer.

Nests of the House and European Wrens may be placed anywhere within males' territories, and single birds can have up to 4 ready for immediate occupation. Courtship in both these species involves the male attempting to lead any passing female to one or more of his nests; this he accomplishes by executing a frenzied dance over the female, whilst singing soft, abbreviated songs to her. The female will sometimes enter the nest she is shown and may remain within for some minutes. Soon afterwards she may be seen carrying feathers and other nest-lining materials to the site of her recent courtship. Usually this can be taken to indicate her intention to make a breeding attempt at that nest. All these facts make it seem highly likely that the nests of the European Wren have an important ceremonial function, associated with mate attraction by males in addition to their more conventional one. Indeed there is some evidence to suggest that the larger the number of vacant nests a male has in his territory, relative to his neighbours, the more likely he is to attract a prospecting female to breed in his territory.

The pattern is basically similar, though even more extreme, in the Marsh Wren. Males build a large number of nests in a cluster amongst reeds or bullrushes. Many of these nests are never completed and they are sometimes stacked on top of each other. These nest-clusters are known as 'courtship centres' because the male typically advertises them by singing nearby and leads any female that approaches to a number of the nests. He will usually build yet another nest, which is used by the female for breeding, away from the courtship centre at a location apparently specified by her. Additional females are often attracted to breed in the same territory after the construction of further courtship centres in different places. During the course of their 3-month breeding season males may routinely complete 30 or more nests and there is a positive correlation between the total number of nests completed and the number of females obtained per male. Thus most Marsh Wren nests appear to have only a ceremonial function, and the habit of nest-building on this prodigious scale is assumed to have evolved in males to increase their attractiveness to females (see BOWERBIRD). In general it seems that the singing and nest-building behaviour of some wren species has been greatly elaborated as a result of sexual selection acting through female mate choice (see LEK; MATING SYSTEM; SEXUAL SELECTION).

The clutch-size in tropical wren species is generally small (2–5 eggs), whilst that in northern temperate populations is of 6–10 eggs. Female wrens of all the well-studied species apparently incubate their clutches (14–15 days) unaided by the male, and there is little evidence of regular or substantial courtship feeding. The male shares responsibility for raising nestlings (16–17 days) and protecting and feeding recent fledglings in monogamous populations. But early broods of young Cactus Wrens have been seen helping their parents to feed later broods (i.e. their sibs) in the nest. Care of the nestlings by the male is much reduced or absent in the polygynous species. For instance, male European Wrens spend much of their time nest-building, singing and courting instead of feeding the nestlings they have presumably fathered in earlier breeding attempts taking place in their territories. This is but one illustration of the general principle that polygyny and male emancipation from the usual duties of an avian parent seem to evolve hand-in-hand (see PARENTAL CARE).

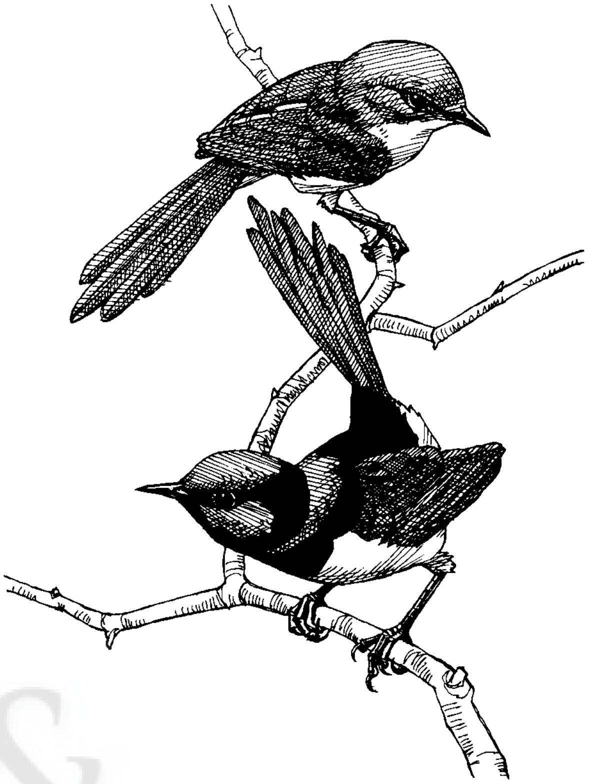
WREN (2): substantive name of many species in the former subfamily Malurinae (Muscicapidae, Passeriformes, suborder Oscines) in the form 'Australian wrens' or 'Australian wren-warblers'. This taxon has now been split into 3 groups, each with the rank of a family: the Maluridae (fairy or blue wrens and allies), Acanthizidae (scrubwrens, thornbills and allies; see WARBLER, AUSTRALIAN) and the Ephthianuridae (see CHAT, AUSTRALIAN). The genera *Cincloramphus* (songlarks) and *Eremiornis* (Spinifexbird) are excluded from these families and tentatively placed in the Sylviidae (see WARBLER (1)).

