GALLIFORMES: an order, alternatively 'Galli', comprising 2 suborders: Galli, Opisthocomi; 4 families: Megapodiidae (MEGAPODE), Cracidae (CURASSOW), Phasianidae (PHEASANT; GROUSE; GUINEAFOWL; TURKEY), Opisthocomidae (HOATZIN). They are often referred to as 'gallinaceous birds', the domestic fowl being a characteristic member; and they are sometimes loosely called GAME-BIRDS, which some of the most familiar species notably are. The order is a cosmopolitan one, but Megapodiidae and Numidinae have restricted distribution in the Old World and the Cracidae, Meleagridinae, and Opisthocomidae in the New; the Tetraoninae are confined to the Northern Hemisphere. Several species have been domesticated and others are often kept in captivity as ornamental birds (see DOMESTICATION).

GALLINACEOUS: resembling a domestic fowl (see GALLIFORMES).

GALLINULE: substantive name of species of *Porphyrio*, *Porphyrula*, and sometimes (alternatively to 'moorhen') *Gallinula* (see RAIL).

GALLITO: substantive name of *Rhinocrypta lanceolata* (see TAPACULO).

GALLOPHEASANT: in the plural, term for *Lophura* spp. (see PHEASANT).

GAME-BIRDS: sometimes used ornithologically to denote the Galliformes, but properly a general term for certain quarry species belonging for the most part to the subfamilies Tetraoninae and Phasianinae (see GROUSE; PHEASANT). In certain parts of the world others of the Galliformes are included, such as turkeys (Meleagridinae), guineafowl (Numidinae), megapodes (Megapodiidae) and guans (Cracidae). Bustards (Otididae) of the order Gruiformes, tinamous (Tinamiformes), and certain 'waders' (Charadrii)—notably snipe and woodcock (Scolopacidae)—are usually regarded as game-birds, although the ducks, geese, and swans (Anatidae) are not (see WILDFOWL); but in New Zealand the introduced Black Swan *Cygnus atratus* and Canada Goose *Branta canadensis* are sometimes referred to as 'game', and 'game ducks' was formerly used for dabbling ducks of the tribe Anatini (see DUCK).

The term 'game' has a legal connotation in Britain, and a game licence is required to shoot Partridge *Perdix perdix*, Pheasant *Phasianus colchicus*, grouse (Red Grouse *Lagopus lagopus* and Ptarmigan *L. mutus*), and 'black game' (Black Grouse *Tetrao tetrix*); bustards *Otis* spp. were also included, anachronistically, in this list until 1954. In addition, the Woodcock *Scolopax rusticola* and snipe *Gallinago* spp., etc., have a more limited status under the game laws, and until 1954 this was true also of the Quail *Coturnix coturnix* and the Corncrake *Crex crex*. The need for special game laws to protect sporting rights originated from the fact that in the common law of England (not Scotland) wild animals in general were nobody's property until brought into possession by killing or capture. In America, game laws have had the object of protecting the birds rather than of preserving enclosure rights (see CONSERVATION).

The shooting of game-birds in most parts of the world consists of 'walking-up' ('jump shooting' is the American phrase), and dogs—setters and pointers—have been bred specially for giving advance warning of crouching game-birds. A more complicated system known as 'driving' was evolved and brought to a high pitch of efficiency in Britain at the end of the 19th century; grouse, pheasant, and partridge 'drives' became and have remained a feature of British country life, and are conducted strictly in accordance with tradition. The breeding and training of dogs for 'pointing', 'setting', and particularly for 'retrieving' wounded birds, is regarded by devotees of the sport as one of the most satisfying aspects of game shooting. P.S.

GAMES THEORY: the mathematical theory of decision making by individuals in circumstances where interests are at least in part conflicting. In the study of bird behaviour, games theory models have been used to analyze questions such as why birds obey conventional signals to settle contests for resources, and why prior residence seems to lead to dominance in territorial combat.

GAMETE: general term for a germ-cell, whether spermatozoon or ovum (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; GENETICS).

GAMOSEMATIC: term for appearance or behaviour that helps members of a pair to find each other.

GANDER: special term for a male GOOSE (1).

GANNET: substantive name for the 3 members (allospecies) of the gannet superspecies—Atlantic, *Sula bassana*, African, *S. capensis*, and Australasian, *S. serrator*—which with the 6 booby species comprise the Sulidae (Pelecaniformes, suborder Pelecani). The 9 species comprise some 17–19 forms, though 6 of the species are monotypic (the 3 polytypics are Masked or White (*Sula dactylatra*), Brown (*S. leucogaster*) and Red-footed Booby (*S. sula*). Sulids are sometimes split into 2 genera, *Morus* (gannets) and *Sula* (boobies).

Characteristics. Gannets and boobies have torpedo-shaped bodies, strong, tapering and slightly hooked bills (no external nostrils) which can gape extremely widely; long, fairly narrow wings and a variable but generally long and wedge-shaped tail. The heaviest sulid (length 90 cm) is the Atlantic Gannet (3,100 g) and the lightest is the Red-footed Booby (940 g). Variable combinations of morphological characters indicate the adaptive radiation which has developed within the family and which relates mainly to their different modes of foraging and feeding, though all plunge-dive deeply. The legs are fairly short and strong, and the feet are webbed between all 4 toes. All adult sulids except the Brown Booby and brown forms of the Red-footed are completely white on belly and breast and the 3 gannets and the Masked Booby are mainly white above. The facial skin, iris, bill and feet may be brightly coloured. All juveniles except Abbott's *Sula abbotti* differ in plumage, varying in degree from adults; the juvenile Atlantic Gannet is mainly black and its parents mainly white. Adult plumage is gained, according to species, in the 3rd to 6th year.

Habitat. Gannets and boobies are so well adapted to life at sea that they can spend long periods without approaching land. Atlantic Gannets nest mainly on cliffs, including precipitous faces; the other 2 gannets nest mainly on flat ground, as do Blue-footed *S. nebouxii* and Masked Boobies. Brown Boobies prefer slopes or semi-cliffs and Peruvian Boobies *S. variegata* utilize cliffs, slopes and flat ground. Red-footed Boobies nest in low scrub or in trees, and Abbott's Booby is restricted to tall jungle trees.

Distribution and populations. Sulids breed from the Arctic (Atlantic Gannets in Norway) almost to the sub-Antarctic (the Australasian Gannet breeds at 46° 36′S). But the boobies are essentially tropical to subtropical, 3 species breeding on islands at these latitudes, across the

Blue-footed Booby *Sula nebouxii*, landing salute. (*J.B.*).

world's oceans. The commonest sulids are undoubtedly the Red-footed and Brown Boobies and the rarest is Abbott's, which is confined to the Indian Ocean Christmas Island. The Peruvian Booby is confined almost entirely to the Guano Islands of the Humboldt current off Peru; the Blue-footed is restricted to 3 areas on the fringes of cold water (Northern Peru and north to Panama; the Galapagos Islands; the Gulf of California and islands off Mexico). Apart from Abbott's Booby, the most accurately censused sulids are the 3 gannets, especially the Atlantic. There are 6 colonies of African Gannets off the southern tip of Africa (some 166,000 pairs at the last census in 1956), approximately 25 colonies and roughly 35,000 pairs of Australasian Gannets and 34 colonies containing some 213,000 pairs of Atlantic Gannets (6 of these colonies, some 33,000 pairs, are in Canada).

Movements. All sulids disperse widely from their breeding stations and the tropical trio may be encountered thousands of kilometres from the nearest land. The Atlantic Gannet is occasionally seen in mid-Atlantic.

The juveniles disperse most widely and in the 3 gannets this movement is a genuine migration which takes virtually all the year's young more than 5,000 km away from their birthplace, to warmer waters. Thus, the E. Atlantic young migrate almost to the Equator off West Africa and those from Canadian colonies to the Gulf of Mexico. The young African Gannets move north as far as the Gulf of Guinea and the Australasian juveniles cross the Tasman Sea mainly to the east and south coasts of Australia. The most stay-at-home is probably the Peruvian Booby, but even it may move thousands of kilometres under certain conditions.

Food. Gannets and boobies eat mainly fish and squid. Of the species for which there is reasonable information (which excludes Abbott's and the Blue-foot) all have both a wide spectrum but also preferred prey. Thus the Atlantic Gannet takes at least 50 species on occasion, but herring *Clupea harengus*, mackerel *Scomber scombrus*, sprat *Sprattus sprattus* and sand-eels *Ammodytes* are probably most important. The trio of tropical boobies all depend heavily on flying fish and squid species; the Peruvian Booby is virtually dependent on the anchovy *Engraulis encrasicholus*, and so on. But probably all are highly opportunistic and will take unusual species or hunt in an unusual manner. Thus, whilst sulids plunge-dive from various heights (up to 45 m in the Atlantic Gannet) they also dive from the surface, pursue prey by underwater swimming and may even hunt on foot in shallow water. Following a plunge, the fish is often taken from beneath as the bird comes up. Even the Atlantic Gannet probably rarely penetrates beyond some 3 m by diving, and perhaps 5–15 m by swimming. Several boobies capture flying fish and squid on the wing. Whilst all sulids (except perhaps Abbott's, for which there is no information) occasionally, or usually, dive in groups which may exceed 1,000 birds, only the Blue-foot is known to co-operate in feeding, by diving synchronously upon a vocalization from a member of the group. This species, and especially the male, also has a marked tendency to plunge-dive into extremely shallow, inshore water. Scavenging is probably not important for any sulid, but is practised by several.

Voice. The Atlantic Gannet's basic call is a rasping *aarah-arrah* given at about 2 calls per second when flying on to the site, and when displaying and (intermittently and with variants) when fighting. Calls given during communal activities (gathering nest material or fishing) are shorter, gruffer but less metallic and quicker. In flight a raven-like *krok krok* is occasionally uttered. During the skypointing display with the bill which precedes and accompanies take-off, a sighing groan, *oo-ah*, is given and is a true vocalization rather than an involuntary expiration caused by the looped-up posture. Individual voices are recognized by mates, neighbours and chicks. The boobies whistle, honk, quack and (Abbott's) call in a deep sonorous bellow.

Breeding and behaviour. All sulids except Abbott's Booby nest in colonies; the largest are those of the Peruvian Booby (up to at least 750,000 pairs) but all except Abbott's may number thousands of pairs. The densest breeding colonies are those of the African Gannet (up to 6.8 nests/m^2). Perhaps the most widely dispersed ground nesting sulid is typically the Masked Booby, which at its densest occupies 3.3 m^2 per pair and has a suggested optimal spacing of 1 pair per 200 m^2. In all the ground-nesting boobies density is much affected by terrain, whereas in the 3 gannets it is relatively inflexible.

All sulids possess a rich repertoire of ritualized behaviour which communicates to fellow members their 'mood' and 'intention'. Thus, upon returning to the colony after a period of sea-wandering, the experienced male breeder typically resumes occupancy of his old site and displays there.

Sulid displays have family characters. Though often complex, their ritualized displays derive from simple movements such as head-shaking, biting or touching the ground or nest material, and so on. In functional terms, display usually substitutes for overt fighting in declaring and preserving the territory (which may be no more than the actual nest site) and in forming and maintaining the pair-bond. Sulids, and especially the 3 gannets, are unusual among seabirds in the extent to which they have developed both of these functional groups of displays, and particularly the pair-bonding ones. There is no courtship feeding. Movement around the territory, and particularly away from the mate, is accompanied by ritualized postures derived from intention-movements. Ritualized appeasement behaviour involves placing the bill in non-attack positions. Comfort behaviour includes oiling, by which the bird transfers the secretion from the preen gland above the roots of the tail feathers to the plumage; various shaking movements; scratching; wing-stretching (never both together) and various forms of heat-regulating movements. These include exposing and excreting on the webs for evaporative cooling, panting and fluttering the throat-skin and hanging the wings loosely away from the body.

Sulids incubate by applying their webs to the egg(s), until these begin to pip at 43–45 days, whereupon they are transferred to the tops of the webs. Egg-shells are not carried away from the nest. The new chick, with but a few sparse tracts of down, is brooded on top of the webs. No sulid chick can regulate its own body temperature until it is about a month old. It takes food directly from the parent's mouth and throat. Later, the chick's begging behaviour varies with species; it is frenzied in the 3 tropical boobies, but highly restrained in the Atlantic Gannet and in Abbott's Booby, in both of which falling from the nest is a major danger.

The detailed breeding ecology of each species of sulid is largely determined by the nature of its food supply. The Peruvian Booby on the doorstep of the prolific Humboldt upwelling rears up to 4 young; the Blue-foot, on the fringes of productive cold water, often rears 2; two of the boobies from impoverished tropical blue-water (the Masked and the Brown) often hatch 2 eggs but the brood is invariably reduced to 1 by sibling-murder; the third tropical booby (the Red-foot) always lays 1 egg. All 3 frequently lose their young by starvation due to the unpredictable food shortages which occur in their relatively unseasonal areas. The 3 gannets all lay one-egg clutches although the Atlantic Gannet, especially, breeds in food-rich waters. However, it (and to a lesser extent its 2 allospecies) invests much of its feeding in the production of young with large fat reserves, since the newly-fledged young are thrown entirely on to their own resources when *c.* 15 weeks old; all the others are fed as free-flying juveniles, the young Abbott's Booby for between 6–12 months.

All sulids except Abbott's Booby are known to be able to rear to fledging one chick from up to 70% of all clutches laid; some can do considerably better. However, among the 3 tropical boobies and Abbott's, breeding success in some areas can fall well below 20%, and although the Peruvian Booby is normally most productive of all, its success can be zero, and the vast majority of adults can die, in (Niño) years in which the upwelling fails and warm water drives the cold-loving anchovies to inaccessible depths.

Responses to the nature of the feeding environment largely determine breeding regime. Thus, Abbott's Booby clearly cannot lay each year, since each cycle occupies far more than 12 months. On the other hand, Brown Boobies on Ascension and Galapagos Blue-footed Boobies may lay only some 9 months apart even when successful; but, typically, sulids lay once a year. The sulid most closely tied to laying at a particular time each year is the Atlantic Gannet, though this time varies by up to 3 weeks even between British colonies.

Sulids breed for the first time at ages ranging from 2–6 years. Some apparently have 'rest' years, when the pair remains together but does not attempt to breed. Atlantic Gannets do not rest in this way. Mortality rate figures lie between 6–10% but are probably lower in some cases. Fidelity to site and mate is very high in the Atlantic Gannet, but much lower in the boobies (possibly excepting Abbott's). Even erstwhile successful pairs of Masked Boobies may split up, though both partners return to the colony and though such divorce tends to reduce breeding success. See photo RITUALIZATION. J.B.N.

GAUSE'S RULE: in 1934 G.F. Gause wrote: 'As a result of competition two similar species scarcely ever occupy similar niches, but displace each other in such a manner that each takes possession of certain peculiar kinds of foods and modes of life in which it has an advantage over its competitor'. Gause's rule is often paraphrased as: 'Species with similar (or the same) ecological niches cannot coexist'; and as its corollary 'Coexisting species differ in their ecology'.

Gause's rule is useful as a general statement: but it is not a testable hypothesis in normal scientific terms, because its reasoning is circular. If species coexist, they must be sufficiently different: if they do not coexist, they are too similar. Unless the terms 'similar' and 'different' can be made more precise, there is no way out of this impasse.

Gause, G.F. 1934. The Struggle for Existence. Baltimore.

GAVIAE: alternative ordinal name (see below); but 'almost from the beginning of systematic Ornithology the word *Gavia* has been used in several senses' (Newton); one of the more recent usages of 'Gaviae' was for an order equivalent to the present suborder Lari of the Charadriiformes.

GAVIIDAE: see below.

GAVIIFORMES: an order, alternatively 'Gaviae', comprising only the Holarctic family Gaviidae (see DIVER). For the question of nomenclature see under COLYMBIDAE.

GENE: see GENETICS.

GENE FLOW: the movement of genes from one population to another, resulting from an individual breeding in a population other than that in which it was born. (In plants, dispersal of pollen or seeds may result in gene flow.)

GENERA: plural of GENUS.

GENERIC NAME: see NOMENCLATURE.

GENETIC DRIFT: change in the frequency of a gene or genes in a population—or, more generally, change in the whole gene-complex—as a result of random processes of reproduction and survival of individuals, independent of NATURAL SELECTION. The importance of genetic drift in evolution has long been a matter of dispute, but it is now generally agreed that it is unlikely to be important except in very small populations.

GENETICS: the study of how characters are passed from parent to offspring, and thus one of the fundamental parts of biology. The basic laws of inheritance were discovered by the Abbot Gregor Mendel (1822–84), but lay unrecognized until their rediscovery in 1900. Relatively little experimental genetic work has been undertaken with birds because of the difficulty of controlling the breeding of many species either in the wild or in captivity.

Simple Mendelian inheritance. It is easiest to begin with the inheritance of simple alternative plumage features such as the presence or absence of bridling in the Guillemot *Uria aalge*, and white or tan crown stripe in the White-throated Sparrow *Zonotrichia albicollis*. These are examples of the simplest system of heredity where the character is inherited as one of two alternative forms. The basic principle in this case is that every individual possesses two factors relating to the character, one of which was inherited from the father and one from the mother. If they are the same, then the individual is said to be 'homozygous', if different then it is said to be 'heterozygous'. A copy of one of the factors is passed on to each of the individual's offspring. We can see how this happens by considering the inheritance of one aspect of coloration in the Budgerigar *Melopsittacus undulatus*. Native Australian Budgerigars are predominantly green, but there is a cage variety that is blue. If we cross a pure-breeding green bird with one from a pure blue stock, the offspring will be 'wild type' green. If some of these individuals are mated together, brother to sister, both wild type and blue forms will be produced in a ratio that will be very close to 3:1 if a large number of progeny are examined.

The explanation is that the green form was pure-bred, and possessed two of the wild-type factors, one received from each of its parents. Its genetic constitution can be designated as the homozygote BB and the blue bird, also pure bred, can be designated as the homozygote bb. These two birds produce ova or sperms each containing a single factor for colour, and the offspring produced by any fertilization of an ovum by a sperm must be the heterozygote Bb. In this example, and many others, the heterozygous individuals closely resemble one of the parents, and are not intermediate between them. Here they resemble the wild-type green parent, a situation described by the statement that the wild-type plumage is 'dominant' to blue plumage, and that blue is 'recessive' to green.

The hereditary factors that are transmitted in the ovum and sperm are called 'genes'. Alternative forms of genes such as the ones giving rise to green or blue plumage are termed 'allelomorphs' or 'alleles' for short. There may of course be many more than two allelic forms of a single gene, but any bird can only carry two of them.

The genetic make-up of an individual is called its 'genotype', while its external appearance is its 'phenotype'. Thus, in the Budgerigar example, the genotypes BB and Bb both give rise to a green phenotype.

When the heterozygous offspring are mated together, each parent can produce two sorts of ova or sperm, one sort carrying B and the other b. However many ova or sperms a bird may produce, half of them will carry each allele, and it is very unusual for the ova and sperms not to fuse at random. This can be shown diagrammatically, as in Fig. 1, where it can be seen that three different genotypes are produced in the next (second filial or F2) generation. Since wild-type is dominant over blue, there are only two phenotypes, the green, including both BB and Bb genotypes, and the blue, including only bb. In this mating, the blue character that had been 'lost' in the F1 generation has reappeared (of course, the gene for blue had not really been lost; its effects were concealed in the heterozygote). This segregation of grandparental types, without con-

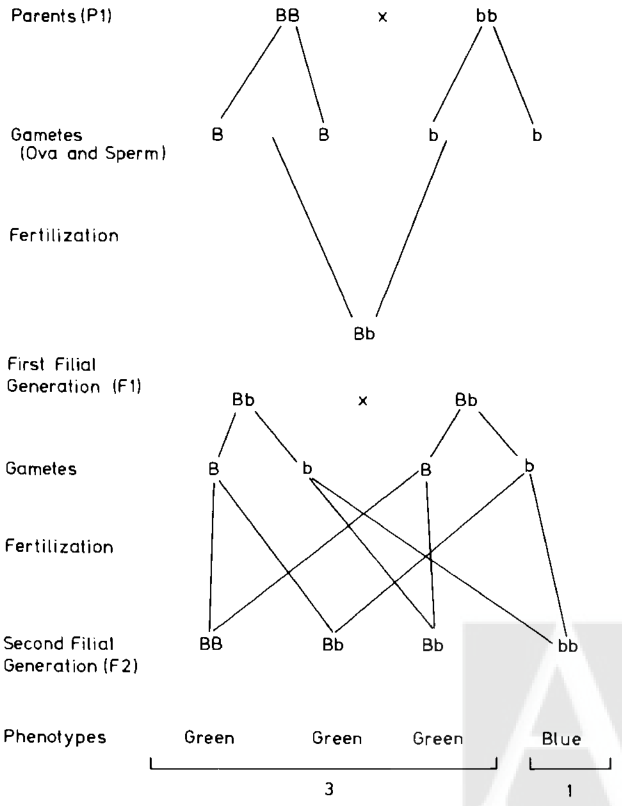

Fig. 1.

tamination or dilution, is one of the fundamental discoveries of genetics. A recessive character may disappear, but its allele still exists, masked by dominance in the heterozygotes, and able to reappear whenever two such heterozygotes mate and produce offspring.

From this example, it is relatively straightforward to see what would happen if one of the heterozygotes were mated with either homozygote. Such a mating is called a 'back-cross' and gives rise to the two parental genotypes in approximately equal numbers. In general, however, the mating of an individual showing the dominant phenotype with a homozygous recessive is called a 'test-cross' because the genotype of the 'dominant' individual can be determined from the resulting progeny. If the recessive phenotype is present among the offspring, then the parent must have been heterozygous. If the offspring are all of the dominant phenotype, then the parent may have been a homozygote. However, this can only be established with certainty if a reasonable number of offspring (say 10 or more) have been produced, for when there are few young a heterozygote could by chance produce nothing but offspring of the dominant phenotype.

The bodies of most animals are made up of many cells each of which contains a nucleus. Within the nucleus are minute thread-like bodies called 'chromosomes'. The genes are carried on these chromosomes, each gene being associated with a definite position or 'locus' on a particular chromosome. A complete set of chromosomes is carried within the ovum and the sperm, so that a fertilized egg carries a double set in which there are two (one from each parent) of each kind of chromosome (excepting the sex chromosome—see below). Normally, all the cells produced by division from the egg during development have a double set each. The nuclear division used by a cell to produce two daughter nuclei each with a double set of chromosomes is called 'mitosis'. However, when the sex cells or 'gametes' are to be produced, there is a special 'reduction division' or 'meiosis' whereby only a single complete set is put into each ripe sperm or ovum. One representative of each pair of chromosomes passes into a single gamete, and as a rule the choice is random from the mixture of grandfather's and grandmother's chromosomes.

If there are two pairs of contrasting characters in a mating, there may be two separate genes each with two alleles. These genes are at separate loci which may or may not be on the same chromosome. If the loci are on separate chromosomes, then the inheritance of the two pairs of alleles proceeds independently of each other.

Returning to the Budgerigar, there is a second locus which also controls colour. Again, a dominant allele at this locus allows the development of a wild-type plumage. The recessive allele in this case, however, produces a yellow bird when it is in the homozygous state. In this case the alleles can be called Y and y, with yy producing the recessive yellow phenotype.

Suppose that two parents with the constitution BB, yy and bb, YY are now crossed. These birds are, respectively, yellow and blue. All of the offspring will be Bb, Yy and thus have a green phenotype. When these birds are 'sib-mated'—i.e. brother to sister—there will simultaneously be two crosses of the same kind as that between the F1 siblings in the first example. The genes will assort independently, and the best way to work out the combination of possible offspring is to tabulate the constitution of possible gametes. Clearly, any individual can produce gametes with alleles B and Y, B and y, b and Y and b and y, since either B or b can occur with Y or y. In male birds, these will be sperms, and in females they will be ova. Thus any one of these combinations can fuse with any other to produce the kinds of zygotes shown in Fig. 2.

		OVA			
		BY	By	bY	by
SPERMS	BY	BBYY Green	BBYy Green	Bb YY Green	Bb Yy Green
	By	BBYy Green	BB yy Yellow	Bb Yy Green	Bb yy Yellow
	bY	Bb YY Green	Bb Yy Green	bb YY Blue	bb Yy Blue
	by	Bb Yy Green	Bb yy Yellow	bb Yy Blue	bb yy White

Fig. 2.

Such a diagram is called a 'Punnet square' after the early geneticist R.C. Punnet. There are clearly many possible genetic constitutions resulting from this cross. If only the genotypes for B and b are counted (Y and y being disregarded), a ratio of 1 BB:2 Bb:1 bb will be found as in the first example. A similar result is obtained if only Y and y are counted. With bb homozygotes producing blue Budgerigars, and yy producing yellows, the proportions of phenotypes from the double cross can be worked out using the table, and they are found to be:

9 B and Y: 3 b and Y: 3 B and y: 1 b and y.

There are actually 9 genotypes, but only 4 phenotypes. The first three are respectively green, blue and yellow. The last, the double recessive homozygote, is in fact white.

It is easy to work out the results of crosses that involve more than two alleles at one locus using the same methods as in the examples above.

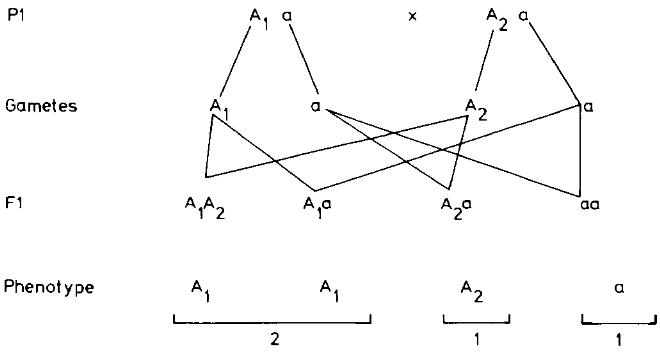

Fig. 3.

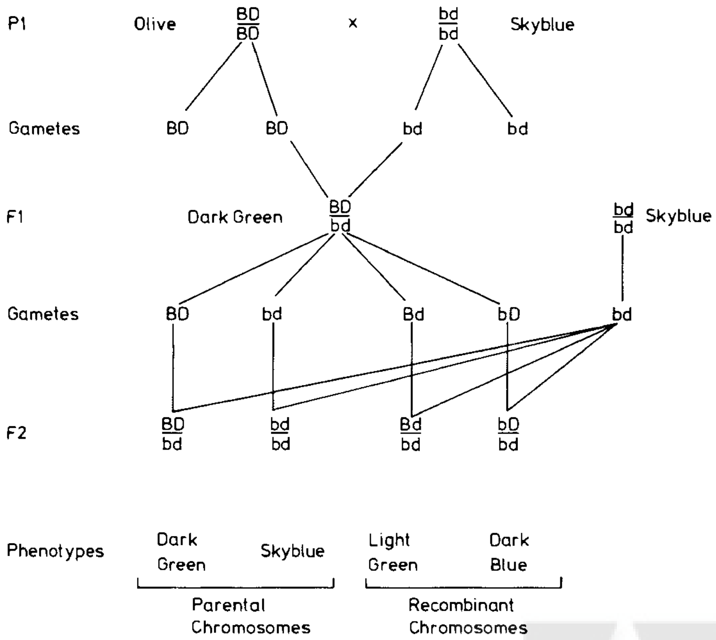

Fig. 4.

Suppose we have a cross that involves three alleles A_1, A_2 and a, in which A_1 is dominant to A_2, and both are dominant to a. If the parents are A_1a and A_2a, then the results of a simple cross are as shown in Fig. 3.

Linkage. It sometimes happens that two or more loci lie on the same chromosome. These are then said to be 'linked', and the rule that the genes assort independently of each other no longer holds. A gene in the Budgerigar has the effect of modifying the action of the wild-type and blue genes, turning light green into dark green or olive and sky blue into cobalt or mauve. Its locus is on the same chromosome as that of the blue gene. This dark gene is also interesting since it has a greater effect when homozygous than when it is present in the heterozygous condition. It is thus said to exhibit intermediate or, to be more precise, an absence of dominance, since the heterozygote Dd is intermediate between the two homozygotes DD and dd.

When an olive bird which is genetically BBDD is crossed with a sky blue bbdd, the offspring are all dark green BbDd. If some of these are backcrossed to sky blues the resulting progeny are as shown in Fig. 4. Because the loci for blue and dark are linked, their alleles do not assort independently. However, linkage is seldom perfect. This is a consequence of the fact that, during the production of eggs and sperms, the chromosomes in the nucleus of their precursor cells come close together in pairs (they have, of course, a double set like almost all the other cells in the body). While the chromosomes lie together in their 'homologous' pairs, they may break and exchange pieces of material (see Fig. 5). Consequently, in the production of some ova or sperms, a process of 'crossing-over' may occur, and a few (or perhaps many) of the crossover classes of gametes may be produced. The closer the two loci lie on the same chromosome, the less likely it is that crossing-over will occur between them. The new combinations of alleles are called recombinants and, in the blue/dark example in Budgerigars, about 14% of the chromosomes produced by the heterozygous parent are recombinant. The results of crossing-over are very consistent, and so maps of the chromosomes have been produced in a few species by observing crossover values and working out in what order the loci are arranged along a chromosome. Perhaps not surprisingly, the best avian genetic map is that of the domestic fowl.

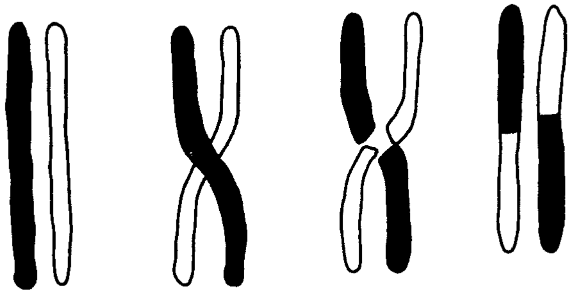

Fig. 5. Diagram to illustrate the interchange of material between the members of a chromosome pair by breakage and recombination.

Quantitative variation. The examples so far quoted all refer to simple alternative characters. However, a considerable amount of variation exists that is of a more continuous nature, such as weight, wing length, tarsal length or clutch-size. This variation is often used for discriminating between subspecies or higher taxa, and the assumption is made that it has some kind of underlying genetic basis. Very little field genetical analysis has been undertaken of such characters in birds, a notable exception being the work of Perrins and Jones (1974) on the inheritance of clutch size in the Great Tit *Parus major.*

Quantitative characters are of particular interest to the poultry industry, and attributes such as egg weight, growth rate and food conversion have been extensively studied. Research indicates that quantitative variation is usually under multi-locus control. Breeding data suggest that a series of loci may be involved, each of which may have several alleles that are individually of rather small effect. Such inheritance has been termed 'polygenic' in the past. Recent studies have suggested that a polygenic locus for one character may be a major locus of large effect for another.

Artificial selection can produce strains of chickens that lay eggs of a larger or smaller size, or that have an increased growth rate or a greater mature body size. The selection presumably acts to produce genotypes that are homozygous for alleles that have the desired phenotypic effect. Interestingly, and perhaps not surprisingly, evidence suggests that the control of egg size and egg number are quite closely related. So it is easier to select for large eggs or larger numbers of eggs than to select for both; presumably limitations are imposed on egg production by the energy metabolism of the bird.

Sex and linkage. The control of sex in most animals is by means of the sex chromosomes. In female birds (but in male mammals and many other vertebrates), the members of one of the chromosome pairs are not identical in appearance; in the male bird or female mammal one of this dissimilar pair is absent and the other is represented twice. In birds, the odd chromosome is called W and the other Z, so that the genetic constitution of females is WZ and of males is ZZ. The W chromosome carries fewer genes and is often largely inert. Since males can mate only with females, every mating in respect of the sex chromosomes is between a heterozygote and a homozygote. Consequently a 1:1 ratio of phenotypes is always produced genetically (although this may be modified somewhat by other factors). The Z chromosome carries genes that affect characters besides the purely sexual ones, and these are then said to be sex-linked. A very few are known on the W chromosome, and such genes may be useful to breeders for sexing young chicks, provided that their effects are seen very early in life. It is also possible that egg colour in the CUCKOO *Cuculus canorus* is controlled by a locus on the W chromosome.

Modification of dominance. It is implied above that a gene may control a character. This, however, is really an oversimplification. The genes that are easiest to work with in genetical investigations are those that always have a definite effect upon a particular character. However, even this apparent independence is achieved by a precise adjustment of some of the other genes themselves, and there is often very considerable modification by genes of each others' action. For example, dominance has been shown in some cases (including genes in the domestic fowl) not to be a property residing in a particular allele, but a result of modifying genes acting upon it. It has been possible to take a stock that is segregating for two alleles, in which the heterozygote is normally intermediate between the two homozygotes (i.e. there is no dominance—see above), and to exercise selection in two lines so as to make one allele dominant over its partner in one line, and recessive to it in the other. Dominance, whether brought about by the action of modifiers, or in other ways, is a device that allows a beneficial allele to express itself even in a single dose, while suppressing a less useful one. It is otherwise remarkable that so many deleterious alleles are recessive, and many geneticists believe that the properties of genes, and of genetic mechanisms such as meiosis or sex, have all evolved through natural selection.

The significance of sexual reproduction. The whole point of sexual reproduction seems to be to pass on to the offspring sufficient genetic information to allow them to survive through to maturity and to breed. It operates by transmitting linked groups of genes in particular allelomorphic states that have by and large been favoured in the past by natural selection. These genes work together to build up the enormously complex systems that comprise an individual, and to adapt it for its role in nature. At the same time, however, the sophisticated process of meiosis and crossing-over allows new combinations of alleles to be developed that might prove superior in performance in the environmental conditions to which they are exposed.

The production of an entirely new inheritable variation is called a 'mutation', and this may occur in one of several ways. For example, one of the constituent parts of the complex biological molecule that forms a gene may actually be lost as a consequence of radiation damage. Alternatively, an extra piece of material may be inserted inside a gene, or a part of it may be replaced by a different fragment. It has become clear recently that crossing over can even occur within individual genes, again possibly producing novel allelic forms.

New arrangements, whether of genes or chromosomes, are not in general likely to be advantageous if their effects are at all considerable; the chances of a sudden large random change in a delicate and complex organism being actually beneficial are very slight. Consequently, mutation rates need to be kept very low (one of the dangers of atomic radiation is that it raises mutation rates), or the individual or population may suffer serious damage. But a slow trickle of mutations maintains variability, and allows the species the possibility of adapting to changing conditions.

Genetical study in the field. Birds are not particularly suitable material for genetical research, because of the length of their generations, and because of the difficulty and expense of maintaining breeding stocks in captivity. The majority of research has concerned the analysis of phenotypic variation between populations, without troubling too much about its genetic basis. However, distinct characters, controlled by one or a few genes, occur in a number of species and the study of these can often illuminate the evolution of a species or species group. Since most birds lay a fair number of eggs, it is possible to determine the genetic control of such characters from field observations of matings and progeny without excessive labour. This type of variation has been studied extensively in some species, and gives useful information about many aspects of avian biology.

One question that can be studied in the field is the amount of genetic variation in nature, or what proportion of loci have multiple allelic forms in a population? Recent developments in biochemical genetics have allowed an approach to this question, for it transpires that many enzymes can be analyzed by a technique called gel electrophoresis. Essentially, this process separates enzyme molecules according to various physicochemical properties, and allows the detection of variant forms. The application of electrophoresis to species such as American thrushes and the House Sparrow *Passer domesticus* suggests that about 10–20% of enzyme loci may be polymorphic. The discovery of this variation, which is of a similar frequency to that in other homeotherms, allows an assessment of the similarity of populations at a genic level, as opposed to the more traditional approach of measuring the means and variance of quantitative phenotypes. GENETIC SEQUENCE: see DNA-DNA HYBRIDIZATION.

GENITAL SYSTEM: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

GENOTYPE: the group in which an individual falls by reason of its genetic constitution (compare PHENOTYPE). The term was at one time misapplied (also 'generitype', 'generotype') in ornithological nomenclature to the type species of a genus (see TYPE SPECIES).

GENS: literally 'race' (plural 'gentes'); has been used in various contexts for infrasubspecific categories, and especially for the divisions of the European Cuckoo *Cuculus canorus* population that lay eggs of particular colours; also 'a chronological series of populations forming a single evolutionary lineage (divisible into palaeospecies) and biospecifically separated at any time from its closest relatives' (Cain); see EVOLUTION.

GENUS: a taxonomic category representing a grouping of species; also a particular example or (plural 'genera') examples of that category. In Mayr's words, a genus is 'a systematic category including one species or a group of species of presumably common phylogenetic origin, which is separated from other similar units by a decided gap'. The category is a primary one in nomenclature, in that it is obligatory that every species should be placed in a genus. If there is only one species in the genus, the latter is 'monotypic'; if there are two or more species, these are said to be 'congeneric'. The name of the genus (which must be unique in the Animal Kingdom, a matter in which the *Nomenclator Zoologicus* is helpful) constitutes the first word of the scientific name (binomen or trinomen) of an included species or subspecies. Every genus has a 'type species'; and a genus may itself be the type of a higher taxon. See NOMENCLATURE; SPECIES; TAXON; TYPE GENUS; TYPE SPECIES.

The genus is a purely subjective concept, and taxonomists vary widely in the standards of difference that they regard as calling for generic separation. The original Linnaean genus was a broad category; and the general tendency now seems to be a swing back for some distance in that direction. This follows an era during which many authors have indulged in a great deal of splitting of genera in accordance with their own standards of difference and ideas of relationship. Apart from this, but accentuated by it, has been the transfer of species from one genus to another in the light of new information or changing views. Unfortunately, all these revisions involve changes in the naming of species—a notable defect of the binominal system. For this reason it is sometimes necessary to show a discarded but familiar generic name in parenthesis.

Subgenus. A genus may be divided into subgenera where the included species appear to fall into well-marked groups; but the subgenus is not a primary category. Taxonomists who use narrow genera naturally have little occasion for such subdivision; in wider genera it serves to express ideas about interspecific relationships, with the advantage that it does not affect the names of species. For particular purposes, however, a subgeneric name may be shown in parenthesis after the generic name in a binomen or trinomen. In each divided genus, one of the subgenera is 'nominotypical', having the same type species as the genus and a name identical with the generic name. A category of 'superspecies' may be interpolated between subgenus and species, but this has no nomenclatural status (see SUPERSPECIES; also SPECIES GROUP (2)).

Neave, S.A. 1939–40, 1950. Nomenclator Zoologicus (Index of generic and subgeneric names in the Animal Kingdom proposed from 1758 onwards), vols. 1–4 and 5. 1966, Vol. 6 (Edwards, M.A. & Hopwood, A.T. eds.) covering 1946–1955. London.

GENUS GROUP: with reference to the ranks of taxa, term embracing genus and subgenus (see NOMENCLATURE).

GEOGRAPHICAL DISTRIBUTION: see DISTRIBUTION, GEOGRAPHICAL.

GEOGRAPHICAL VARIATION: see CLINE; SUBSPECIES.

GEOLOGICAL FACTORS: those relating to the history of the earth's surface as far as they are relevant to the distribution and evolution of the biota (specifically birds). Chief among such geological factors are (a) palaeogeographic changes in the distribution of land and sea and (b) changes of climate and vegetation on the continents since the Cretaceous period (when birds began to occupy many areas of the world). Palaeogeographic changes in the distribution of land and sea were caused by

—vertical movements of portions of the earth's crust either on a broad and fairly gentle scale (epeirogenesis) or on a regionally more restricted and violent scale (mountain building [=orogenesis] and vulcanism),

—lateral movements of the earth's crust due to continental rifting and drift, or

—changes in world sea-level unrelated to vertical movements of the land.

Paleogeographic changes in the distribution of vegetation zones due to changes in the palaeoclimate were caused, e.g., by

—rain shadow effects on the leeward side of rising mountain ranges,

—drift of a continent into or across latitudes with a different climatic regime, or

—periods of glaciation such as those during the Quaternary.

Changes in the distribution of land and sea. Rather gentle, large-scale vertical movements of portions of the continents led to the repeated invasion (and later retreat) of the oceans when varyingly extensive epicontinental seas were formed (which later disappeared again). Continental coastlines in, e.g., Europe and America, differed conspicuously from those of today during the Cretaceous and Tertiary periods when representatives of many extant families of birds were evolving. Populations of land birds were repeatedly isolated on extensive islands and later reconnected through changing coastlines. The large mountain systems of the Alps to the Himalayas and of the Andes-Rocky Mountains developed during the Cretaceous and Tertiary periods from fairly narrow sedimentary basins covered by shallow seas. These mountains rose above sea-level as strings of islands which became connected and were increasingly uplifted through compression, folding and faulting of geological strata (orogenesis), often associated with vulcanism. The movements continued from the Tertiary into Pleistocene and Recent times as indicated by uplifted river terraces, tilted or faulted gravel and fan deposits, and heavy earthquakes. Oceanic vulcanism led to the formation of islands and archipelagos through the build-up of volcanos from the ocean floor which reached the surface of the sea. Such 'oceanic' islands never had any connection with a continent and must have received their flora and fauna across the water (in contrast to 'continental' islands formed by the disappearance of a previous land connection).

Until some 25 years ago the majority of earth scientists accepted the existence of temporary landbridges between certain continents, but denied the former direct connection and later separation and drift of continents (as proposed by Alfred Wegener toward the beginning of this century). However, the collection of new geoscientific data, particularly over the ocean basins, during the last two decades led to the formulation of the concept of Plate Tectonics or New Global Tectonics which offers a unifying interpretation of observable geologic features on a global scale. Basically, several large rigid plates or spherical caps of the earth's crust are supposedly moved relative to one another by convection currents in the underlying mantle. The main phenomena and interactions assumed are (1) extensional zones where plates originate and move away from 'spreading centres', mostly oceanic rift systems, (2) faults where plates move past each other along vertical shears, and (3) compressional zones where plates are thrust under adjoining plates along 'subduction zones', which are usually associated with deep sea trenches. Continents represent the lighter (upper) portion of the crustal plates and are assumed to be rafted passively over the surface of the globe together with the denser lower crustal layer that forms the 'oceanic basement'. The margins of the continents may or may not coincide with plate boundaries.

The history of the continents started in the Triassic period (200 million years ago) when the previous supercontinent (Pangaea) separated into southern Gondwana and northern Laurasia; subsequently, Gondwana split into a western portion (Africa + South America) and an eastern portion (Australia + Antarctica). The opening of the South Atlantic began in the late Jurassic and early Cretaceous. Portions of present tropical South America and western Africa were in rather close proximity into late Cretaceous times, when the east/west directed coastlines passed by each other. The proto-Antilles may have provided a discontinuous connection between North and South America during the early Cretaceous and later were relatively displaced eastward (due to westward drift of North and South America) to form the Greater Antilles. A Tertiary volcanic arc in southern Central America was progressively more uplifted until a continuous landbridge through Panamá was eventually formed during the late Pliocene only about 3 million years ago. Separation of North America and Eurasia commenced in the late Cretaceous but was not complete until the early Eocene. Australia did not separate from Antarctica until the earliest Eocene or latest Paleocene. India probably began a northward drift from a previous connection with Madagascar–Africa–Antarctica in the middle Cretaceous and collided with Asia during the Eocene.

Since many bird families originated in the Cretaceous, these families were in existence when most of the southern continents were still more or less interconnected and when the high latitudes had equable climates. Study of the higher taxa of birds may indicate an influence of the late Mesozoic palaeogeography on avian evolution. Most families of passerine birds and many Recent genera originated during the middle and late Tertiary when the configuration of the continental land masses was approaching that of the present time.

World sea-level fell and rose during the glacial and interglacial periods of the Pleistocene, respectively, when large amounts of water were alternately tied up in the polar ice caps and again released into the oceans. During the glacial periods, world sea-level was about 80–100 m lower than today, thus joining many islands on the continental shelves with the mainland. These connections were again severed and extensive present coastal lowlands flooded when sea-level rose during a following interglacial. High stands of interglacial world sea-level compared to present sea-level ranged between +60 m during the Günz/Mindel interglacial and +17 m during the Riss/Würm interglacial periods.

Changes of climate and vegetation. Rising mountain ranges often caused a change of climate over the lowlands on the leeward side through a 'rainshadow effect'. Thus forests retreated northward in temperate South America during the second half of the Tertiary when the Andes were gradually uplifted and the climate became cooler and drier. With the uplift of the Himalayas from the Miocene onward, climates were altered in some surrounding areas, causing severe aridity in places. Climatic changes observed in some areas, e.g. Australia or India, during the Tertiary may have been due to the drift of these continents into latitudes with a different climatic regime.

The Pleistocene fluctuations of world climate led to alternating advances of the polar ice caps into middle latitudes and retreats to their present position (and beyond). Montane glaciers extended during cold periods and covered many mountains in the temperate zones and in the tropics. Polar steppe and tundra vegetation in front of the glacial north-polar ice sheet extended through central Asia and Europe to Britain and across North America. In the Mediterranean area, cool steppes had a wide distribution during full glacial times. Because of the cool–arid climate of the glacial periods, forests and forested steppes were restricted to the base or lower slopes of some mountain ranges in the western Iberian Peninsula, in Italy, and in the Balkan Peninsula. Isolated forest areas (forest 'refugia') also existed in the Caucasian region, along the base and lower slopes of the Tianshan Mountains, in south–central Siberia as well as in other portions of eastern Asia. Similarly, isolated forest regions existed in various portions of North America (southeastern United States, California, Mexico, Alaska).

Four main glacial/interglacial cycles during the Pleistocene are recognized with many smaller climatic cycles superimposed. The deterioration of the Cenozoic world climate commenced with glaciations which occurred in the polar regions during the Miocene and Pliocene, gradually influencing the climate of the temperate zones and eventually affecting also the tropical latitudes during the Pleistocene.

For several decades many scientists assumed that the Pleistocene climatic fluctuations did not influence the tropical lowlands to any major degree. The rainforest and savanna flora and fauna of tropical South America, Africa and south-east Asia supposedly survived in an equable climate relatively unchanged since Tertiary times. Intensified fieldwork during the last 20 years has shown the concept of environmental stability in the tropics during the Quaternary to be incorrect. Although the temperature fluctuations in the equatorial lowlands were rather small (3–5°C lower than today during glacial maxima), alternating dry and humid climatic periods led to vast changes in the distribution of forest and savanna vegetation. Forests expanded during humid periods and survived in restricted 'refugia' during dry periods; the opposite was true for savanna regions.

Data for a reconstruction of the history of the distribution of tropical vegetation during the last 2 million years come from several different sources: from geological investigations of Pleistocene and post-Pleistocene deposits, from geomorphological interpretations of extant landforms, from analyses of the pollen content of Quaternary strata and from palaeoclimatological modelling and interpretations. Field data are available from only a few study areas in the vast tropical lowlands and many additional surveys are needed to substantiate the basic model of environmental changes and, especially, to map the details of vegetational changes during each of the numerous climatic periods. Their correlation with the glacial and interglacial periods of mid-latitudes is not well established, although the maxima of dry periods probably coincided with the glacial maxima and pronounced humid periods correlated with the peak of the interglacial periods. A number of ecological refugia during adverse climatic periods have been mapped in tropical South America, Africa and in Australia; they have been interpreted as dispersal centres of plants and animals during the post-Pleistocene.

Tectonic or palaeoecological events during the geological history of a particular region led to the separation of portions of the avifauna and later permitted all or part of the species to rejoin their ranges. In a historic–biogeographical analysis of a fauna, attempts are made to relate the origin of extant species and their distribution areas (or of biogeographical features such as secondary contact zones) to particular events or processes during the geological history of the region studied. It is especially difficult to judge the relative importance of ancient and modern causes of particular patterns of differentiation and distribution. For example: how many of the extant species originated in Pleistocene refugia during periods of geographic isolation and how many merely survived in these refugia having originated earlier during the Tertiary through an isolating event caused by some other geological process? If a cluster of secondary contact zones of birds cannot be correlated with any geological feature in the area (e.g. narrow zones of uplift and subsidence, because the contact zones cross the geological units at right angles; or the zoological contact zones are located over a uniform and geologically stable unit, such as a basement shield) then it is unlikely that the processes responsible for the formation of the geological features and those which led to the formation of the contact zones are causally related. If conspecific populations of an upland bird species inhabit mountains with independent geological histories, dispersal of this species from one mountain region where the species originated to the other mountain must be assumed to have occurred (either through the intervening lowlands or by flying, 'hopping', across the lowland barrier); it is very unlikely that the same montane species could have been differentiated from a common lowland ancestor independently several times in these isolated mountain regions. In this example the known independent geological origin (uplift) of the presently isolated mountains rules out the alternative interpretation of a previously continuous species population on a continuous mountain range, which was later subdivided into isolated units through partial subsidence and/or differential erosion. Also, decrease of temperatures in the tropical lowlands during Pleistocene glacial phases was insufficient to have permitted the formation of a continuous lowland population of the montane species (which might have retreated upslope on the isolated mountains during a following warmer interglacial period).