The Maluridae consist of 6 genera and 26 species. The largest genus, *Malurus* (fairy-wrens, 12 species) has a single endemic species in New Guinea, the rest in Australia. *Amytornis* (grasswrens, 8 species) and *Stipiturus* (emu-wrens, 2 species) are wholly Australian; and the remaining 3 genera (*Todopsis*, 2 species; *Chenorhamphus*, 1 species and *Clytomyias*, 1 species) are confined to New Guinea.



Superb Fairy-wren *Malurus cyaneus*. (*N.W.C.*).

Characteristics. Maluridae are small to very small, mostly semi-terrestrial songbirds (14–22 cm), wings are short and rounded, tail habitually cocked and usually more than half the total length, rectrices 'decomposed' in *Stipiturus* (hence the name 'emu-wrens'), bills fairly short, and fine except in some stout-billed *Amytornis* spp. and the broad-billed *Chenorhamphus* and *Clytomyias*. The plumage is basically brown with rufous and whitish tones, relieved or replaced in adult males of *Stipiturus*, *Malurus*, *Todopsis* and *Chenorhamphus* by blues, purples, black, chestnut, red and white in various combinations; females of last 3 genera may also have some blue. In *Malurus* at least, the bright colours of the adult males are assumed only in the breeding season. Plumage in *Amytornis* is cryptic, generally brown and cinnamon tones, streaked above and below, though some sandstone-haunting species are boldly patterned in black, rich chestnut and white. Legs and bills are brownish to blackish, irides usually brownish. Sexual dimorphism is pronounced in *Malurus*, *Stipiturus*, *Todopsis* and *Chenorhamphus*, usually slight in *Amytornis*. The young are unspotted.

An unusual character shared by all species is a gap (apterium) in the spinal feather tract. In addition, *Amytornis*, *Stipiturus* and some *Malurus* spp. have the *ala tympanica* conspicuously produced and inflated to form bullae, a development that presumably increases sharpness of hearing.

Habitat and distribution. The family is confined to Australia and New Guinea. The habitat range is extensive, from rain-forest (*Todopsis*, *Chenorhamphus*, *Clytomyias*) through forest- and mangrove-edge, riparian thickets and acacia woodland (*Malurus* spp.) to heath and swampy grassland (*Malurus* spp., *Stipiturus malachurus*) and arid hummock grassland, saltbush steppe and sandstone (*Stipiturus ruficeps*, *Amytornis*). The habitat preferences of the desert-living *Amytornis* spp. are of particular interest, and include sand dunes clad with the canegrass *Zygochloa paradoxa* (Eyrean Grasswren *Amytornis goyderi*), rocky hillsides clad with porcupine grass *Triodia* (Dusky Grasswren *A. purnelli*), relict lignum-swamps of *Muehlenbeckia cunninghamii* (Grey Grasswren *A. barbatus*), and sandstone terrain with *Triodia* (Black, White-throated and Carpentarian Grasswrens, *A. housei*, *A. woodwardi*, *A. dorotheae*).

Movements. Most species are apparently largely sedentary or make slight local movements; the arid-zone Rufous-crowned Emu-wren *S. ruficeps* and the Eyrean Grasswren, however, may undertake more extensive movements in response to the irregular changes in local conditions.

Food. Chiefly small arthropods and seeds: small centipedes, spiders, lacewings, bugs, ants, wasps, bees, flies, beetles, grasshoppers, moths, caterpillars, and small seeds mainly of grasses and chenopods (*e.g.* saltbushes). The thicker-billed species of *Amytornis* take a higher proportion of seeds, notably the Eyrean Grasswren, which feeds extensively on the seeds of the canegrass *Z. paradoxa*. The swamp-living Grey Grasswren eats, in addition to insects, a significant amount of lignum seeds and tiny water snails.

Behaviour. Most aspects of behaviour are poorly known, except in a few relatively well-studied species, e.g. the Superb Fairy-wren *Malurus cyaneus* and the White-winged Fairy-wren *M. leucopterus*. *Malurus* spp. breed co-operatively, are strongly territorial and remain in their social groups throughout the year. In *Malurus* also, courtship feeding of the female by the male has been described, and a simple display in which the male crouches with contour-feathers laterally spread and concealing the dull-coloured wings, while the head is extended horizontally and the tail drooped. A 'rodent run' distraction display has been observed in *Malurus*, *Stipiturus* and *Amytornis*. An unusual habit in *Malurus* is direct head-scratching.

Malurus, *Stipiturus*, *Todopsis* (*cyanocephala*), *Chenorhamphus* and *Clytomyias* forage on the ground and in the lower stages of vegetation, and *Amytornis* almost entirely on the ground, in monospecific groups. *Todopsis wallacii*, on the other hand, regularly joins mixed feeding parties of warblers and flycatchers, and forages up into the lower canopy.