Accepting these premises, a number of montane hummingbirds, toucans, trogons, antbirds, finches and tanagers which inhabit the Andes and the table mountains of southern Venezuela at a distance of over 500 km must have originated in one of these two montane regions (the majority probably in the Andes) and later dispersed to the other mountains, colonizing them like 'islands' in the 'sea' of the tropical lowlands. The widening of the Amazon basin during the early Tertiary separated the fauna of the ancient land area to the north (Guayana Shield) from that of the Brazilian Shield to the south. This event may have isolated the ancestors of certain contemporary birds which, mostly as monotypic genera, survive in the area of the Guayana Shield (*Rupicola rupicola*, *Perissocephalus tricolor* and others) and of the Brazilian Shield (*Rhea americana*, *Cariama cristata*, *Chunga burmeisteri* and others). A large number of extant bird species and subspecies of the tropics and of higher latitudes probably originated in ecological refugia (forest and nonforest) which repeatedly resulted from recurrent climatic–vegetational changes of the last 2 million years (Quaternary period), e.g. the following European species and subspecies pairs (in each case the western representative is listed first): Carrion Crow *Corvus corone corone* and Hooded Crow *C. c. cornix*, Nightingale *Luscinia megarhynchos* and Thrush Nightingale *L. luscinia*, Blue Tit *Parus caeruleus* and Azure Tit *P. cyanus*, Short-toed Treecreeper *Certhia brachydactyla* and Treecreeper *C. familiaris*, and many other pairs. GEOSPIZINAE: see DARWIN'S FINCHES.

GERM-CELL: a gamete (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

GERMINAL VESICLE: the nucleus of the ovum (see DEVELOPMENT, EMBRYONIC; EGG).

GERYGONE: see WARBLERS, AUSTRALIAN.

GIBBER-BIRD: *Ashbyia lovensis*, one of the Australian chats (see CHAT (3)).

GILL-SLIT: see DEVELOPMENT, EMBRYONIC.

GIZZARD: the ventriculus (see ALIMENTARY SYSTEM).

GLACIATION: see GEOLOGICAL FACTORS.

GLADIATOR: name, alternatively 'Gladiator Shrike', of *Malaconotus blanchoti*, and also of the rare *M. gladiator* (see SHRIKE).

GLAND: a secretory organ. Some glands discharge their secretions through openings or ducts, e.g., those associated with digestion—see ALIMENTARY SYSTEM; the secretions of others are internal, i.e., absorbed into the blood stream (hormones)—see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM. The body-surface of birds has few glands (see OIL GLAND; SKIN).

GLAND, SALIVARY: see ALIMENTARY SYSTEM; PALATE; TONGUE.

GLAREOLIDAE: see under CHARADRIIFORMES. There are 2 subfamilies, Glareolinae (see PRATINCOLE), and Cursoriinae (see COURSER).

GLAREOLOIDEA: see under CHARADRIIFORMES.

GLEDE: old name (also spelt 'glead' and 'gled') in Britain for the Kite *Milvus milvus* (see under HAWK).

GLENOID CAVITY: articulation of the head of the humerus with the pectoral girdle (see SKELETON, POST-CRANIAL).

GLIDING: see FLIGHT.

GLOGER'S RULE: that, in a given species, races in warm and humid areas are apt to be more heavily pigmented than those in cool and dry areas (see ENERGETICS).

GLOMERULUS: part of a nephron (excretory unit of a kidney)—see EXCRETORY SYSTEM.

GLOTTIS: see RESPIRATORY SYSTEM.

GLYCOGEN: see LIVER; METABOLISM.

GNATCATCHER: substantive name of species of the subfamily Polioptilinae of the Sylviidae (Passeriformes, suborder Oscines); in the plural, general term for the subfamily. The Neotropical 'gnatwrens' (*Microbates* spp., *Ramphocaenus* sp.) have arbitrarily been placed in this subfamily but it is possible that their closest affinity is with some other Old World group. The gnatcatchers are distinctive, containing *c.* 8 species that are all placed in the genus *Polioptila*.

Characteristics. Gnatcatchers are tiny birds (ranging from 10–12 cm in length and usually weighing less than 7 g) with long tails and slender bills. Most have pale blue-grey backs, white undersides, and a black tail edged by white outer feathers. The Slate-throated Gnatcatcher *P. schistaceigula* departs furthest from this pattern; it has a darker back and throat and lacks white in the tail. During the breeding season, the males of most species can be distinguished from females by the presence of black markings on the head.

Habitat. Gnatcatchers are typically found in woody, broad-leaved vegetation where the canopy is deep and broken into discrete clumps. These characteristic features of the habitat are provided by a broad array of environments, including desert scrub, dry woodland, cypress swamp, tropical second growth, and, within dense forests, by the edges formed around windfalls and along the crowns of trees that tower above their neighbours.

Distribution and movements. The group is restricted to the warmer regions of the New World. The northernmost populations of the Blue-grey Gnatcatcher *P. caerulea* occur in northern California, Minnesota, and New England during the breeding season and in the southern United States during the winter. This is the only species to undertake extensive migrations. The southernmost species, the Masked Gnatcatcher *P. dumicola*, breeds as far south as Buenos Aires, Argentina.

Food. The diet consists of small insects and spiders. Foraging gnatcatchers are extremely active; as they flit from twig to twig, they move the tail in wide jerks. Even though they pick much of their prey off the surfaces of leaves and twigs, feeding is a strenuous activity for these tiny predators because they must hover to reach many of the insects they spot. Frequently they rush and tumble after insects they have flushed and sally out, flycatcher fashion, to snatch flying insects. Gnatcatchers do not manipulate objects with the foot, so they subdue large prey by thrashing and wiping them against the perch.

Behaviour and voice. Each breeding pair defends a territory (*c.* 1–3 ha in extent) against all other adults. Members of a pair maintain contact with each other by giving *speee* calls every minute or so. These calls, which are usually what first draws an observer's attention, have a sibilant quality, difficult to describe, that is characteristic of all the species. Gnatcatcher songs are relatively faint and are composed of a variable series of brief phrases.

Breeding. Nests are open cups placed above the ground where the bottom and a sector of the wall can be attached to woody surfaces. Gnatcatchers incorporate much spider web in their nests; this sticky material is used to bind the nest to its supports and to attach the bits of lichen that usually cover the outer walls. Blue-grey Gnatcatchers and Black-tailed Gnatcatchers *P. melanura* frequently reuse material from their previous nests. This habit, which serves to speed construction of a new nest, may also foster the infestations of mites that plague some broods. Both sexes build the nest, although the male may do most of the work if the female is occupied feeding fledglings from a previous brood.

Both parents commit a similar effort to incubation and to feeding the young. Clutches contain 3–5 eggs. The incubation period is 13–15 days and the nestlings normally leave the nest after 11–14 days. Typical feeding rates to a brood of older nestlings are 30–40 visits per hour. Fledglings of the Blue-grey Gnatcatcher depend on the adults for the bulk of their food until about the 16th day after leaving the nest but strike out on their own after the 3rd week. GNATEATER: substantive name of the species of *Conopophaga* (Passeriformes, suborder Deutero-Oscines) (alternatively 'antpipit', but this name is best restricted to *Corythopis* spp.—see ANTPIPIT), now included in the ANTBIRD family but formerly placed with *Corythopis* in a separate family Conopophagidae.

The principal morphological characters of the gnateaters (skull, sternum, syrinx and pterylosis) were studied in detail only recently, and proved to lie within the wide range of variation found in the Formicariidae, as that family is now understood. In spite of this, it is obvious that gnateaters differ outstandingly from the other antbirds. This is immediately evident from their general appearance and behaviour, and is confirmed by morphological features such as the structure of the skull, the form of the bill, and the presence of sound-producing flight feathers in the male in certain species. There is no similarity with the antpittas (*Grallaria*, *Hylopezus*, etc.), but a certain resemblance to *Myrmoborus*. There are also several similarities with the tapaculos in structure (sternum, coracoid, scapula, pelvis) and in behaviour.

Characteristics. The 9 species of *Conopophaga* are rotund 'neck-less' little birds (*c.* 14 cm long) with long, thin legs and long toes, rounded wings, short soft tail, and body thickly covered with long feathers. Their shape, and in some cases colour, is reminiscent of the Robin *Erithacus rubecula* of Europe, but they are bigger and heavier. Behind the eye there is a slightly protruding tuft of rather elongated silky feathers, frequently of a brilliant white, normally more or less hidden but puffed out when the bird is excited and then strikingly visible. The sexes are usually quite differently coloured.

Habitat, behaviour and voice. Gnateaters live in pairs in shrubby habitats and forest undergrowth, for much of the time perching on low branches where they stay motionless for a long time and are easily overlooked. They drop to the ground to pick up an insect, then fly to another perch. On the ground they move little, but occasionally hop and sometimes scratch, not unlike a tapaculo *Scytalopus*. The name 'cuspidor' (spitter), used in south-eastern Brazil, refers to the short, rasping alarm note. Generally they are silent.

Distribution and breeding. The Rufous Gnateater *C. lineata*, distributed from Brazil to Paraguay and northern Argentina, is about 14 cm long (weight 21 g), generally earth-brown in colour with a rusty foreneck and nearly white belly; the post-ocular tuft is white in the male and grey in the female. During the breeding season, towards the end of the calendar year, the male emits a simple whistling melody ending in a few lower and more accentuated notes. In the dusk the male persistently flies around his territory, sometimes quite high up, producing a surprisingly loud rattling noise with the wings. The outer primaries (5th to 9th, especially 8th and 9th) are apically enlarged (i.e. the opposite of attenuated), and are evidently under the bird's control, as the sound is made only at the time of pair-formation and only in a certain degree of darkness. The female's wing is normally shaped and her flight is always silent.

The nest of this species is placed on a firm base in low vegetation close to the ground; it is bowl-shaped, open at the top, neatly constructed of large dry leaves and lined with fibres. The 2 eggs are yellowish with light brown, partly smudged spots, especially towards the broad end.

In the Black-cheeked Gnateater *C. melanops* of Brazil the male has a cinnamon crown, the sides of the head black, and the underparts ash-grey and white; the female resembles that of *C. lineata*. It has a full melodious song that ascends in a long drawn-out scale, also the alarm note mentioned above. The nest and eggs are similar to those of *C. lineata*; the sexes seem to share in incubation and, if disturbed at the nest, the parent leaves, feigning injury. H.S.

Sick, H. 1965. Sons emitidos pelas aves independentemente do órgão vócal; o caso de *Conopophaga lineata* (Wied). An. Acad. Bras. Ciênc. 37: 131–140.

Snethlage, E. & Schreiner, K. 1929. Beiträge zur brasilianischen Oologie. Verh. VI Int. Orn. Kongr. Kopenhagen 1926: 576–640.

GNATHOTHECA: term sometimes applied to the part of the rhamphotheca covering the lower mandible (see BILL).

GNATWREN: see under GNATCATCHER.

GOAL-ORIENTATION: term proposed by Lack and Williamson for the directing of flight to compensate for lateral displacement, so that the normal goal is reached; distinguished from 'one-directional navigation', in which flight is directed on a constant heading without compensating for drift, diversion, or artificial displacement (see MIGRATION; NAVIGATION).

GOATSUCKER: now mainly in American usage; in the plural, an alternative general term for the Caprimulgidae and more particularly for the nominotypical subfamily (see NIGHTJAR).

GO-AWAY-BIRD substantive name of some species of Musophagidae (see TURACO).

GOBBLING GROUND: special term in North America for the social display ground of the Lesser Prairie Chicken *Tympanuchus pallidicinctus* (see GROUSE; LEK).

GODWIT: substantive name of *Limosa* spp. (see under SANDPIPER). See photo COMFORT BEHAVIOUR.

GOLDCREST: name (formerly 'Golden-crested Wren', a misnomer) of *Regulus regulus* (see WARBLER (1)).

GOLDENEYE: substantive name of *Bucephala* spp.; used without qualification, in Britain, for *B. clangula* (see DUCK).

GOLDENTAIL: *Hylocharis eliciae* (for family see HUMMINGBIRD).

GOLDENTHROAT: substantive name of *Polytmus guainumbi* and *Smaragdites theresiae* (for family see HUMMINGBIRD).

GOLDFINCH: substantive name of some *Carduelis* or '*Spinus*' spp.; used without qualification, in Britain, for *C. carduelis* (see FINCH).

GONAD: general term for the primary sex organs, testes (paired) in the male and ovary (single) in the female (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

GONOLEK: substantive name of some *Laniarius* spp. (see SHRIKE).

GONYS: the ridge formed by the junction of the two rami of the lower mandible near its tip (see BILL).

GOOSANDER: name used in Britain for *Mergus merganser*, in North America called 'Common Merganser' (see DUCK).

GOOSE (1): substantive name (plural 'geese') of many species of Anatidae; the 'true geese' are placed, with the swans, in the tribe Anserini of the subfamily Anserinae, but the name is also used in 3 other tribes (and both other subfamilies) in such a way that 'ducks' and 'geese' cannot be taxonomically separated (see DUCK). Ornithologically, 'goose' is applied irrespective of sex, but one usage restricts it to the female in contradistinction to the 'gander' or male; the diminutive 'gosling' is used for the young.

GOOSE (2): misnomer sometimes (not in current ornithological usage) applied to certain large sea birds unrelated to the geese, as 'Solan Goose' for *Sula bassana* (see GANNET), and 'Ember Goose' or 'Immer Goose' for *Gavia immer* (see DIVER).

GORGET: a band of colour, in some plumage patterns, on the throat or upper breast.

GOSHAWK: substantive name of *Accipiter gentilis* and nearly related congeners; also of the chanting goshawks *Melierax* spp. and the Gabar Goshawk *Micronisus gabar* (see HAWK).

GOSLING: special term for a young (not full-grown) GOOSE (1).

GOURINAE: see PIGEON.

GRACKLE: substantive name of species in several genera (*Quiscalus*, etc.) of Icteridae (see ORIOLE (2)); also, sometimes applied in Asia to mynahs of the genus *Gracula* (see STARLING).

GRALLAE: the fourth avian order of Linnaeus, but later used in a restricted sense for an order approximating to the Gruiformes.

GRALLINIDAE: a family of PASSERIFORMES, suborder Oscines; MAGPIE-LARK.

GRAMINIVOROUS: feeding on grass.

GRANDALA: generic name used as substantive name of *Grandala coelicolor* (for subfamily see THRUSH).

GRANIVOROUS: feeding on grain or seeds.

GRANULATE: covered with small tubercles, as on the podothecae of some birds (see LEG).

GRASSBIRD: substantive name, in Australia, of *Megalurus* spp. (see WARBLER (1)).

GRASSFINCH: in the plural, general term for a tribe (Erythrurini) of the Estrildidae (see ESTRILDID FINCH). Also, 'Grassfinch' is used sometimes in America as substantive name of *Sicalis* spp. (for family see FINCH).

GRASSQUIT: substantive name of species of *Tiaris*, *Volatinia* and *Loxipasser* (for family see FINCH).

GRASSWREN: substantive name of Maluridae spp. (see WREN (2)).

GREATER COVERTS: see TOPOGRAPHY.

GREBE: substantive name for all species of the Podicipedidae, sole family of the Podicipediformes; in the plural general term for both family and order. Grebes are an isolated, closely homogeneous group of diving, foot-propelled waterbirds. Taking the ornithologically convenient view, there are 22 species of recent grebes in 8 genera, though 20 species in 6 genera were recognized in the latest review.

Characteristics. Grebes vary from *c.* 23 cm to *c.* 76 cm in length and from less than 150 g to nearly 1,500 g in weight. All have thick waterproof plumage of up to 20,000 feathers, those on the underparts being particularly dense. The tufted oil-gland is well developed. The sexes look alike though males tend to be brighter, also bigger, with longer bills. Non-breeding plumages are usually counter-shaded: brown, blackish or grey above, and white or whitish below. Many show white on the wing. In breeding plumage grebes develop special colours, markings or plumes above; some also remain white below, but others become more mottled, even showing no white at all. The grebes that are really plumed—mostly in the genera *Rollandia*, *Poliocephalus*, and *Podiceps*—have crests, tippets (ruffs), auricular fans or hair-like filaments; the necks of some of these species may be red (as also in 2 *Tachybaptus*) or black, and the nuptial colour may extend to breast, flanks or vent, or there may be a white patch under or on each side of the tail tuft. *Podilymbus* grebes also have white under tail-coverts, but are otherwise drab-looking, with no real plumes. The head feathers of most *Tachybaptus* lack plumes but tend to be more elongated than *Podilymbus*; all have a dark cap, contrasting with rufous, grey and/or white on the rest of the head. A striking feature is the yellowish green patch of swollen skin on the gape and base of the lower mandible, lacking only in *T. pelzelni* of Madagascar. This feature is also absent in the Least Grebe *Lymnodytes dominicus*, a drab greyish bird with black chin and throat and head feathers slightly elongated. The slightly crested Western Grebe *Aechmophorus occidentalis* has a sharply contrasting black-and-white plumage. At hatching, grebe chicks have a short, soft coat of dense down, most with a longitudinally striped dorsal pattern, particularly on head and neck. Juveniles resemble adults in non-breeding plumage, but retain the striped pattern about the head and neck to a greater or lesser extent until the post-juvenile moult.

Grebes are almost exclusively aquatic, adapted for diving and swimming under water, the feet placed at the rear of the body and the wings (with 12 primaries and 17–22 secondaries) relatively small and concealed in the plumage. The tail tuft is vestigial, lacking stiff rectrices. Under water, grebes strike out powerfully with both feet together and, because of the very flexible tarsometatarsal joint, are highly manoeuvrable. The 3 front toes are broadly lobed and slightly webbed, the raised hind toe is vestigial. The nails are wide and flat, pectinated on the middle toe. The hind edge of the laterally compressed tarsus is serrated. In flight, the wing-beats are rapid because of the high loading. Grebes shed their flight-feathers simultaneously during the post-breeding moult or later and are flightless for 3–4 weeks. The Short-winged Grebe *Rollandia microptera* is permanently flightless and neither the Atitlan Grebe *Podilymbus gigas* nor the Junin Grebe *Podiceps taczanowskii* have been seen to fly. Grebe bills, with narrow slits for nostrils, vary in size and shape. Variation in the length of bill and neck, as well as in the streamlining of the body, is adaptably correlated with food and feeding habits and the depth of effective diving.

Habitat and movements. At least during the breeding season, grebes inhabit standing fresh water, particularly shallow eutrophic lakes and ponds with emergent, floating or submerged vegetation, but sometimes slow-moving rivers, or occasionally sheltered coastal inlets. Outside the breeding season, especially when forced by cold or drought, many populations move to large inland waters or close in shore on the sea. Here large gatherings of flightless birds may also form during the wing moult. More northerly populations are truly migratory.

Distribution. Grebes, though of nearly world-wide distribution, are largely birds of temperate areas; in the tropics, most species frequent montane lakes only. The centre of origin seems to have been in the New World, where there are now 15 indigenous species, of which 12 are endemic. Though some populations readily colonize gravel pits and reservoirs, many have been adversely affected by modern human pressures; among threatened or endangered species are the Atitlan, Hooded *Podiceps gallardoi* and Colombian *P. andinus* Grebes, the last of these now possibly extinct.

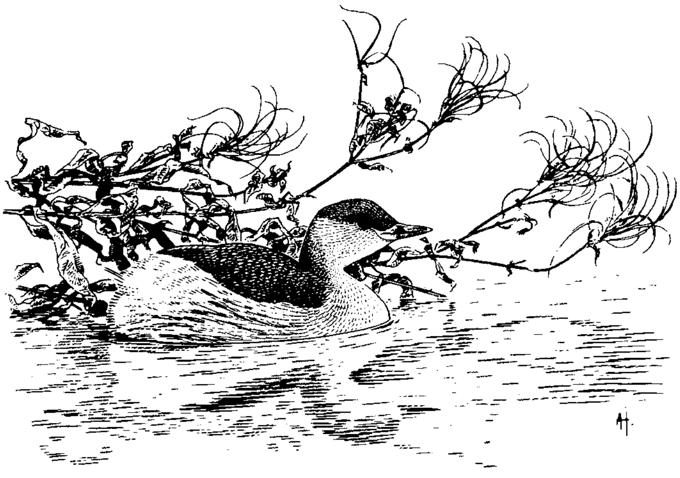
The 2 *Podilymbus* grebes are restricted to the New World: the Pied-billed *P. podiceps* is widely distributed in North, Central and South America (including the West Indies); its quasi-sibling the Atitlan Grebe is confined to Lake Atitlan in Guatemala where the Pied-billed also breeds. Four *Tachybaptus* species are confined to the Old World, where the Little Grebe or Dabchick *T. ruficollis* occurs widely in the Paleartic Afrotropical and Oriental Regions. The Black-throated Dabchick *T. novaehollandiae* is found in Australia, Tasmania, some Australian islands, and has recently nested in New Zealand. There are 2 endemic species on Madagascar, *T. pelzelni* and the tiny Aloatra Dabchick *T. rufolavatus*, which hybridizes with *T. ruficollis*, now occurring on the island. The Least Grebe, often classified as *T. dominicus*, though it differs from the true dabchicks in a number of respects, is a New World species, found from Mexico to northern Argentina and in some West Indies.

The 3 *Rollandia* grebes are South American. The Lesser Golden or White-tufted Grebe *R. chilensis* occurs widely from northern Peru and southern Brazil southwards, forming a superspecies with the much larger Rolland's Grebe *R. rolland*, endemic to the Falkland Islands. The Short-winged Grebe *R. microptera* is confined to Lakes Titicaca, Umayo and Poopo, and their river system in the Titicaca basin. The 2 *Poliocephalus* grebes, the Hoary-headed *P. poliocephalus* of Australia and Tasmania and the New Zealand 'Dabchick' *P. rufopectus* form a superspecies confined to the Antipodes. The Great Grebe, still classified as *Podiceps major*, differs significantly from the rest of the genus; it is found only in South America, from Paraguay and southern Brazil south to Tierra del Fuego.

The 8 other *Podiceps* grebes fall into 2 main sub-groups. There are 4 eared grebes: the Silver Grebe *P. occidentalis* of western and southern South America and the Falklands; its sibling the Junin Grebe, confined to Lake Junin, Peru; the small Colombian Grebe, perhaps now confined just to Lake Tota or even extinct; and the Black-necked or Eared Grebe *P. nigricollis*, widely distributed in North America, Eurasia and Africa. The other main group consists of 3 distinctive, sometimes sympatric species: the Slavonian or Horned Grebe *P. auritus* and the Red-necked *P. grisegena*, both with a Holarctic range; and the Great Crested Grebe *P. cristatus*, an Old World species occurring widely in the Palearctic, Afrotropical and Australasian Regions. The Hooded Grebe is known only from southern Patagonia. Finally, the Western Grebe is restricted to North America.

Food. Though some food is obtained by grebes at water level, most is caught by diving, searching and pursuit below the surface. But even the larger species only remain submerged for less than a minute. On surfacing, the bird often head-shakes laterally but may also drain water from the bill with a special throat-touching movement. The diet consists mainly of aquatic animals, but the food spectrum may vary locally and in the presence of competing species. Those grebes that eat mainly invertebrates tend to be rotund with fairly short necks and bills. Fish-eaters have more elongated bodies and longer necks and bills. Fish-eating species, especially, have the unique habit of eating their own feathers in large quantities and of feeding them to their young. While pellet-formation and regurgitation have been recorded, mainly by insect- and crustacean-eating species, some grebes eat their own helminths and feed them to the chicks.

Behaviour. Grebes pass much of their day between clear-cut spells of food-seeking and loafing, spending much time on feather maintenance (see COMFORT BEHAVIOUR). When resting, they insert the bill frontally into the side of the neck and stow away one or both feet into the flank 'pocket' under the wing. Sun-basking (see SUNNING) is a habit of the smaller species and of the Short-winged, Junin and Hooded Grebes. Grebes typically feed singly but may congregate over dense sources of food. Loose gatherings may form, usually outside the breeding season. A monogamous mating system is the rule, with both parents tending the young. The pair-bond is often only seasonal, but is typically initiated in winter, the birds taking up a nesting territory well before breeding. Pair formation is accompanied by water-courtship, often organized into a number of mutual display chains, male and female playing similar roles simultaneously or reciprocally, or different roles interchangeably, either sex taking the initiative. The rituals continue after pairing, especially at meeting, and are particularly complex and clear-cut in *Podiceps* and *Aechmophorus*, the former having an elaborate 'discovery' and the latter a fantastic 'rushing' ceremony. The pair also engage in platform-courtship, building mating structures together and taking turns in soliciting and mounting each other. Such ceremonies grade into true nest-building (by both sexes) and functional copulation (by the male only) shortly before egg-laying. Regular courtship feeding (male to female) has so far been observed only in the Western Grebe, but casual presentation has been reported for a number of other species.



Little Grebe *Tachybaptus ruficollis*. (*A.H.*).

Voice. Grebes utter a variety of barking, trilling, braying, whistling and wailing calls but, while some species are highly vocal, others are almost silent, even in the breeding season. Many have a vocabulary of about 10–12 calls. An 'advertising' call when alone is often the most distinctive vocalization of the species and frequently leads to water-courtship; and calling may play an important part in courtship itself in species such as the Little and Least Grebes. Dependent young give high-pitched piping calls.

Breeding. The nests of territorial grebes are usually well dispersed in concealing or protected sites, but may sometimes be loosely grouped; 7 species, including the Western Grebe, are true colonial breeders. Breeding is seasonal in higher latitudes, but tends to be less so elsewhere; most grebes have an extended laying period and are opportunistic, e.g. timing laying to coincide with the growth of emergent vegetation for the safe siting of the nest of plant stems and leaves, which is usually built in the water, anchored to vegetation, raised up from the bottom or partly floating. Clutches range from 2–6 eggs, elongated in shape, unmarked white or cream-coloured when laid, but quickly stained brown. Lost clutches and even broods may be replaced; some grebes will raise 2 broods in a season, smaller species even 3. Eggs are laid at intervals of 1–2 days. Incubation, starting from the first or second egg, is by male and female equally, each having a large median brood-patch; when disturbed, the sitting grebe typically covers the clutch with nest material. Incubation lasts 3–4 weeks. Though precocial, the chicks depend on their parents for food as well as warmth and protection, riding on their backs when small or being kept in a nursery nest. Both parents carry and feed the young; later, they tend to divide the brood between them and to give special attention each to their favourite chick. Sometimes the two family groups maintain only loose contact, or even separate entirely. The Hooded Grebe is unique: it lays 2 eggs but takes only a single chick away with it from the nest, abandoning the second egg if the first hatches successfully. Chicks show elaborate begging and appeasement behaviour; in species with a bare crown-spot, this becomes engorged with blood at times and spreads, quilt-like, over the top of the head like a crimson tonsure. Similar flushing signals appear and disappear at will on the bare areas of the face. The young become independent about the time of fledging, or later in the case of favourite chicks. Fledging periods are variable; in west Palearctic grebes they range from 6–7 to 10–12 weeks. Juveniles of some species have been reported to feed or carry younger siblings of a later brood. The age of first breeding is 1 or 2 years. See photo PARENTAL CARE. K.E.L.S.

GREBE, SUN-: see FINFOOT.

GREENBUL: substantive name of species of Pycnonotidae in several genera (see BULBUL).

GREENFINCH: substantive name of some *Carduelis* spp.; used without qualification, in Britain, for *Carduelis* (*'Chloris'*) *chloris* (see FINCH).

GREENHEAD: a name in North America for the Mallard *Anas platyrhynchos* (see DUCK).

GREENHEART-BIRD: alternative name, used in Guyana, of the Screaming Piha *Lipaugus vociferans* (see COTINGA).

GREENLET: substantive name now restricted to *Hylophilus* spp. (see VIREO).

GREENSHANK: *Tringa nebularia* (see SANDPIPER).

GREGARIOUSNESS: see COLONIALITY; FLOCKING; and under MIGRATION.

GRENADIER: alternative substantive name of 2 species of waxbills *Estrilda* (*'Granatina'*) spp. (see ESTRILDID FINCH).

GRESSORES: see CICONIIFORMES.

GREYBIRD: alternative substantive name of some *Coracina* spp. (see CUCKOO-SHRIKE).

GREYHEN: see under BLACKCOCK; GROUSE.

GREYLAG: colloquial short name for the Greylag Goose *Anser anser* (see under DUCK).

GREYTAIL: substantive name of the 2 species of *Xenerpestes* (for family see OVENBIRD (1)).

GREYWING: substantive name of some African francolins (see PHEASANT).

GRIFFON: substantive name of *Gyps* spp.; used without qualification for *G. fulvus* (see VULTURE (1)).

GRIT: particles of stones taken in by birds that eat vegetable matter, to grind the food to pulp through the action of the powerful stomach muscles (see ALIMENTARY SYSTEM). Grit taken passes direct to the stomach through the crop, by-passing the food in the crop. Serviceable grit is not evacuated from the stomach with digested food, and is seldom found in faeces. Birds with stomachs completely free of food retain their quota of grit or sand.

Hard parts of the diet, such as shells of molluscs or crustacea, may replace the grit, e.g. in diving ducks, Dippers *Cinclus cinclus* or Starlings *Sturnus vulgaris*. Birds with a variable diet take in grit when feeding on seeds but little or none when eating insects or fruit (e.g. some Columbidae, Fringillidae). For the swallowing of feathers see GREBE.

Birds resort to regular places at regular times for grit; the Red Grouse *Lagopus l. scoticus*, very dependent on coarse grit, will undertake mass movements after heavy snow when their grit supply is covered. The size and amount of grit ingested is in direct relation to the coarseness of food. Coots *Fulica atra* feeding on soft, growing shoots in spring have less sand in their gizzard than in autumn when eating tougher plant parts. Birds that eat very coarse food (e.g. Capercaillie *Tetrao urogallus* or Himalayan Phasianidae) consume large quantities of coarse grit, whilst swans *Cygnus* spp. and geese *Anser*, etc., eating soft vegetable matter, take in little but coarse sand. The Greater Flamingo *Phoenicopterus ruber*, eating gastropods among other things, takes a fairly coarse grit; whilst the Lesser Flamingo *Phoeniconaias minor*, eating algae and diatoms, takes a very fine sand. The Ostrich *Struthio camelus*, eating very coarse vegetable matter, takes in up to 1 kg of grit composed of pebbles up to 2.5 cm in diameter. Moas (Dinornithidae) of New Zealand consumed coarse plant matter; up to 200 stones weighing 2.5 kg have been found in a stomach. The regular occurrence of small pebbles in adult divers *Gavia* spp. and nestling cormorants *Phalacrocorax* spp. remains to be explained satisfactorily.

Bright-coloured grit is preferred to dull. The discovery of the famous ruby mines in Burma originated with the finding of a ruby in the stomach of a pheasant. The structure of grit can determine the source whence migratory birds commence their flight. Both Whooper Swans *Cygnus cygnus* and Pink-footed Geese *Anser fabalis brachyrhynchus* shot in Scotland have been found to contain black lava grit which can have derived only from Iceland.

Regular duck shooting in traditional sites produces a high proportion of lead pellets in the ground where ducks consume grit. Of Mallard *Anas platyrhynchos* gizzards examined in England, Denmark, Switzerland, Sweden and the USA, 2–17% contained lead pellets. Autopsy of Danish Mallards found dead indicated lead poisoning in 20% of cases. A high pollution of soil by lead pellets exists also in the neighbourhood of grouse-butts that have been used for many years.

Calcareous material (grit, shells of molluscs) is also fed to nestlings in many species, presumably to supply the calcium needed when forming the skeleton (see SKELETON, POST-CRANIAL). Females of many species, including those not normally taking grit, selectively eat material rich in calcium, such as shells of snails, during laying, presumably to build up the egg shell (see EGGSHELL, ULTRASTRUCTURE OF): snail shell fragments were found in the gizzards of female House Sparrows *Passer domesticus* in 10–20% of non-laying birds, in 37.5% of prelaying birds, in 95% of laying females and in 27% of sparrows just after clutch-completion. It has been argued that the availability of calcareous material might influence the limits of distribution in some species such as the Pheasant *Phasianus colchicus* in North America. (R.M.) L.S.

Zuur, B. 1982. Zum Vorkommen von Bleischrotkörnern im Magen von Wasservögeln am Untersee. Orn. Beob. 79: 97–103.

GROSBEAK: substantive name of species of Carduelinae (Fringillidae) in the genera *Pinicola*, *Chaunoproctus*, *Mycerobas* and *Hesperiphona*, and sometimes, in the form of Scarlet Grosbeak, as a poor alternative for Common Rosefinch *Carpodacus erythrinus* or for all members of the genus *Carpodacus* (see FINCH); also of species of Cardinalinae (Emberizidae)—see CARDINAL-GROSBEAK; and sometimes of certain of the Ploceidae—see WEAVER.

GROUND-CHOUGH: alternative, less appropriate name for the GROUND-JAYS.

GROUNDCREEPER: substantive name of the furnariid *Clibanornis dendrocolaptoides* (see OVENBIRD (1)).

GROUND-CUCKOO: general term for most members of the subfamily Neomorphinae (see CUCKOO).

GROUND-JAY: substantive name of the largely terrestrial Asian crows of the genus *Podoces*; preferable to ground-chough, the name formerly used (see CROW).

GROUND-ROLLER: name used for 5 species in 3 genera (*Brachypteracias*, *Atelornis* and *Uratelornis*) in the family Brachypteraciidae (order Coraciiformes), perhaps correctly placed in the same superfamily as the ROLLERS.

Characteristics. By contrast with the cuckoo-rollers Leptosomatidae, this family may represent a second, rather than a first, invasion of Madagascar by roller stock. *Brachypteracias* is perhaps the most primitive genus, and *Uratelornis* possibly synonymous with *Atelornis*. The family is endemic to Madagascar. All 5 species are stout-bodied ground birds, 24–45 cm long; all with a large stout bill, large head, large eyes, short wings, a moderate to long tail and legs. The colours are soft and rich, variously patterned. The sexes are alike in colour.

Four of the species are confined to eastern Madagascar, all 25–30 cm long. These are the Short-legged Ground-roller *Brachypteracias leptosomus*, with crown chestnut, nape washed deep blue, mantle olive-green, rump blue-green, tail tawny with black subapical and white apical markings, chin and throat buffish streaked with brown, an unmarked pale chest band, rest of underparts buffish barred with brown; the Scaled Ground-roller *B. squamigera*, with underparts and head buffish, heavily marked with dark crescents on each feather, the head having a black median stripe and another one behind each eye, the upper back rufous, the rest of the upper-parts mostly green; the Blue-headed Ground-roller *Atelornis pittoides*, with crown blue, mantle green, chin and throat-patch white surrounded with blue, breast and flanks pale rufous; and Crossley's Ground-roller *A. crossleyi*, with head and underparts mostly rufous, a black, white-streaked patch on the throat, and the mantle, rump and tail deep green.

The fifth species, the Long-tailed Ground-roller *Uratelornis chimaera*, seems most closely related to *A. pittoides*. It is *c.* 45 cm long, with a very long tail and long legs. It is confined to the southwest. The upperparts are dull brown variegated with blackish, with some pale blue on the wing-coverts and outer rectrices; the underparts are white with a black breast-band.

Habitat. The first 4 of these species are confined to dense evergreen forest, where the foliage above casts a continual shade, and the ground is nearly bare of vegetation. The fifth is confined to subdesert scrub.

Distribution. The two *Brachypteracias* spp. and *Atelornis crossleyi* are only known from the central and northern parts of the humid east. *Atelornis pittoides* is more widespread in the humid east, and is also known from the Sambirano, in the northwest. *Uratelornis chimaera* is confined to the coastal southwest, from north of Tulear to the Mangoky River.

Populations. Due to habitat destruction, the status of all 5 species is a matter for deep concern. This applies in particular to *U. chimaera*, of which there may not remain more than 250 pairs.

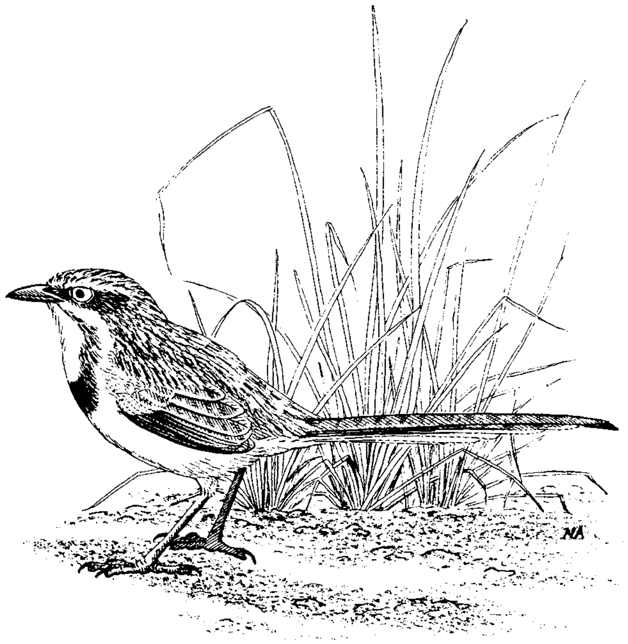
Movements. Probably all are strictly sedentary.

Food. All are insectivorous, although a snake, a snail and chameleons have also been recorded in the stomach-contents of *B. leptosomus*.

Behaviour. Very little known, but all are essentially terrestrial (in feeding probably entirely so), and usually solitary, although *U. chimaera* has been noted in groups of 4 or 5. When alarmed, they may run a few steps, to stand quietly watching. By contrast, however, *B. leptosomus* flies to a low perch, where unless further disturbed it may remain indefinitely, tranquil, and easily approached. Nor at least are *A. pittoides* or *U. chimaera* entirely terrestrial, while the latter is known to be partially active at night.

Voice. A *coee coee* has been heard from *B. leptosomus*, a 'low clucking' from *A. pittoides*.

Breeding. *Atelornis pittoides* lays its white eggs at the end of a horizontal tunnel burrowed by the parents into a bank. The same applies to *U. chimaera*, but the tunnel is gently sloping (into flat sandy ground). In both, the normal clutch-size may be 3 or 4. *Brachypteracias leptosomus* is also said to lay at the end of a burrow, but no information at all is available for the other two species. (A.L.R.) C.W.B.



Long-tailed Ground-roller *Uratelornis chimaera*. (*N.A.*).

GROUND SPEED: see FLIGHT, SPEEDS OF.

GROUND-THRUSH: see QUAIL-THRUSH; RAIL-BABBLER.

GROUND-TYRANT: substantive name of the terrestrial tyrant-flycatchers of the genus *Muscisaxicola* (see FLYCATCHER (2)).

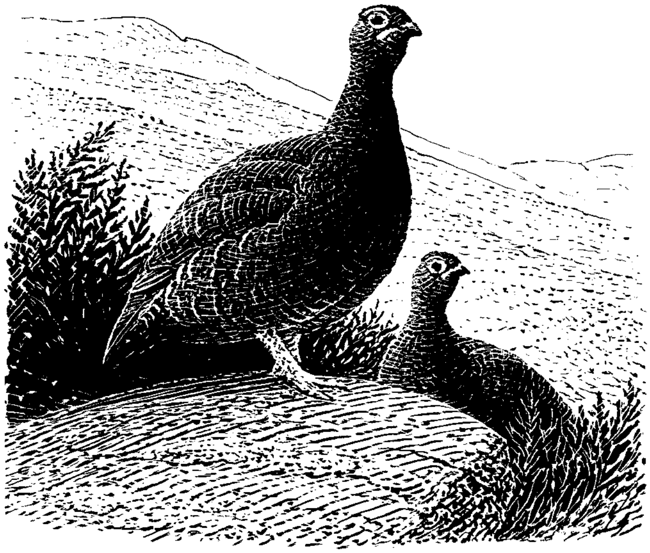
GROUP (1): in nomenclature, 'an assemblage of co-ordinate categories' (see FAMILY GROUP; GENUS GROUP; SPECIES GROUP (1)); and NOMENCLATURE).

GROUP (2): in taxonomy, a loose or deliberately neutral term for a taxon or collection of taxa, non-committal as regards the precise rank or status to be assigned to it.

GROUP SELECTION: processes leading to systematic differences in the survival of different populations of a species, beyond those resulting simply from differences in fitness of the individuals within each population. Rarely of importance in EVOLUTION.

GROUSE: substantive name of most species of Tetraoninae (Galliformes, Phasianinae); in the plural (unchanged), general term for the subfamily. Several arctic or montane species of grouse are called 'ptarmigan', and several other vernacular names are regionally or locally applied to various grouse species. The family has a circumpolar distribution, from about 26°N to about 81°N. From 16–18 species are usually recognized, and are now usually placed in 6 genera. Two species are of Holarctic distribution; 7 additional species are limited to the Nearctic, while 7 are confined to the Palearctic.

Characteristics. Grouse are fowl-like birds ranging in length from 30–90 cm and in weight from 0.3–7.0 kg. Their nostrils are hidden by feathers, their unspurred tarsi are at least partially (usually fully) feathered, and the toes are either feathered seasonally (ptarmigan) or have pectinations 2–3 mm along the sides of each toe; these features are probably associated with the group's northerly distribution. The hind toe is elevated, the bill is fowl-like and relatively short, with a rounded culmen, the wings are short and rounded, and the tail is rather varied in form. In most species the males have seasonally engorged combs over the



Red Grouse *Lagopus lagopus scoticus*. (*D.W.*).

eyes, and can inflate the upper oesophagus to form 'air sacs' during display. The most northerly forms have white winter plumages, and cryptic coloration is typical of all. The downy young are typically galliform, having a variegated brown and light-coloured back pattern, the dark colour usually extending forward on to the crown, various facial markings, and pale underparts. The probable nearest relatives of the grouse are the Old World pheasants, in particular the snowcocks (*Tetraogallus*).

Habitat and distribution. Grouse are essentially terrestrial birds, but many perch readily, and some forest-dwelling species spend much time roosting in trees or foraging arboreally on buds, fruit or berries. Of the 16 species now generally recognized, 3 (the ptarmigans) are arctic or montane-adapted, 3 are grassland or sage semidesert species, 3 are largely associated with deciduous forest, and the remainder are primarily associated with mixed or coniferous forests. There is a considerable degree of ecological segregation in the grouse, and it is rare to find 2 species sharing the same habitat. Several species are associated with forest-edge or successional stages of forest development, and in such situations habitat sharing may occur.

In North America, the Canadian boreal forests support 2 species of *Dendragapus*, the Blue Grouse *D. obscurus* and the Spruce Grouse *D. canachites*, from which the western form *franklinii* is sometimes specifically separated. Of these, the Spruce Grouse is especially associated with rather dense coniferous forests, while the Blue Grouse occupies more open coniferous forests during winter and tends to move into edge situations or even into open grassland-dominated habitats during the breeding period. The Willow Grouse or Ptarmigan *Lagopus lagopus* is a timberline and sub-arctic form while the (Rock) Ptarmigan *L. mutus* is the high-arctic replacement form. In montane areas, the White-tailed Ptarmigan *L. leucurus* occurs in alpine tundra. In western areas of relatively cool, sage-dominated plains the Sage Grouse *Centrocercus urophasianus* represents the most arid-adapted of the grouse group, while in the drier grasslands, forest openings, and early stages of forest succession the Sharp-tailed Grouse *Tympanuchus phasianellus* is widespread. In somewhat older successional stands of forests, supporting aspens, poplars and other hardwoods the Ruffed Grouse *Bonasa umbellus* is prevalent. Originally, the Pinnated Grouse or Prairie Chicken *Tympanuchus cupido* ranged widely over the grasslands of central and eastern North America, with the drier and western areas occupied by the Lesser Prairie Chicken, which is often given species status (*pallidocinctus*).

In Eurasia, all of the grouse except for the 2 ptarmigans can be considered 'forest grouse'; the Red Grouse *L. lagopus scoticus*, occupies moors and peat bogs in the British Isles and is a race of the more widespread Willow Ptarmigan that does not assume the usual white plumage of ptarmigans during winter. The ecological counterparts of the Ruffed Grouse in Eurasia are the Hazel Grouse *Bonasa bonasia* of Europe and *B. sewerzowi* of China, which occupy mature stands of hardwoods, especially those rich in alder, birch and other suitable winter foods. Likewise, the counterpart of the North American Spruce Grouse is the Sharp-winged Grouse *Dendragapus falcipennis* of eastern Siberia and China, similarly associated with relatively dense coniferous forests. The Eurasian Capercaillies, *Tetrao urogallus* of Europe and western Asia, and *T. parvirostris* of Siberia, are also essentially coniferous forest species, occupying a similar ecological role to the North American Blue Grouse. Lastly, the 2 Black Grouse *Tetrao* (or *Lyrurus*) *tetrix* of Europe and Asia, and the Caucasian Black Grouse *T. mlokosiewiczi*, tend to be forest-edge species. In some respects they are similar to the Sharp-tailed Grouse of North America, but also occupy low-altitude heathlands and bogs, subalpine grasslands, and sometimes even montane habitats. At times *T. tetrix* also occurs seasonally in fairly dense coniferous forests where there is a well-developed shrub understory, but like the North American prairie-adapted grouse it always requires rather open areas nearby for display sites.

Population. The densities of grouse are highly variable among species and habitats, but probably exceed a pair per hectare only under the best late-summer conditions. The 3 ptarmigans often have spring and summer densities of from 10–50 ha per pair or territorial male, and about the same is true of the 3 grassland and sage-adapted species of grouse. Densities of the forest-dwelling grouse seem to be highly variable, with breeding populations in North America ranging from about 2–90 males per km^2. There are regional and temporal variations in population densities that are often quite large and still of controversial origin; the apparent cyclical fluctuations of such species as Ruffed Grouse have received considerable attention but have yet to be explained adequately. Such factors as variations in weather, food, disease, and predation levels have all been advanced with varying degrees of success to account for these density changes. There also seem to be behavioural differences in aggressiveness, breeding behaviour, and perhaps such things as dispersal tendencies that are associated with differing population densities, although whether these are the causes or effects of differences in population densities is still to be established.

In most areas, populations of grouse have suffered considerably and many species have vanished from much of their original ranges. Over much of Europe the populations of Black Grouse and Capercaillie have declined greatly, and in Great Britain the Capercaillie had been eliminated by 1760, but has since been successfully re-introduced into Scotland. On the continent, the Capercaillie has also suffered greatly from forestry operations, while the Black Grouse benefits from increased forest clearings produced by limited forestry. Likewise, the Hazel Grouse also copes fairly well with limited forest removal. Perhaps the rarest of the Eurasian grouse are the Caucasian Black Grouse and Sewerzow's Hazel Hen; both have remote and extremely limited distributions, and their status is not known at present. In North America the Pinnated Grouse has been seriously affected by human activities. The Atlantic coast population of this species (called the 'Heath hen') became extinct by 1930, and the Gulf Coast population (Attwater's Prairie Chicken) is now considered endangered. Both of the other forms, the Greater Prairie Chicken and the Lesser Prairie Chicken, are on the Federal list of threatened species. The Sharp-tailed Grouse has been eliminated from much of its original prairie range in the United States, but is still widespread in Canada and Alaska. The Sage Grouse is also probably declining throughout its range as more sage desert areas are converted to irrigated croplands or otherwise cleared of original sagebrush cover. Hunting, pesticide use, and general human disturbance have contributed to population declines in some areas.

Movements. Most of the grouse are relatively sedentary, moving no more than a few km between summer and winter ranges, but the Sage Grouse may move as far as 90–150 km. The forest-dwelling grouse are generally less mobile than are the prairie grouse, the maximum movement in Blue Grouse being about 50 km. The Spruce Grouse is even more sedentary, and males tend to remain on or near their territories for most of the year. Of all the grouse, the ptarmigans are the most mobile. In the alpine White-tailed Ptarmigan the seasonal movements tend to be altitudinal, although autumn movements may exceed 16 km. The Willow Ptarmigan and Rock Ptarmigan are partial migrants, but exhibit true migrations in many northern areas, such as in northern Scandinavia and the USSR. In arctic Canada the Rock Ptarmigan often moves 15–25 km between breeding and wintering grounds, and in northern Alaska the Willow Ptarmigans nesting on the north slope of the Brooks Range regularly migrate to areas about 50 km south of Anaktuvuk Pass in this range. Probably females and juvenile males migrate the greater distances, while adult males tend to winter as close as possible to their breeding territories. The Red Grouse, however, is essentially sedentary, and not many individuals move more than a few km in their lifetimes.

Food. All of the grouse are primarily vegetarian, feeding on leaves, buds, berries and other vegetation for much of the year, particularly during winter, when each species concentrates on rather specific foods for survival. In the forest grouse the food is the buds, leaves and needles of woody species, such as conifers and ericaceous evergreen plants. In spring, the catkins of aspens, birches and alders are important foods, especially for species such as the Ruffed Grouse and Hazel Hen. The young shoots and flowering cones of larches are often eaten in spring by black grouse and capercaillies. Insects are the major foods of young grouse, and sometimes are consumed in considerable quantity by adults during summer. Most species concentrate on berries and fruits during the autumn. All grouse ingest gravel to aid in digestion. Variations in the yearly amounts and nutritional quality of foods are one of the areas that have been investigated with respect to the possible causes of population fluctuations.

Behaviour and voice. In their social organization grouse exhibit a remarkable diversity of mating systems for so small a group of species. These range from essentially monogamous matings (in some ptarmigans) to polygamy or total promiscuity, with promiscuity the most typical. In conjunction with their diverse mating systems, the degree of plumage and size dimorphism varies accordingly, with little or no dimorphism in monogamous species, but a high degree in promiscuous forms. The relatively restricted degree of plumage dimorphism in the grouse as compared with many other promiscuous-mating birds, such as the pheasants, seems to be associated with rather strong ecological pressures for retaining protective coloration patterns that closely match the environment. Perhaps to compensate for their limited ornamental plumage, grouse exhibit a considerable development of variable exposed combs or wattles above the eyes and areas of colourful bare skin in the neck region that can be temporarily exposed by oesophageal inflation. Additionally, mechanical sound production by tail shaking, rapid tail fanning, wing-dropping and scraping, and foot-stamping are frequent devices for male identification and advertisement. Vocally, the *go-back go-back* of the cock Red Grouse is one of the distinctive sounds of British moorlands.

Only in the black grouse and capercaillies is there a fairly strong degree of sexual dimorphism in plumage; the males have iridescent blues and blackish coloration, while the females retain the cryptic brown and buff tones typical of the group. In both of these the contrast between the dark blackish colours and adjoining white spots or larger feather areas appear to be important components of male postural display.

The males of all grouse species are distinctly territorial, although the size of the territory and the length of time that it is held and advertised varies greatly in the group. The sedentary forest-dwelling species tend to have large territories; those of the Spruce Grouse may range from about 2–4 ha, the total home range not being much larger. Territories in the Blue Grouse are often smaller, especially when populations are rather dense. Territories of the Rock and Willow Ptarmigans range from about 1–100 ha in size, depending on habitat, while those of the White-tailed Ptarmigan are often less than a hectare. Far smaller yet are the territories of the socially displaying grouse, such as the Black Grouse, Sharp-tailed Grouse, Pinnated Grouse and Sage Grouse. In these species the males defend small, contiguous territories often less than 100 m^2 in total area, in which all display activity occurs and likewise mating takes place. These areas are known as LEKS, and the term has now been applied to social displaying grounds in general, although in North America they are more often referred to as 'strutting grounds' (Sage Grouse), 'dancing grounds' (Sharp-tailed Grouse), 'booming grounds' (Greater Prairie Chicken) or 'gobbling grounds' (Lesser Prairie Chicken). Whatever they are called, they are all rigidly structured male display areas, in which the size and especially relative location of the territory plays an important role in determining individual mating success among males. Older and more experienced males are more successful in establishing and holding central territorial positions, while younger and less experienced males arrange themselves in peripheral territories. Although females may be initially attracted to the entire displaying group, they invariably exhibit a high degree of selectivity in their mating, gathering around certain central 'master cocks' that perform the large majority of the actual matings. The same areas serve as leks from year to year, and individual males often defend nearly the identical territories in subsequent years, gradually moving toward the centre to replace older males as they disappear from the population. The displays performed on such leks are typically highly stereotyped sequences of postures, movements and calls, nearly all of which are probably derived from aggressive tendencies associated with inter-male competition, and very few of which are specifically associated with male-to-female 'courtship' tendencies.

The solitary displays of such species as the Ruffed Grouse and Blue Grouse differ little from those of the typical lek species with respect to their origins and functions, but are often modified for effective transmission of sound in a wooded environment. Most species produce low-frequency sounds that are transmitted well in wooded environments, and may be vocal or the result of mechanical scraping (of feathers against one another) or percussion (of wings beating the air or one another). One species, the Hazel Hen, is known to produce a weak, high-pitched whistling. This species is believed to be monogamous, retaining a permanent territory, and the male may also have a limited involvement in brood care. Similarly, among the true lek grouse individual males sometimes display and call solitarily some distance away from, but often within hearing distance of, an established lek. Thus there is a complete gradation between lek-forming and solitary species of grouse, with corresponding variations in territorial size and ecological correlates.

Breeding. All species of grouse are ground-nesting; the nests usually have little lining. Clutch-sizes range from about 6–12 eggs, and in all species the female incubates the eggs, although in a few monogamous or semi-monogamous species the male may show a limited degree of nest or brood defence. The incubation period ranges from 21 days in ptarmigan to 26 days in the Sage Grouse. Renesting is infrequent in most species, and only a single brood is raised each breeding season. The downy young develop surprisingly rapidly, and often are able to fly short distances within as little as 5–8 days after hatching. Family bonds are rather weak, and by winter the young birds are typically well scattered.

GROWTH: the process of increase from conception to adult size, with concomitant development in morphology, physiology and behaviour. EMBRYONIC DEVELOPMENT takes place in the egg and post-natal growth spans hatching to adulthood.

Patterns of avian development. Two extreme modes of development are found in birds. Precocial species are those in which the young bird hatches from the egg in an advanced state, largely capable of leading an independent existence. In contrast, altricial species produce dependent young which remain in the nest for a long period, the young being born blind and with little or no down, and requiring some considerable period of post-natal growth in the care of their parents before they can become independent.

In practice there are many intermediates between these extremes, Fig. 1 indicates the major categories used in cataloguing growth patterns, together with the features used to this purpose. These features—the presence or absence of down, and the degree of parental care afforded—are, broadly speaking, restricted taxonomically. The Gruiformes and the Charadriiformes are the major exceptions to this rule, the two orders containing species with quite diverse development.

Altricial species produce small eggs with little yolk; the females can lay these readily, but the young subsequently require considerable investment of parental care. In contrast, precocial development is from large yolk-rich eggs which impose a strain on the female for egg production but require little further energy input from the parents. The different growth patterns are associated with different types of food used by the young. Consequently precocial growth is found predominantly amongst primary consumers (eaters of plant foods) such as waterfowl and galliforms, whilst altricial growth is the rule amongst species whose prey is difficult to catch and therefore not exploited well even by independent young. Precocial development is an energetically costly process, since the young have to metabolize food for their own maintenance during their continued

Fig. 1. Summary of the characteristics of the grades of altricial and precocial development according to Nice's classification. (After Ricklefs in press).

growth; in altricial species these costs are met in part by parental brooding. For these reasons precocial development is much commoner in temperate and subarctic regions where the seasonal food flush makes it relatively easy to support growth. In the Temperate Zone 35% of all young develop precocially whilst in the tropics fewer than 15% of the species are precocial.

Postnatal growth.

Weight versus age curves. Most studies of postnatal growth in birds have concentrated on recording the way in which nestling or chick weights alter with age. For most young such curves show an initial period of relatively slow weight accretion followed by a period of accelerating increase which eventually levels off toward some asymptotic weight. The form and size of such curves can in general be well approximated by one of three sorts of curves (Fig. 2). First is the logistic curve whose equation is

$$W = \frac{A}{1 + e^{-K(t-t_0)}}$$

which describes a pattern of an increasing rate of weight gain until nestling weight is half-way towards its asymptotic value; the rate of weight gain thereafter decreases. The second is the Gompertz equation

$$W = Ae^{-\exp[-K(t-t_0)]}$$

in which the rate of growth peaks rather earlier than would a logistic curve with the same numerical value of the growth constant K. The third equation is the von Bertalanffy equation

$$W = A(1 - e^{-K(t-t_0)})^3$$

in which the early growth is very rapid but later growth is relatively slow.

In each of these equations the parameter A describes the asymptotic weights towards which the nestling is growing and the parameter K describes the rate of growth of the young at the point of fastest growth. Because of the asymptotic nature of these weight curves, instantaneous growth rates vary continuously during growth. Growth rate constants from different growth equations are not strictly comparable but it is possible to derive approximate standardizing factors.

Weight recession. Although the majority of birds grow in logistic fashion there is significant variation in the relationship between nestling asymptotic and adult weights. Nearly half the species studied to date fledge with asymptotic weights below those of adults of the same species. Another 20% of all species grow as nestlings towards asymptotic weights significantly above the adult weight for their species. Most such species subsequently undergo a period of weight recession in which they lose weight and eventually fledge at weights closer to adult levels. For some species this period of weight recession appears to be due to a reduction in food consumption by the nestling and greater consumption of nestling fat reserves, possibly serving to reduce nestling wing loadings and to improve their flying capabilities at fledging, but in the majority of species it appears to be due to water losses from the developing tissues of the nestling. The proportion of water in muscle tissue, in particular, reduces as the tissue approaches mature function.

There are substantial differences in the incidence and amplitude of weight recession between passerines and non-passerines and amongst birds of different habitats and feeding behaviours. Some 78% of passerines with asymptotes more than 10% below adult weight are ground feeders such as finches, thrushes and icterids, whilst foliage feeders and perch feeders tend to have intermediate ratios; the more aerial species (swifts and hirundines, oceanic seabirds) tend to have high ratios of asymptote to adult weight. The correlation is thus with the degree of dependence upon flight ability at fledging, as would be expected if water loss from flight muscles is an important component. Hole-nesting species also have peak nestling weights substantially above adult values, presumably because in their secure nest sites they can afford the longer development time needed to fledge with fully mature muscles.

Amongst passerines, nearly two-thirds of all species fledge at below adult weight, but amongst non-passerines only 28% do this. Whether this taxonomic difference is associated with taxonomic differences in be-

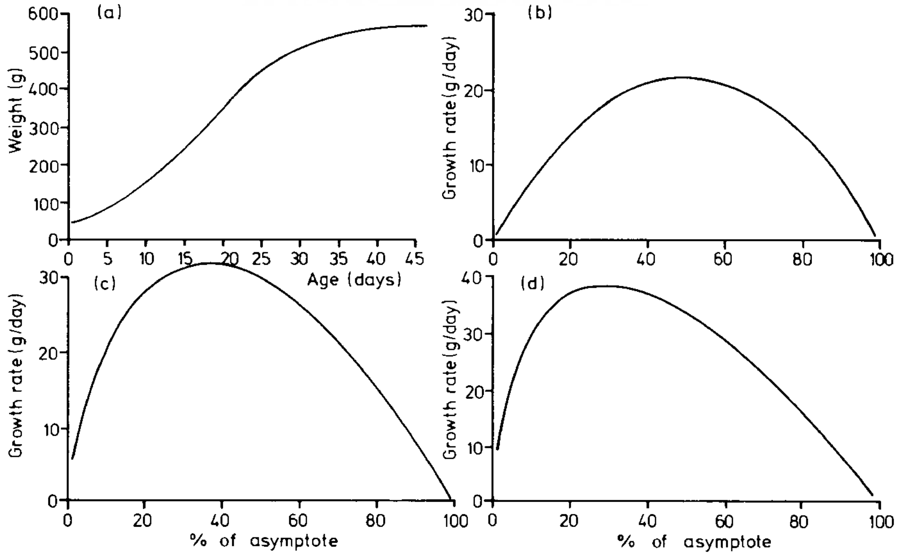

Fig. 2. Examples of different shapes of growth curve with fixed asymptote and rate constance: (a) logistic growth equation fitted to growth data for Barn Owl *Tyto alba* (asymptote 570 g, rate constant 0.152); (b) instantaneous growth rate (g/day) as a function of growth completed for this logistic equation; (c) the same parameters but with a Gompertz growth equation, showing the earlier peaking of growth rate; and (d) the same parameters in a von Bertalanffy growth equation, showing the still slower completion of body growth. (Data and growth equations from Ricklefs 1968).

haviour has not been studied.

Variation in growth rates. Explanations of inter-specific variation in growth rates are of two types, (1) theories based on internal physiological constraints within the growing bird, with each species growing as fast as it can within a body plan optimized with respect to its life history (Ricklefs 1973) and (2) the idea that growth is an independent channel of adaptation to selective forces such as mortality or food supply (D. Lack, T.J. Case).

A large proportion of the variation in growth rates in birds is associated with adult body weight, with larger species growing relatively more slowly than do smaller species (Fig. 3). This relationship is linear and has a slope of 0.722 when growth rate and body weight are plotted on logarithmic axes, and therefore shows that growth rate increases with weight according to a power function virtually parallelling the Aschof and Pohl equation for the relationship between standard metabolism and body weight

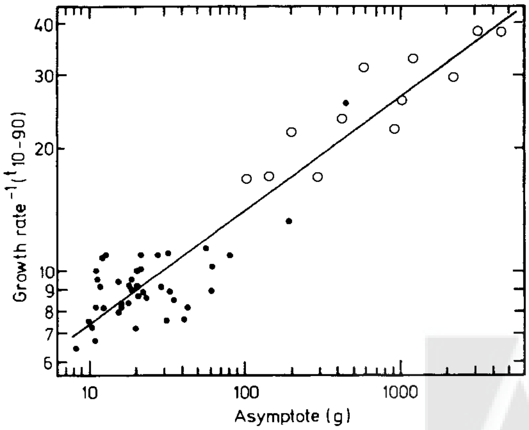

Fig. 3. Growth rate as a function of body size amongst passerines (solid dots) and raptorial birds (open dots). (From Ricklefs 1968).

$$m = 0.761\,A^{0.726}$$

where m is metabolic rate (Kcal/bird/day) and A is adult body weight (g). The parallelism suggests that growth rates may be functionally dependent on each species' weight-determined metabolic rate. Although this growth rate on adult size regression explains a large part of the variation in growth rate between species, there remains significant variation around the regression line, indicating that individual species tend to grow somewhat faster or somewhat slower than expected for their body weight. For example, precocial species lie significantly below the line, indicating that precocial development results in slower post-natal growth than does altricial development.

The time that a nestling spends in the nest is inversely related to the mortality rate for its species, birds in secure nest sites tending to remain longer than birds in sites more exposed to predation or other mortality. This was originally interpreted as reflecting clutch size adjustments, secure nest sites allowing slower development and therefore the production of more young for a given peak rate of energy expenditure in gathering food and caring for the young by the adults. But consideration of the rates at which the nestlings require energy shows that this explanation is not sufficient: species exposed to mortality whilst in the nest do not accumulate weight faster than the species not exposed to such mortality: they simply leave the nest at an earlier stage in development.

Ricklefs points out that this situation can come about because different species have different functional requirements as fledglings: cursorial species need to be able to walk and run efficiently but since even as adults most do not fly to a great extent, they have little need for efficient flight and large flight muscles during early development. In contrast, aerial insectivores must be able to fly efficiently from the moment of fledging if they are to lead an independent life but even as adults have only weak leg muscles. Different species thus achieve equivalent competence of mature function whilst developing morphologically in very different ways. Ricklefs found that growth rates are significantly related to the amount of mature function (measured in terms of relative muscle mass) that a fledgling is called upon to perform (Fig. 4). Species with a large proportion of their body mass given over to functional muscle during the fledging period grow more slowly than do species with a smaller proportion of mass as muscles; this applies irrespective of whether the principal use of muscle is in flight or on the ground.

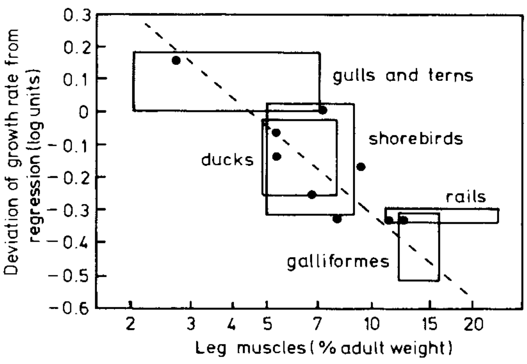

Fig. 4. The relationship between size corrected growth rate (deviation of growth rate from rate-body weight regression) in relation to their proportional leg muscle size in various groups of birds. (From Ricklefs).

Differential development. Young birds do not grow their organs and tissues at uniform rate throughout development. The organs most needed for nestling life develop first, those needed on independence at fledging develop late in the nestling period. Certain organs—the skeleton being an obvious example—need, however, to develop early in order to provide the necessary foundations for later tissues.

Development of sense organs. The timing of eye opening is probably a function of overall development. Most precocial species open their eyes either in the egg or shortly thereafter, whilst altricial species have their eyes closed for several days following hatching. In the Common Grackle *Quiscalus quiscula* eyelids first begin to part midway through the third day and are fully open by day 12. This slow development reflects incomplete development of the organs, for the ciliary muscles in House Sparrows *Passer domesticus* are not functional until day 6 and the optic nerve is incompletely myelinized in the Starling *Sturnus vulgaris* until day 8. The pupillary reflex and the optomotor response appear about half way through the period of eye opening in the Common Grackle.

Once the eyes are open, the behaviour of the nestlings is altered from a general responsiveness to mechanical stimuli (e.g., jarring associated with the arrival of the parents with food) and their begging is oriented towards the head of the parent. In addition, eye function is essential for the nestlings to balance adequately: small young have strong grasping reflexes prior to eye-opening but are unable to balance properly when tested on twigs until after their eyes have opened.

Hearing develops embryonically rather than post-natally. Embryos of precocial species are able to respond to 'bill-clicking' by other embryos from some days before hatching. In domestic chicks a cochlear response to low-frequency stimulation is first detected on day 12 and its sensitivity and frequency range improves with age until shortly before hatching. This is important for the development of postnatal chick recognition of the parents based on calls uttered by them as they arrive with food for the young.

Newly-hatched young have fewer taste buds (perhaps only one-third as many) than have adults and their tasting abilities are correspondingly poorer. Nevertheless, even newly hatched pigeons can discriminate bitter, sour and salty substances and young Bobwhite Quail *Colinus virginianus* can additionally discriminate sweet substances by 10 days of age.

Plumage. Although the main function of down is to provide insulation to precocial chicks, many altricial species have some down which becomes apparent once the amniotic fluids on the newly hatched bird have dried off. Only 11 families seem to have genuinely lost all down. A few species possess highly specialized down, often related to thermal considerations: in young Sandgrouse *Pterocles orientalis* the down barbules are coplanar and controlled by muscles allowing them to be elevated or depressed according to the heat of their desert nest site. In the Cape Barren Goose *Cereopsis novaehollandiae* down is extremely long, as befits a winter nester.

Young birds go through a sequence of plumages, varying in length according to species. For many the first coat of contour feathers forms a juvenile plumage which lasts until the first moult in autumn. Such plumages are often distinctively different in colour from those of the adult and are usually rather lighter and weaker in texture and structure. Where an autumn moult is present, the replacement feathers greatly improve the insulation afforded the nestling. Often the flight feathers are not renewed in this moult.

A variety of explanations has been advanced as to the significance of distinctive sub-adult plumages. Explanations include concealment, heat retention, protection from the sun, and signal functions. Amongst very young precocial birds a cryptic function is common, its value being increased by the chicks' behaviour in seeking appropriate cover and crouching extremely still whilst the predator is about. In young grebes and rails there appears to be a significant signal function to the plumage, used chiefly in feeding and appeasement until individual recognition of chicks by the parent develops.

Other body structures. In most nestlings the bill, especially the gape, is disproportionately large, presumably to serve as a feeding target for the parent. Its value in this respect is frequently enhanced by bright coloration and sometimes by the presence of specialized mouth spots. In young Red-winged Blackbirds *Agelaius phoeniceus* gape width and ramus length nearly double in size over the first 5 days, thus permitting the chick to take in larger meals as its age and energy requirements develop. In older chicks the shape of the beak moves steadily towards the adult structure which will be needed when it fledges. In precocial species bill structures also alter with age, the chicks in general having a short pecking-type beak initially and gradually developing more specialized structures.

In passerine nestlings the legs and their associated muscles increase in relative size over the first few days, thus improving their stability and ability to orientate during begging behaviour. In precocial species the legs are relatively better developed at hatching, in keeping with the greater motor needs of the chicks. In addition, however, the leg musculature provides a heat production capacity by shivering. For example, in the Willow Grouse *Lagopus lagopus* shivering heat production is almost exclusively by leg muscles until the pectoral muscles take over this role. This is shown even more strikingly in Leach's Storm Petrel *Oceanodroma leucorhoa* which does not move about as a chick but whose legs grow at 10% per day when first hatched; this provides the thermogenic capacity needed for thermo-regulation whilst its parents are away on long food searches.

The leg bones progressively calcify during the nestling period. In newly-hatched thrushes primary bone is largely absent and the femur contains only about 1.1% calcium but at fledging the young has a well-developed medullary cavity surrounded by cortical bone and the femur contains an average of 6.2% of calcium. Precocial species are rather better developed at hatching, averaging about 3% calcium. On the other hand, domestic chicks take about 17 days to bring their development to the stage reached by thrushes after only 12–13 days of nestling life.

The wings and their associated pectoral muscles develop relatively late. The bone structure develops rather earlier to provide the base for the growth of flight feathers, and pectoral muscles develop later still. In a few species a degree of flying is required at an early stage, as with young Guillemots *Uria aalge* which have to leave their nesting cliffs when only 25–30% of adult weight. Their secondaries develop earlier and, with the disproportionately large webbed feet, provide a degree of lift for the descent from the cliff. In many such species wing loading is maximal at this stage, declining as the body mass develops faster than does feather growth. Moreover, in adults a greater proportion of body mass is pectoral muscle, so overall flight ability further increases.

In most species the digestive organs (see ALIMENTARY SYSTEM) initially increase relative to the body as a whole and in altricial and semi-altricial species they (notably the gizzard, alimentary tract and liver) quickly peak in relative weight. Such organs are probably maximal at the time of most rapid growth and in some species the intestines may account for 33% of nestling weight. Precocial species do not develop quite so dramatically, though the liver may increase slightly in relative size. The gizzard, on the other hand, remains a relatively constant proportion of a precocial species' weight. Although the liver accounts for only about 5% of body weight over the first few weeks of life, its relative growth in neonatal young is correlated with overall growth rate, both in altricial and precocial species. This presumably reflects the food processing function of the liver.

Organs such as the HEART are required to pump blood about the body from an early embryonic stage, so vary little in relative size during postnatal growth.

In most species the growth of the PLUMAGE and its FEATHERS results in the integument increasing relative to body weight as a whole. However, the feathers generally remain in quill until the period of fastest weight increase is past. In young altricial species the plumage forms about 10% of the entire weight but in precocial species it accounts for 13–15% of dry weight, reflecting the greater relative weight of plumage required for insulation in the precocial group.

Body composition. In most species the amount of water in the body increases with age, but this is largely a function of individual weight curves: when water content is expressed as a ratio between dry weight and age expressed as a percentage of each species' nestling period, most of the variation is eliminated. Thus, water content is determined by the maturity of the tissues carried by the nestling. In altricial species the water index (water content/lean dry weight) has a value of around 7–9 at hatching but decreases steadily to values of 2–3 at fledging. In precocial species, on the other hand, water indices are generally rather lower at hatching, generally around a value of 4.0, and decrease to about half this level by fledging. Similar patterns apply to the water content of individual tissues. Consequently, water indices are probably a measure of tissue maturity, with the proportion of solid matter in individual cells increasing as they accumulate proteins and enzymes.

Fat reserves similarly vary between species and with age within species and a measure of standardization can be achieved by dividing fat content by lean dry weight to yield a lipid index. This index describes the amount of lipid available to support the continued functioning of each unit of tissue. Amongst young nestlings lipid indices are typically low, around 0.05, and only a few species with particular ecological problems, such as oceanic seabirds and aerial insectivores, have values much above this, e.g., 0.30 in the House Martin *Delichon urbica.* For most species lipid indices increase during nestling growth and again the increase is most pronounced in those species ecologically likely to need recourse to fat reserves.

As a result of the accumulation of fat and lean material during growth and a relative decrease in water content with age, the caloric density (Kcal/g wet weight) increases with nestling age (Fig. 5). Altricial species have generally a low intercept in such plots and precocial species have

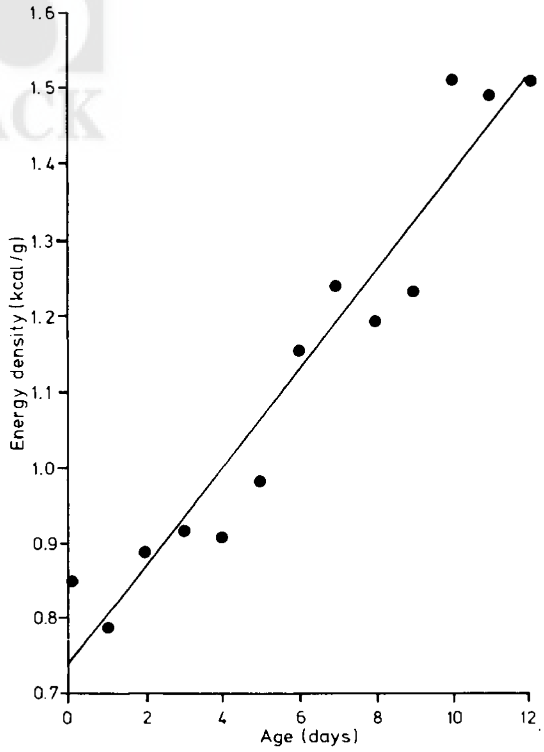

Fig. 5. Energy density (calories per gramme wet weight) in relation to age in House Sparrow *Passer domesticus* nestlings between hatching and 12 days.

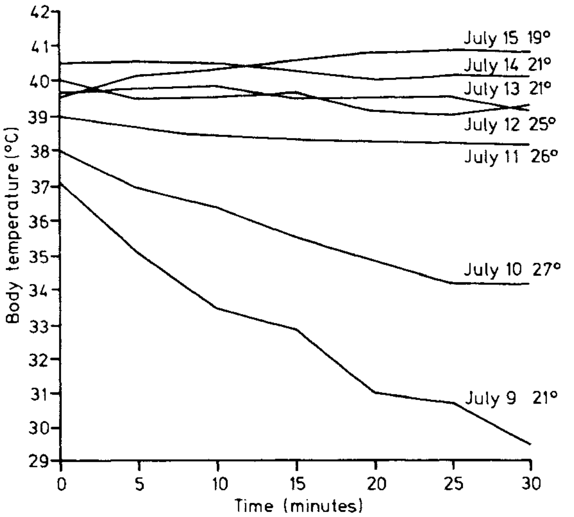

Fig. 6. Cooling curves of nestling Ovenbirds *Seiurus aurocapillus* exposed to ambient temperatures (shown on each curve) outside the nest on various days following birth on 9 July, showing how nestlings progressively improve temperature regulation with age. (After Hann 1937).

generally a high intercept, but adults of the two groups have rather similar final energy densities.

Fat deposits in nestlings are primarily around the abdomen, reflecting the absorption of the yolk sac lipids, but amongst older nestlings the other major depots—cervical and subscapular—are equally important.

Calcium is probably the mineral component of growth that is of most importance to birds. In young thrushes calcium concentration (mg/100 mg lean dry weight) more than trebles between hatching and fledging, its accumulation over this period being more or less sigmoid in time. This high intake of calcium (it has been estimated at 20–30 mg per gram of dietary protein) must underlie the frequently recorded habits of altricial species feeding their young fragments of shell and other sources of extraneous calcium.

Development of thermoregulation.

Body temperatures. Young nestlings are initially unable to regulate their body temperatures to a constant level and in the absence of parental brooding cool towards ambient temperatures (Fig. 6). Both nestling insulation and the abilities of the young birds to produce heat are involved here. Figure 6 shows that older nestlings were more able to resist heat loss than were younger birds and to do so more effectively at warmer temperatures than at colder. If such nestlings are tested experimentally at these temperatures for prolonged periods their abilities to maintain even this degree of temperature control are lost and they become torpid. Similar results are obtained when the nestlings are exposed to particularly low temperatures, so they are unable to compensate for the rate of heat loss from their bodies.

Much of the variation in the timing of thermoregulation is associated with the specific growth rate of the nestling, with fast-growing species becoming thermally independent sooner than slow-growing species. But amongst species with a given growth rate, those with the longer nestling period attain thermoregulation somewhat later.

Amongst precocial species the onset of thermoregulation is harder to define, given the independence of such young. However, there are a number of obvious gradients with ecological factors (Table). The diving ducks were the most resistant to cold stress, followed by dabbling ducks, then the gallinaceous species and semi-altricial gulls. This sequence basically reflects the normal exposure to cold. Amongst the auks young Guillemots show temperature control at 10–12°C from about 3 days of age and Puffins *Fratercula arctica* by 6–7 days of age. However, these are experimental findings and in the wild the chicks are in fact brooded at these temperatures until 5–6 days from hatching. Amongst young waders thermoregulatory abilities seem poorly developed, with various sandpiper chicks averaging 37.2°C when actively brooded but averaging 3° lower when actively feeding and becoming quite torpid when crouching in response to adult alarm calls (see also HEAT REGULATION).

Table of temperature regulation in recently-hatched young of various species when experimentally kept in ambient temperatures of 10°C for 20 minutes. (Data were estimated from the graphical presentation of Koskimies, J. & Lahti, L. (1964 Auk 81: 281–307).)

	Drop in body temp., °C
Goldeneye *Bucephala clangula*	0.2
Mallard *Anas platyrhynchos*	1.0
Teal *Anas crecca*	1.3
Blackcock *Tetrao tetrix*	3.8
Capercaillie *Tetrao urogallus*	4.0
Lesser Black-backed Gull *Larus fuscus*	4.0
Herring Gull *Larus argentatus*	4.2
Pheasant *Phasianus colchicus*	4.4
Black-headed Gull *Larus ridibundus*	5.8
Willow Ptarmigan *Lagopus lagopus*	8.0
Domestic Pigeon *Columba livia*	15.4

Metabolic rate and body weight. Metabolic output of young birds is a power function of their body weight at any age but the exponent is greater than amongst adults. There are significant differences between passerines and non-passerines in the speed with which they reach adult levels of metabolic intensity, the latter achieving this level sooner. There is a similar difference in passerine embryos, their weight-specific metabolism averaging about one-quarter to one-third the levels shown by adults of the same weight, whilst a non-passerine's metabolic intensity is nearly one-half of the adult level.

Body temperatures can be regulated either by controlling body conductance (the resistance offered by the body to the loss of heat produced internally) or by regulating heat production. Because their plumage is initially inadequate, young birds at first thermoregulate by producing excessive amounts of heat, only later reducing this rate of heat production with improvements in their body conductance.

Figure 7 shows the pattern of oxygen production in Blue Tit *Parus caeruleus* nestlings of different ages. In the youngest birds oxygen consumption is directly proportional to the prevailing temperatures, whilst in the oldest young the pattern of respiration approaches that of

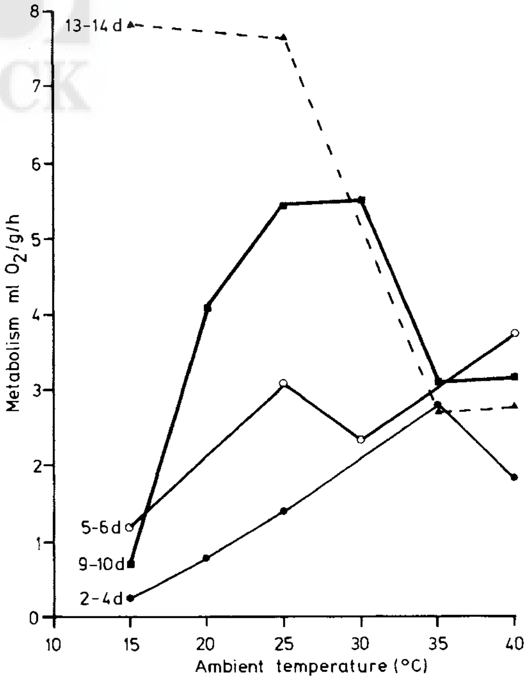

Fig. 7. Age changes in the metabolic rate of Blue Tit *Parus caeruleus* nestlings exposed to various ambient temperatures, showing the development of the nestlings' ability to produce heat. (After O'Connor, 1984).

the adult, with the inverse relationship between temperature and metabolic output. At intermediate ages the situation is more complex, the birds elevating their heat production in response to lower temperatures over a range of the warmer ambients but losing heat too rapidly and becoming torpid at the lower temperatures.

These patterns of thermoregulatory development in nestlings are associated with concomitant changes in the physiology and morphology of the young bird. As it increases in size its surface to volume ratio decreases, reducing the rate at which heat is lost from the body. Secondly, air sacs—functional in adult respiration—do not develop fully until some days into the nestling period and thus contribute increasingly to the metabolism of oxygen later. A third change involves the circulatory system, for the heart increases slightly in relative size and there are major increases in the erythrocyte concentration of the blood and in haemoglobin concentration. These changes contribute to the ability of the circulatory system to transport oxygen to the lungs. Carbohydrates form the main energy reserve for short-term responses to cold stress and their concentration in the body increases with age. Chemical thermoregulation by the young is also promoted (at least in domestic fowl) by injection with such hormones as noradrenalin, and thyroid hormones also contribute to cold stress responses. Thyroid activity peaks in altricial nestlings a day or so before the onset of full homeothermy. Finally, development in heat production by shivering under nervous system control contributes to heat production, appearing 3 or 4 days into the nestling period but increasing efficiency of heat production for sometime thereafter.

In precocial species very similar processes are apparent, though some of the responses, e.g., muscle tremor, begin shortly before the embryos hatch.

Another way in which young birds can regulate their heat loss to the environment operates by way of a lower body temperature than is shown by the adult bird. By doing this, the thermal gradient between bird and environment is reduced, with consequential reduction in the rate of cooling. Nestlings of several species have been shown to increase their equilibrium body temperature with age in this fashion.

Evaporative cooling and hyperthermia are the main defences available to nestlings subjected to heat stress. Hyperthermia operates to cool the nestling by elevating its body temperature above the ambient temperature, thus creating a temporary gradient down which heat can flow from the nestling to the now cooler environment. Conversely, in extremely hot conditions elevation of temperature reduces the rate at which further heat can flow into the nestling. Thermal ability of this type is more marked in very young birds than in older birds: 3-day-old House Wren *Troglodytes aedon* nestlings can safely withstand temperatures as high as 45.5°C but nestlings 11–16 days old can withstand high temperatures only to 42.1°C.

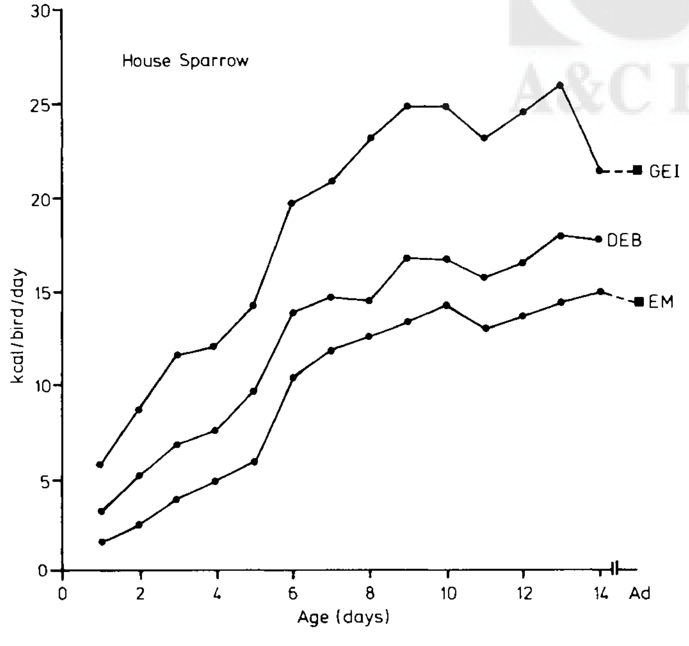

Fig. 8. Changes in energy budgets of House Sparrow *Passer domesticus* nestlings with age, showing changes in gross energy intake (GEI), in daily energy budget after assimilation (DEB), and in existence energy (EM). (From Myrcha, Pinowski & Tomek, 1972. *In* Kendeigh & Pinowski, (eds). Productivity, Population Dynamics and Systematics of Granivorous Birds. (PWN) Warsaw).

Evaporative cooling also serves nestlings faced with heat stress. Each millilitre of water evaporated carries with it 580 cal of latent heat. Consequently a nestling can work, e.g., by panting, to evaporate water and thereby lose more heat through evaporation than is produced by the extra effort of panting. Even quite young nestlings are able to pant when exposed to heat, and in tropical species regularly exposed to high temperatures this cooling can be enhanced by gular flutter.

Energetics of growth. The pattern of energy used during growth differs between altricial and precocial species (Fig. 8). Gross energy intake is higher in altricial species than in precocial species. In the House Sparrow the amount of energy spent on basic existence and maintenance costs rises to nearly twice the adult level before declining, thus implying that the young nestling is less efficient than an adult in its use of energy for maintenance costs. Precocial and altricial young alike have higher gross energy intakes than adults, but the excess is larger and increases virtually until fledging in precocial species. The energy expended in this way comes from the metabolization of food ingested and in the altricial House Sparrow food assimilation efficiency is at first below adult levels but reaches these after 4–5 days. In the precocial Black-bellied Tree Duck *Dendrocygna autumnalis* this efficiency varies little during the first part of postnatal life.

The daily energy requirements (Kcal/bird/day) of young birds increases with body weight according to the equation

$$\mathrm{DEB} = 1.353\,\mathrm{W}^{0.814}$$

(Kendeigh *et al* 1977), showing a faster increase with weight (exponent = 0.814) than would be the case amongst adults (exponent = 0.67). The young thus expend more energy per day than would an adult of the same weight, probably the result of the inferior insulation afforded by feathers whose shafts are vascularized until late in development. The different life-styles of altricial and precocial species result, however, in different proportions of their energy intake being devoted to maintenance costs. Despite these differences, though, there are no major differences in the proportion of energy consumed which is eventually converted into growth (see also ENERGETICS). R.J.O'C.

GRUES; GRUIDAE: see GRUIFORMES; CRANE.

GRUIFORMES: an order comprising 7 suborders: Turnices, Grues, Heliornithes, Rhynocheti, Eurypygae, Cariamae, Otides; 11 families: Turnicidae (BUTTONQUAIL), Pedionomidae (PLAINS-WANDERER), Rallidae (RAIL), Aramidae (LIMPKIN), Psophiidae (TRUMPETER), Gruidae (CRANE), Heliornithidae (FINFOOT), Rhynochetidae (KAGU), Eurypygidae (SUNBITTERN), Cariamidae (SERIEMA), Otididae (BUSTARD).

Of the assemblage as a whole, it may be said that it consists essentially of ground-living birds—ground-feeding and mainly ground-nesting; many of them seldom fly, and a few never. The Heliornithidae and some of the Rallidae, e.g., coots (Fulicinae) and gallinules of various genera, are adapted to an aquatic life; many others frequent marshes or the margins of water. Of the families, the Rallidae include a large number of genera; 4 of the families are monotypic. Only the Gruidae and Rallidae are cosmopolitan, although the Turnicidae and Otididae are widespread in the Old World; the others have restricted distributions.

GUACHARO: alternative name of *Steatornis caripensis* (see OILBIRD).

GUAIABERO: substantive name of the Philippine species *Bolbopsittacus lunulatus* (Psittacinae) (see PARROT).

GUAN: substantive name of some species of Cracidae (see CURASSOW).

GUANO: the excreta of seabirds, dried to a crusty, rock-like or rough powdery consistency. Huanu is an Incan (Quechuan) word and its derivative is now widely used and applied, also, to other animal excreta such as 'bat guano' from caves (see also GUANO, CAVE). Guano, the Inca's 'secret' (see The Royal Commentaries of the Incas (1609) by Garcilaso de la Vega), introduced to the modern world by Alexander von Humboldt, has been extensively used as organic fertilizer, that from Peru giving rise to scandalous 19th-century commercial and political machinations. As Murphy wrote: 'Small though the Chinchas (Peruvian guano islands) are, their name is known in the farthest seaports of the world and their share in making fortunes and abetting calamities, in debauching men and demoralizing administrations, and in serving as the inanimate cause of greed, cruelty, extravagance, economic ruin and wars has given them a historic place quite out of proportion to their size.'

Guano is formed over many years where huge and densely packed colonies of seabirds breed on arid, flattish islands. Guanay Cormorants *Phalacrocorax bougainvillei* nest at a density of 3 pairs per m^2 whilst Cape Gannets *Sula capensis* have been recorded at 6.8 nests per m^2 though 3 or 4 is more usual. Many guano islands at times hold more than a million birds and some hold several millions (Central Chincha, maximum estimate 6 million). Necessarily, these colonies are situated in or near to enormously productive upwelling areas which support inconceivable numbers of fish (the catch of anchovies by Peru, 1969/70, contained more than 10 trillion). The Peruvian guano islands adjacent to the Humboldt current, those off SW Africa in the region of the Benguela and the seabird islands in the Gulf of California in the region of the California current are the best examples. Global wind and current systems are such that the cold and nutrient-laden upwellings are on the western seaboards of land masses (North America, South America, South Africa, India, Australia). These areas are also dry, the cold upwelling accentuating aridity by delivering cold moist air to a hot land mass, thus preventing precipitation (the moisture is retained in the warm air as mist).

Pelecaniforms, especially cormorants (*Phalacrocorax bougainvillei* in Peru; *P. capensis* in South Africa), sulids (*Sula variegata* and marginally *S. nebouxii* in Peru, *S. capensis* in South Africa) and pelicans (*Pelecanus occidentalis thagus*) produce most guano, partly because they are most numerous and also because some species tend to withhold their excreta until they are at the breeding site, where they deposit it to form the nest. Cape Gannets (average nest weight 1,770 gm) have been shown to reproduce more successfully where ample guano was artificially provided than in otherwise comparable areas. Guano can be used as nest material only in a dry climate; otherwise it would become sticky and coat the egg and chick. A Guanay Cormorant deposits on land, throughout its life, a minimum dry weight of 1 kg of guano per month. In addition to the 3 main guano-producing species, penguins (Peruvian Penguin *Spheniscus humboldti* in Peru and Jackass *Spheniscus demersus* in South Africa) and diving petrels (*Pelecanoides garnotii* in Peru) have been significant contributors, whilst the Gulf of California and islands off Mexico were seriously investigated as the potential basis for a guano industry, to which the Blue-footed Booby *Sula nebouxii* would have been the main contributor.

Seabird excreta leached by moisture lose nitrogen and leave calcium phosphate minerals, called phosphatic guano. This is less nutritious to plants than the original high-grade nitrogenous guano. The calcium phosphate from the Indian Ocean Christmas Island (apatite ore for conversion into superphosphate fertilizer in Australia and New Zealand) is said to be modified guano, but if this is so, vast changes in topography, climate and seabird population have occurred since its deposition. In some parts of the world, low-grade 'guano' is collected, consisting of annual increments of excreta scraped up together with much substrate and nest material.

Peruvian guano contains approximately 21% water, 53% organic material capable of being burnt off, 1.7% insoluble materials (silicon dioxide, etc.), 3.5% sodium oxide, 2.5% potassium oxide, between 3 and 11% calcium oxide, 0.5% magnesium oxide, between 7 and 11% phosphorus pentoxide, 2% chlorine, 0.3% sulphur trioxide and 0.9% of a complex of aluminium and ferric phosphate (Hutchinson 1950).

Although the guano caps of the islands were up to 90 m thick, this represented the deposits of no more than 2–3,000 years. However, C^{14} dating has indicated a much greater age for at least one deposit. Earlier guano caps may have been washed away by periods (measured in scores or hundreds of years) during which a wetter climate prevailed. Indeed, the distribution of guano-birds has changed within (relatively) recent times. There are extensive and old (fossil) guano deposits in Peru/Chile well south of the present concentrations of guano birds and the 'modern' deposits of guano. This southern area evidently became uninhabitable whilst the northern one became attractive, having presumably been climatically unsuitable previously. The factors which led to the decline of guano birds in the south may have been oceanographic (change in currents and distribution of food fish and in sea level, submerging many islands off Chile).

Between 1848 and 1875 more than 20 million tons of guano were shipped from Peru, mainly to Europe, USA and Britain. This was the era of total exploitation, both of the resource (including the seabirds) and the labour force. In 1909, the Guano Administration instituted protection for guano birds, the single most effective measure being the stationing of official wardens at the main breeding stations to control human and other animal predators (foxes, gulls, Condors *Vultur gryphus* and Turkey Vultures *Cathartes aura*). Since 1945 extra nesting areas have been provided on Peruvian coastal headlands. Peninsulas have been isolated by high concrete walls, nesting areas enlarged and sites created. Up until 1956 these measures dramatically increased the mainland population and in 1962 headlands held some 4,500,000 guano birds. Other regulations, though rarely enforced, oblige boats to remain at least 3 km away from the islands holding breeding colonies, fishing boats to refrain from operations within a 5-km belt around all stations (8 km around some) and planes to fly over stations at a height no lower than 500 m. Harvesting of guano takes place every second or third year on a rotating basis; the maximum yield per year is in the region of 300,000 tons.

Harvesting inevitably disrupts breeding cycles and may be partly responsible for the considerable movements of birds between nesting islands, although shifts in the distribution of anchovies may also be involved.

The populations of Peruvian guano birds (mainly *Phalacrocorax bougainvillei*, *Sula variegata* and *Pelecanus thagus*), and also the proportions of each, fluctuate massively. Little can be inferred about changes prior to the 20th century though Vogt (1942) suggested that there had been a massive decline due to climatic changes and/or disease. However, this century the population has fluctuated between less than 3 and more than 20 millions of individuals. When estimated from the amount of guano deposited (a surprisingly accurate method), the highest figure is 28 million. The population crashes periodically. The cold upwelling fails, anchovies *Anchoveta engraulis* avoid the warm surface layers and become inaccessible and guano birds starve en masse. Until recently recovery was rapid but overfishing by the Peruvians, for example an official catch of 11 million metric tons in 1969/70, largely for the manufacture of fish meal, has apparently reduced stocks and/or altered the age composition of the anchovy population. Presumably as a result of this, recovery from the most recent crashes (1965, 1972/3, and 1983/4) has been greatly retarded. In addition, in the 1960s, many thousands of breeding guano birds were killed by fishermen. At the present time, after a period during which anchovy stocks remained low, some recovery in them and the seafowl has taken place, the boobies having fared better than the cormorants and pelicans.

In South Africa declining catches by fishermen has led, as in Peru, to requests for an official policy of killing off seabirds. Apart from the fact that the seabirds catch fish and interfere with the nets, it has been argued that man can convert fish into meal more efficiently (at 5 : 1) than birds can convert it into guano (at 9.7 : 1). But birds not only produce a better and cheaper product, they also remain in a stable relationship with their ecosystem. Man should learn to do the same. And a colony of guano birds is more beautiful than a stinking fishmeal factory.

GUANO, CAVE: of avian origin, occurs in limestone caves in South-east Asia occupied by swiftlets of the genera *Collocalia* and *Aerodramus* (see EDIBLE NESTS). Droppings gathering below nest sites are quickly reduced, by a rich fauna of coprophagic arthropods, to a dark brown material with the consistency of damp sawdust. This is composed chiefly of organic matter and normally contains 6–10% phosphate and 3–9% nitrogen. In undisturbed dry caves this fresh guano is underlain by deposits, which can be several metres thick, of a compact, powdery 'fossil' guano containing 10–45% phosphate by weight (characteristically as collophanite, $3CaOP_2O_5H_2O$), often with other minerals, and 10–30% organic matter. Despite low nitrogen and unpredictable phosphate yield, both types of guano are locally popular as fertilizer. Most accessible caves in the region have already been stripped down to bedrock. C.

GUIDING LINE: less appropriate alternative term (translating 'Leitlinie') for LEADING LINE (see MIGRATION).

GUILLEMOT: substantive name of *Uria* spp. ('murre' in American usage) and *Cepphus* spp. (also called 'tystie')—see AUK. Although originally a French word, it is now pronounced in English with the final syllable as in 'hot'.