Whereas most *Malurus* spp. are generally not timid, and show themselves a good deal, *Amytornis* and *Stipiturus* are notorious skulkers, though individuals may occasionally assume a vantage point atop a bush or tussock to sing. Progression is by weak, usually short flights, and by hopping; in the rodent-run, however, a scuttle is affected.

Voice. *Malurus* spp., in addition to various churring and scolding notes, have a distinctive reeling trill, especially well-developed in *M. leucopterus*. *Stipiturus* also has a reeling trill, though much higher and fainter, and also a rapid call of 4–5 high piercing notes. The repertoire of *Amytornis* spp. is particularly varied, elements recorded for *A. goyderi*, for instance, including a high sharp *seep seep*, an upward-inflected buzz, silvery cadences, pips, trills and long bursts of piercing staccato. In addition, this and other *Amytornis* spp. occasionally give forth a short but rich and melodious song.

Breeding. Nests are usually no more than a metre or two above ground (once as high as 6 m in a Superb Fairy-wren), in tussock or shrub. In *Malurus* and *Stipiturus*, the nest is globular or oval, domed, with side entrance, of grass, bark and other vegetable matter, sometimes spiders' cocoons, and lined with feathers and plant down. The only nest of *Chenorhamphus* reported was in moss, low on a tree-trunk, and had a side entrance. Nests of *Amytornis* are generally less domed, more often half-domed or truncated spheres, made of grass leaves, stems, roots, and sometimes fine twigs, placed low in a grass tussock or saltbush. The 2–4 eggs are generally white or pinkish white in ground colour, spotted with light greys, browns and reddish browns, often more heavily towards the larger end. In *Malurus*, nest-building and incubation are by the female alone, though the male may help to choose the site; incubation is 13–16 days, nestling period 12–14 days. There is usually more than one brood a year; nest-duties are shared by the family group (young of previous broods, subordinate males). *Malurus* spp. are heavily parasitized by cuckoos. (D.L.S.) WREN (3): substantive name of 3 out of the 4 species of Acanthisittidae (Passeriformes, suborder Oscines); in the form 'New Zealand wrens', general term for the family (also called Xenicidae). This distinctive group is peculiar to New Zealand and is believed to represent one of the most ancient avian colonizations of that country during the Tertiary Period. Although formerly placed in the suborder Tyranni near the Pittidae, recent studies (C.G. Sibley) indicate that they have no close living relatives and may be best placed in their own Infraorder. The 4 known species, one now extinct, are placed in either 2 or 3 genera. They are the Rifleman *Acanthisitta chloris*, the Bush Wren *Xenicus longipes*, the Rock Wren *X. gilviventris* and the Stephens Island Wren *Traversia* ('*Xenicus*') *lyalli*.

In both Rifleman and Bush Wren a North and a South Island subspecies have been described, differing only slightly; but in the Bush Wren a third and more distinctive subspecies known as Stead's Bush Wren (*X. l. variabilis*) developed on Stewart Island (formerly) and its neighbouring islets. The status of the 'Alpine Rifleman' '*A. c. citrina*' recorded from South Island wet mountain areas and of the 'Fiordland Rock Wren' '*X. g. rineyi*' is doubtful.

Characteristics. In the Rifleman the the sexes differ in both plumage and size, the difference being apparent even in nestlings. Female Riflemen weigh about 7.5 g and males about 6.0 g (length *c.* 8 cm), the reverse of most passerines that show sexual dimorphism. Bush and Rock Wrens (*c.* 9.5 cm) and Stephens Island Wren (*c.* 10 cm) are larger, and males and females differ little in plumage, though males are brighter.

Habitat and distribution. The Stephens Island Wren, discovered in 1894, became extinct almost as soon as it was discovered, the population on the small island being destroyed by a cat. About a dozen specimens were collected. It attracted much attention because it was supposed to be flightless; if so, it would have been the only flightless passerine. Although weak flight is suggested by the short rounded wings and soft plumage, the anatomy of the specimens received little attention and there is no clear evidence of flightlessness. The only observations were those of the lighthouse keeper on the island who saw the birds but twice, in the evening when disturbed from holes in the rocks; they ran like mice and did not fly at all. Subfossil bones, believed to be of *Traversia* have recently been found by P.R. Millener in the North Island and indicate that formerly the bird was distributed more widely.

The Rifleman and the Bush Wren originally occurred widely in both North and South Islands, the Rifleman evidently being much the more abundant. The numbers and range of many species of birds in New Zealand were reduced after European settlement in the mid-19th century; destruction of forest and introduction of predators and disease probably all contributed to the reduction. Changes brought about by settlement have obscured the former ecological relationships of the Rifleman and the Bush Wren, for early reports suggest that they were widespread from high altitudes to sea level. The Bush Wren may now be extinct, and the last known population of Stead's Bush Wren became extinct in 1965 after *Rattus rattus* reached Big South Cape Island. The Rifleman, however, is abundant in *Nothofagus* forest which still clothes

Rifleman *Acanthisitta chloris*, female and male (below). (*N.W.C.*).

much of the mountain chains of both islands, the wet region of Fiordland, and the comparatively dry eastern slopes of the South Island. It is less abundant in mixed forest at low altitudes, the extent of which is much reduced. The Rifleman appears to be adapting to man-modified habitats and enters forests of exotic pines. The Rock Wren is restricted to alpine and subalpine habitats of the South Island and its numbers have probably changed less than those of the other species.