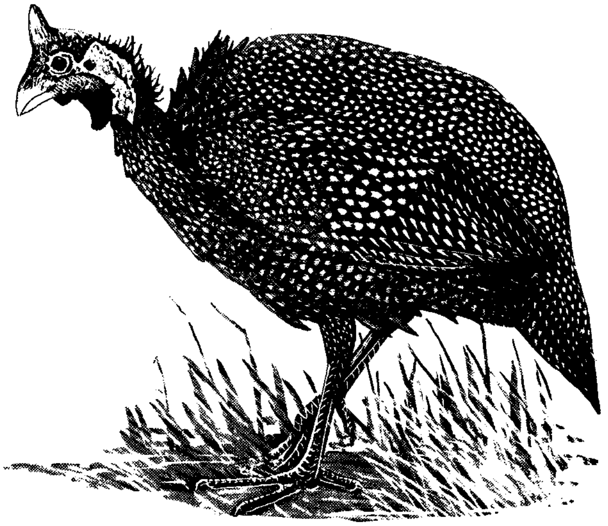
GUINEAFOWL: substantive name of species of Numidinae (Galliformes, family Phasianidae); a group of sedentary terrestrial gamebirds. There are 6–7 species, assigned to 4 genera, 2 of which are superspecies.

Characteristics. The major external feature of guineafowl is a largely unfeathered head and neck, which is adorned with cartilaginous gape wattles and areas of richly pigmented, sometimes folded skin. Some species have a well-developed casque or feathered crest surmounting the crown, and cartilaginous bristles or warts at the cere. These structures provide some of the most useful specific and subspecific taxonomic characters, and presumably play important roles in species and individual recognition, and possibly in thermoregulation. Patterns of geographic variation in these and other morphological features of guineafowl correlate well with, and may be adaptively related to, variation in the thermal and moisture environments.

All guineafowl species show little sexual dimorphism, with males averaging slightly larger than females, range 45–60 cm. Size among the various species appears to be inversely related to the density of the vegetation in which they live. The smallest guineafowl are *Agelastes* spp. (mean wing length 20.4 cm), which inhabit dense, virgin, tropical rain-forest. Among the guineafowl with feathery crests (*Guttera* spp.) *G. plumifera*, which inhabits dense forest, is smaller (mean wing length 22.5 cm) than *G. pucherani* (range of mean wing length among subspecies 24.5–26.0 cm), which lives in secondary and riparian forest, and along the forest edge. Larger still is the Helmeted Guineafowl *Numida meleagris* (range of mean wing length among subspecies 25–28 cm), which lives in relatively open savanna vegetation and mixed savanna-bush. The Vulturine Guineafowl *Acryllium vulturinum* is the largest of the guineafowl (mean wing length 29.5 cm), and frequents the semi-desert steppe of the Horn of Africa.

Distribution and habitat. The ancestral guineafowl is thought to have arisen from an Asian, savanna-living, francolin-like phasianid which colonized Africa during the mid to late Miocene, and radiated into terrestrial biotopes which were relatively unexploited. With the exception of an isolated population in Morocco, guineafowl now occur naturally only in sub-Saharan Africa. Distribution patterns of species and subspecies correlate well with the present-day distribution of vegetation, so that nearly every African biome and biotope has an associated guineafowl species or subspecies. However, guineafowl evolution at all taxonomic levels has been influenced by past changes in the distribution of forest, savanna and desert during geological time (see AFROTROPICAL REGION). One species, *Numida meleagris*, has been domesticated (probably several times independently), and/or captured and introduced widely throughout the world (see DOMESTICATION). This accounts for its presence in south-western Arabia, the Malagasy Republic and on offshore African islands.

Food. They consume varying amounts of grit, and appear to be opportunistic omnivores, probably favouring insects when they are abundant. The bill of the Helmeted Guineafowl *Numida meleagris* is arched, and therefore well-suited to digging for underground bulbs, which are a favoured food item during dry periods and may be an important supplementary source of water.



Helmeted Guineafowl *Numida meleagris*. (*M.W.*).

Social behaviour. With the exception of *Agelastes* spp., which appear to associate in small (family?) parties, all guineafowl species are highly gregarious in the non-breeding season, and flocks of 50 birds or more are not uncommon sightings. All species roost in trees at night. At least 3 species (*N. meleagris*, *G. pucherani* and *A. vulturinum*) exhibit courtship feeding, and this behaviour is highly ritualized in *A. vulturinum*. These 3 species are monogamous in their breeding habits, although males may attempt to copulate with unattended females.

Voice. As with size, the pitch of the rattling alarm calls given by guineafowl species is inversely related to habitat vegetation density. Thus the desert-living *Acryllium* has the highest pitched, while *Guttera* spp. and *Agelastes* spp. have the lowest-pitched calls. *Numida meleagris* and *Acryllium vulturinum* females, especially when separated from their mates during the breeding season, emit a characteristic two-noted buck-wheat call, to which their cocks respond antiphonally with a single note.

Breeding. The nests of *Agelastes* spp. have not been described, but those of all other guineafowl are well-concealed shallow scrapes in the ground, which may be thinly lined with grass. The eggs of all species are pitted, creamy or buff in colour, remarkably thick shelled, blunt at one end and pointed at the other. Nests with 12 or more eggs are not uncommon. Sometimes several hens may lay in the same nest. The incubation period for the various species ranges from 23 days (for *Guttera* spp. and *Acryllium*) to 27–28 days (for *Numida*). At 15–20 days old, *Numida* chicks can fly up to roosts 2 m above ground.

Specific distribution. The most widely distributed and well-studied member of the family is the Helmeted Guineafowl *Numida meleagris*. This open-country, polytypic species has a virtually unfeathered head and neck, with the exception of the hindneck, which is covered by a concentration of short, downy, or long, hair-like feathers. The bill is heavy, a bony helmet (see CASQUE) with a horny sheath surmounts the crown, and a pair of long wattles hangs from the gape. The nostrils are exposed, and are rimmed with cartilaginous bristles or warts in subspecies which live in hot, arid biotopes. The blood vessels which supply the wattles, cere and upper hindneck are finally interwoven into *retia*, which may promote counter-current heat exchange, and thereby assist in the regulation of brain temperature through convective cooling of warm arterial blood coming from the heart. The iris of the chick is grey, but changes to brown by the age of 20 weeks. The tarsus is unspurred, and the legs are long and powerful, as befits a species which relies on running as its primary means of escape, and on scratching in the soil for much of its food. The ground colour of the plumage is black, with white spots intermeshed with a network of similarly-coloured vermiculation. The spots on the outer margins of the secondaries merge to form bars (perpendicular to the rachis), which also have intervening vermiculation. The degree of vermiculation is most intense in subspecies which live in hot and arid biotopes, and may afford some degree of camouflage.

There are 9 well-marked subspecies of *N. meleagris*, which fall into 3 groups: the West African, East African and Central–Southern African subspecies groups. These groups are separated by relatively narrow zones of intergradation, and hence have been regarded as semispecies. The West African subspecies group (*N. m. galeata* and *N. m. sabyi*) consists of small- to medium-sized birds, with very short helmets (i.e., less than 1 cm tall), a naked cere, a grey to blue-grey mantle, rounded red wattles, very pale blue facial skin, and long hair-like feathers confined to the mid-dorsal line of the hindneck. Since *N. m. sabyi*, the isolated Moroccan subspecies, differs relatively little from *N. m. galeata*, the hundreds of kilometres of desert which presently separate the 2 subspecies are likely to be a relatively recent development on a geological time scale.

The domesticated guineafowl is derived from *N. m. galeata*, and artificial selection has significantly modified its external morphology. Since domesticated guineafowl have been bred to be broilers, they are 20–25% heavier than their wild counterparts, which weigh about 1,300 g. They have thicker tarsi, which are orange and not black as in wild stock. The colour of the face, and that of the plumage of some breeds, is entirely white, and the wattles and helmet are 30–50% larger. There are no qualitative differences in displays, social and maintenance behaviour between wild and domesticated guineafowl. Even wild populations of this species can be more or less commensals of man, since the distribution and numbers of Helmeted Guineafowl have increased markedly when critical resources, e.g., water (bore holes and dams), roosts (telephone poles, exotic trees), and food (maize, wheat, lucerne, etc.) have been provided.

The East African subspecies group (*N. m. meleagris* and *N. m. somaliensis*) are medium-sized guineafowl (mean wing length 26.5 cm) with short helmets (mean height 1.2 cm), a cere with long bristles (up to 2.5 cm), a finely barred mantle, rounded blue (or with small red tips) wattles, cobalt blue facial skin, and a blanket of short downy feathers covering the hindneck.

The Central–Southern African subspecies group (*N. m. reichenowi*, *N. m. mitrata*, *N. m. marungensis*, *N. m. papillosa*, and *N. m. coronata*) consists of relatively large birds, with tall helmets (i.e., greater than 1.8 cm), a naked cere (except *N. m. papillosa* which has its cere rimmed by warts), a finely barred mantle, triangular-shaped blue wattles with red tips (except *N. m. reichenowi* which has rounded red wattles), cobalt blue facial skin, and varying amounts of long hair-like feathers confined to the mid-dorsal line of the hindneck.

Although *N. meleagris* is virtually sexually monomorphic, the sex of live birds can be determined accurately by cloacal examination, and through study of individual behaviour. During the breeding season, males develop a cloacal protuberance, which is easily discovered by gently everting the cloaca. Males, again mainly during the breeding season, display laterally to each other, and to hens, in a 'hump-backed' posture (i.e., with the wings raised and laterally compressed against their bodies), and run on the tips of their toes. In this 'hump-backed' posture all important taxonomic characters of this species are displayed to their fullest.

Closely allied to *Numida* is the Vulturine Guineafowl *Acryllium vulturinum*. In captivity the 2 species will hybridize to produce sterile offspring. However, encounters between these 2 guineafowl in the wild are rare, since they segregate according to habitat where they are sympatric. The bare skin of the head and neck of *Acryllium* is blue-grey, and the only plumage thereon is a band of short, downy chestnut feathers which stretches across the occiput from ear to ear. The wattles are rudimentary, and the iris a brilliant crimson. The most striking field characters for this species are well-developed hackles, and a pair of long central tail feathers. The former consist of long, narrow, pointed feathers striped longitudinally with black and white, and margined with cobalt blue. The breast and abdomen are also extensively covered by cobalt blue plumage. The remainder of the plumage resembles that of *Numida* except that the outer margins of the secondaries are lilac, and the inter-spot vermiculation is much denser. The only external feature which shows obvious inter-individual variation is the tarsal adornment, which is a series of degenerate, rounded spurs or 'bumps'. No two individuals have both the same number (up to 6) and size of 'bumps', and there is even variation in 'bump' arrangement between legs. As with important characters in *Numida*, this species' characteristic features are displayed to their fullest in aggressive and courtship postures.

The first guineafowl encountered as one enters forest biome is the Crested Guineafowl *Guttera pucherani*. Most taxonomic treatments recognize 2 species of these 'forest-edge' birds, but breeding experiments with captive individuals have demonstrated complete interfertility between 'species', and morphological intermediates have been identified among museum specimens collected in zones of contact. Nevertheless, all subspecies attributed to *G. pucherani* are much more well-marked than are those for *N. meleagris*, which supports the idea that forest-dwelling guineafowl have been more effectively isolated in refugia during the geological past than have savanna species.

The body plumage of *G. pucherani* is similar to that of *Numida* and *Acryllium* except that the spots are tinged with blue, and there is no vermiculation between them. The outer margin of the secondaries is white, and the tarsus is unspurred. The crown is surmounted by a crest of curly, downy feathers; gape wattles are rudimentary; there is a well-developed fold of skin at the occiput and, in all but one subspecies, at the base of the neck; and the skin of most of the head and neck is dull blue-grey. A striking feature of the internal anatomy of this species is the hollow furcula of the clavicle through which passes the trachea. This feature may act as a resonant organ which allows the broadcasting of calls over relatively long distances.

The 5 subspecies attributed to *G. pucherani* can be divided into 3 groups: the West–Central, East and Southern African subspecies groups. These groups can be distinguished through differences in the morphology of the head, neck and mantle. Subspecies of the West–Central African group (*G. p. verreauxi* and *G. p. sclateri*) have red throats and brown irides. Those of the Southern African group (*G. p. edouardi* and *G. p. barbata*) have dull blue-grey throats and red irides. The Kenyan Crested Guineafowl *G. p. pucherani* has a red throat and red irides, and differs further from other subspecies in having virtually no black feathers in the mantle (all other subspecies have a distinct black 'collar'), and a ring of red skin around the eye.

Moving deeper into forest biome, the next guineafowl which may be encountered is the Plumed Guineafowl *Guttera plumifera*. This species and *G. pucherani* form a superspecies. The body plumage of *G. plumifera* is similar to that of *G. pucherani*, except that there is little or no tinge of blue to the spots, and the entire mantle is spotted (i.e., lacks a 'collar' of black feathers). Other characteristic features of *G. plumifera* are: a tall crest of straight bristly feathers, brown eyes, long gape wattles, and a rudimentary occipital skin fold. Like *G. pucherani*, *G. plumifera* has a hollow furcula, but it is much less well-developed. Although the Congo forest (to which this species is confined) stretches relatively uninterrupted from the Atlantic coast to Uganda, there are 2 subspecies of *G. plumifera*. One subspecies (*G. p. plumifera*) is confined to the western reaches, the other (*G. p. schubotzi*) to the eastern portion of the forest. The major difference between the 2 subspecies is that *G. p. schubotzi* has patches of orange-yellow skin at the base of the nape and just anterior to the ear, while the head of *G. p. plumifera* is entirely dull blue-grey. The fact that this relatively uninterrupted forest can harbour more than one subspecies of forest-dwelling bird suggests that it was formerly fragmented into island-like refugia.

Deeper still in virgin tropical rain-forest live the Turkey Guineafowl *Agelastes meleagrides* and the Black Guineafowl *A. niger*. There is only fragmentary or anecdotal information on the natural history of these forest guineafowl, and this has already been summarized above. These species differ conspicuously from other guineafowl in having a wholly unspotted body plumage. That of *A. niger* is uniformly blackish-brown, and that of *A. meleagrides* blackish-brown with fine grey vermiculation. The bare skin of the heads of both species is red, brighter in *A. meleagrides*. The head of *A. meleagrides* is unfeathered, and that of *A. niger* is surmounted by a crest of short feathers which extends from the base of the bill to the occiput. The mantle and breast of *A. meleagrides* are snowy white. Both species have brown irides and well-developed spurs on their tarsi.

GUIRA: *Guira guira* (see CUCKOO).

GULAR: pertaining to the throat (see TOPOGRAPHY).

GULAR FLUTTER: rapid oscillation of the thin floor of the mouth and upper throat (see HEAT REGULATION).

GULL: substantive name of nearly all the species of the family Laridae (Charadriiformes, suborder Lari); in the plural, general term for the family. The other families of the suborder are the Sternidae (see TERN), Rynchopidae (see SKIMMER), and Stercorariidae (see SKUA).

Characteristics. All species are medium to large (length 31–76 cm) and have relatively long and narrow wings (span 64–165 cm), with 10 functional primaries and one vestigial. The tail of 12 rectrices is usually almost square and of moderate length, generally 35–45% of the length of the closed wing. The bill is usually stout, sometimes slightly hooked, with a tapering nail, and a marked gonydeal angle. The tarsus is rather long and slender, the 3 front toes webbed, the hind toe very small or in a few species vestigial. The plumage of adults is basically white and grey. Head, underparts, rump, tail and underwings are white, sometimes washed grey to a variable degree, the head often covered for part of the year by a dark brown or black hood, leaving contrasting white marks above and below the eye, the tail adorned in a few species by a subterminal black band. Mantle and upper wing-coverts are grey, white in one species, black in a few. The tips of the primaries are usually patterned with black or black and white. Irides are usually brownish-black, sometimes white or pale yellow. The fleshy eye-ring is usually red or deep red tending to black, but yellow or purple in a few species. The bill is usually red, reddish-black or black, sometimes yellow with black or red distal marks or entirely yellow. Legs and feet are red to black, but yellow, bluish, greenish or flesh-coloured in a few groups of species.

Adults have an annual complete moult, starting during or immediately after the breeding season, but, in a few species, after the autumn migration, and in the Ivory Gull *Pagophila eburnea* before the breeding season. A second moult, not involving, except in a very few species, the wings and tail, takes place before the breeding season. Breeding and non-breeding plumages differ in most species.

Downy chicks are usually grey or buff, variously patterned with dark brown stripes and spots. Juveniles of almost all species are brown and buff with strongly patterned mantle and upper wing-coverts, dark remiges and rectrices. This plumage is replaced after a few weeks to a few months by a usually distinct first-winter dress. Adult plumage is acquired after as long as 4 or more years in some large species, through a succession of plumage stages reached by moults which generally take place earlier in the year than those of adults.

Systematics. The morphological uniformity of the family has made the construction of phylogenies difficult. The principal revisions are those of Dwight (1925), based entirely on structure and plumage, and Moynihan (1959), based partly on behaviour. The present arrangement is derived from these but more recent information on behaviour, morphology and distribution is taken into account.

Pelagic gulls. A small number of species, pelagic or semi-pelagic when not breeding, differs sharply from the core of typical gulls in voice, behaviour, proportions, tail-shape (either forked or wedge-shaped) and several adult and juvenile plumage characters. When hooded, they lack the white eye marks characteristic of gulls. Many of their characters are primitive within larids and they probably represent early offshoots near the common ancestors of typical gulls and terns. Their originality is best expressed by placing them in several small genera. The Swallow-tailed Gull *Creagrus furcatus* is a large species with long forked tail, slaty breeding hood and prominent wing pattern. Three small species, Sabine's Gull *Xema sabini*, Ross's Gull *X. rosea* and the Little Gull *X. minuta* have similar juvenile plumage. *X. sabini* and *X. minuta* have dark breeding hoods, without white eye marks, while *X. sabini* and *X. rosea* share unique black neck rings, bordering the slaty hood in *sabini*. The 2 kittiwakes, Black-legged *Rissa tridactyla* and Red-legged *R. brevirostris*, have juvenile plumages, which are reduced versions of those of *Creagrus* and *Xema*, and a shallowly forked tail. They are white-hooded in summer. It is unclear whether the peculiar Ivory Gull, white when adult, spotted brown in juvenile plumage, belongs near these primitive species.

All other gulls may be placed in a single genus *Larus*, subdivided into 5 main groups.

Central Eurasian gulls. The Great Black-headed Gull *Larus ichthyaetus*, Mediterranean Gull *L. melanocephalus* and Relict Gull *L. relictus*, breeding on the inland seas and lakes of Eurasian steppes are much alike in downy and juvenile plumages and, when adult, differ mostly in size and mantle shade. They are hooded in breeding plumage and have a characteristic auricular bridle in non-breeding dress. The agonistic behaviour of the Mediterranean Gull is very un-*Larus*-like, while that of the Relict Gull seems to have similarities with those of possibly primitive species in other groups such as Audouin's Gull *L. audouinii* or the Slender-billed Gull *L. genei*, so that the central Eurasian gulls may well occupy a position near the centre of evolution of the *Larus* gulls.

Masked gulls. The relatives of the Black-headed Gull *L. ridibundus* form a successful homogeneous group, best characterized by the presence of a conspicuous white triangle along the leading edge of the wing, dark underside to the primaries, and the development of the Forward Display in the Long-Call performance. They are hooded or not in breeding plumage, differ in wing-tip pattern, but generally have a characteristic double band across the top of the head in non-breeding or immature plumage. The core species are the Black-headed Gull, the Grey-headed *L. cirrocephalus*, the Brown-headed *L. maculipennis*, the Andean *L. serranus*, the Silver *L. novaehollandiae*, Buller's Gull *L. bulleri*, and Hartlaub's Gull *L. hartlaubii*. Somewhat more distantly related seem to be Bonaparte's Gull *L. philadelphia* which lacks the dark underwing, the Slender-billed which lacks the Forward Display, the Indian Black-headed Gull *L. brunnicephalus* and Saunders' Gull *L. saundersi*. The masked gulls seem to represent the top of one evolutionary line among *Larus* gulls, perhaps derived from the previous group.

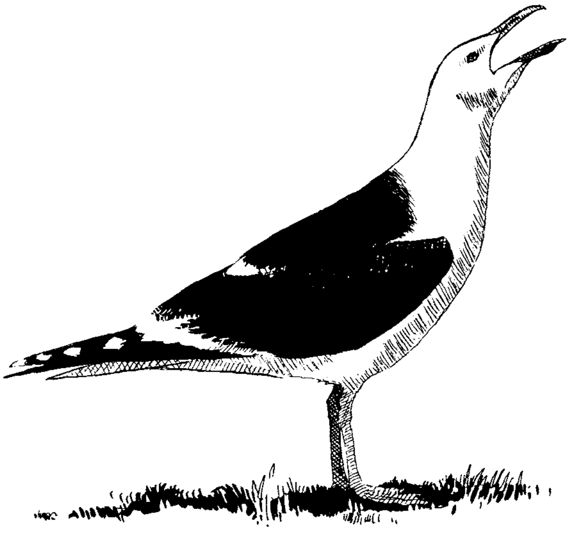
Herring gulls. This is also a large, homogeneous, successful group, probably at the summit of another evolutionary line; all species are large, with patterned or white wing tips, a white head in breeding dress, and usually a streaked hood in winter. Their legs are yellow or flesh-coloured, their bills usually with a red gonydeal patch, a unique pattern in *Larus*. The group comprises many closely related species, of almost identical behaviour, e.g., Glaucous *L. hyperboreus*, Iceland *L. glaucoides*, Thayer's *L. thayeri*, Glaucous-winged *L. glaucescens*, Western *L. occidentalis*, Yellow-footed *L. livens*, Dominican *L. dominicanus*, Slaty-backed *L. schistisagus*, Vega *L. vegae*, Great Black-backed *L. marinus*, Herring *L. argentatus*, Yellow-legged *L. cachinnans*, Lesser Black-backed *L. fuscus*, Armenian *L. armenicus* and California Gull *L. californicus*.

American hooded gulls. The Laughing Gull *L. atricilla* and Franklin's Gull *L. pipixcan* are very similar in adult breeding plumage and almost identical in voice and behaviour. They are unquestionably closely related. The Lava Gull *L. fuliginosus*, endemic to the Galapagos, is an obvious dark derivative of the Laughing Gull. The affinities of the group with other gulls are not entirely clear but may be with the central Eurasian gulls on the one hand, the 'black-tails' (see below) and their allies on the other.

Black-tailed gulls and allies. The Pacific Gull *L. pacificus*, Olrog's *L. atlanticus*, Belcher's *L. belcheri* and Japanese Gull *L. crassirostris* have a black band in the tail of the adult plumage, plain black wing-tips, a white head in breeding plumage; they approach the herring gulls in their ritualized behaviour, their juvenile and downy plumages, the yellow bill with a red or black and red tip, and the yellow legs; they may constitute an early offshoot of the line that leads to the *argentatus* group. A few fairly isolated species, the Grey *L. modestus*, Scoresby's *L. scoresbii*, Sooty *L. hemprichii*, White-eyed *L. leucophthalmus*, Audouin's and Heermann's Gull *L. heermanni* may all be related, more or less distantly, to the black-tailed gulls.

Common and Ring-billed gulls. These 2 species are difficult to place and have usually been considered related. The Ring-billed *L. delawarensis* closely resembles the herring gulls in plumage but its behaviour seems to differ more from them than it does from some members of the black-tailed group. The Common Gull *L. canus* differs more from the herring gulls in downy and juvenile plumages, recalling the Laughing Gull or some 'black-tails', and is behaviourally isolated.

Habitat. Most gulls are coastal throughout their life cycle. A few (the kittiwakes, Swallow-tailed and Sabine's Gulls) are truly pelagic during the non-breeding season, others (Ivory, Ross's Gull) frequent the edge of ice, or (Little Gull, Mediterranean Gull) offshore waters. A few feed inland in open terrain, away from water. For breeding most species resort to flat or fairly flat open ground near water, often on islands. A few (the kittiwakes, Swallow-tailed, Ivory and Thayer's Gulls) breed on cliffs and have developed a series of adaptations to minimize the risk of eggs or young falling (Cullen 1957, Hailman 1964). Others breed in coastal or inland marshes (e.g., the Black-headed, Grey-headed and Franklin's Gulls) where they may build floating platforms (Burger 1974). Bona-



Great Black-backed Gull *Larus marinus*. (*B.P.*).

parte's Gull breeds in trees in wooded tundra, the Grey Gull in total desert far from the sea (Howell *et al* 1974). A few species (e.g., Black-legged Kittiwake, Herring, Yellow-legged and Dominican Gulls) have adapted in some areas to nesting on man-made structures.

Distribution. Worldwide, but with a scarcity of species in the tropics. Main centres of differentiation, with several original and isolated species, seem to exist in South America and in central Eurasia, while a more recent radiation of the herring gulls has given the northern shores a wealth of closely related forms.

Populations. Many species are numerous and some, in association with man, are increasing at remarkable rates. These belong mostly to the herring and masked groups. A few species, however, are uncommon with a restricted range and thus vulnerable. Examples are the solitary Lava Gull of the Galápagos, the very local Olrog's Gull of the coast of Argentina and the Mediterranean Audouin's Gull.

Movements. No gull is completely sedentary, and most species undertake migratory movements of at least restricted amplitudes, often along the coasts they frequent. These generally take the form of a post-breeding movement to lower latitudes, but a few species disperse to higher latitudes (Heermann's Gull and the Yellow-footed in western North America, the Yellow-legged Gull in Europe) and some populations shift longitudinally (the Mediterranean Gull from the Black Sea to the Mediterranean and the Atlantic, Ross's Gull from Siberia east in the Arctic Ocean). Three species regularly perform trans-tropical or trans-equatorial movements, the Lesser Black-backed Gull from northern Europe and western Siberia to Africa and India, Franklin's Gull from the northern American prairie to South America, reaching Tierra del Fuego, Sabine's Gull from the Arctic as far as the open seas off South Africa and South America.

Food. Many species feed on marine invertebrates in the intertidal zone. A few, such as the Slender-billed or Grey Gulls (when feeding young) are specialized fish predators; pelagic gulls take fish and invertebrates. Many species feed for at least part of the year on freshwater or even terrestrial invertebrates. Some (e.g., Great Black-backed, Glaucous and Dominican Gulls) are predators of mammals and birds. Fishing and hunting techniques include probing and prying, actively chasing on foot (e.g., Grey Gull), pecking at the surface of the water, up-tilting, quartering, hovering and snatching, plunging. Many species are scavengers, some specializing in robbing eggs, young or spilled food at sea-bird colonies, or in associating with marine mammals (Scoresby's Gull). Piracy on terns or smaller gulls is widespread, as is association with flocks of fishing mergansers *Mergus*, cormorants *Phalacrocorax* or divers *Gavia*. Many species, notably of the herring and masked gull groups, also Franklin's Gull, exploit human refuse and fishing activities.

Behaviour and voice. Gulls are almost completely diurnal, though some migrate at night; the Grey Gull undertakes at night the long flights between the sea and the desert where it feeds its young and the Swallow-tailed Gull is mostly nocturnal, at least on the breeding grounds. Almost all species are highly gregarious, often breeding in large, dense colonies, roosting in vast multispecific roosts, and feeding socially. They have thus developed a rich repertoire of both visual and auditory social signals, the significance of which has been best described by Howell *et al.* The form taken by the expression of self-advertisement, anxiety, threat, intention to flee or attack, dominance, and submissiveness differs somewhat from species to species, though along consistent lines. It has been studied in detail for several species, representing most groups, and comparative, partial summaries have been made, for example by Tinbergen (1959a) and Moynihan (1962). Among the most important, widespread, and conspicuous displays are the silent Upright, indicating anxiety or aggression, the aggressive Choking, the begging Head-toss, and the Long Call, a usually ringing and far-carrying vocal utterance, accompanied by a complex posture and proclaiming a readiness to interact either aggressively or amicably. Besides the Long Call and Long Call notes, the most often heard vocalizations are the guttural alarm notes, the cat-like mewing, and the whining soliciting calls of females and juveniles. The Swallow-tailed Gull has a peculiar 'rattle and whistle' alarm call, which has been correlated with the threat from frigate-birds (Fregatidae) (Snow and Snow 1968).

Breeding. Most gulls breed upon assuming adult plumage, at 1–5 years old. The pair-bond is normally monogamous, and fidelity to colony, nest-site and partner is high in established breeders. Pair formation may occur at the nest-site or in 'clubs' of non-breeders, which are characteristic of some species. The breeding cycle of most species is annual but 2 broods a year are known in some populations of the Silver Gull (Nicholls 1964) and Hartlaub's Gull. The Swallow-tailed Gull breeds throughout the year. Gulls' nests are sometimes extremely rudimentary, sometimes bulky and sometimes untidy. One to 4, mostly 2 to 3 brown, olive, blue or grey, heavily mottled eggs are laid. The incubation period is from 3–4 weeks; both parents incubate and care for the young. The chicks are alert at birth and are fed in or near the nest for 2–3 weeks, usually until fledging at 4–5 weeks and, in the herring gulls, sometimes for several weeks thereafter.

H

HABITAT: the particular environment inhabited by a particular living organism. The environment thus described comprises the whole complex of flora, fauna, soil and climatic factors to which the organism is adapted.

The term has been extended to cover the particular environment inhabited by a community of organisms. When it is used like this, the emphasis moves from the relationship with an organism to the biological nature of an area, and hence the term becomes virtually synonymous with BIOTOPE. The meaning of the word 'habitat' is further confused because at one time it could also mean the geographical distribution or range of a species.

The habitat of a bird species can only be determined by field studies in which the full range of opportunities and constraints in nature is related to the adaptive characteristics of the bird. Much is known about the general requirements of different species and their general adaptations, but very little about the exact constraints, and so it is not yet possible to describe the habitat requirements of most birds definitively. For example, the distribution of many species can be fitted to isotherms, but it is not usually known whether temperature is operating directly or through food supply or some other component of the environment. In some cases limited food or nesting site requirements clearly limit the species' habitat. For example, the Snail or the Everglades Kite *Rostrhamus sociabilis* is restricted by the distribution of the freshwater Apple Snail *Pomacea* on which it is almost entirely dependent for food. The Golden-shouldered Parrot *Psephotus chrysopterygius* is dependent for nesting on the large termite mounds found in parts of the Cape York Peninsula of Australia. Nest sanitation of this species depends upon its symbiotic relationship with larvae of the moth *Neossiosynoeca scatophaga*. The timing of nesting of a particular bird species may indicate its dependence on a particular food species, for example, the nesting of the White-cheeked Honeyeater *Phylidonyris niger* coincides with the peak flowering of *Banksia ericifolia*, the beak of the Honeyeater being adapted to obtain the nectar from the Banksia flowers. In general the more specialized species are found in stable tropical habitats (see ECOLOGY). At the other extreme, highly adaptable opportunist species (the 'r' species) such as House Sparrows *Passer domesticus* and Starlings *Sturnus vulgaris* can live in numerous kinds of biotopes throughout the world. Most species appear to be intermediate in their habitat requirements: they are confined to major botanical formations, e.g. temperate broad-leaved woodland, but not restricted by the distribution of particular plant or animal species.

In some birds the breeding habitat is very different from the wintering one. For example, in Europe the Chiffchaff *Phylloscopus collybita* breeds in light broadleaved woodland and coniferous forests but winters in dry savanna in Northern Africa. The Little Auk *Plautus alle* breeds on Arctic sea cliffs and mountains, but is largely pelagic in winter, and the Black Tern *Chlidonias niger* breeds in freshwater marshes and lagoons but spends the winter on tropical sea coasts.

In some species the habitat differs in different parts of its range. For example in Britain the Dartford Warbler *Sylvia undata* is confined to areas dominated by tall heather *Calluna*, thick gorse *Ulex* or mixtures of the two, but in North Spain it also occurs in open pinewoods.

Sudden changes in habitat requirements have been observed from time to time. These have enabled the species concerned to enlarge its range, as when the Little Ringed Plover *Charadrius dubius*, whose principal original habitat was sand banks in large rivers, extended its range by colonizing gravel pits.

The habitats of birds (and mammals) tend to be much wider than those of insects. This reflects their more catholic feeding habits and more plastic behaviour. Structure of habitat is usually more important to birds than the plant species which form it. Therefore it is possible to devise quite simple classifications of bird habitats, for example that of J.F. Reynolds, which has 16 basic categories consisting of easily identified structural types of vegetation (e.g. grassland, bushed grassland, wooded grassland etc.).

The relatively simple habitat requirements of birds have an important bearing on their conservation. It is possible to create suitable habitats for many species of birds simply by digging ponds, flooding fields or planting trees and bushes, whereas many plant and invertebrate species, with their more exacting requirements, are unable to colonize these places for many years and so can only be conserved by retaining their existing habitats.

HACK: term used in FALCONRY.

HACKLE: a long slender feather on the neck; such feathers are found, especially, in various species of Galliformes.

HADADA: *Hagedashia hagedash* (see IBIS).

HAEMATOPODIDAE: see under CHARADRIIFORMES; OYSTERCATCHER.

HAEMOGLOBIN: see BLOOD.

HAGGARD: term for a hawk caught as an adult and trained (one caught as full-grown but in its first plumage is a 'passage hawk')—see FALCONRY.

HALCYON: poetic name for KINGFISHER.

HALLUX: the first toe, usually 'opposed' (i.e. directed backwards) in birds and often much reduced (sometimes absent)—see LEG; SKELETON, POST-CRANIAL.

HAMERKOP: name, alternatively 'Hammer-headed Stork' or 'Anvilhead', of *Scopus umbretta*, sole genus and species of the Scopidae (Ciconiiformes, suborder Ciconiae). In the past a relationship to the Charadriiformes has been proposed for *Scopus* as it shares with them 2 genera of Mallophaga and only one with the Ciconiidae, but its egg-white protein suggests it may be related to the storks. However, Kahl (1967) found its behaviour quite different from either the storks or herons and concluded that it has no 'particularly close relationship with any other living bird so far studied'.

Many legends are centred about the bird and they receive some protection from the taboos that have developed. One common native legend is that other birds bring nesting material to their remarkably structured nest (see below).

Characteristics. The Hamerkop is a rather heavy-looking bird (*c.* 56 cm long), with short legs, a moderately long bill that is laterally compressed and slightly hooked, and rather long wings and tail. The conspicuous feature is a long backward-pointing crest which, together with its bill, produces an anvil shaped head from which it gets its common names. The plumage, which is the same for both sexes, is dark chocolate-brown, and the bill and legs are black, giving it a sombre appearance. Powder-down patches are lacking, but the middle toe is pectinated as in herons, and the 3 forward toes are connected by a partial web. Hamerkops are very agile fliers and their relatively large, rounded wings give them an owl-like shape when in flight. During normal flapping flight the head is only partially retracted on the shoulders but, when soaring or gliding, both less frequent than in storks, it usually extends its neck fully.

Habitat and distribution. It is found throughout the Afrotropical region and its range extends also to Madagascar and south-western Arabia. The birds inhabiting the coast of West Africa belong to a dwarf race. Hamerkops may be found in a wide variety of wetlands including estuaries, mangrove creeks, swamps, rice fields and ponds provided these are bordered generously with trees and/or cliffs. Because of taboos the birds are often tame and found in villages.

Food. A variety of small fish, shrimps and insects may be taken, but the principal food is frogs of the genus *Xenopus* and their tadpoles, which also form a major part of the nestling diet. When foraging, the bird usually walks along the edge of a pool or stream or wades in shallow water. In muddy water the Hamerkop probes repeatedly for prey, whereas in clear water the prey are snatched from the water surface. In both cases, it uses its feet to disturb prey from the substrate. Hamerkops pick tadpoles from off the surface by flapping low over the water and flying at low speed into the wind with very deep wing strokes.

Behaviour. Social gatherings, sometimes involving up to 20 birds, are common away from nesting areas; the most demonstrative displays take place in groups when they feed. Several displays have been described by Kahl (1967), one of the more bizarre being the false mounting display. This may occur outside the breeding season and consists of one bird jumping on to the back of another as if intending to copulate, and standing there while beating its wings and giving a specific series of calls. Either sex may assume the top position and often the birds may alternate positions a number of times. This behaviour often occurs between mates but is not confined to mated pairs, and may occur on a tree, on the ground or on top of a nest. There are some preliminary displays that precede the false-mounting display and also precede true copulation. Paired birds indulge in a wing-flapping and bowing display while uttering braying calls. Hamerkops are apparently monogamous and birds may remain paired for several years, but co-operative nest building has been observed (Gentis 1976).

Although active during the day, Hamerkops become more active at dusk and are semi-nocturnal in their habits. They often use the backs of hippopotamuses as perches.

Voice. When 3 or more birds are together they generally join in mutual calling displays; the calls start with a series of loud, high pitched *yips*, becoming more rapid until they run together into a trilling note. These notes also accompany the false-mounting and other displays. Sometimes when a pair is flying together the birds keep in mutual contact by means of a few soft *kep* notes.

Breeding. The Hamerkop, a non-colonial nester, builds a remarkable enclosed nest of sticks, grass and mud placed 5–12 m up in the fork of a tree (often over water) or, less commonly, on the ground or on a cliff face. It may take a few months to build and measures about 1 m in diameter. Inside is a carefully shaped internal chamber, which is about 30–50 cm in diameter and height. The entrance tunnel (*c.* 13–18 cm in diameter and *c.* 40–60 cm long) is heavily plastered with mud to give it a smooth surface.

The 3–6 eggs are chalky white; the incubation period is about 21 days, and the nidicolous young, fed by both parents, spend about 7 weeks in the nest before fledging. The initial plumage of the young is brown apart from white on the head, neck, back and wings, but by the time they leave the nest they are brown all over. W.R.S. and L.G.G.

HAMMERHEAD: see HAMERKOP.

HAMULUS: a hooked barbicel (see FEATHER).

HANDBOOK: see regional articles.

HANDEDNESS: see FOOTEDNESS.

HANDSAW: see HERNSHAW.

HANGNEST: name sometimes applied, in North America, to *Icterus* spp. (for family see ORIOLE (2)).

HAPLOOPHONAE: see under PASSERIFORMES.

HARDY–WEINBERG LAW: a law of population genetics, established in 1908 by G.H. Hardy and W. Weinberg, which relates mathematically the frequency of alleles in a population at a particular genetic locus to the frequency of genotypes at that locus. In its simplest form the law states that if at a particular locus there are 2 alleles A and A^1, and if the frequency of $A = p$ and the frequency of $A^1 = q$ (such that $p + q = 1$), then the frequency of the 3 genotypes AA, AA^1 and A^1A^1 will be $p^2 : 2pq : q^2$. This is the binomial expansion of the expression $(p + q)^2$. Thus if a population is in Hardy–Weinberg equilibrium, it means that there is a predictable and defined ratio between the 3 genotypes. The law is only true if a number of stringent conditions apply. These are (1) that the population must be large enough for sampling errors to be ignored, (2) that there is no mutation, migration or differential selection, and (3) that mating among individuals of the different genotypes be random. The law is valuable to population biologists in two ways. Firstly, if a polymorphism is suspected to have a genetic basis, then it defines the expected relative frequencies of the distinct phenotypes. For instance, if it is suspected that the 3 morphs of the Arctic Skua *Stercorarius parasiticus*, dark, intermediate and light, are determined respectively by 3 genotypes AA, AA^1 and A^1A^1, then at equilibrium the 3 morphs will occur in a predictable ratio dependent only upon the frequencies of the 2 alleles A and A^1. If as an example 36% of the population (p^2) were dark, 48% (2 pq) should be intermediate and 16% (q^2) light. The law is also useful when the genetic basis for the polymorphism is already known. If then the genotypes are not in the predicted frequencies, it may be suspected that one or more of the conditions stated above are not holding. Deviations from the Hardy–Weinberg equilibrium have been used as a crude first indication that selection is occurring or that a population is not mating at random (see also GENETICS.) F.C.

HAREM POLYGAMY: see POLYGAMY.

HARLEQUIN: sometimes used by itself for the Harlequin Duck *Histrionicus histrionicus* (see DUCK).

HARPY: sometimes, at least formerly, used alone for the Harpy Eagle *Harpia harpyja* (see under HAWK). See also FABULOUS BIRDS.

HARRIER: substantive name of *Circus* spp.; in the plural, general term for the subfamily Circinae of the Accipitridae.

HARRIER EAGLE: substantive name, alternatively 'serpent eagle', of species of Circaetinae (Accipitridae); in the plural, general term for the subfamily (see HAWK).

HARRIER-HAWK (1): substantive name of species of Polyboroidinae (Accipitridae); in the plural, general term for the subfamily (see HAWK).

HARRIER-HAWK (2): sometimes used as the substantive name, alternatively 'forest falcon' (Brown and Amadon), of *Micrastur* spp.; in the plural, serves as a general term for the Herpetotherinae (see FALCON).

Whimbrel *Numenius phaeopus* chicks hatching. (*Photo: E.J. Hosking*).

HATCHING: emergence of the developed chick from the egg after incubation; the term is applied both to the egg and the chick, e.g. the eggs 'hatch', the young 'are hatched' or 'hatch out'. Eggs showing the first cracks in the shell are 'pipped', 'chipping' or 'starred'.

Hatching is prepared for by several synchronized processes. It often takes some hours, but may be reduced to about half an hour in small birds. The young bird has to change from breathing in the amniotic fluid to respiration in air, and it must break the hard eggshell by its own means. The time of hatching is fixed for each species by an innately determined series of events.

Some days before it breaks the shell, the embryo starts swallowing the amniotic liquid. The tissues, particularly the muscles, thus acquire a very high water content at birth, but this diminishes rapidly. The contents of the albumen-sac go the same way. The yolk-sac is driven into the body cavity by movements of the abdominal musculature. The new-born bird always has an internal yolk-sac, of which the mass varies from 25% of the birth weight in the Ostrich *Struthio camelus* to *c.* 5% in small passerines. The yolk mass vanishes rapidly in the first 6 days after hatching.

During incubation a constant water loss by evaporation produces an air chamber between the two shell-membranes (at the blunt pole of the egg). An aerated space is thus formed, into which the embryo penetrates. This moment marks the beginning of air respiration and is often announced by the cheeping of the baby bird, 2 or even 3 days before hatching. The blood supply of the allantois is still functioning and provides the necessary oxygen, the air-chamber being rich in carbon dioxide and insufficient for the needs of the young bird.

Very soon partial respiration by the lungs is started, the eggshell is opened, and the rapid drying up of the allantois begins. The vessels of the allantois are functional until the last moment before the navel is closed. At the moment of hatching the adult type of breathing is firmly established.

Immediately before the bill enters the air-chamber, the embryo changes from a transverse position into a longitudinal one, thus directing its bill towards the air space. This movement permits the use of a special tool for hatching, the egg-tooth on the tip of the maxilla. The formation of this structure, present in the great majority of birds, begins about the sixth day of incubation (domestic fowl, duck). It is horny, without any mineral substance. In some birds a corresponding thickening is produced also at the tip of the lower mandible.

The egg-tooth produces the first openings; stretching of the head and movements of the legs help to burst the shell. Sooner or later after hatching the shell-breaking tool is lost, in some groups, such as the penguins, not for some weeks.

No egg tooth is formed in the Ostrich and the megapodes, but it is not known whether this condition is primitive or secondary; the young of these birds are very far developed and strong enough to break the eggshell by movements alone. The shell is always weaker after incubation through the loss of mineral substances dissolved out of it, transported by the blood and used to prepare the first ossification of the skeleton.

The hatching of different eggs in a clutch may be almost synchronous or there may be a considerable interval between first and last. In many species the parents remove the fragments of eggshell from the nest; but those with nidifugous young tend to leave them *in situ*. See also BEHAVIOUR, DEVELOPMENT OF; DEVELOPMENT, EMBRYONIC; EGG; GROWTH; INCUBATION; PARENTAL CARE; YOUNG BIRD. See photo PARENTAL CARE. A.P. and W.S.

HATCHLING: term sometimes applied to a newly hatched bird (see YOUNG BIRD).

HAWAIIAN HONEYCREEPER: substantive name for species of the family Drepanididae (Passeriformes, suborder Oscines). This family, treated by some as the subfamily Drepanidinae of the family Fringillidae, is endemic to the Hawaiian Archipelago including 63 ha Nihoa Island and Laysan Atoll in the North-western Hawaiian Islands. The recent discovery of the Poo-uli *Melamprosops phaeosoma* on Maui (Casey and Jacobi 1974) brings the total number of described species to 23. To this at least 15 recently discovered fossil species, as yet undescribed, must be added (Olson and James 1982). Geographic isolation within the archipelago has produced impressive variation—40 taxa are currently recognized.

Evolution, morphology and characteristics. The Hawaiian honeycreepers are supposed to have been derived recently from cardueline finches: *Telespyza c. cantans* on Laysan and *T. c. ultima* on Nihoa are most similar to the founder species (Raikow 1977). The subfamily is best known for its remarkable adaptive radiation. Bill shapes (Fig. 1) range from powerful seed-cracking cones (Grosbeak Finch *Psittirostra kona*) to attenuate, decurved probes 6.6 cm long, one third the bird's length (Kauai Akialoa *Hemignathus procerus*). Between these extremes are found bills shaped like those of parrots (Maui Parrotbill *Pseudonestor xanthophrys*) and warblers (*Loxops parva*, *Paroreomyza maculata*), and the unique bill of the Akiapolaau *Hemignathus wilsoni*, whose upper mandible, long and decurved, is nearly twice the length of the stout, straight lower mandible. Despite this diversity in bill structure, the Drepanididae have very similar appendicular myology, much like that of cardueline finches. The similarity of the tubular tongues of the nectarivores to New World 9-primaried oscines is due to convergence. Plumage colours include black, brown, white, green, yellow, red, and dazzling orange. Sexes are alike in colour in some species, unlike in others. Overall lengths

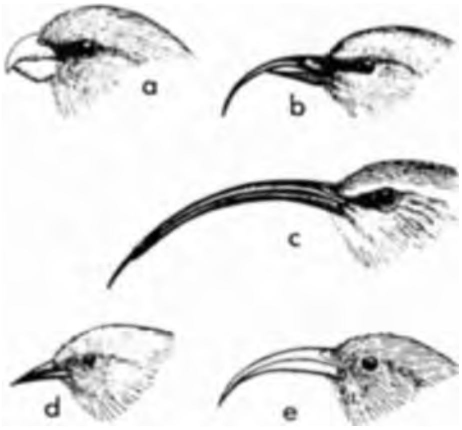

Fig. 1. Bills of some Hawaiian honeycreepers: (a) *Psittirostra bailleui*; (b) *Hemignathus wilsoni*; (c) *Hemignathus procerus*; (d) *Loxops coccinea*; (e) *Vestiaria coccinea*.

range from 10 cm (Anianiau *Loxops parva*) to nearly 20 cm (Greater Koa Finch *Psittirostra palmeri* and Hawaii Mamo *Drepanis pacifica*).

Habitat. The majority of the extant drepanidids are presently confined to wet (rainfall up to 1,164 cm per year) montane forests dominated by Ohia *Metrosideros collina* or Koa *Acacia koa*. On the island of Hawaii several species inhabit the much drier Mamane *Sophora chrysophylla*—Naio *Myoporum sandwichense* forests up to 3,000 m elevation. The family was formerly widespread in dry lowland forests, but these habitats, and their fauna, have been largely destroyed in the islands.

Food. The Hawaiian honeycreepers feed upon a diversity of foods. Some, like the Apapane *Himatione sanguinea*, Iiwi *Vestiaria coccinea*, and Crested Honeycreeper *Palmeria dolei* are primarily nectarivorous, while others feed upon fruit (Ou *Psittirostra psittacea*) or green seeds (Palila *Psittirostra bailleui*). Most species, however, are primarily insectivorous. The omnivorous Nihoa Finch includes seabird eggs in its varied diet. The Apapane and Iiwi undertake daily migrations, often of many kilometres, in search of patchily distributed but locally abundant Ohia flowers, their primary source of nectar. Perhaps as a result of this mobility, they are monomorphic in the main islands (one other widespread species, the Ou, is undifferentiated between islands), and the Apapane reached Laysan Island, about 1,125 km north-west of Kauai, where it was represented by a local race that is now, unfortunately, extinct.

Voice. Song is highly variable within the family, ranging from disconnected squeaky notes to melodic trills. The Apapane sings a bewildering variety of songs that vary within, and between, islands.