Movements. All species probably are, or were, sedentary.

Food. So far as is known, members of the family are largely insectivorous but Riflemen and Rock Wrens eat some fruit. The Rifleman obtains much food from bark crevices and from epiphytic mosses and lichens on trees and shrubs, although it explores all parts from the bole out to the twigs, and on fallen logs, but seldom on the ground. The Bush Wren, of which little has been recorded, apparently has less creeper-like habits than the Rifleman. It feeds less on trunks and more amongst foliage, and sometimes on the ground. The Rock Wren obtains its food on and beneath the rocks of open screes, rock falls, and moraines. To some extent it enters subalpine scrub to feed, and in larger measure for shelter. In winter it does not move to lower altitudes but probably continues to feed under the snow in the air spaces among jumbled rocks and scrub.

Behaviour. Both the Bush Wren and the Rock Wren have the habit of bobbing the whole body, a vigorous action repeated frequently on alighting; this action, in the Rock Wren, varies in different portions of the range.

Voice. The Rifleman's main note is a high-pitched *zee* and the Rock Wren's a less frequently repeated *zipt*.

Breeding. Breeding habits are, as far as known, uniform. The birds are all hole-nesters and their domed nests consist of abundant material, loosely woven, usually lined with feathers and with a side entrance. Rifleman and Bush Wren nests are concealed in holes in trunks or branches and Rock Wren nests in rock crevices in comparable sites, to those of the arboreal species. Eggs are white in all species.

Rifleman and Rock Wren lay 2–5 eggs in a clutch, but Bush Wrens may have smaller clutches. The eggs of the Rifleman are large—each is about one-fifth of the female's body weight and is laid at 2-day intervals. The Rifleman has long incubation and nestling periods of 19–20 days and *c.* 24 days respectively; growth rates are extremely low but chicks at fledging are considerably heavier than adults. One or two broods are produced in a season. Both birds of a pair share in incubating and feeding; M.F. Soper and G.E. Sherley have observed that at some nests additional adults and juveniles of both sexes help to feed the young. Little is known about the breeding biology of Rock Wrens or Bush Wrens. (E.G.T.) B.M.F.

WREN (4): an alternative substantive name, popularly misapplied to certain birds of small size other than those mentioned above, e.g. the 'Willow Wren' (Willow Warbler) *Phylloscopus trochilus*, 'Wood Wren' (Wood Warbler) *P. sibilatrix*, and 'Golden-crested Wren' (Goldcrest) *Regulus regulus* (for all of which see WARBLER (1)), and babblers in the genera *Microura*, *Spelaeornis*, and *Sphenocichla* (see BABBLER); also forms part of various compound substantive names as shown below.

WREN, ANT-: see ANTWREN; and ANTBIRD.

WREN-BABBLER: see under BABBLER.

WREN, BUSH-: see WREN (3).

WREN, GNAT-: see GNATCATCHER.

WRENTHRUSH: *Zeledonia coronata* (see WARBLER (2)).

WRENTIT: *Chamaea fasciata* of western North America, a bird of much-debated affinities treated in this work as belonging to the family Timaliidae (see BABBLER).

WREN-WARBLER: substantive name of *Prinia* spp. (see WARBLER (1)); also, in the plural, alternative term for the Maluridae (see WREN (2)).

WRIST: see under SKELETON, POST-CRANIAL; WING.

WRYBILL: or Wrybilled Plover, *Anarhynchus frontalis* (see PLOVER (1)).

WRYNECK: substantive name of *Jynx* spp. (see under WOODPECKER).

X

XANTHOCHROISM: alternative term for flavism. See PLUMAGE, ABNORMAL.

XANTHOTIS: substantive name sometimes used for *Meliphaga polygramma*, a New Guinea HONEYEATER.

XENICIDAE: synonym Acanthisittidae, a family of PASSERIFORMES, suborder Oscines; WREN (3).

XENOPS: generic name used as substantive name of *Xenops* spp., sometimes called 'recurved-bills' (see OVENBIRD (1)).

XENOPSARIS: substantive name of *Xenopsaris albinucha*, a South American bird of uncertain affinities now generally placed in the tyrant-flycatcher family (for family see FLYCATCHER (2)).

XEROPHILOUS: adapted to living in a dry climate.

Y

YAFFLE: alternative name for the Green Woodpecker *Picus viridis* (see WOODPECKER).

YAWNING: an involuntary action in which the mouth is opened and a deep breath taken. While there is no doubt that yawning movements, superficially resembling those of mammals, do occur in most birds, it is not certain that these include the inhalation and exhalation of air in all species. Some writers have argued that yawning birds do not inhale, and that 'jaw-stretching' is therefore a more appropriate term for this action. Heinroth (1930) was the first to take this view, and many subsequent students of animal behaviour (including Konrad Lorenz) have accepted this interpretation. However, Sauer and Sauer (1967) in the most comprehensive study of yawning in any bird, clearly observed the inhalatory and exhalatory components of the yawn in the Ostrich *Struthio camelus*. Moreover, Ainley (1974) was able to distinguish both a jaw-stretch (without any appreciable opening of the throat) and a yawn (with inhalation) in both Brandt's Cormorant *Phalacrocorax penicillatus* and the Pelagic Cormorant *P. pelagicus*. Simmons (1977) likewise recognized a separate jaw-stretch and yawn in the Great Crested Grebe *Podiceps cristatus* and Brown Booby *Sula leucogaster*. The jaw-stretch is easier to observe in cormorants and sulids because the upper mandible can be flexed upwards at the naso-frontal hinge. In most other species in which yawn-like movements have been described in detail (including penguins, ducks, geese, waders Charadrii, warblers Sylviinae and finches) it has so far proved impossible to determine whether these movements are jaw-stretches or true yawns because of the difficulty of observing whether or not the throat opens and inhalation occurs.

Yawning occurs early on in the development of the Ostrich, being first seen in chicks which have just rested after freeing themselves from the egg shell and egg membranes. Thereafter, in both adults and young, it occurs most frequently at times when movement is reduced to a minimum and when birds are just about to fall asleep or have just awoken. It is often associated with other COMFORT BEHAVIOUR movements such as stretching, preening, scratching, head shaking (to remove mucus from the nostrils) and defaecation. During the yawn itself, the eyes are often fully or partially closed, the neck is often stretched and some head feathers are erected. In other species of birds, yawning (or jaw stretching) is broadly similar in its occurrence, and it thus shows remarkable parallels with the situation in mammals.

The physiological function of the true yawn remains a mystery. It has been suggested that in mammals it serves to purge the deeper parts of the lungs of carbon dioxide accumulated during shallow, restful breathing. However, if any such accumulation occurs during sleep, it is apparently innocuous, since no yawning occurs then. Filling the lungs with fresh air could provide a means of enhancing alertness during drowsiness (to help prevent sleep) or of speeding up the transition to an active state after slumber. Jaw-stretching presumably fulfils a similar function to the stretching of other parts of the body, though this function is itself something of an enigma. It has been suggested that stretching stimulates the blood supply to muscles as a prelude to activity, but this fails to explain why animals often stretch before sleeping.

Yawning in an individual bird often stimulates surrounding individuals of the same species to yawn, just as it does in mammals. The function, if any, of this 'snowball' effect is by no means clear, but it could serve to synchronize certain kinds of communal activities such as sleep itself, or the departure from a roost. Yawning and jaw-stretching may sometimes occur as DISPLACEMENT ACTIVITIES in apparently inappropriate contexts, such as in the middle of bouts of fighting.

Care needs to be taken to distinguish yawning or jaw-stretching from other kinds of gaping activities such as panting, threatening displays (which often involve opening of the mouth) and persistent gaping due to infection with syngamid nematodes (gapeworms). Some garden birds may appear to yawn in the presence of a human observer when waiting to be fed at a bird table. In fact this is probably a case of soliciting for food by gaping—a form of behaviour shown by altricial young both before and after fledging, and used by some adult females to elicit food from the male. YELLOWBILL: *Ceuthmochares aereus* (for family see CUCKOO); also used for another African species, *Anas undulata* (for family see DUCK).

YELLOWHAMMER: name, alternatively 'Yellow Bunting' (compare German 'Ammer' = bunting), of *Emberiza citrinella* (see BUNTING); colloquially applied in North America to the Flicker *Colaptes auratus* (see WOODPECKER).

YELLOWHEAD: *Mohoua ochrocephala* of New Zealand (for subfamily see WARBLER, AUSTRALIAN).

YELLOWLEGS: substantive name of 2 American species of *Tringa*; in British usage sometimes unnecessarily altered to 'yellowshank' on the analogy of 'redshank' and 'greenshank' (see SANDPIPER).

See photo LOCOMOTION, TERRESTRIAL.

YELLOWSHANK: see above.

YELLOWTHROAT: substantive name of species of *Geothlypis*; used without qualification, in North America, for *G. trichas* (see WARBLER (2)).

YOLK: see EGG.

YOLK-SAC: see DEVELOPMENT, EMBRYONIC.

YOUNG BIRD: a rather vague term applicable to a bird from the time of hatching (when it ceases to be an embryo) until the attainment of sexual maturity; the use of a more exact term is generally preferable. The bird is technically a 'pullus' ('pull.') until it is full-grown and flying; the ability to fly is the usual criterion, except in flightless species, but does not suffice alone in birds that have precocious flight. During the same period a bird may, in ordinary speech, be called a 'chick', especially in species where the pulli are active; or a 'nestling' while remaining in the nest. After the pullus stage a bird is described as 'juvenile' while wearing its first plumage of true feathers. Thereafter a bird may still be 'immature' (the beginning point is vague) until it attains sexual maturity, the usual criterion of which is the assumption of full 'adult' PLUMAGE (and see MATURITY); in some species this immature stage lasts for a few years, and the successive plumages may be distinguishable one from another (see also under MOULT).