Breeding. The breeding season extends from February to June for most species. Chasing is an important part of courtship, and often directly precedes copulation. Nests of only half the family have been described (Scott *et al* 1980). Most are open cups composed of twigs and lined with fine materials, such as mosses, tree fern scales, and other fibres (Berger 1972). They are generally placed within the canopy and are well hidden within terminal leaf clusters. Clutch size ranges from 1–4 eggs; 2 or 3 is the usual complement. Normally only the female incubates; she is fed away from the nest by the male. Nests of 3 species have been found in tree cavities; 2 species are known to use rock cavities, the Nihoa Finch preferentially so. The Laysan Finch nests in grass tussocks.

Current status. It is tragic that of 40 described taxa, 16 are recently extinct and an additional 17 endangered. Their demise has resulted from a number of interrelated stresses that began with the first Polynesian settlement. Habitats have been vastly altered by man, and introduced mammals, notably pigs, goats, cattle, sheep, and Axis Deer *Axis axis* have devastated additional thousands of hectares. The Hawaiian honeycreepers proved highly susceptible to introduced diseases, especially avian malaria and pox, which were transmitted to them by an introduced mosquito *Culex quinquefasciatus* (Warner 1968). Predation by cats and rats may have also been important (Atkinson 1977), and competition with introduced forest birds, many now quite common, may have produced additional stress. Many of these factors remain uncontrolled, and more species may be lost unless vigorous corrective action is taken. A programme that successfully eradicated feral sheep from Mauna Kea in 1982 should help restore the essential habitat of the Palila. Similar programmes in prime rain-forest sites throughout the state could do much to improve the outlook for these fascinating birds. C.B.K.

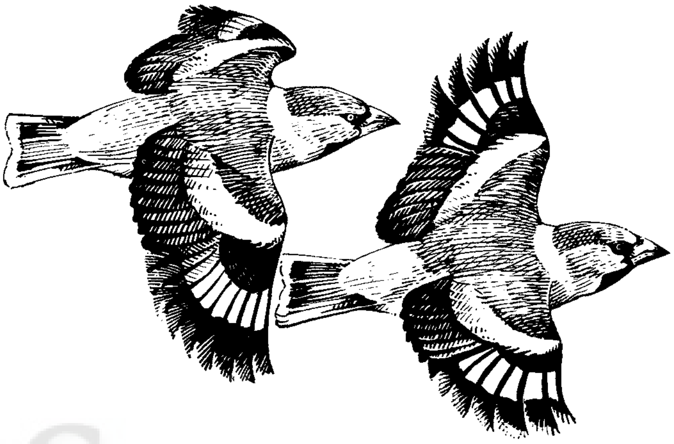
HAWFINCH: substantive name of *Coccothraustes coccothraustes* and of *Eophona* spp.; used without qualification for the first mentioned (see FINCH).



Hawfinch *Coccothraustes coccothraustes*. (*D.A.T.*).

HAWK: substantive name, or part of the substantive name, of many members of the Accipitridae (Accipitriformes, suborder Accipitres)—in North America the name is given to species of Accipitridae that in British usage have special substantive names (e.g. 'buzzard', 'harrier'), and is even applied to some species of Falconidae (see FALCON); in the plural, general term for the Accipitridae, the subject of this article except that the several genera of Old World vultures are separately treated (see VULTURE (1)). Apart from the vultures, the family is often divided into subfamilies: the Accipitrinae (true hawks, including accipiters, buzzards, and eagles), Circaetinae (harrier eagles or serpent eagles), Circinae (harriers), Polyboroidinae (harrier-hawks in one sense), Milvinae (true kites and fish eagles), Perninae (honey-buzzard etc.), Elaninae (white-tailed kites), and the monotypic Machaerhamphinae (Bat-hawk). For convenience this grouping is followed here, but K.H. Voous regards all but one of these suggested subfamilies as united in a single group constituting the Accipitridae; and the monotypic Pandionidae as a separate family.

Characteristics. The birds in this large and varied assemblage range from small sparrowhawks *Accipiter* spp. to huge and powerful eagles, those of the genera *Harpia*, *Pithecophaga*, and *Haliaeetus* being among the largest and strongest birds of prey in the world and among the largest of flying birds. Several of these large eagles exceed 6 kg in weight, 1 m in body length and 2 m in wingspan. In almost all birds-of-prey the female of the species is larger than the male; she is often duller and browner in colour, and immature birds may be quite different in appearance from the adults. The degree of size dimorphism between the sexes is correlated with feeding habits, as species which specialize on snails, insects, reptiles, mammals or birds respectively show progressively greater dimorphism (Newton 1979). In some extreme bird-feeders, such as the European Sparrowhawk *Accipiter nisus*, the female weighs almost twice as much as the male.

The family has the characteristics of the order, of which the most obvious are the decurved and pointed bill, with base covered by a cere in which the external nares are situated, and the powerful gripping feet with strong sharp claws. Leaving aside the carrion-eating Old World vultures, they are—with some exceptions—hunters of live prey; the latter ranges from birds in flight to fish, and from sizeable mammals to insects. Unlike many of the owls, which have similar adaptations of bill and foot by convergence, they are diurnal in their habits—occasionally crepuscular (*Machaerhamphus*).

Habitat and distribution. The Accipitridae are represented on all continents except Antarctica and in all kinds of habitat from thick forest to open grassland and desert. As expected of predators, these birds live at relatively low densities, and mostly in individual territories or home ranges, which include feeding areas. Under natural conditions, small species occur at densities up to about 1 pair/km^2, but larger ones are very much sparser. The large African Martial Eagle *Polemaetus bellicosus* occurs at one pair per 125–300 km^2, with 30–40 km between pairs, and is thus one of the most thinly-spread birds in the world. However, in 'developed' regions, most species have been much reduced in numbers by human activities, especially habitat destruction, direct persecution and pesticide use. In consequence, many species which were numerous a century ago are now quite scarce, and some are among the most endangered of all birds.

Where undisturbed, some species show extreme stability in breeding population, with the numbers over large areas changing by no more than 10% of the mean over long periods of years (e.g. Golden Eagle *Aquila chrysaetos*). Such species usually feed on a wide spectrum of prey species, and thus have fairly stable food-supplies. Other species, which have restricted diets based on cyclic prey, fluctuate greatly in numbers from year to year, depending on their prey (e.g. Rough-legged Buzzard *Buteo lagopus* which feeds on lemmings and other rodents).

Movements. From northern regions many species migrate south for the winter. The broad-winged types, such as buzzards and eagles, travel by soaring and gliding, and are thus dependent on updraughts or thermals. They form narrow migration streams along routes where conditions are favourable, such as north to south mountain chains or narrow sea crossings. In Europe, many thousands of individuals en route to Africa circumvent the Mediterranean each year via the Straits of Gibraltar in the west and the Bosphorus or Dardanelles in the east. In North America similar concentrations occur along mountain ranges, of which the most famous for observation is Hawk Mountain in Pennsylvania.

Voice. Different species of the Accipitridae have screaming, yelping, mewing or cackling cries, which are heard mainly in the breeding season. Such vocalization is used primarily for communication between the sexes, but also in some species for territorial advertisement. Many call loudly when the nest area is invaded by a human or other predator.

Behaviour and breeding. These raptors have mainly aerial displays, involving soaring over the nesting area, diving or undulating flights, which probably serve to advertise possession of the territory. Other displays, early in the breeding cycle, are centred on nest-sites. Most species breed in trees, either making their own nests or sometimes adopting the nests of others; some eagles and buzzards breed on crags. The nests are built of sticks and are often lined with green leaves, sometimes with grass, rags, and oddments. The larger species build huge structures to which they return year after year. The main trends in breeding within the group are related to body-size. The larger the species: (1) the later the age at which breeding begins, (2) the longer each successful attempt takes, and (3) the fewer the young produced with each attempt (Newton 1979). Small clutches of 1–2 eggs are typical of large eagles, but the smaller species may lay 3–5 or even more. Incubation times vary from about 28 days in small sparrowhawks to 49 days in large eagles, and fledging periods from 28 days to 120 days. After leaving the nest, the young continue to be fed by their parents for another 21 days in small accipiters to several months in large eagles. In one or two eagle species, breeding cycles may be so long as to prevent breeding in successive years: the largest species are long-lived, slow-breeding birds.

While breeding, there is a clear division of labour between the sexes, the male providing the food and the female incubating the eggs and tending the young. Only when the young are large enough to be left does the female help with the hunting. The young themselves could be described as 'semi-precocial' in that they hatch with a full covering of down and with their eyes open, in contrast to most other nidicolous birds. Initially the mother tears up small pieces of meat for them, which they take from her bill, but before fledging they learn to tear up prey for themselves.

True hawks and eagles. The Accipitrinae are the largest and most varied subfamily, containing most of the world's hawks (in the strict sense), buzzards, and eagles. They may conveniently be divided into several smaller groupings. First, the genera *Accipiter, Melierax*, and *Urotriorchis* are small to medium-sized hawks of swift flight, generally inhabiting woodlands or forests, and preying upon birds, small mammals, and reptiles. Of these only *Accipiter* occurs in the New World, while the others (*Urotriorchis* being monotypic) are confined to the Ethiopian Region. Three other genera, to be mentioned later, also belong to this group.

The genus *Accipiter* contains the true sparrowhawks and is the largest of all the genera of the birds-of-prey, cosmopolitan in distribution, and with representative members in any woodland ecotype, from the pine forests of the far north to the most luxuriant tropical rain-forests and the thorn-scrub of Africa. All are broad-winged, long-tailed hawks, with rather long thin legs; they fly from tree to tree in the forest, and when hunting adopt methods of stealthy approach behind cover, culminating in a short, fast attack. Few of them can fly down birds in the open, but they are adept at catching them in thick vegetation. The largest member of the genus, the Goshawk *Accipiter gentilis*, is about 48–62 cm long, grey above and white barred grey below, with a fierce yellow eye; it has been trained for falconry, as have several others of the genus, and is capable of killing birds as large as a Pheasant *Phasianus colchicus* and mammals up to the size of a hare (see FALCONRY). At the other extreme is the tiny African Little Sparrowhawk *Accipiter minullus*, about the size of a thrush, and living to a considerable extent on insects; these it catches in a short sortie after the manner of a flycatcher (Muscicapinae). Between these two extremes are hawks of every intermediate size, but all bold and aggressive, all inhabiting woodlands, and all living mainly on birds, with mammals and reptiles as side-lines. Close to the genus *Accipiter* is *Melierax* (including '*Micronisus*'); these are birds of the open African thorn-bush, grey above, with white undersides barred with grey. The two chanting goshawks *Melierax* spp. are large birds (length 35–50 cm) capable of killing guineafowl, but living chiefly on insects and lizards, which they often catch on the ground, running about like small editions of the Secretary-bird *Sagittarius serpentarius*. The Gabar Goshawk *Melierax gabar* is like a sparrowhawk in its habits. Finally there are the Long-tailed Hawk *Urotriorchis macrourus*, a strange dark-coloured hawk, black above with chestnut below and a long tail ornamented with white dots, which inhabits dense forests in West Africa and lives chiefly on arboreal squirrels and birds; 2 Australasian genera, *Erythrotriorchis* and *Megatriorchis*, of large and powerful hawks; and the Lizard Buzzard *Kaupifalco monogrammicus*, which preys chiefly on lizards and is found in east and southern Africa.

The next subdivision of the Accipitrinae comprises large hawks with soaring flight, inhabiting woodlands or open country, and preying upon mammals and reptiles caught on the ground, with birds forming a minor part of the diet. The genus *Buteo* (including '*Rupornis*' and '*Asturina*'), containing the true buzzards, is the largest of this group, and is cosmopolitan in distribution save for Australasia and Malaysia. The genera *Heterospizias, Leucopternis, Parabuteo, Buteogallus*, and *Busarellus* are confined to Central and South America, and *Butastur* to Africa, India, and the East. *Butastur* spp. (e.g. the Grasshopper Buzzard *B. rufipennis* of Africa) are the least like buzzards of the whole group, having more the habits of harriers (Circinae). All these birds are large, with a body length of 50–65 cm, and a wing-spread of 1–1.5 m. They all can soar, but they perch a great deal on trees, telegraph posts, or rocks, and catch their prey on the ground. Some frequent lowland swamps, others mountainous country; the Augur Buzzard *Buteo rufofuscus* occurs in Africa up to 5,500 m, and the Mexican Black Hawk *Buteogallus anthracinus* is found in swampy areas or tropical forest regions at low altitudes. They are mainly brown in colour when immature, but as adults often develop handsome plumages of brown, white, and red-brown, or black and white. Females are generally only slightly larger than males. Some are migratory, e.g. the Rough-legged Buzzard *Buteo lagopus*, which is also one of the few members of the group with the tarsus feathered to the toes. Others remain in their haunts all the year round, the tendency being for those that live in the far north to migrate, while most tropical and subtropical species do not.

The third subdivision of the Accipitrinae consists of large or very large birds-of-prey, with wing-spread of up to 2.5 m and weight of 1–7 kg, generally called eagles. They include the following American genera: *Harpyhaliaetus, Spizastur, Oroaetus, Morphnus*, and *Harpia*. *Stephanoaetus* and *Polemaetus* inhabit Africa, and *Ictinaetus, Harpyopsis*, and *Pithecophaga* occur only in India and the Far East. The genera *Aquila, Spizaetus*, and *Hieraaetus* are of wider distribution. *Aquila* in particular is found in all regions of the world except South America and the Malaysian area, being represented in Australia by *Aquila audax*. All these birds are both large and aggressive, preying on large and small mammals, birds, and reptiles. Some eagles, especially *Aquila* spp., eat carrion; the Tawny Eagle *A. rapax* (length 65–77 cm) pursues and robs other raptors of their prey. Although some are hardly bigger than buzzards, they are in general fiercer and more active than the birds of that group. They vary in size from small, active hawk-eagles of the genera *Spizaetus* and *Hieraaetus* to huge and powerful birds-of-prey (*Stephanoaetus, Polemaetus, Aquila, Harpyopsis, Pithecophaga,* and *Harpia*). *Aquila, Spizaetus, Spizastur, Hieraaetus, Stephanoaetus, Polemaetus, Oroaetus,* and *Ictinaetus* have feathered tarsi, the rest bare tarsi. The largest and most powerful of all is the Harpy Eagle *Harpia harpyja*, inhabiting tropical South America; and scarcely smaller is the Philippine Monkey-eating Eagle *Pithecophaga jefferyi*, which has unusual blue eyes. The smaller members of the group include Ayres' Hawk-eagle *Hieraaetus ayresi*, a rare bird of Africa which is like a sparrowhawk in its habits, living on birds of the tree-tops, and the very handsome *Hieraaetus kieneri* of India. Those that live in open country (*Aquila, Polemaetus*) tend to live principally on mammals and gallinaceous birds, caught upon the ground but often seized in spectacular fashion. All these birds are capable of beautiful soaring flight, and some of them are probably as fast as or, faster than, any other birds-of-prey, although they may appear, by reason of their large size, to move more slowly than some falcons. Their plumage varies from dull brown (*Aquila*) through various patterns of grey and white and black and white to very rich and beautiful combinations of black, buff, chestnut, and white (*Stephanoaetus* and *Spizaetus ornatus*). Two, Verreaux's Eagle *Aquila verreauxi* and the Black Eagle *Ictinaetus malayensis*, are mainly black, with white on the rump; the former lives almost entirely on hyraxes *Procavia* and *Dendrohyrax*; the latter species has the peculiar habit of feeding upon the eggs of other birds, taken in the nest.

Snake eagles. The snake eagles, serpent eagles and harrier eagles are sometimes placed in a subfamily Circaetinae; they live principally on snakes and other reptiles and have feet specially adapted, with short rough toes of immense power, for grasping and holding this prey. *Circaetus, Terathopius,* and *Dryotriorchis* are African genera, the latter two monotypic and the first with one of its species, the Short-toed Eagle *C. gallicus* (length 62–68 cm) extending over the warmer parts of Europe, Asia, and Africa. The crested serpent eagles *Spilornis* spp. occur from India to the Philippines, and *Eutriorchis astur* inhabits Madagascar. The habits of these birds in the field are much like those of other large eagles. They are given to soaring for long periods, or to perching on outstanding trees and rocks whence they can see their prey; the Short-toed Eagle can hover like a Kestrel *Falco tinnunculus*, although relatively large (see FALCON). They drop on their prey and either snatch it in the air or kill it on the ground. When eating snakes, they crush the head first, afterwards swallowing the rest of the body whole. They inhabit open country, forests, and bushland. The most remarkable of the whole group is the Bateleur *Terathopius ecaudatus* (length 80–85 cm) of Africa, which has exceptionally long wings (wing span 170–180 cm) and a very short tail (8–10 cm). Birds of this species fly perhaps 300 km on most days of their lives, canting from side to side and occasionally performing astonishing aerobatics. They eat carrion and mammals as well as reptiles, and will pursue and attack other carrion birds in the hope of making them disgorge. The Serpent Eagle *Dryotriorchis spectabilis* of West Africa is a strange bird of dense tropical forests and has large eyes that perhaps help it to see in poor light.

Harriers. The subfamily Circinae, cosmopolitan in distribution, contains the harriers *Circus* spp., a very characteristic genus inhabiting open country, cultivations, or swampy land. They are either mainly brown in colour or, in some species, the males are grey and the females and juveniles brown; two species, *Circus maurus* of South Africa and *C. melanoleucus* breeding in north-eastern Asia, are black and white. All harriers are slender, long-winged, long-tailed birds with long legs, and rather owlish heads, ranging between 40–56 cm in body length. They spend most of the day on the wing but also perch on posts and hillocks. Their habits are similar all over the world: they fly low over the ground, systematically quartering to and fro, and dropping on prey in the grass. Unlike most birds-of-prey, they both roost and breed on the ground; and the male, when bringing prey, characteristically passes it to the female in flight, a little way from the nest. One species, the Spotted Harrier *C. assimilis* of Australia, nests in trees. Some of the species are migratory, the Palearctic Pallid Harrier *C. macrourus* being one of the commonest birds-of-prey in the plains of Africa and India in winter. On migration they tend to be gregarious, and they roost in company in 'forms' in the grass (Pallid Harrier and Marsh Harrier *C. aeruginosus*). Some tend to concentrate in swampy localities and others in dry open plains or steppe, but they never frequent woodland country for long. They live on small mammals, frogs, and some insects and reptiles, but occasionally also take birds on the ground.

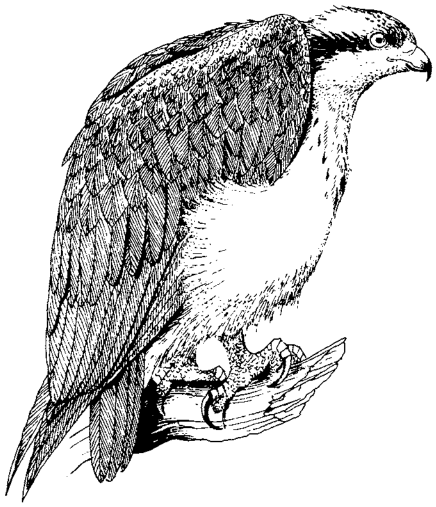
Harrier-hawks. The subfamily Polyboroidinae contains the harrier-hawks, curious long-tailed, long-legged birds the size of a buzzard, grey and black in plumage with yellow legs and bare skin on the face; they inhabit Africa and Madagascar, usually in wooded country. The South American genus *Geranospiza* is probably closely related. The African continental species is the Harrier-hawk *Polyboroides typicus*. They are unable to kill any large prey, and have buoyant, rather erratic flight. They feed largely on the young of other birds, and in attacking weaver-bird (Ploceidae) broods, they often hang head downwards with flapping wings. The double-jointedness of their legs enables them more easily to extract nestlings from tree-holes and other enclosed nests. They are also fond of the fruits of the Oil Palm *Elaeis guineensis*. The term 'harrier-hawks' is also applied to certain Neotropical Falconidae (see FALCON).

True kites and fish eagles. The Milvinae are a large and varied subfamily of cosmopolitan distribution, containing the genera *Milvus, Lophoictinia, Hamirostra, Haliaeetus, Ichthyophaga, Haliastur, Rostrhamus, Harpagus,* and *Ictinia*. The Black Kite *Milvus migrans* (length 55–60 cm), in its many races, is one of the commonest and most obvious birds-of-prey in the warmer parts of the Old World, scavenging in hundreds in towns and villages of the East. It is migratory throughout its range to a greater or lesser extent, and decidedly gregarious on migration. However, it was apparently the Red Kite *M. milvus* (length 60–66 cm) that was formerly a common scavenger in London.

Haliaeetus and *Ichthyophaga* are 2 genera of large or very large birds-of-prey living mostly on fish. *Haliaeetus*, comprising the fish eagles and sea eagles, is nearly cosmopolitan in distribution and contains some of the largest and finest of all birds-of-prey, among them the European Sea Eagle *H. albicilla* (length 70–90 cm), the American Bald Eagle *H. leucocephalus* (length 70–90 cm), Steller's Sea Eagle *H. pelagicus* (length 80–100 cm) of north-eastern Asia and the Fish Eagle *Haliaeetus vocifer* (length 74–84 cm) of tropical Africa. The smaller fishing eagles *Ichthyophaga* spp. inhabit inland lakes, rivers, and ponds in southern Asia and live on fish amongst other food. *Haliastur* is a genus of 2 species, inhabiting India, the Far East, and Australia, and in places very common; the Brahminy Kite *H. indus*, regarded as sacred in India, inhabits swampy areas, and lives on frogs and offal.

The American genera *Rostrhamus, Harpagus,* and *Ictinia* are rather unlike the Old World kites in their general habits, and their members are considerably smaller. The Snail or Everglade Kite *R. sociabilis* breeds in colonies and feeds exclusively on snails, which it extracts from the shell with the long point of its upper mandible. *Rostrhamus hamatus* also has a remarkably long and sickle-shaped bill. The genus *Ictinia* contains small grey kites, in appearance very unlike the typical *Milvus* spp. of Europe and Asia; they live in open country, feed largely on insects, spend a great deal of time on the wing, and are capable of remarkable aerial evolutions; they are migratory and tend to be gregarious on migration.

Honey-buzzards. The subfamily Perninae contains a variety of genera difficult to relate to others—*Leptodon, Chondrohierax,* and *Elanoides* in America, *Pernis* and *Aviceda* in Europe, Asia, and Africa, and *Henicopernis* in New Guinea and nearby islands. The Honey-buzzard *Pernis apivorus* (length 52–60 cm) of Europe and Asia is a medium-sized buzzard-like bird which feeds chiefly on the grubs in bees' and wasps' nests. It is a migrant, moving south from Europe in numbers to Africa, and from northern Asia to India and farther east. The Swallow-tailed Kite *Elanoides forficatus* of America (not to be confused with the African bird of the same English name, mentioned below) is a very beautiful bird, with black back, tail, and wings, the rest of the plumage being white; it has remarkable powers of flight, and on account of its beauty has been much persecuted. The so-called cuckoo-falcons *Aviceda* spp. are widespread in Africa, India, and the Far East, one reaching Australia. Superficially rather like sparrowhawks, but distinguished by having two notches on the upper mandible, they are crested and generally conspicuously patterned in plumage; the Black Baza *A. leuphotes* of north-eastern India and Malaysia is a very striking black-and-white bird, while other members of the genus are grey or brown above and often handsomely barred below. They are generally insectivorous, and in most parts of their range rather rare. They were formerly placed close to *Harpagus*, to which they have certain similarities.



Osprey *Pandion haliaetus*. (*K.J.W.*).

White-tailed kites. The Elaninae are a nearly cosmopolitan subfamily of small or very small birds-of-prey (length 30–35 cm), inhabiting open country. *Elanus* spp. occur in America and the warmer parts of Europe, southern Asia, Africa, and Australia; examples are the White-tailed Kite *E. leucurus* of America and the Black-shouldered Kite *E. caeruleus* widespread in the Old World. All members of the genus are small grey-and-white hawks, superficially like falcons, with black markings at the fore edge of the wing. They are attractive birds, perching constantly on telegraph posts or tall trees, dropping on insects and small mammals in the grass. They can hover very gracefully, like the Kestrel.

The other two members of the subfamily are very small and beautiful birds-of-prey in monotypic genera, the Pearl Kite *Gampsonyx swainsoni* of America and the Swallow-tailed Kite *Chelictinia riocourii* of northern tropical Africa. The Pearl Kite is one of the smallest birds-of-prey, and is blackish above, with rufous on head and back, and white below; it has well developed powder-down tracts. *Chelictinia* is an exquisitely graceful little bird with swallow-like forked tail, grey and white plumage, and a flight so buoyant that it resembles a tern rather than a bird-of-prey. It is gregarious, migratory, and breeds in small colonies, sometimes associated with larger birds-of-prey; it feeds on insects.

Bat-hawk. The subfamily Machaerhamphinae contains a single species, the Bat-hawk *Machaerhamphus alcinus*, which inhabits Africa and parts of the Far East and has the remarkable habit of catching bats as they emerge from caves or buildings at dusk; this prey is commonly swallowed in flight. In general appearance like a large falcon, the Bat-hawk has a wide gape and very large eyes adapted to its habits; it flies extremely swiftly, looking up, down, and sideways when hunting. It requires an open space such as a large pool in a river, a station platform, or an open lawn to be successful, and in addition to bats it eats swallows and martins (Hirundinidae); it spends the day in shady trees, and it is a rare bird, solitary in habit, throughout its range.

Osprey. The Pandionidae comprise only the Osprey *Pandion haliaetus* (length 55–58 cm) a bird of almost cosmopolitan distribution, absent only from South America as a breeding species but occurring even there on migration. It feeds exclusively on fish, catching them with a tremendous headlong dive in which it often completely submerges, throwing its feet forward at the last moment before entering the water so as to grasp the prey. The feet are specially adapted, with a spiny rough surface, for holding such prey. Where it is common it breeds in colonies, notably on the coasts of North America and on islands in the Red Sea. It is commoner on sea coasts but occurs also on inland lakes. It is frequently robbed of its prey by eagles of the genus *Haliaeetus*. In parts of the range it declined in the 1960s through pesticide poisoning.

HAWK-EAGLE: substantive name of species of *Spizaetus*, *Hieraaetus*, and allied genera (Accipitrinae)—see HAWK.

HAWKING: synonymous with FALCONRY; also used to describe the behaviour of a bird of any kind flying in search or pursuit of prey.

HEAD: see TOPOGRAPHY; also BILL.

HEADING: the direction in which a bird is flying through the air, as distinct (in a wind) from its 'track' relative to the earth's surface (see MIGRATION; TRACK).

HEARING AND BALANCE: senses here treated together because in both cases the sensory apparatus is in the ear.

Ear. As with other vertebrates, the ear may be functionally divided into outer, middle, and inner parts. The outer ear of birds usually includes specialized feathers covering the opening of a short auditory canal. An enlarged ear funnel has developed in some species, especially the owls, and in some instances these ear funnels are movable. The ear funnels in owls are asymmetrical, aiding in sound localizations. The ear canal in some diving birds can be closed by muscle contraction.

The middle ear cavity is composed of several cranial bones and this air filled cavity communicates with other air filled cavities of the skull. Thus, the middle ear cavities are not acoustically isolated from one another and sound impinging on the external surface of one typanic membrane is transmitted through the skull and affects the interior surface of the opposite tympanic membrane (Rosowski and Saunders 1980). This may provide a special mechanism by which birds with small heads can localize sounds in the frequency region of 1–8 kHz. Impedance matching from the tympanic membrane to the oval window is accomplished by the columella, extracolumellar cartilage, supporting ligaments, and middle ear muscle. The movements of the columella during sound stimulation are probably more complex than was earlier thought and may involve rotational forces.

The inner ear of birds is a short, slightly curved tube consisting of three fluid filled cavities similar to mammals. The receptor surface, the basilar papilla, was first thought to contain a homogeneous cell population (Retzius 1884). Now it appears that a complex scheme exists consisting of tall, intermediate, and short hair cells which also differ on the basis of shape, cuticular plate dimensions, and innervation. Efferent nerve fibres form extensive networks from which many branches are given off to the hair cells. The basilar papilla is shorter and wider than the mammalian basilar membrane. There are no rods or tunnels of Corti and thus no division between inner and outer hair cells. As many as 40 hair cells can be seen across the width of the basilar papilla and it appears that the cilia may be more firmly inserted into the tectorial membrane than is the case in the mammalian cochlea. The scala vestibuli is not well-developed in birds and there is some question whether the two perilymphatic canals communicate by means of a helicotrema, as is seen in mammals. The size of the helicotrema influences low frequency sensitivity in mammals and the lack of a similar structure in birds may provide a mechanism for enhanced sensitivity to low frequency sounds.

Hearing. Birds as a group hear best in the frequency rage of 1–5 kHz. Within this range, absolute sensitivity approaches the levels reported for man. Sensitivity declines dramatically for frequencies above this range and most birds show a high frequency hearing limit of about 10 kHz. Owls show slightly better high frequency sensitivity with a hearing limit around 12 kHz. Even those birds which are known to echolocate utilize signals in the frequency region of 2–8 kHz (Konishi and Knudsen 1979). Below 1 kHz sensitivity decreases gradually but there is evidence in some birds (Rock Dove *Columba livia*) of a special sensitivity to infra-sound. Since infra-sound travels great distances, it is hypothesized that sensitivity to these sounds may aid in navigation.

Discrimination of acoustic signals by birds is of considerable interest due to their use of complex vocal signals. Within the frequency region of 1–5 kHz, birds are almost as sensitive as man to changes in the frequency, duration, or intensity of simple pure tones (R. Dooling 1982). On more sophisticated measures of frequency resolving power such as masking, at least one species (Budgerigar *Melopsittacus undulatus*) consistently out-performs man. It may be that the auditory system is especially tuned to complex acoustic signals in this frequency region. On several measures of temporal resolving power, birds have shown levels of sensitivity similar to those reported for other mammals, suggesting that the bird ear may not be specialized for a high speed of response as once thought.

Sound localization abilities in owls and other avian predators are extremely well-developed both in azimuth and elevation (Knudsen 1980). The cues for sound localization in these species are interaural arrival time and interaural spectrum. For common bonds with unspecialized auditory systems both the cues and the mechanisms for sound localization are less clear. Behavioural studies indicate that birds localize high and low frequencies better than mid-range frequencies and broad band noise better than pure tones. The complexity of avian vocalizations probably provides a rich source of potential cues for sound localization and it is clear that birds can and do localize the sounds of conspecifics. But the existence of an interaural pathway in birds suggests that the mechanism for sound localization in birds is considerably different from that used by man and other mammals.

Balance. As with other vertebrates, the three semi-circular canals lie in nearly orthogonal planes and function to indicate the angular motion of the head. The receptors of the superior division of the labyrinth consist of the ampullary crests, utricular macula, and the papilla neglecta. The inferior division, in addition to the basilar papilla, consists of the saccular macula and the lagenar macula. No data are available on the function of this complex system but common observation of the flying skills of most birds would suggest a highly developed system with a short time constant. Differences in labyrinth structures across species do indeed show a correlation with flying ability. (R.J.P.) R.J.D.

HEART: in its pericardial sac the heart occupies the cranial part of the thoracic cavity, its apex pointing caudoventrally. Its pulmonary surface (or base) lies below the lungs, trachea, and proventriculus. The dorsal ventricular portion of the heart lies against the liver. Nearly its entire ventral aspect rests on the body of the sternum.

Surface features (Fig. 1). The heart consists of cardiac muscle (myocardium) invested with the shiny layer of epicardium; its lining of endocardium is continuous with endothelium of vessels entering and leaving the heart. The grooves between the heart chambers are often obscured by subepicardial fat (Fig. 1A). The cone-shaped heart is truncated in some species, elongated in others. The wide cranial end of the heart is formed by the two atria and their ear-shaped appendages, the auricles. The pulmonary trunk and the ascending aorta intervene between the atria. The coronary sulcus separates atria and ventricles. The shallow ventral interventricular (I–V) sulcus extends obliquely between the short right ventricle and the longer left ventricle, and is continuous with the dorsal I–V sulcus of the hepatic surface of the heart.

Skeleton and musculature. The skeleton of the heart is composed of rings (annuli) of fibrous connective tissue that surround the atrioventricular (A–V) openings (ostia) and the openings of the aorta and pulmonary trunk. The annuli support the cusps of the valves of these ostia and prevent collapse of the ostia during valve closure. The annuli serve as origin and insertion of atrial and ventricular myocardium. The smooth-walled parts of the atria are thin; the thicker rib-like pectinate muscles of the auricles stand out in relief. Certain pectinate muscles coalesce into prominent median and transverse arches. The bundles of ventricular myocardium sweep spirally from the annuli toward the apex then back toward the bases of the ventricles. This arrangement causes the wringing of the ventricles during their contraction. Ventricular walls are much thicker than those of the atria.

Heart chambers. The adult heart of some birds (ratites) retains the foetal heart chamber, the sinus venosus. The three caval veins empty into

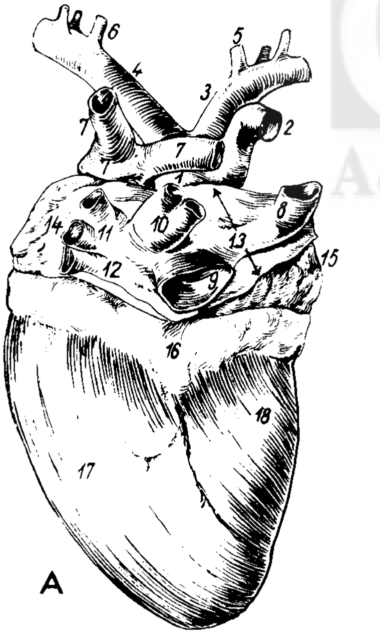

Fig. 1. Heart of the goose, *Anser*. (From Ghetie *et al* 1976).
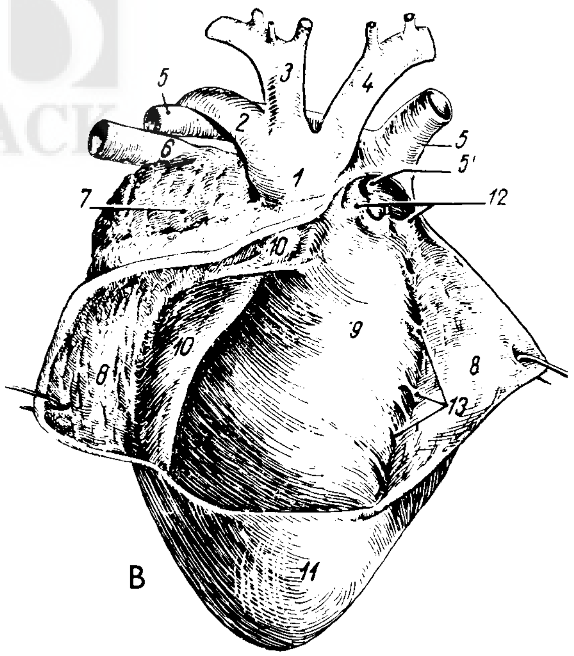
(A) Dorsal aspect of heart and great vessels. Upper half of figure is the base or pulmonary surface. Note that the right cranial vena cava has a greater calibre than the left, reflecting the greater dimensions of the right jugular vein prevailing in most birds.
1 ascending aorta; 2 aortic arch; 3,4 brachiocephalic aa.; 5,6 common carotid aa.; 7 pulmonary trunk and aa.; 8 right cranial vena cava; 9 caudal vena cava; 10,11 pulmonary aa.; 12 left cranial vena cava; 13 right atrium; 14,15 left and right auricles; 16 coronary (atrioventricular) sulcus covered with fat; 17,18 left and right ventricles.



(B) Sternal surface of heart and great vessels, right ventricle opened.
1 ascending aorta; 2 aortic arch; 3,4 brachiocephalic aa.; 5 pulmonary aa.; 5′ ostium of pulmonary trunk; 6 right cranial vena cava; 7 right auricle; 8 right ventricle; 9 interventricular septum; 10 right atrioventricular valve (muscular); 11 left ventricle; 12 valve of pulmonary trunk; 13 trabeculae carneae.

this chamber which communicates with the right atrium via the slit-like sinu-atrial (S–A) opening. In other birds (e.g. *Gallus*) the sinus receives only two caval veins, the left cranial vena cava emptying directly into the right atrium. In most birds that have been studied the three caval veins open individually into the right atrium (Fig. 1A); no definitive sinus venosus is present. Most of the foetal sinus becomes incorporated into the right atrium; remnants of the S–A valve persist.

The right atrium receives venous blood from all parts of the body and the heart wall itself. The inflow ostia of the right atrium are those of the huge caval veins (or sinus venosus) and the cardiac veins; the single outflow opening is the right A–V ostium. The main part of the interior of the right atrium, including the interatrial septum, is smooth-walled and communicates with the subchamber of the auricle. Another feature of the interior is a cul-de-sac, the left recess of the right atrium.

The right ventricle is short and wide. The entrance of the right ventricle is equipped with the right A–V valve, a crescent-shaped muscular fold with its free edge projecting into the ventricle. During ventricular contraction (systole) the valve clasps the interventricular septum, preventing regurgitation of blood into the atrium. Blood entering the ventricle passes apically, then flows into the conus arteriosus, the funnel-shaped subchamber of the right ventricle. Its outflow opening is the pulmonary trunk, where the pulmonary valve is located. Blood then travels via the pulmonary arteries to the lungs for aeration.

The avian I–V septum is a curved partition between the ventricles; almost two-thirds of the circumference of the left ventricle is enveloped by the free wall of the right ventricle (Fig. 1).

The left heart receives blood from the lungs and propels it throughout the arterial tree to all parts of the body. The paired pulmonary veins (Fig. 1A) enter the left atrium independently or become confluent (Fig. 1). The cavity of the left atrium is partitioned by a transverse fold known as the valve of the pulmonary vein, which directs blood into the left A–V ostium.

The left ventricle forms the apical one-third of the heart. Its wall is 2–3 times thicker than that of the right ventricle, reflecting its function as a high pressure pump. One or more papillary muscles project from the wall of the left ventricle. The left A–V ostium is rounded in contrast to the semilunar one of the right A–V ostium. The left A–V valve differs from the right one in that its two or three cusps are membranous. The cusps are restrained by tendinous cords from the papillary muscles or ventricular wall. The vestibule of the aorta lies between the septal cusp of the valve and the interventricular septum and leads to the outflow channel, the aorta.

Blood supply and drainage. The right and left coronary arteries originate from the aortic sinuses, enlargements at the base of the aorta, just distal to the aortic valve. Ordinarily each coronary artery divides into superficial and deep rami. Unlike the mammalian heart, most of the blood to the myocardium of the avian heart is distributed via deep rather than surface arteries. The superficial rami course in the coronary sulcus, supplying atria and ventricles. The deep rami course within the I–V septum, gradually inclining toward the surface.

The major venous trunks course just beneath the epicardium; generally the veins do not accompany coronary artery branches. The smallest cardiac (luminal) veins carry some of the myocardial blood directly into the heart chambers.

Conducting system. The cardiac conducting system initiates and carries the impulses that bring about the co-ordinated contraction sequence of the heart muscle required for pumping blood through the pulmonary and systemic circuits. This impulse-conducting system is derived from transformed cardiac muscle cells (or fibres), and forms impulse-conducting chains. The terminal network is partly subendocardial and partly periarterial around branches of the coronary arteries. The terminal rami branch further, ultimately becoming contiguous end-to-end or side-to-side with contractile myocardial cells. The cardiac impulse is automatically generated in the nodal tissue, then transmitted over the bundles, branches, and terminal rami. The rami excite the myocardial fibres, bring about their contraction, the wave of excitation passing to adjacent myocardial fibres. Cell-to-cell transmission is electrical, conducted from one cell to the next over nexuses (gap junctions), low resistance zones of continuity between adjacent cells.

The compact S–A node ('pace-maker') is located in the right atrial wall somewhere near the apical end of the right S–A valvule or its vestige. The A–V node is embedded in the caudodorsal part of the interatrial septum. The A–V node continues apically as the A–V bundle of His which enters the I–V septum and divides into its right and left crura that travel on each side of the septum. From the region of its bifurcation the A–V bundle gives off its Ramus recurrens (truncobulbar fasciculus). The ramus then joins the ventral extremity of the right A–V annulus. Here the truncobulbar node is reported to be present in adult heart of *Gallus*. The right A–V annulus courses in the right A–V valve; its dorsal extremity arises directly from the A–V node.

Atrial musculature is not continuous with ventricular musculature. Both are 'insulated' from one another by attachment to the non-conducting skeleton of the heart. The only direct connections between the two muscle groups are by way of the bundles of conducting tissue.

Heart innervation. The innervation to the heart modulates the activity of the conducting tissue. The most densely innervated regions of the avian heart are the S–A node, right atrium, and the A–V node. The periarterial and subendocardial conducting tissue of the ventricles also receives a double innervation of interacting (autonomic) nerves. In general the cholinergic vagal efferent nerves produce effects that slow the heart beat. On the other hand, the thoracolumbar (sympathetic) adrenergic nerves from the lowest of the cervical paravertebral ganglia accelerate the beat. The vagal afferent fibres are involved in cardiac reflexes. The direct innervation of the heart muscles probably modifies their response to stimulation from the conducting system, adrenergic innervation enhancing the force of their contraction and cholinergic innervation the reverse. Coronary arteries also receive a double innervation of noradrenergic and cholinergic fibres for regulation of coronary blood flow.

Heart size. The weights of avian hearts, as a percentage of body weight (B.W.), range from 1.4–2 times larger than mammals of comparable size. Species living at high altitudes have larger hearts than the same species at lower altitudes.

The ratio of heart size to body weight is significant for flight, i.e. birds with large hearts but only modestly developed flight muscles can fly for long periods. Thus, although the tinamous (Tinamiformes) have powerful limb muscles and extremely large flight muscles, they are capable only of explosive flight over short distances. Their hearts are relatively the smallest of all birds (0.19–0.25% of B.W.), which appears to limit prolonged flight effort. Compare this with flying abilities of pigeons (Columbidae) whose flight muscle weights are equivalent to those of tinamous while the heart ratio is greater (0.93–1.29% of B.W.).

Since the avian heart rate is so high (see below) the relatively large heart in birds may provide the means for quickly increasing heart output by utilizing the reserve portion of the blood not ejected from the ventricles at each beat during moderate activity. Large hearts requiring a relatively reduced degree of muscle shortening may facilitate adequate filling of the chambers at the high rate prevailing in birds.

Heart rate. Normal heart rates for resting birds (e.g. pigeon, chicken, duck) range from 150–350 beats per min. The resting rate in the ostrich (*Struthio*) is 60–70 per min, in a small passerine (Black-capped Chickadee *Parus atricapillus*) 500 per min, in hummingbirds (Trochilidae) up to 1,000 per min. During excitement, stress, or sustained flight the above rates more than double. For example, during flight the heart rate of small birds (10–20 g) is 2.4 times that at rest; in large birds (500–1,000 g), the flight rate is 3 times resting rate. In diving birds the heart rate is slowed reflexly about 50% during the dive.

Some coupling of heart rate to wing beat frequency in flight has been observed: in some forms 1 : 1, in others 1 : 2. It has been suggested that the pectoral muscles of small birds in flight may operate as a venous pump in order to maintain adequate venous return to the heart, compensating for high cardiac output. HEATH FOWL: antique term (in British game laws) for Black Grouse *Tetrao tetrix*—contrasted with 'Moor Fowl' for Red Grouse *Lagopus*

Ostrich *Struthio camelus* showing exposed bare skin to reduce heat, sexual dimorphism and male giving distraction display. (*Photo: J.F. Reynolds*).

lagopus scoticus (see GROUSE).

HEATH HEN: name of the now extinct nominate race of the Greater Prairie Chicken *Tympanuchus cupido* (see GROUSE; EXTINCT BIRDS).

HEAT REGULATION: also called thermoregulation; the process by which a bird maintains a stable body temperature, irrespective of variations in the surrounding temperature.

Birds are endothermic animals (= warm-blooded or homoiothermic), that maintain a high body temperature of 40 ± 2°C. Their body heat is generated metabolically by the oxidation of absorbed nutrients (see METABOLISM) and accounts for a large proportion of the total energy metabolized by the body. Apart from species that can go torpid (see TORPIDITY) body temperature shows only a small daily variation; in diurnal birds the daytime core temperature may be 42°C, dropping to 39°C at night; in nocturnal birds the cycle is reversed.

In an inactive bird metabolic heat production is normally never less than the Basal Metabolic Rate (see ENERGETICS) and when the bird is active it may be much more. To maintain a stable body temperature it is necessary that heat production is balanced by heat loss. At low to moderate ambient temperatures this is achieved mainly by conduction and radiation and at high temperatures by the evaporation of water. The rate at which heat is lost by conduction and radiation is proportional to the temperature difference between the body core and the outside, thus

$$\text{Rate of heat loss} = C(T_{\text{body}} - T_{\text{ambient}}),$$

where C represents the heat conductance ($\text{Joules} \cdot \text{sec}^{-1} \cdot \text{cm}^{-2} \cdot {}^{\circ}\text{C}^{-1}$) of the body and plumage (its reciprocal is the insulation). Over a range of ambient temperatures known as the *thermoneutral zone* the heat production of an inactive bird is able to remain constant at the Basal Metabolic Rate, because changes in ambient temperature, which would alter the rate of heat loss, are compensated by changes in the thermal conductance (or insulation) of the body. By a complex neuromuscular arrangement connecting adjacent feather follicles, the ptilomotor system, a bird can fluff out its feathers to their maximum extent, so trapping a greater amount of still air between them and greatly increasing the insulation value of the plumage. Conversely, the feathers can be sleeked back to increase the conductance. Birds may also make postural changes to alter heat loss; to reduce heat loss the face may be hidden under the scapulars and the feet withdrawn up into the feathers, or (especially on ice or in water) the bird may stand on one leg. Heat loss through the feet may be reduced by an arrangement of the blood vessels in the upper leg that acts as a counter-current heat exchanger. Warm arterial blood from the body passes through fine arteries in close contact with the veins returning cold blood from the feet. The venous blood is thus warmed before it can return and cool the body, while the arterial blood is cooled before it can lose its heat to the exterior. A gull with its feet in ice water may lose only 1.5% of its metabolic heat through its feet because of the efficiency of the heat exchange. Even so the feet cannot be allowed to freeze; below freezing point additional heat is supplied to the feet to prevent freezing and heat loss is therefore increased.

If the insulation is already maximized, but the ambient temperature drops still further, heat loss increases in proportion to the increasing temperature difference ($T_b - T_a$). A stable body temperature can then be maintained only by increased heat production in the body core. The ambient temperature at which this occurs is the *lower critical temperature* and marks the lower end of the thermoneutral zone. It is generally much lower in well-insulated Antarctic and Arctic species (and hence the thermoneutral zone is wider) than in temperate or tropical birds. The lower critical temperature may vary seasonally in some species, being lower in winter than in summer. The lower winter value may be due to a better insulating plumage, or a higher basal heat production, or both (see ENERGETICS). As ambient temperature decreases, metabolic heat production increases more rapidly in poorly insulated tropical species than in well-insulated Arctic ones. Small birds are doubly disadvantaged because their size prevents them from carrying as thick a plumage as large birds, as well as requiring them to increase their heat production more rapidly with falling temperature, since the area of the body surface, through which the heat is lost, is proportionately greater than the volume of the body core, where heat is produced. All species, however, are eventually limited by the maximum additional metabolic heat that they can produce. The maximum heat production determines the minimum ambient temperature below which hypothermia and death result.

At high ambient temperatures heat may be lost by increased blood circulation to the periphery, particularly to the legs and to any bare, well-vascularized patches of skin. The wings may be partly spread, e.g. in coursers, allowing radiation from the sparsely-feathered under surface of the wing. Incubating birds, e.g. plovers, may sit with their backs to the wind and raise the mantle feathers, allowing the wind to break the insulating boundary layer of air trapped in the plumage. However, as ambient temperature approaches that of the body, conduction and radiation become less effective at dissipating heat and cooling by the evaporation of water becomes increasingly important. Since birds do not possess sweat glands, water is usually evaporated through the respiratory tract, where the rate of evaporation is greatly increased by panting or, in some non-passerines, by gular flutter, a rapid oscillation of the thin floor of the mouth and upper throat. Nevertheless among birds, unlike mammals, evaporative water loss at high ambient temperatures rarely dissipates more than half the total heat production. Some species, e.g. incubating Fairy Terns *Gygis alba*, reduce heat production by slowing the heart rate and reducing the basal metabolic rate. Others, particularly some desert birds, e.g. the American Mourning Dove *Zenaidura macroura*, allow the body temperature to rise above normal to 45°C, thus re-establishing a temperature gradient to their surroundings so that heat loss by conduction and radiation can continue. The temperature at which this occurs is the *upper critical temperature* and marks the upper limit of the thermoneutral zone.

Where the environment is hotter than body temperature, the bird absorbs heat. Small birds are again at a disadvantage compared with large ones; they already have a high basal metabolic heat production and their surface area being large relative to body volume causes them to gain heat faster from their surroundings. Small birds seek shade to lessen the heat intake from solar radiation and large soaring birds take to the wing to reach cool air at high altitude; but birds can cope with heat stress only for as long as they have an adequate supply of water that they can evaporate fast enough. Some large birds may even excrete down their legs to provide an additional site for evaporative cooling. The capacity for evaporative cooling determines the ambient temperature at which body temperature begins to rise (the upper critical temperature). As hyperthermia proceeds, the metabolic heat production, which is temperature dependent, also increases, resulting in an explosive heat rise and death at body temperatures of 46–48°C.

See photos BELLY SOAKING; ENERGETICS; INCUBATION. P.J.J.

HEDGESPARROW: name (misnomer), alternatively 'Dunnock', of *Prunella modularis* (see ACCENTOR).

HEEL PAD: a callosity behind the intertarsal joint in nestlings of some piciform and other birds (see LEG).

HELIGOLAND TRAP: see BIRD OBSERVATORY; TRAPPING.

HELIORNITHES; HELIORNITHIDAE: see under GRUIFORMES; FINFOOT.

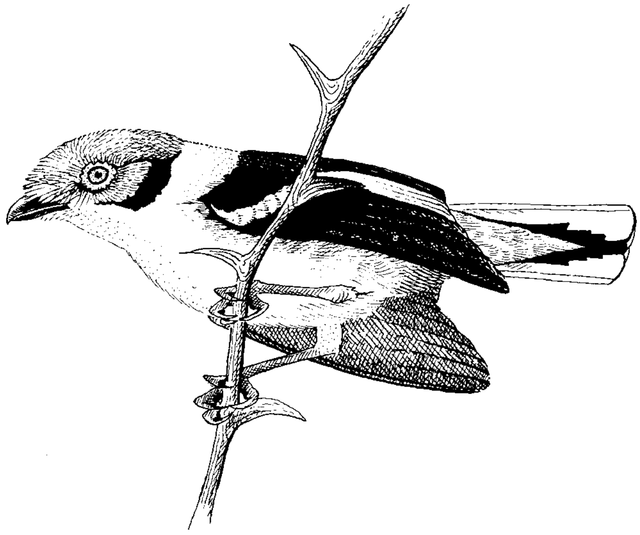
HELL-DIVER: popular American name for the Pied-billed Grebe *Podilymbus podiceps* (see GREBE).

HELMET: an ornament, usually composed of feathers, on the top of the head, as in helmet-shrikes (Prionopinae)—compare CASQUE.

HELMETBIRD: *Euryceras prevostii* (see VANGA).

HELMETCREST: *Oxypogon guerinii* (for family see HUMMINGBIRD).

HELMET-SHRIKE: substantive name of most species of Prionopidae (Passeriformes, suborder Oscines); in the plural general term for the family; formerly considered a subfamily of the shrikes (Laniidae) by Rand (1960). The helmet-shrikes, all endemic to the Afrotropical region, have bills that are hooked and notched near the tip, similar to the true shrikes (Laniidae). The wing has 10 primaries and the tail 12 rectrices. Legs and feet are strong and claws sharp for catching prey. Lengths range from 18–25 cm. They are unusual in having a tarsus scutellated on both side and front, and most species have specialized head feathering and eye-wattles that are distinctively coloured. The feathers on the forehead are stiff and project forward, covering the nostrils. Two genera are recognized, following Hall and Moreau (1970), *Prionops* (7 species) and *Eurocephalus* (2 species); others place some species of *Prionops* in a separate genus *Sigmodus*, and place *Eurocephalus* in the Laniidae. The sexes are alike.



Common Helmet-shrike *Prionops plumata*. (*M.W.*).

Field characteristics, habitat and distribution. The species of *Prionops* fall into two groups, 3 black-billed species and 4 red-billed. Of the black-billed species the Common Helmet-shrike *Prionops plumata* has the widest distribution in savanna and light woodland throughout the Afrotropical region; 5 races are recognized by Hall and Moreau. It is a black, grey and white bird, with orange eye-wattles. The Grey-crested Helmet-shrike *P. poliolopha* differs from it in having no eye-wattles and replaces it in the Kenya highlands and in drier areas further south. The Yellow-crested Helmet-shrike *P. alberti*, closely related to *poliolopha*, is confined to land above 1,400 m in the eastern Congo and is wholly black with a yellow crest and orange eye-wattle.

Of the red-billed species one, the Red-billed Shrike *P. caniceps*, is restricted to the West African and Congo forest block. It has a black back, throat and tail, whitish head and white and chestnut underparts, but no eye-wattle. Another, the smallest of the family, is the Chestnut-fronted Helmet-shrike *P. scopifrons* (length 18 cm) which has a blue eye-wattle and is confined to a narrow forest belt along the eastern sea-board of Africa.

The White-crowned Shrikes, *Eurocephalus anguitimens* and *E. rueppelli*, sometimes considered conspecific, are brown and white and inhabit acacia steppe in southern Africa and north-eastern Africa respectively. Their white heads and rumps are conspicuous in flight which resembles that of a large butterfly.

Movements. There are no ringing data to confirm the presence or absence of movements; observations suggest that local movements may occur in some populations of the Common Helmet-shrike.

Food. Helmet-shrikes search trunks, branches and leaves mainly for insects, each species foraging systematically in a group much like tits.

Behaviour. All species are intensely sociable, occurring in groups numbering 6–12 birds or more, throughout the year. Nothing is known about the permanency of the pair bond. Only the Common Helmet-shrike has been studied using colour-ringed birds. All group members co-operate in nest-building, incubation and feeding young; in addition, clumping and allopreening occur. A group normally has only one active nest used by one female but occasionally (8 cases in 225 recorded in Zimbabwe) 2 females may lay complete clutches in the same nest; pairs sometimes nest close to each other in neighbouring trees. In Retz's Red-billed Shrike *P. retzii* some pairs (1 in 36 recorded in Zimbabwe) breed alone. The 2 *Eurocephalus* species appear to breed only in pairs, although outside the breeding season they are found in groups of up to 10 birds. Group territorial defence and predator attack have been recorded in the Curly-crested Helmet-shrike *P. cristata* and may be common to the genus. Helmet-shrikes are often accompanied by other bird species when feeding. Their flight is buoyant, much like jays, and they are usually silent on the wing.

Voice. Although helmet-shrikes have a variety of calls, of which the most frequently listed are repeated whistles or flute-like notes, they are usually located in the field through the noisy chattering of a mobile flock. In addition, bill snapping is characteristic of the group.

Breeding. The nests of the helmet-shrikes are inconspicuous but neatly formed shallow cups, either secured to a horizontal branch or placed in a fork of a tree or thicket from 2–7 m above the ground. Materials used include tendrils, spider webs, lichen, rootlets, grass and bark fibre.

The normal clutch is 3 or 4; eggs have a range of ground colours, variously described as white, greyish-white, pale blue grey, blue, greenish blue, and pale pinkish. The eggs are either streaked, speckled or blotched with various shades of brown, purple-brown and chestnut-brown, the markings being concentrated usually at the large end. Incubation periods are in the range 12–14 days, nestling periods in the range 16–20 days. The breeding seasons are prolonged and overlap both the dry and wet seasons. L.G.G.

Hall, B.P. & Moreau, R.E. 1970. An Atlas of Speciation in African Passerine Birds. London.

Rand, A.L. 1960. Family Laniidae. *In* Mayr, E. & Greenway, J.C. Jr (eds.). Check-list of Birds of the World, vol. 9.

HELPERS AT THE NEST: see CO-OPERATIVE BREEDING.

HEMIPODE: alternative substantive name of species of Turnicidae and Pedionomidae, and also used as a general term for the suborder Turnices (see BUTTONQUAIL; PLAINS-WANDERER).

HEMIPROCNIDAE: see APODIFORMES; SWIFT.

HEMISPINGUS: substantive name of South American TANAGERS of the genus *Hemispingus*.

HEN: a female bird; applied without qualification to the female of the domestic fowl (compare COCK). Special terms apply to the females of some species, e.g. PEN, GREYHEN, PEAHEN, REEVE. The names of certain species have also a special use as terms for the female, e.g. DUCK, GOOSE, FALCON; but note that in North America the female of any duck species is the 'hen'.

HERALDIC BIRDS: avian symbols used as charges in armorial bearings. In heraldry the animals fall into roughly the same classes as in zoology, but with the addition of heraldic monsters. The four main classes are beasts, monsters, fishes, and birds. Most books on heraldry deal fairly fully with beasts; monsters can be studied in the many excellent beastiaries and books of monsters; Thomas Moule's *Heraldry of Fish* (1842) is the last word on that subject; but birds have been neglected. It is, therefore, particularly pleasant to be able to remedy here, if only in some slight measure, this deficiency.

Heraldry is a form of hereditary personal symbolism in which the basic medium for the display of the devices used is the shield. It is European in conception and application, just post-Conquest in time of origin and, to a great extent, dependent for much of its early symbolism and many of its conventions on the Crusades, jousts, and tournaments. Two symbols are used, the arms borne upon the shield and the crest. The crest is a device which was originally modelled on top of the helmet and which, together with the mantling which flows from it, is often shown in pictorial representations of arms. That heraldry was from its inception at once utilitarian and also pictorial and decorative accounts for the fact that crests are often absurdly impracticable and could never have been in actual use, but only engraved upon seals and otherwise used pictorially.

It is not surprising that birds are to be found in early heraldic symbolism, when it is considered how frequently they appear in more ancient symbolisms. The eagle on the standard of a Roman legion is well known; perhaps less familiar in this regard is the owl, which in a most heraldic form graced the reverse of an Athenian tetradrachmon minted about the time of the Persian Wars.

In Christian symbolism the dove holds pride of place as a symbol of the Holy Spirit and His attributes of peace (see also ART, BIRDS IN). If only for this reason, it has always been a favourite heraldic charge, whilst the pelican as a type of Christ is popular in the heraldry of ecclesiastics. In early heraldry she is often drawn more like an eagle, and is almost invariably depicted 'in her piety', i.e. on a nest and pecking her breast to feed her young with her own blood. The origin of this fable of self-wounding may lie in the habit of resting the pouched bill upon the breast. A well-known example of the pelican in heraldry occurs in the arms of Richard Foxe, Bishop of Winchester, *Azure a Pelican wings elevated and addorsed Or vulning herself proper*. Foxe, who died in 1528, founded Corpus Christi College, Oxford, in 1515, and his arms still form part of the cumbersome coat borne by his foundation.

An early arrival in the heraldic aviary was the martlet. This bird has always been shown *sans* legs and looking perhaps rather more like a fat swallow than anything else. Indeed, to preserve the obvious pun, it is described as an *hirondelle* (swallow) in the arms of Arundell (*Sable six hirondelles 3, 2, and 1 Argent*): variants of these arms are used by both the East Sussex and West Sussex County Councils. Most heraldic writers state that 'martlet' is a synonym for 'martin', a bird which has such short legs that it relies upon them but little, and is therefore always depicted heraldically without legs, albeit it is almost invariably shown 'close' and not in flight. Other writers assert that it represents a swift, for these birds are found in great numbers in the Holy Land and crusaders may have come to associate these elegant yet sturdy (and apparently legless) creatures with their own exploits in the Near East and adopted them as symbols of speed and endurance, as well as a reminder to others that the bearers had fought for the Faith. It is amusing to note that the martlet is used to denote a fourth son in heraldry. The story is that the first son inherited, the second became a soldier, and the third entered the church; but for the fourth there was nothing, so he flew away to seek his fortune. That the martlet is of great antiquity in heraldry is borne out by its presence in a great many of the coats depicted in 'Glover's Roll' (*c.* 1255).

It was a common mediaeval practice to show in arms not only military but also sporting symbols. Thus one finds hunting horns, greyhounds, and, of course, hawks. These last are usually shown belled and jessed, and sometimes hooded. The hawk is drawn in a somewhat stylized way and indifferently called a 'hawk' or 'falcon', except where a pun is required or where for some special reason a particular species was chosen for a charge. Then the hawks may be found looking much like any other, but blazoned a 'goss-hawk', 'sparrowhawk', 'gerfalcon', 'marlion', or 'hobbey'. See also FALCONRY.

The birds so far mentioned are to be found in heraldry principally owing to the qualities which they symbolize. Very many other kinds of bird grace armorial bearings, but principally because they pun on the name of the bearer of the arms. There is no need to mention what birds are to be found in the arms of Larkins, Bustard, Sparrow, Hancock, Cobbe, and Storke, to mention but a few.

Whilst it is often apparent why a certain bird appears in a certain coat of arms, as the pheasant which is found in the crest of the Worshipful Company of Cooks, this is not always the case. In 1550 one William Strickland, of Yorkshire, was granted arms and a crest, the latter consisting of *A Turkey Cock Argent beaked and legged Sable combed and wattled Gules*. The reason for this grant is that William Strickland was said to have introduced turkeys into England from North America; the sketch which is part of the docquet of this grant must therefore be one of

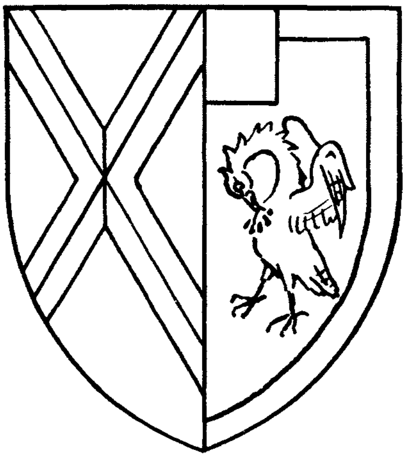


Fig. 1. Pelican; in the arms of Richard Foxe (as Bishop of Bath and Wells), from College of Arms Ms. L. 10.

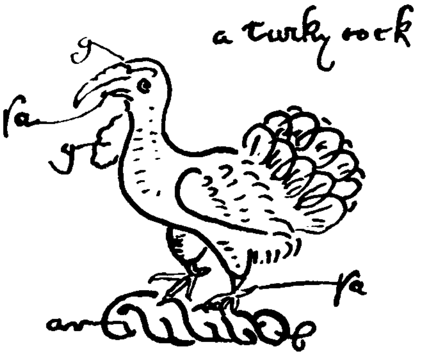

Fig. 2. Turkey; an early drawing in the records of the College of Arms.

the first ever made of a turkey in Britain—indeed, one look at the sketch lends support to this view! The arms of the Worshipful Company of Musicians are full of royal emblems, and this might suggest that the swan in the arms is a royal swan; however, the reason for its appearance is almost certainly an allusion to the legend that the soul of Apollo, the god of music, passed into a swan when it was at the point of death, thus enabling the bird to sing a beautiful song before it died.

The swan deserves particular mention as it was the famous badge of the powerful family of Bohun, Earls of Hereford and Essex, and the crest of the Beauchamps, Earls of Warwick, and from these families it percolated through to many others. Why these and other families adopted the swan is uncertain. It has been suggested that the reason is to be found in the fact that they can all trace descent from the house of Boulogne, connected in legend with the Knight of the Swan. This theory is carefully examined by A.R. Wagner in his essay 'The Swan Badge and the Swan Knight' (*Archaeologia* 97: 127). It is interesting to consider how legend and romance were mirrored in an heraldic charge which, because it was adopted by one or two powerful families, soon found its way into the heraldry of smaller families, as representing either consanguinity with, or feudal dependence upon, these early magnates.

Although birds are seen to best advantage as crests and charges in arms they are also used as supporters. It is a privilege of peers and certain grades of knight to have supporters on either side of the shield. Although a bird is a rather unsteady supporter, compared with a beast or a human being, it is becoming increasingly popular.

Birds have become increasingly popular as heraldic charges and particularly as crests during the present century. Although unspectacular birds frequently appear, they are not so popular as the more exotic breeds; unornithological Kings of Arms tend not to distinguish between, say, a blackbird, thrush and starling. Thus if a starling is granted as a crest, someone wanting a thrush will be unlucky as it will be dubbed 'the same sort of bird'. A glance through the recent grant books at the College of Arms has revealed hummingbirds, albatrosses, many cormorants, a rockhopper penguin, a Canada goose, many red cardinals, moas and sedge warblers.

When the Zoological Society of London was granted arms in 1959, it was desired to represent different classes of creature. Therefore, to the principal charge of a lion were added two zebra as supporters (Lord Zuckerman's idea) and a crest consisting of an osprey with a fish in its talons, as suggested by Sir Landsborough Thomson, and effected by the writer of this article. J.P.B-L.

HERBST'S CORPUSCLES: see TOUCH.

HERD: see ASSEMBLY, NOUN OF.

HEREDITY: see GENETICS.

HERITABILITY: the proportion of total variation in a population which is due to genetic causes (see GENETICS).

HERMIT: substantive name of species of HUMMINGBIRDS of the genera *Ramphodon, Glaucis, Phaethornis* and sometimes of *Threnetes*, so-called because of their generally sombre plumage colours.

HERMIT THRUSH: *Catharus guttatus*, a North American THRUSH, noted for its outstandingly beautiful song.

HERN; HERNSHAW: obsolete or dialect names, in Britain, for the Heron *Ardea cinerea*—the latter variously spelt, including 'handsaw' in Shakespeare.

HERODIONES: see CICONIIFORMES.

HERON: substantive name for most species of the Ardeinae (typical herons), one of 2 subfamilies of Ardeidae (Ciconiiformes); in Britain commonly used without qualification for the sole native species, the Grey Heron *Ardea cinerea*; in the plural, a general term for the Ardeinae and the Ardeidae. The substantive name 'egret' is used for several species. The other subfamily is the Botaurinae (see BITTERN). The Boat-billed Heron *Cochlearius cochlearius* was previously placed in a separate family.

Characteristics. Herons are medium to large birds, ranging from the Zigzag Heron *Zebrilus undulatus*, 30 cm long, to the Goliath Heron *Ardea goliath*, 140 cm long. Particularly in the day herons, the body is slender and neck and legs relatively long. Night herons are stouter with shorter necks. Long-necked herons keep their heads retracted in prolonged flight. A kink in the neck is caused by the structure of the relatively long sixth cervical vertebra. Toes are long and slender; the inner toe is shorter than the outer and is attached to the middle toe by a short basal web; the hind toe is lengthened and level with the inner toe; a pectinated middle toe nail is used for grooming. Bill structure ranges from very long and thin in the Chestnut-bellied Heron *Agamia agami*, to broad and thickened in the Boat-billed Heron. The tail is short, usually with 12 rectrices. Wings are long, broad, with 10 primaries, 9 in the Boat-billed Heron. Flight is slow but strong. Herons assume an erect or semi-crouched posture when active and retract their neck when resting.

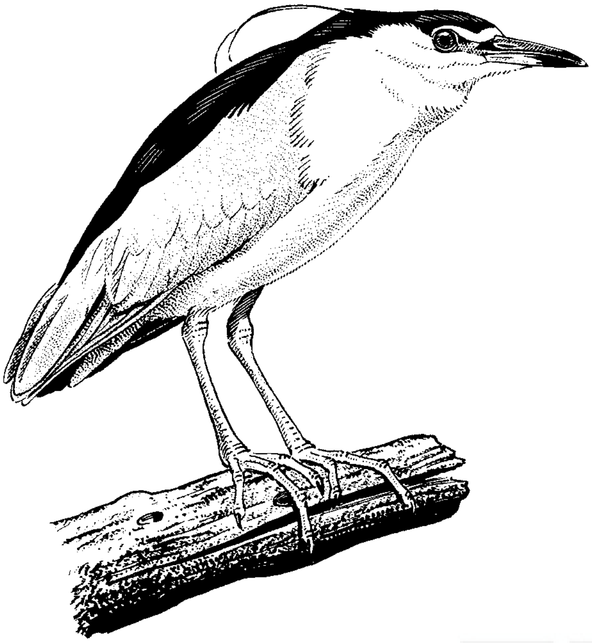
The plumage of herons is loose, the basic colours emphasizing black, brown, blue, grey, and white. Colour patterns may be complex, especially in cryptic species. The head is completely feathered except the lores. Some species, especially day herons, have lanceolate or filamentous display plumes on their head, neck, breast, or back. Sexes of most species are alike in plumage, but polymorphism occurs in several. Down is confined to apteria; feather tracts are extremely narrow (see PTERYLOSIS). Powder-down patches, characteristic of herons, occur in pairs on the breast and rump. Additional pairs are located on the back and thighs of some species. Powder down is used during preening (see COMFORT BEHAVIOUR). Moult and plumage development patterns are complex and variable, seasonally and with age. Juvenile may differ from adult plumage, the night herons being cryptically barred and the Little Blue Heron *Egretta caerulea* white.

Habitat. Herons are adapted for walking about in water and are with ibises and storks often referred to by the descriptive name of wading birds. They characteristically inhabit shallow marshes and swamps, the shores of rivers and lakes. Small herons tend to frequent dense marshes; larger species tend to forage in the open. The amount of wetland habitat available directly influences population size. Terrestrial habitats are frequented by many typically aquatic species and used extensively by Cattle Egrets *Bubulcus ibis* and the Black-headed Heron *Ardea melanocephala*. Many species use shallow marine habitats, but several are marine specialists.

Taxonomy and distribution. The Ardeinae are divided into 3 tribes, the tiger herons Tigriornithini, night herons Nycticoracini, and day or typical herons Ardeini. Herons as a group are cosmopolitan, but most species are tropical.

The Tigrionithini are considered to be the most primitive group (but see Payne and Risley (1976)). The secretive and solitary tiger herons, including 6 species in 4 genera, 3 of which are monotypic, have a discontinuous apparently relict distribution. The New Guinea Tiger Heron *Zonerodius heliosylus* is confined to Papua-New Guinea. Its nearest relative, the White-crested Tiger Heron *Tigriornis leucolophus* inhabits the equatorial rain forest of West Africa. The Zigzag Heron, the least known ardeid, occurs in South America in forest pools and streams. The 3 *Tigrisoma* herons are Neotropical, occurring in swamps and along streams from Mexico to Argentina, with the Bare-throated Tiger Heron *T. mexicanum* confined to Central America.

The Nycticoracini are medium-sized herons that typically, but not universally, feed at night. In general they are stockier, shorter-legged, and heavier-billed than day herons. The 8 species in 3 genera have



Black-crowned Night Heron *Nycticorax nycticorax*. (*R.G.*).

distinctive skeletal differences from the day herons. The 4 oriental night herons *Gorsachius* are Palaeotropical. The Black-crowned Night Heron *Nycticorax nycticorax* is found on all continents but Australia and on many islands. It is replaced in Australia by the closely related Nankeen Night Heron *N. caledonicus*.

The Neotropical Boat-billed Heron is distinguished by its peculiarly widened bill, 7.5 cm long by 5 cm wide, and by its exceptionally large eyes. It has diverged from other herons in its display repertoire and has 3 rather than 4 powder-down patches. It resembles night herons in plumage and frequently feeds at night. Some believe that the unusual bill primarily serves a display function. It seems more likely to be a feeding adaptation.

The Ardeini include the well known, typically day-feeding herons and egrets. Many species nest colonially and forage in aggregations. The day heron group of 35 species is cosmopolitan.

The little known Capped Heron *Pilherodius pileatus* has a distribution centred in the Amazon basin of South America. Considered in the past to be a night heron, taxonomic and field studies indicate it to be a typical heron, characteristic of forested stream edges. The Whistling Heron *Syrigma sibilatrix* has a disjunct distribution in northern and southern South America. Its whistling calls, duck-like flight, and complex social behaviour are distinctive. It is a bird of the tropical savannas.

The pond herons *Ardeola* include 6 diminutive, short-legged Old World herons of shallow, reedy marshes. In several species breeding and non-breeding plumage differ markedly. The Cattle Egret is primarily a terrestrial heron that forages in commensal association with African buffalo, domestic cattle, other large animals, and even agricultural equipment. In Africa this mostly white bird favours seasonally-flooded plains. Both Indian and African races have expanded their ranges markedly within historic times, probably taking advantage of changing agricultural practices. The Cattle Egret had become established in South America by the late 1800s, in Australia by the early 1900s, and in North America and Europe by the early 1950s.

The Green Heron *Butorides striatus* includes 3 small, dark herons previously considered to be separate species. The most distinctive population, on the Galapagos, includes individuals that are almost entirely dark grey. Green Herons are secretive, often foraging under the cover of trees along the shores of rivers and lagoons. The Galapagos form typically feeds on rocky shores.

The genus *Egretta* includes 13 species, the medium sized white Little Egret *E. garzetta* of Europe, Africa, and Australia being typical. The Little Egret has a mainly inland distribution and breeds in mixed-species colonies. The Snowy Egret *E. thula* of North and South America is similar but has different breeding plumes. Two polymorphic reef herons *E. gularis* and *E. sacra* tend to replace the Little Egret along the coast in Africa and in Asia to Australia, respectively. But see a recent discussion in *The Herons Handbook* (p. 132). Another similar heron, Swinhoe's Egret *E. eulophotes*, is now confined to China and Korea. Three New World forms are similar in habitats to the Old World reef herons. The Pied Heron *E. picata* has a patchy distribution in Australia to New Guinea. Two more occur in Africa, and the Intermediate Egret *E. intermedia*, larger than the Little Egret, has a discontinuous distribution from Africa and Asia to Australia. The Great White Egret *E. alba* is cosmopolitan, occurring in many habitats on all continents.

The genus *Ardea* includes 11 species of medium to very large dark-plumaged herons. The Grey Heron and Purple Heron *A. purpurea* are widely distributed in Eurasia and Africa. The Grey Heron forms a natural, mutually allopatric, group with the North American Great Blue Heron *A. herodias* and the South American Cocoi Heron *A. cocoi*. The White-necked Heron *A. pacifica* replaces these species in Australia. The White-faced Heron *A. novaehollandiae* is a medium-sized species of Australia, which has been introduced and has spread in New Zealand. The African Black-headed Heron is characteristically terrestrial, feeding in cultivated areas and open grassland. Finally, there are 4 very large herons of allopatric distribution: the Malagasy Heron *A. humbloti* of the Malagasy Republic, the Goliath Heron of Africa and Asia, the Imperial Heron *A. imperialis* of South Asia, and the Sumatran Heron *A. sumatrana* from Malaya to Australia.

The Agami or Chestnut-bellied Heron is a peculiarly attractive neotropical species of uncertain affinity. It has a long neck and bill and brilliant dark green, chestnut, and pale blue plumage. It occurs along stream banks in deep forests.

Populations. Over their known history many populations have been reduced by hunting and by habitat loss. Extensive surveys in North America have assembled information on nesting colonies in recent years. The Grey Heron is the best known species, colonies in the United Kingdom being tallied as early as 1872 and the nesting population of England and Wales being censused annually since 1928. The population decreases markedly after hard winters.

Movements. Herons demonstrate several types of population movements. In temperate latitudes, regular seasonal migrations are undertaken by many species. Herons of the eastern Palearctic move toward Malaysia and Indonesia; western Palearctic herons migrate on a broad front to central Africa and also to India; Nearctic herons move to southern North America with eastern birds moving through Florida and western birds moving through Central America; southern African herons and southern South American herons undoubtedly migrate northward but their routes require additional study; Australasian herons appear to migrate as far north as New Guinea. Nearly all herons show post-breeding dispersals of juveniles, and of adults after nesting failure. Such dispersing birds may be moving from areas where food is scarce. Dispersals before migration bring many birds as late summer visitors to localities well away from their breeding range. Intra-regional movements, nomadic responses to seasonally variable food resources, have also been documented for various species.

Food. Herons are almost entirely carnivorous, depending heavily on aquatic prey. Diets are broad and variable in time and place and reflect seasonal flushes of prey. Exploiting seasonal prey abundances is of critical importance to many populations, affecting nesting success, movements, migration, and food choice.

The foraging behaviour of herons can be as simple as standing motionless in the shallows or at the water's edge until a potential prey approaches, as is typical of the largest and smallest species. Food is commonly sought by walking stealthily in the water or on dry ground, or by more active behaviours. A bird may combine walking with running or hopping in a repetitive sequence, as is characteristic of Reddish Egrets *E. rufescens*. Use of the feet is common, particularly in species with distinctively coloured toes. Aerial feeding methods are used by several species. Special wing actions characterize actively foraging species. The Black Heron *E. ardesiaca*, stands with its wings extended completely over its head forming a canopy that appears to attract prey and may increase their visibility.

Prey are grasped or, less frequently, impaled by a quick thrust. Dead or slow-moving prey are grabbed or picked up. When bill thrusts are directed into the water, herons must compensate for refraction. Herons may tilt or cock their heads to improve visibility. Captured prey are mandibulated by bites or stabbing if they are large or possess counter-adaptations such as spines, hard bodies, or violent post-capture behaviour. Pellets of undigested material are disgorged. Smaller herons take longer to handle large prey, which may affect their choices. The New World Yellow-crowned Night Heron *Nycticorax violaceus* specializes in feeding on crustaceans. Most herons feed diurnally, but some species, e.g. the night herons, characteristically feed nocturnally or crepuscularly, while others, e.g. Great Blue Heron, may do so at times.

Behaviour. Some herons, such as the tiger herons, are typically solitary; others forage in isolation but nest colonially. Some species, such as the Cattle Egret, feed in flocks and nest in large colonies. Others are socially flexible, and individuals may alternately feed alone or in an aggregation. Social foraging provides opportunities for complex interactions, including aggression, commensalism, competition, and prey robbing. Territorial behaviour on the feeding grounds is common, and individual territories may be occupied over long periods. Individual distances are always maintained.

Many herons form mixed-species communal roosts in protected sites, often after assembling at staging locations. Nesting in groups on isolated sites confers some degree of protection. Herons may also use colony associates to obtain information on the direction of available food resources.

Pair formation behaviours are varied and elaborate, including aerial and non-aerial elements. Pair-bonding begins at the colony, with intensive displays by males. Three types of pair formation are distinguishable. A succession of females may visit a displaying male at his future nest site (Grey Herons). Several females may visit a male on one or more temporary display sites (Cattle Egrets). Both males and females may move as a group around the colony (Little Egrets). A male typically initiates courtship by advertising calls, defends his site, and attracts a female with various displays.

In many species lores, irides, bill, legs, or feet change colour during courtship. Often the colour remains for only a few days. Coloration may vary among populations, such as in the Great White Egret. The irides and feet of the Green Heron turn from yellow to orange; bills of the European Great White Egret turn yellow; and bills of the Squacco Heron *Ardeola ralloides* turn blue. Colour changes appear to be partly a result of the deposition of pigments (see COLOUR) and partly of increased vascularization.

Voice. Herons have a limited repertoire of guttural honks, frarnks, coos, and growls. Tiger herons and oriental night herons have booming bittern-like calls. The Whistling Heron has high-pitched calls. Calls are most frequent during agonistic encounters and early in pair formation. Bill-snapping also produces sounds. Acoustic signals are emphasized by species such as the Boat-billed Heron which occur in dense vegetation.

Breeding. Nesting generally occurs during the local spring and summer or when the rainfall cycle produces optimal foraging conditions. Some tropical herons nest year-round. Nests typically are stick platforms in trees, reeds, or on the ground. They are built by the female from sticks brought by the male. The 3–7 eggs are usually unmarked white, buff, or pale blue. Both the parents incubate the eggs for 16–30 days. The altricial, nidicolous young are fed regurgitated food. Young may leave the nest in as little as a week, returning to be fed. At this time both parents forage simultaneously. Young become progressively more independent and are seldom fed away from the nest site.

HOARDING: see FEEDING HABITS.

HOATZIN: *Opisthocomus hoatzin*, sole member of the Opisthocomidae (Galliformes, suborder Opisthocomi). It is an inhabitant of the flooded forested borders of quiet streams in Amazonia, one of the most peculiar birds evolved in this greatest river system in the world. Local names are 'Cigana' (gypsy, because of its extravagant dress) and 'Catingueiro' (musk-smelling).

Characteristics. The Hoatzin resembles in general appearance the guans and chachalacas (Cracidae, see CURASSOW). Its total length is some 60 cm but it weighs little more than 810 g as the body is quite small. The sexes are almost alike. The remarkably small head on its long, thin neck bears a long, erect and bristly crest. The short but heavy bill is operated by strong muscles and the upper mandible is articulated with the skull and so is moveable, a feature found in the parrots (Psittacidae) and some other groups (see BILL). The wings are very large in relation to the body but are weak owing to the reduced flight muscles (see below). The tail is both long and broad, the legs and toes are stout. The plumage of the upper parts is dark brown, spotted with white in places; the crest is reddish brown, and the bare facial skin is brilliant blue. The under parts are reddish yellow, the belly rust-coloured.

Systematically the Hoatzin poses a still unsolved problem. Since 1837 it has been tentatively linked with 8 different orders, usually with the Galliformes, but also with the Cuculiformes (Musophagidae), Columbiformes, Gruiformes (Rallidae) and others. Primitive characteristics occur alongside specializations (crop, nasal fossa, wing-claws of the chick, syrinx). The comparative study of the egg-white proteins by Sibley and Ahlquist (1973) indicated that the Hoatzin was most closely allied to the Guirine cuckoos (Crotophagidae), but immunological data (Brush 1979) suggest a closer relationship with the Galliformes and it is retained here in a sub-order of its own. No systematic clues are given by the bird's parasites: the feather lice of the Hoatzin are allied to those of the Green Ibis *Mesembrinibis cayennensis*, found in the same habitat.

A curious anatomical feature is the wing structure of the chick; it recalls that of *Archaeopteryx* and led to the idea that the Hoatzin itself was an archaic relict. The first and second digits carry large claws, moveable by special muscles. These aid it to grasp branches like a climbing reptile, a technique that *Archaeopteryx* may well have used. Correspondingly, the development of the flight feathers is retarded, contrary to what happens in gallinaceous birds generally. As the young grow, they lose their wing-claws and the ability to swim and dive, but continue to use the spread wings to help them awkwardly about the branches, often breaking their primaries in the process.

Another very peculiar morphological character is the digestive tract. While in other vegetarian birds the food is broken up in the gizzard, the crop of the Hoatzin performs this function; it is of unusual size and consists of a number of separate sections which squeeze out and break up the food. To do this, the crop has thick muscular walls and a horny internal layer, whereas the true gizzard is much reduced. The size and weight of the full crop makes the Hoatzin top-heavy and when crouching on branches it keeps its balance by leaning on its sternum, which is covered by a specially-developed callosity. The pectoral girdle is totally transformed by the size of the crop. When the bird jumps from branch to branch, it maintains its equilibrium by spreading its wings and flapping its tail. The feet do not provide a sufficient grip on the branches, unlike the curassows' which can cling firmly even on thin branches.

Hoatzins have a musky odour varying in intensity with the individual and the season (hence the name 'stinking bird'). There is a widespread notion that the flesh also has this smell, which has caused the natives to leave the birds alone, except to use them as bait for fishing. Sometimes they are used for medicinal purposes. The eggs are always much in demand and Hoatzins are rapidly diminishing near human settlements.

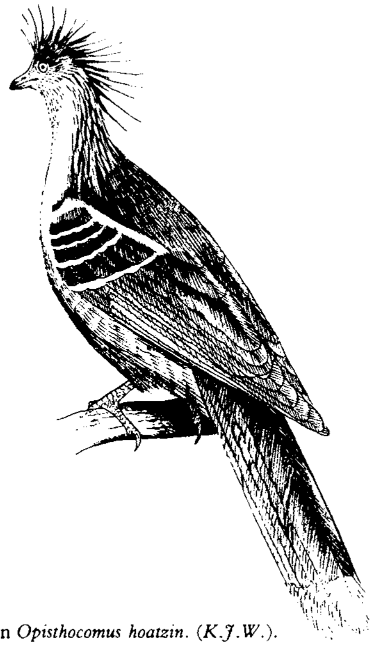
Habitat and food. The Hoatzin occurs from Guyana and Brazil to Ecuador and Bolivia, in permanently flooded forests along the overgrown shores of the Amazon, the Orinoco and rivers of the Guyanas; it can only exist where certain marshy plants are available as food; these include the great *Montrichardia* (Araceae) and the arboreal White Mangrove *Avicennia*. The birds feed on the tough, caustic leaves, flowers and fruit of these plants. Occasionally they take small animals, including fish and crabs, which they catch in the mud or shallow water under hanging vegetation. While so occupied they sometimes fall into the water, or even jump into it when shallow.

Behaviour. Hoatzins are sedentary; they consort in pairs but live in flocks of 10–20 (numbers up to 30 or more were formerly recorded). They are most active in the morning and evening and on moonlit nights. They like to climb to the tops of low trees along the shore, whence they look about them and fly clumsily across small bays and creeks, frequently gliding. During the hottest part of the day they rest hidden in the shadow of the dense woodland.

The Hoatzin has a very conspicuous display: it raises its enormous wings vertically, showing a big black area against a whitish background and contrasting sharply with the deep reddish colour of the rest of the wing and the flanks. It is a kind of 'eye effect', although the area is not round but square.

Voice. Their loud, hoarse cries and hissing sounds make their presence known from afar. The name 'Hoatzin' is said to be Indian and onomatopoeic, based on some of their cries. When calling, the birds usually spread wings and tail.

Breeding. Hoatzins breed more or less throughout the year in colonies and make their nests on branches 2–6 m above the water. The nest is flat, of dry twigs, loosely entwined. There are 2–4 eggs, relatively small, yellowish with pink spots; their shape varies considerably; the average size is 46 × 33 mm. The young hatch after about 4 weeks and have two successive down plumages. Although they stay in the nest for some weeks, they soon become adventurous and start making excursions, using their wings as hands. As, at that time, they also have a good grip with feet and bill, like parrots, they are able to clamber about without mishap. This method of locomotion is an excellent adaptation to the mangrove jungles. When danger threatens, the chicks let themselves fall into the water, where they dive and swim off, using both wings and feet. Afterwards they climb out again and continue their way through the branches.



Hoatzin *Opisthocomus hoatzin*. (*K.J.W.*).

The parents feed the young from the crop, the chick putting its head well into the widely gaping bill of the adult. As at times there are more than two mature birds visiting a nest and females exceed males in collections, some authors have suspected polygamy. H.S.

HOBBY: substantive name of certain small *Falco* spp.; used without qualification, in Britain, for *F. subbuteo* (see FALCON).

HOLARCTIC REGION: the Palearctic and Nearctic Regions combined—see DISTRIBUTION, GEOGRAPHICAL; NEARCTIC REGION; PALEARCTIC REGION.

HOLDING: using the feet to grasp food or other objects (except perches—see PERCHING). Most birds do not use the feet in this way, 'manual' functions devolving entirely on the bill (see BILL). Some birds indeed have feet obviously incapable of a prehensile function, e.g. when adapted to running or swimming (see LEG). Among the exceptions, parrots are specially notable, often using a foot very much as a hand when feeding. Birds-of-prey and owls make much use of the feet in seizing, killing, holding, and dismembering their food. To some extent this is true also of some of the 'minor raptors', such as figure prominently in the list of families given below. Tits *Parus* spp. not only hold food with the foot but can learn to pull up a hanging string with food at the end of it, the pulling being done with the bill but the successive lengths being secured on the perch with the feet. Further examples of use of the feet for holding food and so on are to be found among the toucans, nuthatches, shrikes, pepper-shrikes, shrike-vireos, drongos, wattle-birds, bell-magpies, and crows; this list is not necessarily exhaustive—the Purple Gallinule *Porphyrio porphyrio* (in Africa) is, rather unexpectedly, described as holding food up to its bill while it bites pieces off. In at least some of these cases the held object may be carried in flight (see CARRYING).

HOMALOGONATAE: birds with an ambiens muscle (Garrod)—see MUSCULATURE.

HOME RANGE: the area occupied by an individual, a pair or a group of birds. When the area is defended, it is referred to as a TERRITORY.

HOMING PIGEON: a domestic pigeon *Columba livia* var. used for 'homing', either as a carrier of messages or in the sport of pigeon racing. Pigeons have been used to convey messages since the days of the ancient Egyptians, and were much used by the Greeks and in the Roman Empire and generally throughout the Middle East. Regular pigeon-posts were established and military operations were supported. The most famous siege use of pigeons was in Paris in 1870–1871, when 150,000 official and a million private messages (microphotographed) were passed. With the advent of telegraphy and wireless the civilian use of pigeon-post disappeared, but in both World Wars much use was made of them. In the 1939–45 war some 200,000 birds were supplied by private breeders to the British Services and 50,000 were reared by the US Army; nearly 17,000 were parachuted to the Resistance in German-occupied Europe and 2,000 returned safely. Many airmen owed their lives to the SOS messages carried by pigeons released when aircraft crash-landed at sea.

To fit pigeons for close support of modern warfare, birds were trained to home to mobile lofts, moved a short distance each day; only moderate success was obtained with intense training, and the birds were particularly likely to go astray if they were required to cross old flight lines, as in a retreat. Attempts were also made to establish a two-way message service by feeding the birds in one place and giving them grit, water, and roosts in another; this was useful only over short distances. Drastic selection provided pigeons that would fly short distances at night, up to 25 km. All these specialized techniques of training laid heavy emphasis on the birds being given an intimate knowledge of the country in which they were to fly. Pigeons sent long distances and returning to an established base were trained by a series of releases, at increasing distances, in the direction from which they would eventually have to return.

Directional training of that kind is also the basis of pigeon racing. This is an important sport and there are perhaps 100,000 pigeon fanciers in Britain alone, with something like 2 million pigeons in their lofts. The sport developed with the advent of the railways, which provided swift transport to distant release points. The first pigeon race over 150 km was held in 1818 in Belgium, and similar races had been established in England by 1875. Such distances are nowadays considered suitable for young birds of the year; yearlings will fly races of 480 km, and older birds up to 800 km. Because of heavier losses at sea-crossings the longer races, 1,000–1,300 km from the Faeroe Islands in the north and from San Sebastian (Spain) in the south, are seldom flown. In continental North America races of 1,600 km are often flown, although no birds return in one day. Only a small fraction, perhaps 1 in 20, of pigeons come through all the initial stages and return from the long-distance races.

Elaborate precautions are taken to ensure correct timing and to eliminate fraud. Before release a temporary rubber leg-band with a code number is put on each bird by officials. On its return the owner removes the band and drops it into a sealed time-check clock which marks the hour and minute of arrival. The distance from the release point to the home loft is measured to the nearest yard on a great circle, and the speed of the bird expressed in yards per minute. In good conditions homing speeds of 1,200 y.p.m. are common, while with tail winds they may be in excess of 2,000 y.p.m. Birds may, apparently, fly for up to 16 hours a day. Competition is within clubs and within area federations; prize money is relatively modest but is increased by systems of 'pooling' for the big national races. Birds that have been successful in such races are much in demand as breeders and can command extremely high prices. Much attention is paid to pedigrees, but there is general agreement that the only real test of an individual is its performance in races. Various fads about body shape and colour come and go; there is a school of thought that stresses 'eye-sign', the configuration of the ciliary muscle of the pupil, and in view of the overriding importance of the eye it is not impossible that there may be something in this idea. There are also numerous techniques that are supposed to increase the speed of homing, but little agreement as to whether, for instance, cocks or hens home faster or whether they should preferably be incubating eggs or feeding young. The 'widowhood' system seeks to send cocks off to a race in a frenzy of sexual passion.

Although pigeon races are essentially one-directional, the direction selected being that which gives the longest runs to the home area, it is well known that good homers can return, although not so swiftly or certainly, from other than the training direction. This indication of a more advanced form of navigational ability has been seized upon in testing theories of bird navigation (see NAVIGATION). The pigeon is certainly a bird readily amenable to experimental treatment, but a great deal of confusion has resulted from the use of birds of inferior stock. There is a wide range of individual variation in homing ability.

Other species have been used for message carrying. The Romans used swallows (Hirundinidae) to convey the winning colours of chariot-races, but these were wild birds caught at their nests on the day required. Pacific islanders, however, have tamed frigatebirds *Fregata* sp. and use them for inter-island communication.

In a different category were the 'shore-sighting' birds carried by ships of olden times. The technique was known in countries as far apart as Scandinavia and Ceylon. Ravens *Corvus corax* were particularly favoured and were released when land should be near; if the bird made off, it not only confirmed the presence of land but indicated its direction.

Levi, W.M. 1951. The Pigeons. Columbia, S.C.

HOMOIOTHERMAL: 'warm-blooded', as contrasted with 'poikilothermal' or 'cold-blooded'; other spellings and alternative terminations are sometimes used (see ENERGETICS; HEAT REGULATION).

HOMOLOGUE: a structure basically equivalent to another (but possibly adapted in a different way)—compare ANALOGUE.

HOMOLOGY: a fundamental concept in comparative evolutionary studies, whether of morphological or behavioural features. Bock (1969) gives the following definition: 'Homologous features (or conditions of features) in two or more organisms are those that can be traced back phylogenetically to the same feature (or condition) in the immediate common ancestor of these organisms'. 'Analogy' is often taken as the opposite term but, as this term is used in a variety of other senses, Bock advocates the term 'non-homology' where attributes in two or more organisms cannot be traced phylogenetically to the same attribute in their immediate common ancestor. Discrimination of homologous features becomes a problem in morphologically uniform groups such as many bird taxa, and Bock has proposed the term 'pseudohomology' for some of the closely similar features or conditions that may arise independently in two or more members of such groups. P.J.K.B.

HOMONYM: see NOMENCLATURE.

HOMOZYGOUS: see GENETICS.

HONEY-BUZZARD: name of *Pernis apivorus* and allies (see HAWK).

HONEYCREEPER: substantive name of some species of Thraupinae (see TANAGER), which were formerly combined with the BANANAQUIT, ORANGEQUIT, CONEBILLS and FLOWER-PIERCERS in the family Coerebidae (Passeriformes, suborder Oscines). In this older classification, 'honeycreepers' was the general term for the family. This term is inappropriate for the family Coerebidae as here recognized, since none of the 3 genera now included, *Coereba* (Bananaquit) and *Conirostrum* and *Oreomanes* (conebills), are generally known as honeycreepers. In what follows, the term 'honeycreeper' is restricted to the thraupine genera *Cyanerpes*, *Chlorophanes*, *Dacnis* and *Xenodacnis*, the last a little known genus represented by one species in the Andes and perhaps not closely related to the others. The 4 genera comprise 15 species, all confined to the American tropics.

The honeycreepers represent a line of specialization within the large assemblage of tanagers leading, from the typical tanagers' diet of insects and fruit, to nectar-eating. In *Dacnis* the bill is sharp, slightly decurved, and quite short, and thus not very different from that of some typical tanagers. *Chlorophanes* has a longer, more curved bill, and the extreme is reached in the Purple Honeycreeper *Cyanerpes caeruleus*, in which the bill is very long and curved and nectar and fruit juices are important elements in the diet. Together with the bill, the tongue is progressively modified into a tubular structure adapted for sucking. Even the most specialized honeycreepers, however, feed also on insects and small whole fruits, the long bill enabling them to probe for insects and to extract the arillate seeds from the splitting capsules of such plants as *Clusia*.

Male honeycreepers are brilliantly coloured, with unrivalled shades of deep blue, turquoise-blue and blue-green; the females are much duller, predominantly greenish. The male Blue (or Red-legged) Honeycreeper *Cyanerpes cyaneus* is peculiar in moulting, at least in parts of its range, into a female-type plumage during the non-breeding season. Honeycreepers are typically birds of forest and forest-edge, doing most of their foraging in the forest canopy; but cultivation with trees forms a suitable habitat for several species. In general behaviour they are typical TANAGERS; they live in pairs, have poorly developed, unmusical vocalizations, and build cup-shaped nests in trees and shrubs. D.W.S. (1)

Skutch, A.F. 1962. Life histories of honeycreepers. Condor 64: 92–116.

HONEYCREEPER, HAWAIIAN: see HAWAIIAN HONEYCREEPER.

HONEYEATER: substantive name of many species of Meliphagidae (Passeriformes, suborder Oscines); in the plural, general term for the family. This is a group of mainly arboreal, nectar-, insect- and fruit-eating birds of Australasian distribution.

Characteristics. The most striking family character is the brush-tongue, an adaptation to nectar feeding, but in its structure notably different from that of other major nectar-feeding groups of birds.