Colloquially, there are special terms for the young of certain species (see CYGNET; DUCKLING; EYASS; GOSLING; OWLET).

Certain terms describe the condition of pulli in different kinds of birds. The young of some species are 'precocial', i.e. capable of locomotion more or less immediately after hatching; others are 'altricial', i.e. incapable of locomotion. The young may be 'ptilopaedic', i.e. covered with down, usually dense, when hatched; or they may be 'psilopaedic', i.e. naked or with only sparse dorsal down (and usually blind) when hatched. Young that leave the nest immediately or soon after hatching are termed 'nidifugous'; those that remain in the nest are termed 'nidicolous'. Nidifugous young are necessarily both precocial and ptilopaedic, but nidicolous young are not in all the species psilopaedic or even wholly altricial.

Nice (1962), in an important monograph on the development of behaviour in young birds, classified the state of maturity of 'hatchlings' as follows:

Precocials—eyes open, down covered, leave nest first day or two

1. Independent of parents (e.g. Megapodiidae)
2. Follow parents but find own food (e.g. Anatidae, Charadriidae)
3. Follow parents and shown food by them (e.g. Phasianidae in part)

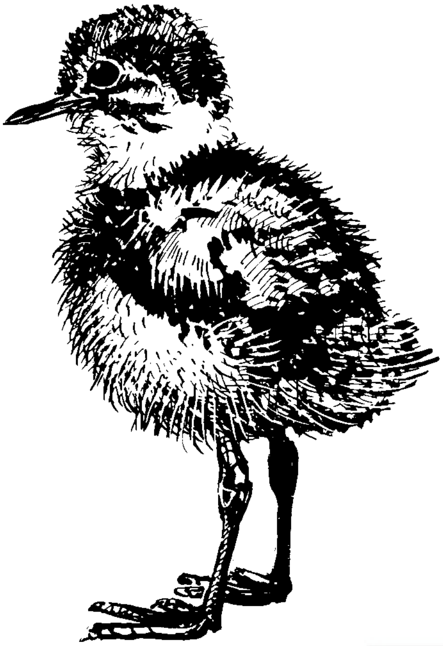

Fig. 1. Newly hatched Lapwing *Vanellus vanellus*—precocial, nidifugous, ptilopaedic, and open-eyed. (*K. Shackleton*).

4. Follow parents and are fed by them (e.g. Podicipedidae, Rallidae).

Semi-precocials—eyes open, down covered, stay at nest until able to walk, fed by parents (e.g. Laridae).

Semi-altricials—down-covered, unable to leave nest, fed by parents

1. Eyes open (e.g. Ardeidae, Falconiformes)
2. Eyes closed (e.g. Strigiformes).

Altricials—eyes closed, little or no down, unable to leave nest, fed by parents (e.g. Passeriformes).

Precocial and semi-precocial birds are actually or potentially mobile, while semi-altricial and altricial young are sedentary. Semi-precocial birds are physically well developed, but because of the feeding habits of the adults must stay on or near the nest until fledged. Semi-altricial and altricial young are physically unable to leave the nest, but the former are well provided with down from the start and some are hatched with their eyes open. Only in the first three kinds of precocials are the young not fed by the parents, and only in the first two are they not even shown food. Thus there is a progression from chicks so developed in every respect that they need no parental care to chicks so helpless that they demand prolonged and specialized care.

Fig. 2. Newly hatched Blackbird *Turdus merula*—altricial, nidicolous, psilopaedic, and blind. (*K. Shackleton*).

The newly hatched chick of the domestic fowl has only about 3% of the weight of an adult; yet growth to full size is achieved in a remarkably short time. In some small passerines the period is as short as 10 days. On the other hand, young King Penguins *Aptenodytes patagonicus* hatched late in the season have a period of arrested growth during the winter and may lose half their autumn weight during that time (see PENGUIN).

For characters and behaviour particularly associated with the pullus stage see especially BEHAVIOUR, DEVELOPMENT OF; BROOD-PARASITISM; EGG-TOOTH; FLIGHT, PRECOCIOUS; GROWTH; HATCHING; PARENTAL CARE.

See photo FLIGHTLESSNESS. A.L.T.

Nice, M.M. 1962. Development of behavior in precocial birds. Trans. Linn. Soc. N.Y. 8: 1–211.

YUHINA: substantive name of the species of *Yuhina*, a south-east Asian genus of small BABBLERS.

Z

ZONE: see LIFE ZONES.

ZOOGEOGRAPHICAL SPECIES: a species or superspecies (i.e. group of closely related allopatric species) which for purposes of zoogeographical analysis may be treated as a single unit.