The tongue is prolonged and protrusible. The basal part is curled up on each side, forming two long grooves. The distal part is deeply cleft into 4 parts, which on their edges are delicately frayed and together form the 'brush' which licks up the nectar. The tongue is extended into nectar, or other liquids, about 10 times per second and liquid is taken up by capillary action. The tongue is then withdrawn into the beak which is closed, and projections on the roof of the beak appear to compress liquid from the brush along the groove to the throat. In spite of much variation and secondary changes, the basic characters of the tongue are present in all members of the family. A more rudimentary brush-tongue is found in other birds which feed on nectar less frequently e.g. silvereyes *Zosterops*, wood-swallows (Artamidae) and Australian chats (Ephthianuridae).

Other characters widespread in the family are the pervious nostrils, and the tendency to absence of feathers from parts of the face, on which develop bare spaces, or even lobes, wattles, or other appendages. The plumage is in most species rather dull, greenish, greyish brown, or streaked; the sexes being similar. The most notable exception to this is in several species of *Myzomela*, which possess contrasting patches of sanguineous red in the plumage and display a pronounced sexual dimorphism. In many honeyeaters there is a conspicuous yellow, golden or white patch on the posterior part of the ear region; this character is particularly well developed in the members of the large genus *Meliphaga*.

The honeyeaters display extraordinary variation in structure (lengths 9.5–32 cm), bill form, body proportions, and even mode of life. They include birds resembling goldcrests *Regulus* spp., other warblers (Sylviinae), and thrushes (Turdinae); species that could be mistaken for sunbirds (Nectariniidae) or hummingbirds (Trochilidae); species with falcate bills like Hawaiian honeycreepers (Drepanididae) or bee-eaters (Meropidae); larger species approaching the appearance of orioles (Oriolidae), jays and magpies (Corvidae); and even birds looking very similar to tits (Paridae), nuthatches (Sittidae), babblers (Timaliidae) and flycatchers (Muscicapinae). This extreme variation has been compared with that of the marsupials among mammals; and, although this may be exaggerated, there is obviously a striking parallelism in history and evolution in these two groups.

Habitat. In such a large and diversified group as the honeyeaters, ecology and behaviour are of course extremely varied. Common to almost all honeyeaters is their arboreal habit. Only a few descend to the ground for feeding e.g. *Manorina* and the Tawny-crowned Honeyeater *Phylidonyris melanops* and not a single species places its nest on the ground, although the latter species makes use of high grassy tussocks as nesting sites. Honeyeaters are mainly birds of forests and heathlands, where they frequent tree-tops and flowering trees and shrubs. Several species, most of them inhabiting the continent of Australia, have become adapted to the more open and arid woodlands. No species can exist in completely treeless country, however, but a single species, the Singing Honeyeater *Meliphaga virescens*, ranges right to the coastal sand-dunes and also inhabits the small islands off the barren south and west coasts of Australia. Many species are attached to the mangrove swamps, savannas, heathland and mallee, a few even to the mulga scrub, while in the desert-like spinifex country in the interior of Australia only one species, the Pied Honeyeater *Certhionyx variegatus*, is occasionally encountered. There is a tendency for different species in some genera, *Meliphaga, Melithreptus, Manorina*, to occur in separate, though often neighbouring habitats. Several species are restricted to the high mountains of New Guinea (*Melipotes, Melidectes* and others), while some, most of them belonging to the genera *Myzomela* and *Lichmera*, are inhabitants of small oceanic islands.

Tui *Prosthemadera novaeseelandiae*. (C.E.T.K.).

Distribution. Honeyeaters belong to the Australasian region, where they are widely distributed and form one of the most characteristic bird groups. Only one species, the Brown Honeyeater *Lichmera indistincta*, has crossed Wallace's Line and settled in Bali; another species, *Apalopteron familiaris*, inhabits the Bonin Islands, which are regarded as belonging to the Palearctic Region. To the east the range of the honeyeaters includes the greater part of Micronesia, Melanesia, Polynesia (east to Samoa and Tonga), the Hawaiian Islands, and the New Zealand islands.

The 167 species of honeyeaters (including a total of about 450 sub-species) are divided among 38 genera, of which 14 are monotypic. The largest genera are *Meliphaga* (36 species), *Myzomela* (24 species), and *Philemon* (16 species). New Guinea and the Australian mainland form the centres of distribution and are inhabited by an almost equal number of species—New Guinea (with satellite islands) by 63 species, Australia (with Tasmania) by 68 species. The New Guinea honeyeaters are generally more primitive and unspecialized, while the Australian (and New Zealand) forms include a great number of specialized and derivative types.

Food. Nectar and insects form the major part of the diet of most honeyeaters. In addition, many of the larger honeyeaters feed also on fruits and berries and may do some damage in Australian orchards. The tropical rainforest species are predominantly frugivorous. Pollen is consumed but probably not digested. Honeydew from scale insects, manna (sugary granules from damaged eucalypt leaves) and lerp (coats of sap-sucking insects) also form an important part of the diet of some species.

Behaviour and movements. Honeyeaters are more or less gregarious; no species is solitary. They tend to move around in small parties, especially outside the breeding season, and under certain conditions large swarms concentrate around flowering trees. Some open-country species are markedly nomadic; a few subtropical-temperate species make regular seasonal movements, whereas in many other species the movements are more complex and appear less regular. The flight may be swift in smaller species, and more clumsy and undulating in the larger species, almost like that of the Magpie *Pica pica*.

Voice. The vocal utterances differ widely. Many of the smaller species are excellent songsters, while the larger ones are not so musical and utter various harsh and noisy babbling sounds, usually characteristic of the genus. The Bell Miner *Manorina melanophrys* has a peculiar song, resembling the tinkling of a silver bell; the song of the New Zealand Bellbird *Anthornis melanura*, a distant ally, is somewhat similar. The strange Tui *Prosthemadura novaeseelandiae*, also of New Zealand, a glossy bluish-green bird like a Starling *Sturnus* sp. with 2 tufts of white curled feathers on the lower throat, is known to be an excellent mimic of other birds' songs. A few species frequenting open country have song-flights. Some of the species inhabiting dense rainforests are silent.

Breeding. The nest is a cup-shaped, sometimes pendulous, structure, varying considerably in composition and situation. It is placed in trees or bushes, often high up. In several species the nests are placed on branches overhanging water, along rivers or lake borders. Group nesting, in colonies up to 20 or more, is a rather frequent phenomenon, at least in Australian species. Many species of *Meliphaga* and probably all species of *Melithreptus* and *Manorina* are co-operative breeders with several adults, probably chiefly males, feeding the nestlings and fledglings from each nest. The Noisy Miner *Manorina melanocephala* has a particularly complex breeding system. The breeding season of honeyeaters in southern Australia is extended and late winter is the peak for the more nectarivorous species and spring for the more insectivorous ones. Breeding in autumn is quite frequent. A peculiar habit is developed in some species of *Melithreptus* and *Meliphaga*: to obtain nest material they habitually pull hairs off cows, larger marsupials (possums), and even man. The species of *Ramsayornis* are unique among honeyeaters in building closed nests, dome-shaped with a side entrance. The Blue-faced Honeyeater *Entomyzon cyanotis* of Australia differs from all other honeyeaters in using deserted nests of babblers (Timaliinae), preferably those of *Pomatostomus temporalis*, and it is known sometimes to oust the legitimate owners by force.

The eggs are spotted, most often with reddish brown. The clutch consists, in the tropical species, of 1 or 2 eggs, in the subtropical of 2, occasionally 3 eggs, in the larger species often of 4 eggs; and in the temperate species (in New Zealand) also usually of 4 eggs. The participation of the male in nest building and incubation differs widely, and in many species the female alone performs these duties. On the other hand, both sexes share in feeding the young. Incubation periods are from 12–16 days; and fledging periods 10–16 days.

Ecological relations. Many species of honeyeaters (e.g. *Phylidonyris, Acanthorhynchus* and *Anthochaera*) are dependent on the nectar of blossoms of trees and shrubs for a large part of the year. Insects are taken primarily as a source of protein. Others (e.g. *Meliphaga* and *Melithreptus*) feed more on insects, though they readily take nectar, especially in winter in southern Australia, and alternative sources of sugar (honeydew etc.). The species belonging to the Australian genus *Conopophila* have mostly given up nectar feeding and are mainly insectivorous, capturing their prey in the air like flycatchers (Muscicapinae). One species, the Painted Honeyeater *C. picta*, has specialized on mistletoe berries, apart from insects. The members of the New Guinean genus *Melipotes* have also become fruit-eaters; their tongue structure has been secondarily simplified. The 6 species of *Melithreptus* are tit-like, active birds, of which the Strong-billed Honeyeater *M. validirostris* of Tasmania has developed food habits and even a bill-form almost like that of a nuthatch *Sitta* sp. It runs up trunks, taking insects from under the bark, which it pulls off with its powerful bill. The O-o-aa *Moho braccatus* of Hawaii is predominantly insectivorous and searches for food by climbing the boles of trees like a woodpecker (Picidae), aided by its stiff tail-feathers. The spine-bills *Acanthorhynchus* spp. of Australia have long and extremely thin decurved bills, and during nectar feeding are able to hover in front of the blossoms like hummingbirds. The 4 miners *Manorina* spp. are jay-like, noisy, and inquisitive birds. The friar-birds or leatherheads *Philemon* spp. generally resemble jays or jackdaws (Corvidae) but have parts of the head naked and inky black, and many species have a horny protuberance on the bill. They are strange in appearance and utter loud and querulous chatterings. The wattle-birds *Anthochaera* have a pendent wattle on each side of the head, longest and most conspicuous in the Yellow Wattle-bird *A. paradoxa* of Tasmania; they utter peculiar guttural notes, resembling coughing or barking.

All 3 New Zealand honeyeaters feed on nectar, insects and fruit. The large Tui takes much nectar, often defending flowers from the 2 smaller species. The rare Stitchbird *Notiomystis cincta*, now only found on Little Barrier Island, visits the flowers of shrubs, while the Bellbird is more insectivorous.

Blossoms of trees and shrubs constitute the main feeding place of most honeyeaters. Owing to this fact they are very efficient pollinators; in fact they form, together with certain parrots, the most important agents in the fertilization of the greater part of the indigenous Australian tree and shrub flora, such as members of the Myrtaceae, Proteaceae, Epacridaceae, Loranthaceae, Rutaceae, Myoporaceae and Haemodoraceae (see POLLINATORS). An intimate connection exists between the plants and the honeyeaters, and the ornithophilous flowers have developed a number of adaptations to bird visits, just as the honeyeaters in their anatomy demonstrate striking adaptations to nectar feeding; this is true of the tongue, as mentioned above, and also of the alimentary tract. The intestinal canal is rather short and wide, the opening of the oesophagus into the stomach and that of the intestinal canal (pylorus) are placed very closely together, in a little chamber partly separated from the stomach proper. This structure permits nectar and other easily digestible matter to pass directly from the oesophagus to the intestines, while insect food can be retained in the stomach for the necessary period of digestion there.

The structure of the flowers visited by honeyeaters varies from simple and cup-shaped in *Eucalyptus* to long and gullet-shaped as in *Eremophila* and *Anigozanthos*. Pollen is chiefly deposited on the forehead and throat, but also on the crown and even the back, and the pollen of the Epacrids sticks to the beak and nostrils. Areas where nectar is abundant frequently attract large numbers of individuals and species of honeyeaters. Competition for nectar is often severe. Under these conditions larger species may defend territories around rich nectar sources, forcing smaller species into less rich areas.

Sugarbirds. The 2 sugarbirds *Promerops* spp. of South Africa, which are characterized by a long, curved bill and a prolonged, drooping tail, agree with the honeyeaters in most structural characters as well as in life-habits (nest, eggs, feeding). They have, therefore, been incorporated in the Meliphagidae until recently, but must for other reasons (for instance, electrophoresis) be regarded as a special family, not least on account of their remote breeding range (see SUGARBIRD (1)).

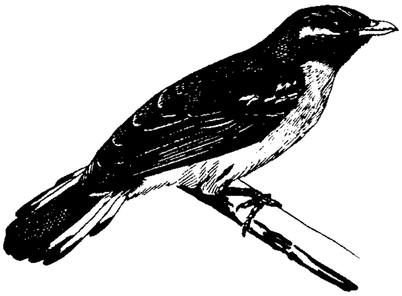
HONEYGUIDE: substantive name of the species of Indicatoridae (Piciformes, suborder Galbulae); in the plural, general term for the family. The family contains 16–19 species, depending on controversial taxonomic decisions exacerbated by inadequate knowledge of the biology of most forms; one (*Melignomon eisentrauti*) discovered as recently as 1965.

Characteristics. All honeyguides are small, 10–20 cm long and weighing 10–55 g. Plumage is dull and inconspicuous, generally olive, grey or brownish above, sometimes obscurely streaked, and lighter below, with dark or dull-coloured bill, legs and feet; *Indicator xanthonotus* has the forehead and rump orange. Most species have pale sides to the tail, often with a pale rump patch, and 2 species have yellow patches on the wing-coverts. Some species have a white spot on the lores and a black malar streak. Sexual dimorphism is usually slight, except in *I. indicator*



Greater Honeyguide *Indicator indicator*. (*C.E.T.K.*).

where the female is typically dull-coloured but the breeding male has the head boldly marked with white cheeks and black throat, and has yellow shoulder patches and a pink bill. The bill is typically stout and blunt, with raised edges around the nostrils except in the 3 small flycatcher-like *Prodotiscus* species which have a fine pointed bill. The legs are short, toes zygodactyl, with strong hooked claws. The wings are pointed, the flight rapid and often weakly undulating. The tail is graduated in most species; in *Melichneutes* it is lyre-shaped. The skin of some species is notably thick, possibly as a defence against insect stings.

Habitat and distribution. All 4 genera (*Indicator, Prodotiscus, Melignomon* and *Melichneutes*) inhabit evergreen forest or forest edge, the first 2 also occurring in more open woodland. All but 2 of the species are confined to Africa south of the Sahara; the 2 exceptions (both *Indicator*) are Oriental, one occurring in south-east Asia, the other in the Himalayas. Most of the African species form closely related groups whose members are so similar that taxonomic treatment remains controversial, especially as the groups themselves are very similar to each other. Within each group, there is a trend towards darker-plumaged species inhabiting evergreen forest and paler species occupying more open woodland. Three or more sibling species may be sympatric, and it is not known how they remain segregated.

Populations and movements. No information for any species.

Food. All the species whose food is known eat insects, but a characteristic peculiarity of the family is that they also eat wax, usually as bee comb but also, in *Prodotiscus* spp., as waxy scale-insects. Some species have been seen eating comb at bees' nests but in others 'cerophagy' (eating wax) is inferred from the presence of wax in the digestive system of collected specimens. Two species (*I. indicator* and *I. minor*) have been shown experimentally to digest wax and to survive for around 4 weeks on wax alone; *I. indicator* can also survive without wax for several months. It is not yet entirely clear whether the wax is digested by symbiotic bacteria, as one experiment suggests, or by an enzyme unique to honeyguides. The parts of the honeycomb most commonly eaten by *I. indicator* in captivity are the larvae and the wax; the honey that contributes to the family name, the pupae and adult bees are taken rarely or not at all. Bees' nests may be detected at least partly by scent since honeyguides can be attracted by the smoke from burning wax.

The habit of feeding on bee comb is associated in the 2 largest species, *I. indicator* and *I. variegatus*, with that of guiding man and other mammals to bees' nests. This behaviour is best known in *I. indicator*; the bird, usually alone, draws attention to itself by a distinctive chattering call, and then flies a short distance towards a bees' nest. This behaviour is repeated until the nest is reached, when the bird sits quietly nearby, coming down to feed at any comb that may be left after the follower has opened the nest. The usual follower apart from man is the Ratel or Honey-Badger *Mellivora capensis*, but baboons *Papio* and even mongooses (Herpestinae) may also respond. Tribesmen in many parts of Africa use honeyguides to lead them to bees' nests, but the habit seems to be declining as alternative sources of sugar become more available. The evolution and development of this complex symbiotic behaviour, especially surprising in a nest parasite, remain obscure.

Behaviour. So far as is known all honeyguides are solitary, individuals aggregating chiefly for mating or at localized food sources.

Voice. Poorly known; in several species the male song is a simple monotonous one repeated from an elevated song post. The guiding chatter of *I. indicator* is distinctive, and a variety of generally rather simple calls, often nasal or squeaky, is recorded from several species. Some species show vigorous vocal interactions with potential hosts even when hosts are not breeding.

Breeding. Of the 7 species whose breeding habits are known, 6 are certainly parasitic but *I. xanthonotus* of the Himalayas apparently is not; it may be significant that this species lacks the white outer tail feathers typical of honeyguides, supporting the possibility that these may be used in luring hosts away from their nest. An observation of an adult *Prodotiscus insignis* feeding a recently-fledged juvenile raises the intriguing possibility that parasitism may not always be complete even in habitually parasitic species (Brosset 1981). Most species parasitize hole-nesting birds, especially barbets, woodpeckers, hoopoes and wood-hoopoes, kingfishers, rollers, bee-eaters and starlings; but the small flycatcher-like *Prodotiscus* species (*P. insignis, P. zambesiae*) parasitize open-nesters such as white-eyes, and *P. regulus* parasitizes hosts with closed nests such as swallows, swifts and some *Cisticola* warblers.

The mating system is known only in *I. xanthonotus.* Males defend territories centred around bees' nests, to which they allow access only to females with which they have mated and their attendant young; this mating system has been described as 'resource-based non-harem polygyny'. Other species have been assumed to be promiscuous, but males of several species have been observed accompanying females attempting to enter host nests, a behaviour unlikely in a promiscuous species. No other honeyguide is known to defend either food sources or mating sites. In *I. indicator* and probably other species, males sing from a conspicuous 'stud post' where females come for mating, which is preceded by rudimentary courtship behaviour and may be followed in *I. indicator* by the male executing a dramatic circling flight in which a loud rattling noise is made by the wing feathers. In *Melichneutes* the lyre-shaped tail apparently also makes a distinctive sound. This may also be connected with courtship behaviour, which includes a display flight above the forest canopy.

Honeyguide eggs are normally thick-shelled and white, except in *P. zambesiae* where they are sometimes blue like those of the *Zosterops* host. Usually only one egg is laid in each nest but there are a few records of 2 honeyguides being reared in one nest. The incubation period is known only for *P. zambesiae* (less than 13 days) and *I. minor* (12 days). The fledging period is about 38 days for *I. minor*, 40 days for *I. indicator*. The chicks of several species bear on each mandible a hook, which is used to destroy host eggs or chicks. The chick is fed exclusively by the hosts at least until fledging; the begging call of nestling *I. indicator* resembles the combined calls of several chicks. A.W.D.

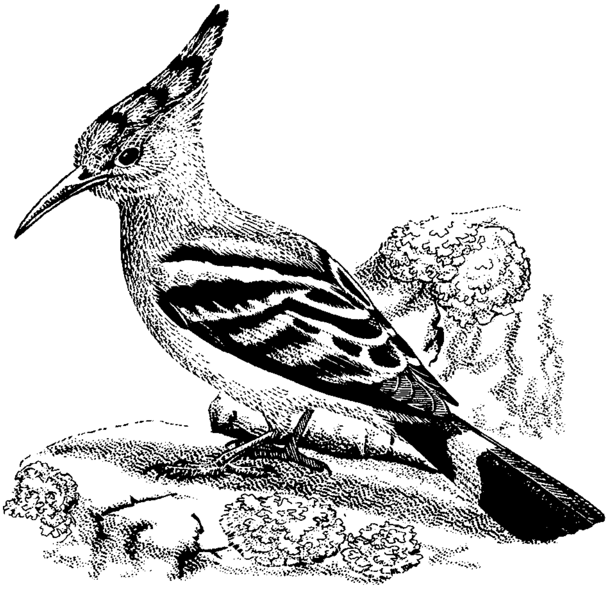
HONKER: name applied in North America to the Canada Goose *Branta canadensis* (see under DUCK).

HOOD: an area of distinctive colour, in some plumage patterns, covering a large part of the head (see TOPOGRAPHY).

HOOKBILL: *Ancistrops strigilatus* (see OVENBIRD (1)).

HOOPOE: *Upupa epops*, sole species of the family Upupidae (Coraciiformes, suborder Coracii), found in some 9 subspecies throughout most of the Palearctic, Afrotropical and Oriental Regions. The Hoopoe is such a striking and unmistakable bird that it has a long pedigree in human culture: it was used as a hieroglyphic in ancient Egypt, figured prominently in Aristophanes' *The Birds*, features widely in folklore, and has long been celebrated in literature. Both of the scientific names, and the vernacular names in several languages including English, are onomatopoeic.



Hoopoe *Upupa epops africana*. (*N.A.*).

Characteristics. Hoopoes are hole-nesting, ground-foraging, insectivorous birds with a long thin decurved beak, short legs and rather weak feet, and plumage of predominant hue varying geographically from pinkish through cinnamon to chestnut. The sexes, and the fledgling, look much alike. There is a long, black-tipped crest which is usually flat, but is opened into a conspicuous fan when the bird alights or is excited. The rump is white and the tail broad and black, with an inverted white chevron across it. The wings are rounded, black, with 1–4 broad bands of white across the secondaries and greater coverts and in some races a further white band crossing both primaries and secondaries subperipherally. Flight is distinctive, with erratic, butterfly-like flapping, the wings closed at each beat; it appears weak and indecisive, but Hoopoes are in fact strong fliers. They are about 31 cm long and weigh 50–60 g (range 40–70 g).

The mutual affinities of coraciiform and piciform families remain controversial (Sibley and Ahlquist 1972). But there is wide agreement that the Hoopoe's closest relatives are the Phoeniculidae (WOOD-HOOPOE), with which it agrees in feather structure (except the absence of an aftershaft), pterylosis, tongue, anatomy, egg-white proteins, visceral and skeletal characters; and there is good evidence also for allying these 2 families closely with the Bucerotidae (HORNBILL). However, *Upupa* differs from all other coraciiform birds in the absence of the expansor secondarium muscle, and in some characters it converges with passerine birds.

Hoopoes being migratory, at certain seasons and places 2 or more subspecies occur together. Where they are distinguishable in the field, it has led to them being treated as specifically distinct (e.g. *U. senegalensis*, *U. africana* and *U. epops* in Africa); but in the absence of breeding sympatry it accords better with current systematic practice to treat Hoopoes as a single polytypic species.

Distribution, habitat and movements. Hoopoes occur in open country in virtually the whole of Africa and Madagascar, and the Oriental and Palearctic Regions north to the Gulf of Finland, the Sakmara River, the southern shores of Lake Baikal, the middle Amur and Khungari Rivers. They breed in the Canaries and most Mediterranean islands, but only exceptionally in Britain and Scandinavia. In south-east Asia they breed throughout Sri Lanka, Indochina and Taiwan but rarely further south in the Malayan peninsula than Pattani. Borneo has only one record, probably a migrant; but a few may nest in northern Sumatra. They do not occur in Korea or Japan. Throughout their breeding range, they prefer open land with scattered trees and some short grass sward or bare soil: pastures, parkland, orchards, steppe, dry and wooded savannas, and broken ground with scattered shrubs to an altitude of 2,500 m. In Africa, drier regions are favoured and lush evergreen woods and forests are shunned. West Palearctic Hoopoes winter in sub-Saharan Africa south to 10°S, and central and east Palearctic populations winter in south Asia from Mesopotamia to southern India and south China. African races are migratory within the tropics. The bird is a diurnal migrant, and over the Mediterranean commonly falls prey to falcons.

Food. Mainly small insects, particularly soft larvae; cockchafers and smaller beetles (larvae and imagines), grasshopper nymphs, caterpillars, ants, flies, termites, earwigs, ant-lions. Also spiders, occasionally earthworms and woodlice, and rarely larger items like centipedes, which have to be broken up before being eaten. Evidently Hoopoes do not regurgitate pellets, but void arthropod sclerites with the faeces. They feed mainly on the ground, walking over turf, dusty or moist soil, pecking and probing assiduously, and may insert the beak full-length into soft soil and dig small holes with the beak to extract prey. Sometimes Hoopoes hawk flying insects, and search the ground beneath flicked-over refuse and dry cow-pats.

Behaviour and voice. Hoopoes are monogamous, and territorial when breeding. No winter territories appear to be held. They occur in pairs or solitarily, but immigrants to breeding grounds form parties up to 9 before reproductive behaviour commences. The young do not feed themselves at all for 6 days after fledging, and thereafter remain in loose family parties with their parents for some weeks. Sexual behaviour is heralded by males beginning to call even when still in prebreeding flocks—a far-carrying, dove-like *hoo hoo* (2–4 notes) given inside or on top of a tree. As territories are established, favoured song-posts are adopted and rival males advertise from 300 m or more apart. 'Swizzle' and 'rattle' calls are given during male–male and male–female chases, and these and other calls during courtship feeding and nest-hole-demonstration by the male to the female (Hirschfeld and Hirschfeld 1973; Skead 1950). There is no additional courtship display; and copulation takes place on the ground.

Nestlings defend themselves by: hissing; rapid upward poking of the head with beak-clapping; a single rapid wing-strike; a stinking secretion of the preen gland (Löhrl 1977); and by the aimed spraying of excreta. Adults have a striking defence posture with the wings and tail widespread on the ground, the head thrown back and the beak upward.

Breeding. Hoopoes nest in holes in trees and walls, or crevices in boulders and old buildings; sometimes in nest-boxes. Nest holes are found and cleared by the male. Sometimes no nest material is used (although droppings accumulate) but at others a distinct bed of grass-bents is made. The whitish eggs are laid daily, clutch sizes being 4–7 in the tropics and 5–8, exceptionally 12, in Europe. The female incubates and is fed by the male, occasionally emerging to feed herself too. She remains in the nest for about a week after the last egg hatches, then both parents provide food. The incubation period is 17 days and the nestling period 26–32 days (South Africa). Nest sanitation is primitive. The species is double, possibly treble, brooded. C.H.F.

HOOTING: term applied, where appropriate, to the calling of certain birds, especially owls (Strigiformes).

HOPPING: see LEG; LOCOMOTION, TERRESTRIAL.

HORIZONTAL AND VERTICAL CLASSIFICATION: a horizontal system of CLASSIFICATION is one that includes only birds existing at the same level of geological time. A system thoroughly phylogenetic in its scope must, however, take into account also those fossil forms that produce a vertical arrangement in which, so to speak, time is a dimension. Such an arrangement can be depicted as a branching tree.

HORMONES: internal secretions having specific physiological actions (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

HORNBILL: substantive name of all members of Bucerotidae (Coraciiformes, suborder Bucerotes). A discrete and distinctive family, most closely allied to the hoopoes (Phoeniculidae, Upupidae), but not related to the toucans (Ramphastidae) of the New World, although they may be their ecological counterpart.

Characteristics. Hornbills have fused axis and atlas vertebrae, and are noted for their long, heavy bills, each with a casque on top. In some species the bill has ridges or notches on its sides. The casque is light and hollow, supported internally by thin bony struts, and may be elaborately shaped and as large as the bill. Hornbills have long eyelashes, short legs with syndactylous toes and broad soles, broad, rather short wings, and long tails which are graduated in some species. The flight is direct and consists of bouts of flapping and gliding, and is often noisy as air rushes through the bases of the flight feathers not covered by stiff coverts. Most species hop on the ground, but a few terrestrial ones walk. The plumage is white, black or brown, sometimes with a metallic sheen. Bare areas of skin on the face and throat, the eyes, and the bill and casque are often brightly coloured, the colours changing with age. Differences in these colours also occur between the sexes which are dimorphic, to a greater or lesser extent, through size (males being slightly larger than females), through differences in plumage, and through the shape and size of the casque. All hornbills (apart from 2 ground hornbills in *Bucorvus*) seal the entrance of their nesthole.

These characteristics have made hornbills mystical birds. Some African tribes place *Bucorvus* heads on their own heads as camouflage when hunting game, and many taboos exist about who may eat hornbills, when and for what reasons. Asian and Polynesian tribes use tail feathers of the large hornbills for head-dress and cloak ornamentation. In Borneo the Rhinoceros Hornbill *Buceros rhinoceros* is revered, the recurved casque being symbolized as spirals on large carved effigies, and it forms the centre-piece of the coat-of-arms of Sarawak. Ivory from the casque of the Helmeted Hornbill *Rhinoplax vigil* is intricately carved as earrings, belt buckles and other trinkets, and has been a highly valued export from the region to China since at least the 12th century. As a result hornbills are being protected, legally or by taboo, in many areas. (See also ORNAMENTATION, BIRDS IN HUMAN.)

Systematic characteristics. The 45 species of hornbills are usually placed in 14 genera; *Tockus* (14), *Rhyticeros* (7), *Bycanistes* (5), *Anthracoceros* (4), *Buceros* (3), *Penelopides* (2), *Bucorvus* (2), *Ceratogymna* (2), and the monotypic genera *Aceros, Anorrhinus, Berenicornis, Ptilolaemus, Rhinoplax* and *Tropicranus*. As far as is known all nestlings of *Tockus, Anthracoceros, Penelopides, Anorrhinus, Berenicornis, Ptilolaemus* and *Tropicranus* have pink skin on hatching and this remains pink, whereas in the remaining genera the pink coloration changes to a deep purple–black within a few days of hatching.

Hornbills vary in size from the relatively small *Tockus* species (*c.* 38–46 cm), through the medium-sized species in *Anorrhinus, Anthracoceros, Berenicornis, Ptilolaemus* and *Tropicranus* (range *c.* 68–92 cm), to the very large species in *Aceros, Buceros, Bucorvus* and *Rhinoplax* (*c.* 116–126 cm).

The African *Tockus* species and the closely related Long-crested Hornbill *Tropicranus albicristatus*, with its white crest and long graduated tail, are the only hornbills that bring single items of food to the nest. The others, apart from the ground hornbills, regurgitate food at the nest, item by item, from the gullet. The Asian species of *Tockus* may deserve their own genus for they differ from the African species in having young with yellow bills, as do other Asian genera, and when calling do not display, whereas the African species are very vocal and do display. They appear to be linked to the poorly defined *Anthracoceros* genus, most of which have very large casques in both sexes, but differ among themselves in calls, behaviour and breeding biology.

Although the Bushy-crested Hornbill *Anorrhinus galeritus* and the Brown-backed Hornbill *Ptilolaemus tickelli* have similar calls and share their own genus of louse, they are kept in monotypic genera as their colour and breeding biology are different.

Sexual dimorphism is pronounced in the White-crested Hornbill *Berenicornis comatus, Penelopides* spp., the Rufous-necked Hornbill *Aceros nipalensis* and in *Rhyticeros* spp. In the last 2 genera the head and neck are brown and white in males and black in females, and the immatures are like adult males. In most species their tails are short and white. Each species of *Rhyticeros* has a distinctive casque shape, variously wreathed and wrinkled, and the bare areas on the face are often extensive and colourful. The White-crested Hornbill has a long crest and a long graduated tail. Little is known about it, and it may be related to *Anorrhinus* and *Ptilolaemus*. The *Penelopides* species, one highly polymorphic, have similar calls and tail patterns to *Anorrhinus* and both may be closely linked.

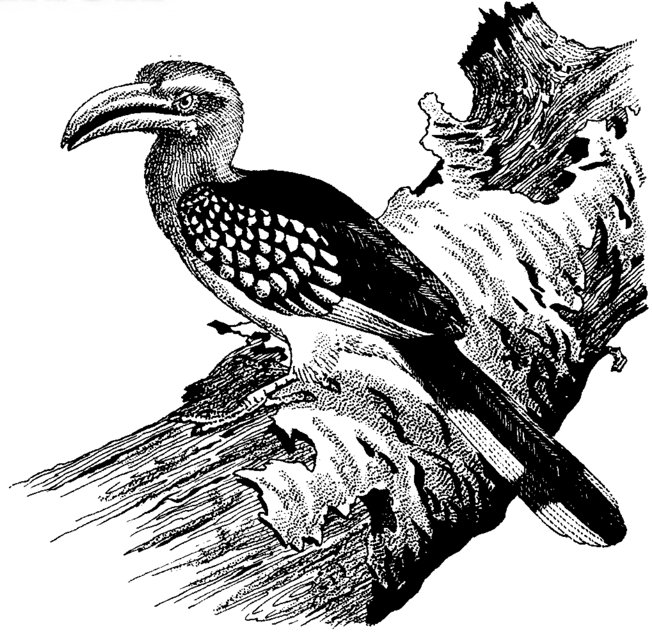
Several species of hornbills, the Helmeted Hornbill *Rhinoplax vigil, Buceros*, and *Bucorvus*, have oil glands which provide cosmetic coloration for bills, casques and white areas of plumage. In *Buceros* the yellow and orange coloration is applied using a special tuft of feathers that surrounds the gland. All *Buceros* species and the Helmeted Hornbill have brightly coloured feet, greenish-yellow in *Buceros*, reddish-brown in *Rhinoplax* and usually dark slate grey in other genera, white tails with a black band, and elaborate and large casques. The Helmeted Hornbill differs in having extensive bare skin on the head and neck, greatly elongated tail feathers, and the front of the casque composed of solid 'ivory' so that its skull is 10% of the body mass. These 3 genera also share a unique genus of louse, although *Buceros* and the Helmeted Hornbill are arboreal while *Bucorvus* species are terrestrial. The ground hornbills are aberrant: in addition to the differences already mentioned, they have an extra cervical vertebra (15 instead of 14), long tarsi and a short tail, and extensive and inflatable facial skin areas. They walk on the tips of their toes, and scrape and dig the ground with their bills in search of food. They are the only hornbills that excavate their own nest hole if required, and show no nest sanitation. They also deliver the food to the nest as a collection of items in the bill.

Seven species in the genera *Bycanistes* and *Ceratogymna* are closely allied. Immatures resemble adult females in having brown on the head and neck, and males have greatly enlarged casques. *Bycanistes* species are distinguishable by their white rumps, and *Ceratogymna* species by the throat wattles of loose skin.

Habitat. All but 11 of the 45 species occupy forest of one type or other, although some of these (in *Tockus, Bycanistes* and *Anthracoceros*) show wide habitat tolerance and may be found along forest edge and in riparian woodland extending into savanna areas. The savanna species (9 *Tockus*, 2 *Bucorvus*) are found in habitat ranging from woodland to arid grassland and even semi desert in south-west Africa where Monteiro's Hornbill *Tockus monteiri* occurs. All are confined to Africa except the Indian Grey Hornbill *Tockus birostris*.

Distribution. There are 22 hornbills in the Afrotropical region, 19 in the Oriental region and 4 species in the Australasian region. The genera *Tropicranus, Bycanistes, Ceratogymna*, and *Bucorvus* are African. The majority of *Tockus* species are African but 2, not considered closely related, are Oriental. The remaining genera are Oriental, with representative species in *Rhyticeros* (3) and *Penelopides* (1) extending into the Australasian region. Two species of *Rhyticeros* (the Narcondam Hornbill *R. narcondami* and Sumba Hornbill *R. everetti*) have a very restricted range, each confined to a South East Asian island. A fossil hornbill is known from Germany.

Movements. Most species seem to be sedentary and territorial throughout the year. Some savanna *Tockus* species form into flocks in the non-breeding season, moving locally in search of food, and these movements may entail regular local or altitudinal migrations in some areas. In Nigeria, the resident population of the Grey Hornbill *Tockus nasutus* in the Sudan zone (11°–13°N) is joined by immigrants from the



Yellow-billed Hornbill *Tockus flavirostris*. (*N.A.*).

Guinea zone (8°–11°N) after breeding there. Frugivorous species in forest, such as *Bycanistes*, *Ceratogymna* and *Rhyticeros*, may never hold territories, ranging randomly over a wide area in search of fruiting trees.

Food. Most species are omnivorous, eating fruit as well as small animals. *Tockus* and *Tropicranus* species are largely insectivorous, some of them following army ants or troops of monkeys for the insects they disturb. The ground hornbills appear to be entirely carnivorous, catching reptiles, including large and venomous snakes, birds, squirrels, rodents and animals the size of hares. Tortoises are dug out of their shells as well as fossorial toads and beetles from the ground. Their main diet, however, is insects, especially grasshoppers and beetles. Most of the forest species rely on fruit as their main diet but supplement it with any small animal disturbed in the foliage. Many are known to increase the amount of animal prey during the breeding season but this is minimal for *Bycanistes* and *Ceratogymna* species. During the nesting period of the Silvery-cheeked Hornbill *Bycanistes brevis*, it has been estimated that the male makes 1,600 deliveries of food with average loads of 15 fruits.

Food is simply picked up or plucked where found, the long bill being an effective pair of forceps to handle sticky or dangerous items. Some species dig out their food, and the more aerial species hawk or capture food while in flight. Limited observations suggest that *Rhinoplax* may use its bill in the manner of a giant woodpecker.

Only *Ceratogymna* species have been recorded drinking water and then only twice, once in natural habitat and the other in a zoo.

Behaviour. Most species are sedentary and live as pairs within their territory, which ranges from 10 ha in small *Tockus* species to 10,000 ha in *Bucorvus*. Some species form flocks during the non-breeding season but these break up into pairs at the beginning of the breeding season. In a few species there are social groups which defend a common territory and breed co-operatively, a breeding pair being assisted throughout the year by other members in defence of the territory and in bringing food to the nest. This is known to occur in *Anorrhinus* and *Bucorvus* species and probably in some *Berenicornis*, *Buceros* and *Tockus* species. Hornbills display threat by raising the bill and exposing the throat, which is often coloured distinctively, at other times by beating on a log, and occasionally by bill-grappling and fighting. Submission is shown by bowing the head, and often leads on to ALLOPREENING between pairs or group members. Dominance within a group may be mediated by gestures either of food acceptance or its refusal. Several species have special warming postures. Bathing in standing water is unknown, but several species bathe in wet foliage or in rain and so become soaked. The majority of species sunbathe regularly with outstretched wings.

Voice. Hornbills are very vocal and have a variety of calls. Most of the smaller species, which are probably the most primitive, utter a series of clucks with the head bowed. They also use high pitched cries and whistles while raising their heads and pointing their bills vertically upwards. These vocal displays are often accompanied either by wing-flapping or flicking movements of the tail or head, or by fanning the tail over the back as found in Hemprich's Hornbill *Tockus hemprichii* and *Aceros*, 2 unrelated birds. The larger species utter soft hoots (*Berenicornis*), short barks (*Rhyticeros* and *Aceros*), a variety of whistles, wails, clicks and brays (*Bycanistes* and *Ceratogymna*), and deep booming noises, usually before dawn, which may be heard at 5 km distance (*Bucorvus*). Calls of *Buceros* species and *Rhinoplax vigil* are given often as duets. The latter has a most striking call, an accelerating series of hoots, breaking into maniacal laughter, which makes it one of the never-to-be-forgotten noises of the Asian forests.

Breeding. Apart from the ground hornbills, it is usual for a pair of hornbills to select a natural hole in a tree, sometimes in a rock face, as a nest site. The entrance is sealed to form a vertical slit. In most species this is the task of the female, although males in some species may assist, and in *Bycanistes* and *Ceratogymna* they supply the female with specially prepared sealing material. The sealing proceeds in stages, often initially with mud from the outside, until the female is just able to enter the nest hole. The timing of the final entrance of the female, before she seals herself in, is probably determined to some extent by the amount of food she receives from the male during courtship. The male may now pass lining, such as leaves and bark, through the slit to the female and mollusc shells that may be important as a source of calcium for egg production. The sealed nest protects the female and chicks from predators, but, in addition to this, most nests have a long funk-hole above them into which the female and chick can crawl out of reach. Ventilation in the nest is maintained by convection.

Egg-laying may be delayed for several days after the female has sealed herself in, but once started occurs at intervals of a day in *Tockus* species but at longer intervals in the larger species. Females of *Bycanistes*, *Ceratogymna* and *Bucorvus* species do not moult while breeding but have a normal successive replacement of feathers as do males and non-breeding females. They are, therefore, able to fly at all times and this may be a result of an unpredictable food supply or predation risk, both making flight necessary at times. Although not thoroughly studied, many breeding females of other genera, possibly all, are flightless within a few days of laying because of a rapid moult of rectrices followed by the remiges. A staggered moult of the body feathers also begins. By the time the females leave the nest, their flight feathers are renewed.

The breeding of many species is little known and only a few species have been studied thoroughly. Incubation of the white eggs, which are oval and rather pitted, begins with the first egg, and the incubation period ranges from 25 days (*Tockus*) to 40 days (*Bucorvus*). Some species lay 1 or 2 eggs, usually 2, but others may lay more (*Anthracoceros* 3–4, *Aceros* 3, *Penelopides* 4, Asian *Tockus* species 4, and *Ptilolaemus* 5) and African *Tockus* species may lay up to 7. The nestling periods range from 45 days (*Tockus*) to 86 days (*Bucorvus*). The long breeding periods exclude second broods except in some forest species, which have no fixed breeding season and show co-operative breeding behaviour. Females of *Bycanistes* remain in the nest with the young and they all emerge together after a period of 4 months or more. In *Tockus*, *Tropicranus*, some *Anthracoceros* and *Buceros* species the females emerge before the chicks are full grown. In *Bucorvus* the female, when incubating or brooding, is brought food by the male or group members and only leaves the nest 3 or 4 times a day, mainly to defaecate.

The chicks hatch at intervals, are naked and blind at hatching, and their upper mandibles are markedly shorter than the lower. Their legs develop rapidly and this enables them to sit and beg for food from the male, rather than from the female inside, and lift their anus, as does the female, to the entrance in order to squirt out their droppings. The nest is kept clean of food remains and debris by throwing these out through the slit; any left is eaten by insects. The feathers on the chicks remain for some time in quill, giving a porcupine-like appearance but, when they burst out, the feathers develop rapidly. In species where the female emerges before the chicks, the nestlings re-seal the entrance themselves (without help from the parents) using their own droppings. The chicks fly as soon as they leave the nest and do not return there. Food is brought to the nest entirely by the male except in those species where the female emerges from the nest before the chick. In *Bucorvus* members of the group bring food to the nest in addition to the male. Smaller chicks often die of starvation and this seems to be obligatory in *Bucorvus* and may be so in the other species (*Bycanistes*, *Ceratogymna*, *Buceros* and *Rhyticeros*) which lay 2 eggs but rear only 1 chick. HORNERO: South American substantive name of the true ovenbirds *Furnarius* spp., especially *F. leucopus*, now used also as English substantive name (see OVENBIRD (1)).

HOST: see BROOD-PARASITISM; ECTOPARASITE; ENDOPARASITE.

HOT SEARCHING: term used to describe finding nests by working vegetation so as to flush the sitting bird; sometimes after watching it back to the nest area; contrasted with 'cold searching', when the nest is found by close examination of likely habitat.

HOUBARA: sometimes used alone as the name of the Houbara Bustard *Chlamydotis undulata* (see BUSTARD).

HOVERING: see FLIGHT.

HUET-HUET: *Pteroptochos tarnii* (see TAPACULO).

HUIA: *Heteralocha acutirostris* (see WATTLEBIRD (2); EXTINCT BIRDS).

HUMAN IMITATION OF BIRD SOUNDS: for a number of reasons and by a variety of means. Perhaps the commonest form is onomatopoeia, when we speak bird names that are intended to sound like the sounds of the birds, e.g. Cuckoo *Cuculus canorus*, Chiffchaff *Phylloscopus collybita*, Killdeer *Charadrius vociferus* and Bobwhite *Colinus virginianus*. The human vocal cords can be employed to copy, for example, the song of the male Cuckoo. Imitation may be otherwise effected by whistling through the lips, 'spishing' through the teeth or 'squeaking' by sucking in air between lips held against the back of the hand. By cupping the hands together and blowing between thumbs held parallel and against the lips, calls such as those of the Tawny Owl *Strix aluco* and the Cuckoo can be reproduced.

Among the various 'bird-calls', the commonest is the whistle or pipe. The simplest design is a tube with a mouth aperture and a single outlet hole. Some whistles may have a 'pea' inside or may incorporate a reed. The pipe known as the 'Nightingale' (and used in the music of Scarlatti and Haydn) involves blowing through a container partly filled with water. The small thin circular instruments used, for example, to copy the distinctive *wheooo*! of the drake Wigeon *Anas penelope* are sucked rather than blown. Diaphragm callers (e.g. for Wild Turkeys *Meleagris gallopavo*) are held inside the mouth against the palate. A few whistles have bellows (e.g. the French Quail *Coturnix coturnix* pipe); or a compressible bulb (the British Quail pipe) both of which are operated with the hands. In the case of a large bellows (as in the American 'Scotch' make of Mallard *Anas platyrhynchos* call) a foot may be used (thus leaving two hands free for a gun?).

Quite different instruments are those that rely on friction for the creation of sound. An Irish Corncrake *Crex crex* caller comprises two mammalian rib bones; one has saw-teeth, across which the other bone is rhythmically drawn to reproduce the rasping 'song'. The 'Audubon' bird call consists of a small cylindrical piece of birch wood into which is inserted (and then turned) a resined small pewter plug; its high-pitched squeaks are reputed to attract song birds. A common design of Wild Turkey call involves scraping a piece of wood across a slate. Box calls are operated by hand; one side of the box is pivoted at one end and elongated at the other to form a handle and its flat side is drawn across an upright edge, the box acting as a resonator. These are used mainly for Wild Turkeys and wild geese. One French company sells 25 different bird-calls, a Brazilian one, 40. Although 'electronic callers' are not strictly relevant they do represent the reproduction of bird sounds by human agency and they have come to replace earlier manual callers. These consist of recordings of real birds reproduced from a disc or tape on a portable battery-operated gramophone or player. The use of this method for hunting is now illegal in the USA and Britain.

Siffleurs use a siffler—'a song whistle' with a moveable 'plunger'—to give generalized impressions of bird song accompanying music. The copying of birds in human music is done with conventional instruments, or (recently) with synthesizers for radiophonic music. One recent and highly original example of human imitation of bird voice combines the simplest with the most sophisticated technique: human vocal mimicry recorded on tape and then electronically enhanced to increase its verisimilitude before being published on disc and cassette as an identification aid for birdwatchers (Ward *et al* 1980).

Primitive peoples imitate birds, either in their ceremonies, or to locate or decoy them. For example, the American Indians of the north-west Pacific coast have a dance in which they imitate the voice and the actions of the Raven *Corvus corax*. The Cree Indians use callers to decoy Canada Geese *Branta canadensis*. The Esquimo of the Canadian Belcher Islands attract them vocally. There is a published recording of the Kayabi tribe of the Paranatinga River in the Matto Grosso of Brazil mimicking 4 species of bird. Tribespeople in Laos use a bird-call fashioned from bamboo to attract the Bamboo Partridge *Bambusicola fytchii* within range of a weapon. Whistles made from bone and found in a few prehistoric sites in Europe, and more commonly across North America, may well have been used for the purpose of attracting birds. Indeed, whistles similar to those found by archaeologists in New Mexico were still used by the Pueblos to lure Wild Turkeys in the early 20th century.

Present day hunters use a variety of means to decoy their quarry, but nowhere more elaborately than in North America, where the sales of duck and goose calls and, most of all, of Wild Turkey calls must be considerable. Schorger (1966) gives a detailed account of turkey calling from prehistoric times to the present day. Not only are the food species decoyed, so too are so-called 'vermin'. Hunters may copy the species they are pursuing or they may attract them by mimicking a predator that the birds assemble to mob. Thus plumage hunters in Trinidad used to call up hummingbirds by mimicking the call of a local owl. Human imitations are usually intended to attract the birds but, in the case of dove calling, they merely cause the bird to answer from its perch and thus give away its location to the hunter. Bird-trappers on the south-west coast of France, and no doubt elsewhere, lure birds to the catching areas of their clap nets with a decoy whistle.

For bird-watchers to call up owls for a better view is comparatively simple, and in North America 'spishing' and 'squeaking' are commonly employed, usually to put wild birds on view for the purpose of identification, and occasionally to census (Smith 1975, Tucker 1978). The reproduction in the field of tape recordings is widely used, e.g. for censusing and ringing. For example, Swallows *Hirundo rustica* approaching a roost location before sunset can be very effectively drawn in the direction of the ringer and his mist net by playing the 'Swallow roost twitter' recording. Even more remarkable is the success achieved by reproducing from coastal headlands at night the purring call of the Storm Petrel *Hydrobates pelagicus*. Although well away from nesting colonies, 3 workers in 6 years mist-netted 16,000 birds (Fowler *et al* 1982). The use of tape PLAYBACK in the breeding season, particularly with rare species, needs scientific investigation to determine how easily, if at all, harm may be done.