Mayr, E. & Short, L.L. 1970. Species Taxa of North American Birds. Cambridge, Mass.

ZOOGEOGRAPHY, THEORY OF: the description and causal explanation of patterns of geographical distribution of extinct or living animals are the subject matters of zoogeography, a science that has changed considerably since the days of Schmarda (1853) and Wallace (1876). The texts of Darlington (1957), Udvardy (1969) and Pielou (1979) among others reflect both the growth in breadth and the evolution of concepts in zoogeography in a little more than a century. Keast (1977) and Vuilleumier (1975) reviewed the history and development of zoogeography especially from an ornithological perspective.

History. Zoogeography seems to have gone through three major phases. During the first phase the description of zoogeographical regions (Palearctic, Ethiopian, Oriental, Australasian, Neotropical, and Nearctic) and the delimitation of their subdivisions was the main focus of study. This phase is largely a thing of the past now, although the analysis of distribution patterns by means of multivariate statistics has allowed several authors to refine or re-define the older zoogeographical regions, their components or their boundaries. Regions and sub-regions may now be defined by non-arbitrary criteria which permit one to compare similarities or differences in distribution patterns between different taxa within the class AVES or to compare Aves with other animal groups.

The second phase corresponded to the identification of faunas and the determination of faunal elements. An avifauna is the sum of species of birds living in a given geographical area (for instance North America) or ecological zone (the boreal forests). A faunal element is made up of one or more species having a given pattern of geographical origin. Thus the North American avifauna is composed, according to Mayr (1946), of Pantropical, Panboreal, Old World, North American, Pan-American and South American elements. Among the variants of this kind of analysis one may cite the recognition of dispersal centres (Müller 1973) made by plotting the ranges of many species and inferring areas where taxa have originated according to the areas of greatest species density or congruence.

The third phase in the evolution of zoogeography began when general and conceptually simple theories of distribution were used to make specific predictions about geographical distribution. These predictions are verified by checking specific details of distribution. If distributional evidence is contrary to prediction, then the theory is falsified. This rigorous way of using theory and empirical evidence is considered by modern zoogeographers to be much more scientific than previous endeavours. For example the theory of insular or equilibrium zoogeography (MacArthur and Wilson 1967) is derived conceptually from the mathematical theory of birth and death processes in population ecology. Colonization and extinction are two processes that in the absence of SPECIATION (formation of new species) operate against each other and jointly determine the number of species on an island or a patch of habitat, such as a mountain top. A prediction from this theory is that turnover of species (the balance between colonization or immigration and extinction) should occur at certain rates. Empirical validation or invalidation of the equilibrium theory thus hinges in part on the measurement of turnover rates. The practical difficulties of measuring colonization or extinction rates and of calculating turnover rates from them have not so far permitted unequivocal tests of the theory. Some results giving very low or zero values of turnover have been published and could be construed as falsification of the theory.

Contemporary schools of thought. Zoogeography has not, however, evolved smoothly over the years, one phase leading gradually into another. Instead it has developed by leaps and bounds, and the three phases actually overlap largely in time. Zoogeography is a heterogeneous science composed of several contrasting points of view, within three main schools of thought.

The first school of thought corresponds to what some authors call the 'centre of origin' theory. The geographical origin of species or other taxa (for instance genera) is sought and their subsequent distributional history is reconstructed. By analogy with the neo-Darwinian view of evolution this point of view could be called neo-Wallacean because its antecedents can be traced in large part to the work of Wallace. The practitioners of the second school of thought, called 'vicariance biogeography' (Nelson and Rosen 1980) ask similar questions but use a methodology based on a special form of taxonomic analysis (cladism). Whereas in both schools great weight is placed on solid taxonomy as the necessary foundation for zoogeographic analysis, there is no agreement about how the taxonomic work should be carried out. Cladism attempts to classify taxa in a scheme of relationships based on a rigid analysis of taxonomic characters (usually morphological differences between individuals in populations, species, or other categories). Characters are divided into primitive or derived ones and the relative occurrence of each sort among closely related taxa permits one to draw a branching diagram called a cladogram (see CLADISTICS). In vicariance biogeography cladograms are used together with the mapped distributions of the organisms so classified to understand their geographical history. Furthermore, proponents of vicariance biogeography believe that active dispersal of organisms is either unimportant or far less significant in their geographical history than the movements of the land masses on which they live or lived. The movements of land (by continental drift) or of habitat (because of climatic changes through time) thus determined or made up the 'vicariant events' that are the primary causal factor of disjunct distribution patterns. This concept is quite different from the one held by members of the centre of origin school of thought, who envisage dispersal as an extremely important factor in distributional histories. Their view is based in large part on the common observation that modern bird species do not have a static distributional area but instead show either dynamic range expansions (the Cattle Egret *Bubulcus ibis* for instance) or range contractions (see RANGE CHANGES).

The members of the third school of thought, or equilibrium biogeography, not only consider dispersal to be an important factor in zoogeography but try to quantify it together with its opposite force, extinction, to determine the state of equilibrium or disequilibrium of faunas, especially insular ones. The idea that a balance between colonization and extinction influences the species composition of insular faunas did not originate with MacArthur and Wilson, but they expressed this relationship in mathematical models analogous to the differential equations of population dynamics. Their presentation opened the way to numerous studies and produced a revolution in the field of zoogeography.

Plate tectonics as a model of continental evolution have been used by zoogeographers to explain faunal histories (Cracraft 1974). Plate tectonic theory rallies together zoogeographers who otherwise prefer one or the other of the three schools of thought outlined above. Thus vicariance explanations of faunal history have been amalgamated by some workers with plate tectonic history, whereas other authors have used equilibrium models in conjunction with plate tectonic models. However, proponents of the centre of origin school have usually maintained that the history of modern faunal elements does not need plate tectonics, because drift of land masses took place earlier than the evolution of the taxa in the elements.

Future developments. Many of the differences of opinion between the various points of view embodied in the prevailing schools of thought could be resolved if zoogeographers realized more clearly that, although they all work in a framework of space and time, they do not consider the same scales or the same taxonomic levels. Thus in equilibrium biogeography time and space are both very small and populations of species are the biological unit used; in vicariance biogeography time and space are much larger and species or even higher taxonomic categories are considered. There seems little doubt to zoogeographers who study birds in the field that both dispersal and vicariant events are important in determining their ranges.

It seems also clear that several theoretical concepts and several methods can be employed to study zoogeographic problems. A large range of techniques is now available and it should be normal practice to carry out research along several lines. As zoogeography evolves, some of the theories that now seem solid will doubtless be discarded and new methodologies will be invented to permit testing of predictions from new theories. For example, recent advances in the biochemical systematics of birds (using DNA-DNA hybridization or other techniques, such as gel electrophoresis) permit the measurement or estimation of the degree of relatedness between species or genera. Such information should be used in analyses of geographical distribution of these taxa; it will be most interesting to find out whether the conclusions drawn from the older systematics match those obtained from the modern data. The contribution of paleornithology to zoogeography will also be larger in the future. Discoveries of new FOSSIL BIRDS, including both island and mainland taxa, as well as re-evaluations of fossil taxa described long ago have already given us a rich source of information that has hardly been tapped for zoogeographical reconstructions. ZOOLOGICAL RECORD: an annual publication of the Zoological Society of London, the 'Aves' and other sections being obtainable separately. This is an essential tool for keeping abreast of the current literature, or searching the past literature, in any branch of zoology. As complete a list as possible of books and papers published during the year is given alphabetically under authors' names; and there are elaborate indices to this under subject, geographical, and taxonomic heads. The series goes back to 1864; Alfred Newton was the first recorder of the ornithological literature. See also BIBLIOGRAPHY.

ZOOLOGY: the scientific study of animals; as such, one of the main divisions of BIOLOGY. Zoology may be subdivided according to the particular classes of animals under study; thus the study of birds (Class AVES) is a branch of it (see ORNITHOLOGY).

ZOONOSIS: general term (plural 'zoonoses') for any disease naturally transmitted, directly or indirectly, between other vertebrate animals and man. Birds are in some cases the other vertebrate animals concerned; psittacosis (ornithosis) is an example of a zoonosis transmitted directly from birds to man, and some types of virus encephalitis are transmissible from birds to man by an insect or other arthropod vector (see DISEASE; PSITTACOSIS; VECTOR).

Williams, M.C. 1957. Birds in relation to the arthropod-borne virus zoonoses. Ibis 99: 303–306.

ZOSTEROPIDAE: a family of the PASSERIFORMES, suborder Oscines (see WHITE-EYE (1)).

ZOSTEROPS: generic name often used as common name (see WHITE-EYE (1)).

ZUGSCHEIDE: German term, sometimes used in English writings for a 'migratory divide', i.e. a line (or more or less narrow zone) on either side of which the breeding populations of a species migrate in different, divergent directions; best known in the White Stork *Ciconia ciconia*, which has a *Zugscheide* in central Europe, the birds to the west migrating south-west in autumn, and those to the east migrating south-east.

ZUGUNRUHE: German term, sometimes used in English writings, for pre-migratory restlessness (see MIGRATION).

ZWISCHENZUG: German term, difficult to translate, for nomadic movements performed by birds of some species between the breeding season and true migration. 'Between migration' not being a possible expression in the English language, either in grammar or sense, the nearest literal equivalent is probably 'interim movements'.

ZYGAPOPHYSIS: one of the articulating processes of a vertebra (see SKELETON, POST-CRANIAL).

ZYGODACTYL: having two toes directed forwards and two back (see LEG). When toes I and II instead of I and IV are directed backwards, the condition may be called 'heterodactyl'.

ZYGOMATIC ARCH: the bony arch of the cheek (see SKULL).