Bird impressionists—notably in mid 20th century Britain, Percy Edwards—provided entertainment on stage, radio and television. Gramophone records of avian imitators have been issued surprisingly often since the earliest one in 1891 (Copeland and Boswall 1983). Mechanical birds that sang from little French enamel boxes appeared in the late 18th century in France, and 'automaton' mechanical caged birds were no doubt a familiar sight in Victorian drawing-rooms. Two of the jewelled eggs of Imperial Russia were designed by Fabergé to feature birds (a Nightingale *Luscinia megarhynchos* and a cockerel) that appeared by clockwork to offer the world mechanical utterances.

The direct imitation by human composers dates from the 13th century and is dealt with in detail under MUSIC, BIRDS IN. See also SCARING and VOCALIZATION.

HUMERUS: a bone of the fore-limb (see SKELETON, POST-CRANIAL; WING). The flight feathers ('tertials') borne on this part of the limb are sometimes called 'humerals'.

HUMIDITY: see WEATHER AND BIRDS.

HUMMINGBIRD: substantive name of many species of Trochilidae (Apodiformes); in the plural general term for the family. The name derives from the noise made by the wings when hovering.

Characteristics. All hummingbirds feed by extracting nectar from flowers with their specialized tongues and usually elongated bills and nearly all hover while doing so. This feeding method accounts for the most striking characteristics of the family. These are: wings adapted for hovering both forwards and backwards, long bills, and very small legs and feet. In addition most hummingbirds have brilliant glittering or iridescent plumage. Hummingbirds are mostly small (6–13 cm long) and range in weight between 2 and 9 g. Two genera with specialized bills, *Ensifera* and *Eutoxeres*, are larger (12–13 g), and the substantially larger Giant Hummingbird *Patagona gigas* weighs 20 g.

The wing structure of hummingbirds differs from other birds, except swifts, by a great reduction in length of the humerus, radius and ulna and an elongation of the hand bones to which the flight feathers are attached. This modified wing moves freely in all directions at the shoulder attachment so that a rotary movement is possible. The wing-beat rates of hummingbirds vary between 22 and 78 per second (Greenewalt 1962); and they have a forward speed in level flight of about 45 km/h. The high wing-beat rate, small size and high temperature (39–42°C) means that hummingbirds have a high rate of metabolism, requiring the frequent intake of energy-rich food. In order to conserve energy, hummingbirds are capable of becoming torpid at night when their temperature falls close to that of the surrounding air.

Most hummingbirds show striking sexual dimorphism, the females having a relatively plain, and the males a more brilliant, plumage, with glittering patches particularly on the throat and crown. In some species males have other special adornments, such as elongated and brilliant tail feathers and crests. In most of the hermit hummingbirds, sometimes placed in a separate subfamily Phaethorninae, the sexes are the same or only slightly different in plumage; this is also true of the violet-ears *Colibri* and many emeralds *Amazilia*.

The 320 species of hummingbird have been placed in 112 genera, 63 of which are represented by only a single species. Eighty-eight genera occur in South America and 24 additional genera occur to the north, mostly in middle America but also the Caribbean islands and North America.

Habitat. Hummingbirds occupy a wide range of habitats from the open paramos of the Andes, over 4,000 m, to the tropical forests of Amazonia, arid scrublands and coastal mangrove swamps. Most species are resident, but a few migrate to breed in such diverse habitats as the deserts of Arizona and the coniferous forests of Canada and Alaska. The essential ingredient of all these habitats is a sufficient abundance of nectar-secreting flowers to supply the energy which the birds need. Although a large and variable proportion of insect food is taken by hummingbirds, most habitats are soon deserted when flowers become scarce.

While most hummingbird nests are small simple cups which may be sited in almost any vegetation and even on overhead electric wires, a few species have more exact nest-site requirements. Thus the hillstars *Oreotrochilus* of the high Andes require a cave roof or a rocky overhang on which to affix their pendent nests. The long-billed hermit hummingbirds of the forests (Phaethorninae) attach their pendent nests to the underside of large tapering leaves such as palms or the wild banana *Heliconia* spp. While this type of leaf is abundant in unaltered forest habitat, it may be absent from areas highly modified by man so that they become largely unsuitable for the Phaethorninae.

Distribution. Hummingbirds occur only in the New World, where they range from Alaska and Labrador in the north to Tierra del Fuego in the south, and from Barbados in the east to the Juan Fernandes group of islands 650 km from the western seaboard of Chile. Very few species, however, occur at high latitudes, the Green-backed Firecrown *Sephanoides sephanoides* in the south (to *c.* 54°S) and the Rufous Hummingbird *Selasphorus rufus* (*c.* 60°N) and the Rubythroat *Archilochus colubris* (*c.* 54°N) in the north. The great majority of species inhabit the latitudes between 10°N and 25°S, with the greatest diversity in Colombia and Ecuador.

Of the 88 South American genera, 5 genera with 8 species occur in the arid coastal zones of the western and northern seaboards, 41 genera with 119 species occur mainly at tropical levels (sea level to 1,525 m), 15 genera with 26 species occur mainly at subtropical levels (1,525–2,580 m, also including 4 genera inhabiting subtropical habitats due to latitude), and 19 genera with 62 species occur mainly at temperate levels (2,580–3,500 m) with the monotypic *Sephanoides* occupying a temperate habitat due to latitude. The number of species decreases sharply in the paramo and puna zones (from the tree line up to the snow line); here 3 genera, *Oreotrochilus*, *Oxypogon* and *Chalcostigma*, show special adaptations to high altitudes (Carpenter 1976) but some temperate-zone species make seasonal visits. This breakdown of species by habitat shows the importance of the Andean mountain range for hummingbird speciation; no other bird family is represented by so many species at temperate levels in the Andes as are the Trochilidae.

Within the Trochilidae there is great variation in the geographical range of different species. The Brown Violetear *Colibri delphinae*, for example, is nowhere abundant but ranges from Guatemala to Bolivia at subtropical and tropical levels. Others have extremely restricted ranges, such as the Spatule-tail *Loddigesia mirabilis* which is known only from the temperate zone of one valley in Peru. Further species with restricted ranges may yet be discovered. As recently as the 1970s, a new species of sunangel, *Heliangelus regalis*, was discovered at subtropical levels in one locality in N. Peru and a metaltail, *Metallura odomae*, at temperate levels in one range in N. Peru.

Movements. The few hummingbird species that breed at high latitudes undertake long migrations. The Rubythroat of eastern N. America migrates for the winter to middle America, reaching as far as Panama. For some populations this journey includes a 1,000 km crossing of the Gulf of Mexico. The Rufous Hummingbird, which breeds as far north as Alaska, winters in southern Mexico 3,500 km away. The Green-backed Firecrown, which breeds as far south as the Straits of Magellan, moves north in the southern winter, some birds at least as far as 23°S.

Besides long-distance movements, many species of hummingbird make more local movements in response to the flowering season of nectar-rich flowers. This has been well documented for the Anna Hummingbird *Calypte anna* in the Santa Monica mountains of California, with its winter breeding season in the chaparral linked to the flowering of a species of *Ribes*, followed by a movement in mid-summer to the high mountain meadows. In the highlands of Costa Rica (2,950–3,200 m) 4 species of hummingbird breed, but only one, *Panterpe insignis*, is present in large numbers throughout the year; the other 3 species make seasonal movements related to flower abundance (Wolf *et al* 1976). At much higher altitudes around 4,000 m on the altiplano of Peru the Sparkling Violetear *Colibri coruscans* is present only in the summer and migrates to lower altitudes in the winter (Carpenter 1976).

In rain forest at tropical levels most hummingbird species appear to be sedentary. This has been proved by marking individuals of the Hairy Hermit *Glaucis hirsuta* and Guy's Hermit *Phaethornis guy* in Trinidad, and the Long-tailed Hermit *P. superciliosus* in Costa Rica.

Food. The diet of hummingbirds consists of nectar supplemented with insects and sometimes spiders. This is true of all species that have been studied in any detail but the proportion of insect to nectar food, the method of capturing insects, the flowers from which nectar is extracted and the behavioural factors which secure this nectar supply, are extremely varied. This variation allows a very large range of feeding niches, which must be the major factor accounting for the large number of hummingbird species.

The structure of hummingbird flowers, especially the length and shape of the corolla tube, is in many cases adapted to permit exploitation by particular kinds of hummingbirds, which pollinate the flowers while feeding at them. A large number of plant genera in the Americas have flowers adapted for pollination by hummingbirds, among the most important being *Heliconia*, *Passiflora* and many genera in the families Bromeliaceae and Gesneriaceae. In several plant genera there is a clear distinction between insect-pollinated species (presumed to be the primitive condition) and species with longer, usually red, corolla tubes adapted for pollination by hummingbirds. (See also POLLINATORS.)

One of the major divisions in feeding methods is between territorial and trap-line feeding. For territorial behaviour to develop, a flower species must provide sufficient nectar to fulfil the energy needs of an individual hummingbird in an area small enough to defend from other nectar feeders. Medium-sized hummingbirds with medium-length bills, such as the emeralds *Amazilia* at tropical levels and the sunangels *Heliangelus* and pufflegs *Eriocnemis* at subtropical and temperate levels, are typical territorial feeders. Trap-line feeders do not defend a nectar resource but travel round visiting scattered flowers rich in nectar. Typically they are hummingbirds with long bills which may be curved, and most show a high degree of co-evolutionary development with the flowers they visit, which have correspondingly long or curved corolla tubes. The hermit hummingbirds are typical trap-line feeders. An advanced degree of co-evolutionary development is shown between 2 hummingbird genera with the most extreme bills, the Swordbill *Ensifera* with a bill length which may exceed 100 mm and the sicklebills *Eutoxeres* with extremely curved bills, and the flowers they visit, which have respectively extremely long and extremely curved corollas. The nectar in such flowers is not available to other hummingbirds if they use the legitimate corolla aperture, but a few genera, e.g. *Heliothryx*, have evolved short and exceptionally sharp bills and habitually pierce long or curved corolla tubes to gain access to the nectar.

In addition to the relatively large, long-billed trap-line feeders, many small hummingbirds, with relatively small unspecialized bills, trap-line feed at insect-pollinated flowers or the less specialized hummingbird flowers which are too scattered to be defended by territorial hummingbirds.

In North America 4 species of hummingbird are known to take sap from trees where it is made available by sap-sucking woodpeckers (Picidae); and hummingbirds have also been recorded taking juice from ripe fruit.

Hummingbirds employ 2 methods of capturing insects: hawking insects in flight, and gleaning resting insects and spiders from the vegetation and from spider's webs. The hermit hummingbirds, nearly all of which have curved bills, employ the gleaning method almost entirely, hovering to search the undersides, edges and tips of leaves low down in the forest or in the middle canopy. A specialized form of insect gleaning while clambering over the ground is employed by 3 species of hummingbirds inhabiting the high Andes, where the bare hillsides are suitable for such methods and the energetic cost of hovering in the thin cool air is particularly heavy. Hawking for airborne insects has been observed in many straight-billed species, some of which also glean for resting insects in the same way as hermit hummingbirds. Hawking is especially prevalent among species with relatively long wings and short bills such as the Green-tailed Trainbearer *Lesbia nuna* and the Buff-tailed Coronet *Boissonneaua flavescens*. Methods and vantage points for hawking vary between species, some species using high exposed perches above the canopy, and others lower perches near or within vegetation or in the open. Some species catch a single flying insect at a sally, others make a number of captures per sally or attempt to do so.

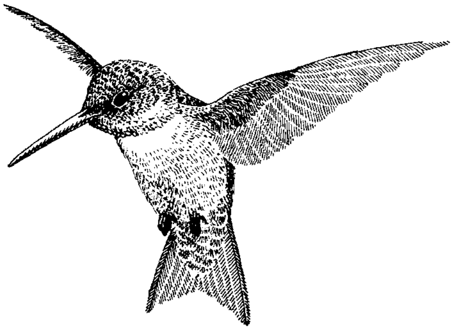
Behaviour. Hummingbirds are polygamous, the males advertising themselves by song and display either at traditional leks (singing assemblies) or at more scattered song posts or at their feeding territories. Spectacular aerial diving displays are characteristic of species that inhabit open country, as in North America. The female's visits to advertising males culminate in copulation. In all except one of the species that have been studied, the female builds, incubates the eggs and rears the young unaided by the male. The exception is the Sparkling Violetear. Males of this species are reported to guard the nest, and one took over incubation when the female was shot at the nest (Moore 1947). At another nest 2 adults shared incubation; one of them the observer believed to be the male (Schäfer 1954).

A LEK mating system is usual among species, such as many of the hermits, that feed by trap-lining. The size of leks varies greatly; T.A.W. Davis noted assemblies of 100 or more Long-tailed Hermits in Guyana, while a lek of the same species in Costa Rica censused for 5 years varied between 14 and 23 males (Stiles and Wolf 1979). Leks of the Reddish Hermit *Phaethornis ruber* may consist of only 5 males, and the Barbthroat *Threnetes ruckeri* may sing at solitary perches or within sound of 1 or 2 conspecifics. Within a hermit hummingbird's lek, each male defends several song perches, which are slender horizontal twigs in the undergrowth. Song, display, territorial encounters with other males and copulation take place on or near these perches. During courtship and other encounters, the plain-coloured hermits nearly all display their brightly coloured gapes. The many species with brilliant plumage and iridescent patches display these, usually when airborne.

In the Purple-throated Carib *Eulampis jugularis* mating takes place within the male's feeding territory where the female is permitted to feed prior to copulation (Wolf 1975). The male Hairy Hermit forms loose pair-bonds with one or two females that nest along a section of stream side which he defends from other hermits (Snow and Snow 1973). Prior to mating, the female Andean Hillstar *Oreotrochilus estella* feeds the male in her territory. In this species only females hold territories in the breeding season.

Voice. Both male and female hummingbirds call in flight. Flight calls are usually monosyllabic, lasting about half a second; they are uttered by a bird flying alone and not near leks or assemblies. It is characteristic of hummingbirds which defend floral feeding territories to utter a brief monosyllabic note between feeding probes. Many species utter a chase call, a chattering series of rapid notes uttered when attacking and chasing intruders at their feeding territories or at lek territories. There are strong aggressive elements in these two calls, which may be employed by either sex, are particular to a species and appear to be innate.

Most hummingbird advertising song is short and simple, lasting from a fraction of a second to 1½ s. These short songs are frequently repeated, the brief monosyllabic ones typically up to 70 times a minute and the longer 1–1½ s phrases some 30 times a minute. The songs are often of high frequency and sound squeaky and thin to human ears. Some species sing longer more musical songs with longer intervals between them: the Barbthroat has a warbling song lasting 4–5 s and the Wine-throated Hummingbird *Atthis ellioti* has a song of nearly a minute's duration.



Rubythroat *Archilochus colubris*. (*N.A.*).

Many species, particularly the Phaethorninae, are extremely persistent singers, and sing throughout much of the day and throughout the often long breeding season. An extremely low-volume continuous warbling sub-song has been heard from many species; recently fledged birds and adults of both sexes may sing this sub-song. Some displays are accompanied by vocalizations not heard at other times. Duet singing, with first the male then the female uttering a phrase, occurs in the Hairy Hermit.

All evidence indicates that the advertising song of males is not innate but learnt, becoming fixed in young males probably in their first year. Abnormal songs may apparently be developed by individuals that learn from the wrong species. Skutch (1974) reported a striking example, of a male *Amazilia amabilis* which for 7 years sang the song of *Amazilia tzacatl* but at the tempo usual to his own species. In the lek-forming hermit hummingbirds, young males learn the song form of their closest neighbours. Even when the song is a monosyllabic note lasting less than a quarter of a second, as in the Long-tailed Hermit, many audibly distinct forms are sung. One lek of 20 males had 4 distinct song forms, adjacent males all singing alike.

Breeding. The unaided female builds the nest, incubates the eggs and rears the young. Throughout the Trochilidae the clutch consists of 2 eggs which are always white and of an elongated shape; there is normally a 48-hour interval before the second egg is laid. In two hermit hummingbird genera *Glaucis* and *Threnetes*, nests with 3 or 4 eggs are not uncommon; these are apparently attributable to more than one female.

There are 2 basic nest-types. The commoner, built by all species except the Phaethorninae and some cave-nesting species, is a small compact open cup placed astride a stem or twig. The nest is composed of vegetable down and sometimes moss and is bound together and to its support with cobweb.

The Phaethorninae build pendent nests which are fastened by cobweb to the underside of a blade-shaped leaf or strip of leaf, so that the leaf forms the inner wall. The nest tapers to a tail, to which twigs and debris are attached to act as a balancing weight. Species that nest in caves and buildings, such as the hillstars, have thick-walled pendent nests attached to the rock by a glue. The only known nest of the Blue-fronted Lancebill *Doryfera johannae* was also pendent and attached by cobweb to a rocky overhang near the bottom of a 75 m shaft. Normally hummingbirds nest solitarily except those that need specialized nest-sites such as caves.

Incubation begins when the second egg is laid and ranges from 14–19 days. The altricial young are sparsely covered with down at hatching, and are brooded frequently, but by 8–12 days brooding ceases even at night. Small nestlings defaecate in the nest and the female removes the droppings, older nestlings defaecate over the rim of the nest. The female regurgitates food to the young, inserting her bill into their throats. Fledging periods vary between 18 and 28 days. H.O. Wagner, studying the Green Violetear *Colibri thalassinus* in Mexico, found the fledging period varied from season to season with different weather conditions. The female continues to feed the young after they have fledged, the longest recorded period being 41 days (Skutch 1974).

Hummingbird breeding seasons are linked with the flowering seasons of their main sources of nectar. In the far north and south of their range the main flowering seasons have a simple relationship with day length and temperature, corresponding to the northern and southern summers. At 34°N in California, 2 migratory species have a typical northern breeding season starting March/April with a peak in May, while the non-migratory Anna Hummingbird has a peak of breeding from January to March coinciding with the peak of precipitation in this dry region and the peak flowering season of 2 species of *Ribes* (Stiles 1973).

In the humid tropics and subtropics the hummingbirds which build open cup nests liable to saturation do not nest at the peak of the rainy seasons when day-long rain may occur. This group of hummingbirds breeds mainly in the dry season, but not towards the end of a long or severe one when flowers become scarce. The beginning and end of rainy seasons, when both sun and rain are usually intermittent, are important breeding periods as hummingbirds are well able to protect the nest and its contents for limited periods of rain.

The nests of hermit hummingbirds are protected from rain by the living leaf to which they are attached, so excessive rain is not a limiting factor of the breeding season. Thus at 600–900 m in Costa Rica the Hairy Hermit and the Barbthroat nest almost entirely in the rainy season (Skutch). In the lowlands of Costa Rica the Long-tailed Hermit breeds from January to August, well into the wet season. In Trinidad the Hairy Hermit also breeds from January to August, which spans the main dry season, but with a peak of laying in the first 2 months of the wet season. Nests of Guy's Hermit in the same locality were found in all months except August to October. All these hermit breeding seasons show correlations with the flowering of the mainly herbaceous plants on which these species feed.

Individual female Hairy Hermits and Guy's Hermits in Trinidad may make 3 nesting attempts in a season, as deduced from the reuse of repaired nests. A female Anna Hummingbird in California successfully raised 2 broods in a season, as did a Black-throated Mango *Anthracothorax nigricollis* in Trinidad.

HUNTING: see FEEDING HABITS.

HWAMEI: *Garrulax canorus* (see BABBLER).

HYBRID: term used to denote the product of a cross between individuals of unlike genetic constitution, usually distinct morphologically. It is often restricted to a cross between individuals of different species, but this begs the question of the taxonomic status of the forms before one can designate the products of their crossing. Genetically the term denotes a first generation product but in practice it is impossible under field conditions to distinguish such F^1 hybrids from second generation hybrids (resulting from a cross between hybrids) and from backcross products, i.e. individuals resulting from crossing hybrids with individuals of the parental forms (see GENETICS).

Interspecific and intraspecific hybrids are generally uncommon but may involve some 10% of the world's bird species. Interspecific hybrids between distantly related species that occur sympatrically are rare, but are usually easily distinguishable, and readily come to the attention of ornithologists. More common are hybrids between closely related species, either in zones of parapatry (where their ranges meet) or in zones of overlap and hybridization between geographically replacing allospecies that together form a superspecies (see HYBRIDIZATION, ZONE OF SECONDARY; INTROGRESSION; SPECIATION). Intraspecific hybridization results in zones of secondary contact between morphologically and genetically distinct subspecies; the hybrids are variable, occurring in a hybrid zone that both genetically connects and geographically separates the parental SUBSPECIES.

Generally, the more distantly related 2 species are, the more dissimilar they are genetically and hence the less likely they are to hybridize. Under captive conditions, and in the wild at borders of the ranges of species where choice of mates may be restricted, barriers to interbreeding can break down, resulting occasionally in hybridization. Another factor that promotes hybridization is mating systems in which pair formation occurs rapidly and males take no part in the nesting effort, as in many ducks, birds-of-paradise and hummingbirds (see also PAIR FORMATION).

Hybrids between species that manage to interbreed, despite behavioural or other factors tending to reduce mixed pairing, may be eliminated at various stages of development, from the period of fertilization onward. There is usually reduced fertility of the eggs of hybridizing individuals, and hybrid embryos often fail to develop to hatching. Anomalies often occur in hybrids that do hatch, reducing their chances of survival and breeding. Those hybrids that survive vary greatly in their degree of viability. They may be intermediate in their morphological, behavioural and other characteristics between those of their parents, but often show a variable array of traits, some like one or other parent, some intermediate, and others occasionally unlike either parent. Hybrids that do survive may exhibit 'hybrid vigour', being larger, or stronger, or faster growing, or more aggressive than either parental species, but as they usually have reduced viability, this prevents or limits introgression (passage of genes from the gene pool of one species into that of another). Fertile interspecific hybrids seem more frequent in some orders of birds than in others, and certain large genera such as *Anas*, that contain a number of relatively closely related species, show numerous natural hybrids as well as hybrids produced under captive conditions.

Although hybrids are of behavioural, physiological and genetic interest they are of little significance in terms of evolution unless they exhibit some degree of fertility and backcrossing occurs. Frequent hybridization with backcrossing is significant in an evolutionary sense to the degree that the interbreeding allows gene flow, giving the gene pool of each parental species some access to favourable genes and gene combinations of the other species.

There is no more recent list of bird hybrids than that of A.P. Gray (1958), although reports treating various aspects and occurrences of hybrids and hybridization are frequent in ornithological literature. Mayr and Short (1970) analyzed the North American avifauna of 516 breeding non-marine birds and found 24 cases of interspecific hybridization and 30 instances of intraspecific hybridization involving a total of 73 species, roughly 10% of all North American species. L.L.S.

HYBRIDIZATION, ZONE OF SECONDARY: an area in which 2 or more closely related forms contact and interbreed with backcrossing, having earlier differentiated under conditions of geographical isolation (see SPECIATION). It is not clear that the isolation need be complete, as strong selection could counter gene flow if the contact between the differentiating forms is restricted. Such zones are characterized by great individual variability.

Short (1969) classed these zones into 2 types: a zone of overlap and hybridization, and a hybrid zone. The zone of overlap and hybridization involves forms that hybridize to a greater or lesser degree, but the hybridization is incomplete, both parental forms occurring along with the hybrids. In this case the 2 forms remain sympatric and the continued occurrence and in some instances the preponderance of parental-type individuals indicate the presence of some barrier to interbreeding, or hybrid breakdown—the forms are considered to represent hybridizing species, designated allospecies, and together these allospecies form a superspecies (Amadon 1966). The hybrid zone is an area of greater or lesser extent populated entirely by hybrids between well-differentiated but freely interbreeding forms. This type of zone both genetically connects and geographically separates the parental forms, which are conspecific. The conspecific hybridizing forms often are so distinct that they have been considered full species at one time or another, and Amadon and Short (1976) have designated such differentiates as 'mega-subspecies'.

Examples of zones of overlap and hybridization are rather numerous and include those involving the Rose-breasted Grosbeak *Pheucticus ludovicianus* and Black-headed Grosbeak *P. melanocephalus*, and the Mallard *Anas platyrhynchos* and the American Black Duck *A. rubripes* in North America, and the Azure Tit *Parus cyanus* and Blue Tit *P. caeruleus* in Europe. Hybrid zones occur between the megasubspecies *cafer* and *auratus* of the North American Northern Flicker *Colaptes auratus*, and between the megasubspecies *cornix* and *corone* of the Carrion/Hooded Crow *Corvus corone*, of Eurasia. The extent of these zones depends upon a variety of factors, not the least of which is the availability of characters used in defining the zone. When characters are few, as in the case of the crows, the zone defined by the one or two characters may be narrow. The use of other, especially biochemical characters may show that the zones actually are broader than they appear, as has been found in lizards and other animals. Topographical and ecological factors may severely limit the possibility of contact and thus affect the size of the zone. There are several cases of range expansion that increase the area of a zone of overlap and hybridization, in the course of which hybridization is prevalent mainly at the edge of the range of the expanding species, followed by lessened interbreeding in the area of overlap, as in *Parus caeruleus-cyanus*, and in the European Syrian Woodpecker *Dendrocopos* (*Picoides*) *syriacus*, and Great Spotted Woodpecker *D. major*. Another peculiar situation is that of a range extension with very frequent hybridization accompanying it, followed by replacement of one species by the other, the example here being that of the Blue-winged Warbler *Vermivora pinus*, hybridizing with and largely or entirely replacing the Golden-winged Warbler *V. chrysoptera* in eastern North America (see also RANGE CHANGES).

A few situations are so complex as to defy any attempt to categorize them. The Rufous-sided Towhee *Pipilo erythrophthalmus*, and Collared Towhee *P. ocai*, are 2 strikingly differently plumaged finches, the former occupying much of North America and the latter inhabiting highlands of Mexico. In Mexico there is generally an ecological and altitudinal separation of the 2 forms, but they meet in many places with varying outcomes. In a few small areas they occur together, overlapping in range without interbreeding. In many areas they hybridize apparently freely, forming hybrid zones. Some entirely hybrid populations are geographically isolated, forming 'hybrid swarms' totally out of genetic contact with their parental forms. Certain of the hybrid swarm populations show by their distribution and gradation of their average characters the effects of a hybrid zone, but with geographical gaps among the isolated populations. The diverse situations probably reflect differences in the time of occurrence of the contacts relative to the development of reproductive isolating mechanisms, although some may have occurred as the result of a local breakdown in reproductive isolation.

The Crimson Rosella *Platycercus elegans* of wet eastern and south-eastern Australian woodlands and the Yellow Rosella *P. flaveolus* of the interior Murray River system meet and sporadically hybridize west and north of Australia's Great Dividing Range. The range involved is massively modified by man's activities, but at least one tenuous hybrid zone exists between them along the Murrumbidgee River. In South Australia's Adelaide Hills and the Flinders Range occurs a variable population that clearly represents a huge hybrid swarm; often treated as a species, the 'Adelaide' Rosella *P. adelaidae*, this population interbreeds freely but narrowly with the Yellow Rosella, destruction of habitat limiting the contact possibilities near the lower Murray River. There is no extant contact between the 'Adelaide' Rosella and the Crimson Rosella but 'Adelaide' Rosellas grade from yellowish in the north to red in the south, tending strongly toward *P. elegans*. This situation has been regarded by some as a 'ring' in which the extremes (*flaveolus* and *elegans*) are connected by an intermediate population but do not interbreed at the ends of their ranges (in the east). Actually the 'ring' is broken in the lack of contact of '*adelaidae*' with *elegans*, and *elegans* and *flaveolus* do hybridize in eastern Australia, so they appear to represent well-differentiated megasubspecies.

A true ring of races appears to exist between the Herring Gull *Larus argentatus* and the Lesser Black-backed Gull *L. fuscus*. These are sympatric in parts of northern Europe, and usually do not interbreed. However, from eastern Europe across Siberia to North America occur connecting, interbreeding populations, and thus the northern European situation would seem to represent the non-interbreeding ends of a chain of genetically connected populations. All of the connections have not been thoroughly studied and the complexity of this problem is enhanced by the propensity of the Herring Gull to interbreed with the Glaucous-winged Gull *L. glaucescens* in western North America, with the Glaucous Gull *L. hyperboreus* in Iceland, and with the Slaty-backed Gull *L. schistisagus* in eastern Siberia.

The matter of hybridization is of great interest and is directly involved in the matter of defining species (see SPECIATION). Many of the situations are highly dynamic and subject to modification through man's effects on habitats. Mayr and Short (1970) note that many hybridizing species of temperate regions seem biologically very successful, even in the face of man's activities. L.L.S.

HYDROBATIDAE: see under PROCELLARIIFORMES; PETREL.

HYLIA: substantive name of *Hylia prasina*, an African warbler-like bird of uncertain affinities.

HYOID: see MUSCULATURE; SKELETON, POST-CRANIAL; TONGUE.

HYPAXIAL: see MUSCULATURE.

HYPHENS: as regards their use in vernacular or scientific names of birds, see NAME, ENGLISH; NOMENCLATURE.

HYPOCOLIINAE: see BOMBYCILLIDAE; and below.

HYPOCOLIUS: generic name used as common name of *Hypocolius ampelinus*, sole member of subfamily Hypocoliinae of the Bombycillidae (Passeriformes, suborder Oscines); an aberrant species placed near the waxwings (see under BOMBYCILLIDAE). Its home is south-western Asia, whence irregular migrations take place to north-western India and perhaps casually to north-eastern Africa.

Characteristics. The plumage is pale grey, tinged blue on the back and buff on the forehead and underparts. A black band extends from the bill through the lores and round the back of the neck, where it can be erected into a small crest. The primaries are black, tipped white; the tail is grey, tipped black. Females lack the black on face and neck. Juveniles are buffy-brown without black markings, except for the tips of the rectrices; the tips of the remiges are marked buff as well as white.

The Hypocolius is about 23 cm in length with a long tail and short, broad, slightly hooked bill; the feet and legs are short and strong. The wings are relatively short and rounded; the tenth primary is relatively

Hypocolius *Hypocolius ampelinus*. (*C.E.T.K.*).

longer than in the waxwings. The flight is strong, swift and direct, not undulating, but the birds are sluggish, shy and sociable except in the breeding season. Fruits and berries are staple foods, although insects are also taken.

Voice. Vocalizations include mewing calls, associated with pair formation, and a continuous loud *kirrrkirrrkirrr*, uttered by pairs during courtship flights over the nesting territory.

Breeding. Nests have been found in the Tigris–Euphrates valley of Iraq and in south-western Arabia. Large and loosely built of twigs, they are lined with soft vegetable matter and sometimes hair, like those of waxwings; they are usually well hidden among the leaves of palm trees, but sometimes in other bushy trees. The 4–5 eggs are laid in mid-June and the parents are prone to desert if disturbed. The eggs are very pale slaty grey, with darker blotches and spots at the larger end; occasionally these form a ring or cover the whole egg. (J.C.G. Jr). D.W.S. (1)

HYPOPHYSIS: the pituitary gland (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

HYPORACHIS: see AFTERSHAFT.

HYPOSITTIDAE: a monotypic family separated by some authors, but of doubtful affinities and now provisionally merged with the Vangidae (for family see VANGA).

HYPOTHALAMUS: part of the forebrain (see NERVOUS SYSTEM).

I

IBIDORHYNCHIDAE: see CHARADRIIFORMES; IBISBILL.

IBIS: substantive name for most of the approximately 23 species and 16 genera in the subfamily Threskiornithinae of the family Threskiornithidae (Ciconiiformes, suborder Ciconiae).

Characteristics. Ibises are medium-sized water or terrestrial birds, about 50 to 100 cm in total length, including medium to long legs, long necks, and long, decurved bills. All species have heads that are partially or wholly bare, and some species are crested or have other modified feathers. The wings are relatively long and broad, and the tail is short. The flight is strong and rapid with neck extended. Among the more gregarious species, flocks often fly in long lines or V's with all birds flapping or gliding in unison. Sexes are similar except that the males of some species are slightly larger than the females. Immature birds are often darker than adults, and may be more extensively feathered on the head.

Systematic characteristics and distribution. Ibises are widespread in the warmer parts of the world, with 9 genera restricted to the Old World, 6 to the New World, and one that is cosmopolitan.

In the Old World, the genus *Threskiornis* contains 4 species, the Sacred Ibis *T. aethiopicus* occurring primarily in Africa south of the Sahara, the Straw-necked Ibis *T. spinicollis* of Australia, the Australian White Ibis *T. molucca* found between Indonesia and Australia, and the similar Oriental White Ibis *T. melanocephalus* in southern Asia. The species of *Threskiornis* are primarily black and white in colour, with entirely bare heads and upper necks.

Also in Asia is the Black (or White-shouldered) Ibis *Pseudibis papillosa* of India, south-eastern Asia and southern China, the Giant Ibis *Thaumatibis gigantea* of Indo-China, and the Crested Ibis *Nipponia nippon* of Japan, China, and Korea. The Black and Giant Ibises are dark species, the former having a patch of red papillae on the bare skin of the crown, and the latter characterized by its large size and barred nape and hind neck. The Crested Ibis is white, with the anterior half of the head bare red skin, and a crest of elongate white feathers at the nape.

In addition to the Sacred Ibis, 7 other species occur entirely or in large part within Africa. The endangered Waldrapp *Geronticus eremita* survives as a breeding bird of Morocco and Turkey, while the Bald Ibis *G. calvus* is restricted to mountains of South Africa. Both are large, dark ibises with strong metallic sheens to their plumage, red bills and entirely bare heads and upper necks. Three crested species are the Olive (or Green) Ibis *Lompribis olivacea*, the Spotted-breasted Ibis *L. rara* and the Crested Wood Ibis *Lophotibis cristata*, endemic to Malagasy. The Hadada *Hagedashia hagedash*, widespread in Africa south of the Sahara, is a broad-winged, all dark bird, and the Wattled Ibis *Bostrychia carunculata* in the Afrotropical Region, also a dark species, has a wattle hanging from the throat.

In the New World are 2 species of *Eudocimus*, the American White Ibis *E. albus*, a mostly white species with bare red face, which occurs between the south-eastern United States and northern South America, and the Scarlet Ibis *E. ruber* with a brilliant red plumage, found along the north-eastern coast of South America and in Trinidad. Immatures of both species are dark brown above.

Six species belonging to monotypic genera are essentially South American. The Plumbeous Ibis *Harpiprion caerulescens*, occurring in the southern continent east of the Andes, is a slaty grey bird with a bushy crest, while the Buff-necked Ibis *Theristicus caudatus*, found throughout tropical South America, is a grey and white species with buffy head and neck and large white wing patches. Four mostly blackish species are the Green Ibis *Mesembrinibis cayennensis* and the Bare-faced Ibis *Phimosus infuscatus*, both ranging throughout most of tropical South America, the Sharp-tailed Ibis *Cercibis oxycerca*, occurring from eastern Colombia to northern Brazil, and the Puna Ibis *Plegadis ridgwayi*, a high altitude species of the central and southern Andes. All 4 have feathered heads with varying amounts of bare skin on the face or chin, which is red on the Sharp-tailed and Bare-faced and dark in the other two.

The one cosmopolitan species is the Glossy Ibis *Plegadis falcinellus*, occurring in warmer regions of Eurasia, Africa, Australia and the New World, although the population that breeds from South America to the western United States is separated by some taxonomists as *P. chihi*, the White-faced Ibis. The Glossy Ibis is a dark, chestnut-coloured bird, glossy green on the wings, and with the head mostly feathered.

Habitat. Most ibises feed in a broad range of shallow, wetland habitats, primarily freshwater or estuarine, including swamps, marshes, rain-flooded agricultural lands, rice fields and river and lake edges. Exceptions include the 2 *Geronticus* species, the Buff-necked Ibis and the Black Ibis, which feed in dry pastures, savannas or other open, upland habitats. Most ibises place their nests in patches of low woody or herbaceous vegetation in either permanently or seasonally flooded sites, although *Geronticus* nests on ledges of cliffs or in piles of boulders, and the Crested Ibis and Black Ibis nest in large trees near water.

Population. Although several species of ibis are known to have experienced slow and persistent declines in numbers and some loss of range, in part due to habitat loss, shooting and pesticide problems, most species remain fairly common in large portions of their ranges. Two species, however, have become seriously threatened with extinction. The last 5 remaining Crested Ibis in Japan were live-trapped in 1981 in an attempt to increase numbers through a captive breeding programme; the species has become extremely rare in other parts of its range. Waldrapps had disappeared from their central European range by the 17th century, and declined in north Africa and the Near East until less than 300 nesting pairs remained by the late 1970s. On the other hand, the Glossy Ibis in North America has experienced a tenfold increase in numbers and has greatly extended its breeding range along the Atlantic Coast since the 1940s.

Movements. In more tropical regions, ibises are generally non-migratory. Instead, they may be resident or perform somewhat irregular movements apparently regulated by the influence which rainfall patterns and water levels have upon food resources and nesting sites. Ibises that nest in temperate regions, including populations of Glossy Ibis, American White Ibis and Crested Ibis, are migratory, and move into warmer regions during winter. Post-breeding dispersals, including northward movements in some North Temperate populations, are also characteristic of ibises, especially among younger age-classes.

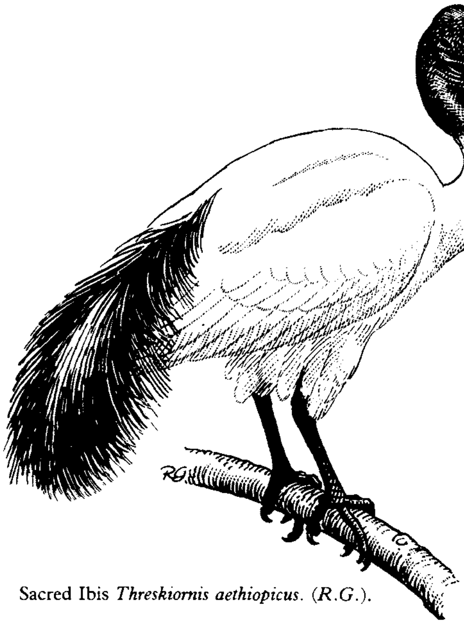
Food. In aquatic habitats, ibises feed primarily on crustaceans, molluscs, aquatic insects, and insect larvae, small fish and frogs. Prey taken at upland sites includes numerous grasshoppers, locusts, beetles, ants and other insects, spiders, molluscs, reptiles, and occasionally carrion, bird and reptile eggs or small rodents. Most food is captured by probing the long bill along the bottom in shallow flooded areas or in terrestrial sites. Feeding sites may be some distance from nesting or roosting locations, entailing flights of 10–25 km each way.

Voice. Ibises utter a variety of harsh, guttural or grunting calls, usually when in flight or during social interactions in colonies. Most species are otherwise quiet, although an exception is the Hadada, which is extremely loud and vociferous.

Behaviour. Ibises tend to be highly gregarious, although the degree of social behaviour varies between species. Roosting and feeding occur in small to large flocks, although some tropical species such as the Sharp-tailed and Green Ibis in South America and Black Ibis in India are usually seen as pairs or in small groups of less than 10 birds.

Breeding. Most species nest in colonies, either single-species or mixed with other species of long-legged water birds. Nesting colonies vary considerably in size, depending upon local habitat conditions and the species of ibis, with colonies of a few nests to several hundred the most common. The extremes are represented by the Crested Ibis which once nested as single pairs in the eastern USSR, to the American White Ibis which forms colonies containing tens of thousands of pairs covering many hectares of swampland forest. In the few species whose breeding behaviour has been studied, pair bonds are monogamous and of seasonal duration. Pairing occurs at the nesting site, and may include a display with head and neck stretched low and forward by one or both adults, and intertwining of the head and neck by the pair. During incubation, nest exchanges may include mutual billing and allopreening. Pairs defend immediate nest sites only. Both sexes participate in incubation and care of the young.

Nesting occurs on an annual cycle in temperate zones, but on less



Sacred Ibis *Threskiornis aethiopicus*. (*R.G.*).

well-defined cycles in tropical regions where local water conditions may greatly influence its timing. Pairs generally are single-brooded during each breeding cycle. Clutch size generally ranges from 2–5 eggs, incubation starting with the first egg in the Glossy Ibis and Waldrapp, and with the last egg laid by the American White Ibis and Sacred Ibis. Incubation lasts from 21–29 days. Nestlings are nidicolous and semi-altricial, and are fed by regurgitation either directly between adult and nestling or into the nest bottom. Nestlings are brooded for the first 5–7 days after hatching, begin to move away from the nest by 14–21 days, but will return to it to be fed, and are capable of full flight between 30 and 50 days of age. Nesting success in individual colonies ranges from complete failure when rapid deterioration of feeding conditions occurs, to as high as 80% of nests producing 1 or more young in years of good feeding conditions. Young ibises of most species apparently reach maturity by at least 3 years of age. J.C.O.

IBISBILL: *Ibidorhyncha struthersii*, sole member of the family Ibidorhynchidae (Charadriiformes, suborder Charadrii). Formerly grouped with avocets and stilts in the Recurvirostridae, this aberrant wader of the high plateaux of central Asia, from Turkestan to Kashmir and northern Burma, is rather over 17 cm in length, greyish brown above, bluish grey to white below, with a black face and broad black gorget. The decurved bill, 7–8 cm long, is bright red, the legs are blood red, the eyes dark red.

Small parties of birds remain by the slower-flowing reaches of mountain streams all the year, but a few descend into the foothills in winter. They feed, both on the banks and by wading deep into the water or swimming, on a variety of invertebrate animals. In the light elegant flight the neck is stretched out and white patches show on the wings, and a repeated whistling call is uttered.

The Ibisbill breeds from the end of March to early June according to the season. A shallow scrape is made among stones and shingle and the clutch of 4 eggs, brown-spotted on a grey ground, is incubated by both parents for an as yet unknown period. H.B.

IBIS, WOOD-: see STORK; WOOD-IBIS.

ICE-BIRD: sailors' name for some prions *Pachyptila* spp. (see PETREL). Note, however, that the German name 'Eisvogel' applies to the Kingfisher *Alcedo atthis*.

ICHTHYORNITHIFORMES: order erected to include such fossil forms as *Ichthyornis* and *Apatornis* (see FOSSIL BIRDS).

ICTERIDAE: a family of the Passeriformes, suborder Oscines; ORIOLE (2).

IIWI: *Vestiaria coccinea* (see HAWAIIAN HONEYCREEPER).

ILEUM: the posterior part of the small intestine (see ALIMENTARY SYSTEM).

ILIUM: a paired bone of the pelvic girdle, partly fused with the other elements (see SKELETON, POST-CRANIAL).

ILLADOPSIS: substantive name of African BABBLERS of the genus *Trichastoma*, in West Africa known as Adalats.

ILLUSTRATION, BIRD: the pictorial representation of birds. Birds were among the first subjects to be drawn by Neolithic man on the walls of his cave. It is thought that these pictures of birds and other animals may have had some mystical significance, being sympathetic or restitutive magic, shamanism, totemism or a representation of the duality of male and female. It is even possible that they may have been just home decoration or Art for its own sake.

Representations of birds were found in several ancient cultures, but most notable must be those from Ancient Egypt. These usually depicted recognizable species. On the fresco of the tomb of Ne-Few-Maat at Medum are very life-like illustrations of Bean Goose *Anser fabalis*, Red-breasted Goose *A. ruficollis* and White-fronted Goose *A. albifrons*. Each bird has a specific JIZZ, suggesting that the artist, working at least as long ago as 3,000 BC, was familiar with his subjects.

It was not until the Middle Ages that the first didactic bird illustrations appeared in medieval bestiaries. The monastic manuscripts also contained accurate representations of species that are recognizable today. There are excellent marginal decorations of birds in *De Arte Venandi cum Avibus* (*c.* 1248) by the German Emperor Frederick II (see also FALCONRY). Probably the best representations of this period are to be found in the Sherborne Missal (*c.* 1400). Of the 170 decorations, two-thirds are identifiable and cover 40 species.

The invention of printing brought bird illustrations to a wider readership. Notable among the earliest printed books to contain bird pictures were *Das Buch der Natur* (Augsburg, 1475) and *De Proprietatibus Rerum* of Bartholomaeus Anglicus, printed in England by Wynkyn de Worde (*c.* 1495). A third significant book at this period was *Hortus Sanitatis*, printed by Jacob Meydenbach at Mainz in 1491, which contained 103 figures of birds.

The first book that can be described as an 'ornithological treatise' was by Pierre Belon of Le Mans, whose *Histoire de la Nature des Oyseaux* was published in Paris in 1555. The 160 woodcut illustrations were described by the author as 'simple portraits of birds, the nature of which no one else has illustrated before'. More accurate and sophisticated woodcuts by the Strasbourg artist Lukas Schan are to be found in Conrad Gesner's *Historia Animalium* (Zurich, 1565), the third volume of which was devoted to birds. Gesner, in describing Schan as equally skilled in painting and in fowling, summed up the essential truth that the best bird illustrators know as much about birds as they do about painting and drawing.

It was not until 1676 that the first illustrated text book of birds appeared in England, when Willughby and Ray's *Ornithologiae Libri Tres*, was published. It was significant because in it the authors attempted a scientific classification of birds. The illustrations were not of a very high quality, but they were attempts at clear representations of birds.

Engraving on metal, which had begun to supersede wood towards the end of the 16th century enabled the artist to achieve finer detail. This development coincided with the great 17th and 18th century voyages of discovery, which gave rise to books with magnificent, hand-coloured plates. Excellent examples of these are Mark Catesby's *Natural History of Carolina* (2 volumes, London 1731–43) and Eleazer Albin's *Natural History of Birds* (1738).

In France the work of Buffon had provoked enormous interest with the publication of the collection of plates of animals drawn and engraved under Buffon's supervision by F.N. Martinet. Work began in 1765 and by 1783 1,000 plates had been published, 973 of which contained figures of birds. This comprehensive ornithological iconography is usually referred to as *Les Planches Enluminées, Executées par Daubenton le Jeune* or *Buffon's Planches Enluminées*. This was the period of the *de luxe* monograph in France. Works of great beauty, such as *Oiseaux Dorés* (Paris 1800–2) by J.D. Audebert, F. Levaillant's *Histoire Naturelle des Perroquets* (1801–5) with figures by J. Barraband, and A.G. Desmarest's *Histoire Naturelle de Tangaras* (1805–7) with plates by Barraband's pupil, Pauline de Courcelles, made the Empire the golden age of ornithological illustration in France.

The foremost bird illustrator at this time was Thomas Bewick, who by 1800 was developing wood engraving. By cutting into the end grain he obtained from the wood the delicacy of shadowing that only intaglio copperplates had achieved before. He also attempted by means of detailed backgrounds to indicate the bird's habitat. Bewick was a major influence on both wildlife illustration and the art of engraving.

The first and, arguably, the finest of the great colour-illustrated books of the 19th century was *The Birds of America*, a four-volume elephant folio illustrated with 435 aquatint engravings. This book was the work of John James Audubon, who as well as being the greatest 19th century bird illustrator must also have been the most romantic. He was born in Haiti, son of a Creole woman and a French sea captain who later made a considerable fortune as a merchant. Educated in France, he went to live in the United States at the age of 18 and it was only after various business ventures had failed that he thought of publishing a book. Unable to interest American publishers, he sought subscribers in Europe and *The Birds of America* was published in London. The carefully composed plates often contain several birds and are full of action, showing that as well as being a very skilled artist, Audubon was a skilful observer of bird behaviour.

The invention of lithography brought a means of reproducing tone successfully and one of the pioneers of the process was Edward Lear, whose illustrations of the *Family Psittacidae* (1830–32) contains 42 large lithographic plates 'drawn from life and on stone'. These plates were beautifully and laboriously coloured by hand.

Lear was one of a stable of artists used by John Gould to prepare plates for his books. Gould's first book *A Century of Birds from the Himalaya Mountains* was published in 1832 and when he died in 1881 he had published more than 40 illustrated books. Although he prepared preliminary sketches and completed some very fine finished drawings, most of the illustrations were the work of his wife Elizabeth, Edward Lear, Joseph Wolf, William Hart, H.C. Richter and, latterly, J.G. Keulemans and Joseph Smit.

The portraits of birds in the school of Gould showed an adult or, especially in the case of sexually dimorphic species, two adults in the foreground with a scene suggesting the habitat or an interesting aspect of the species's habits. This formula for composition became accepted and was used by many artists for many years after Gould's death.

The paintings for exhibition or commission by Joseph Wolf and others were on an heroic scale, the fashionable obsession with the macabre and with the Scottish Highlands producing many dramatic paintings of Golden Eagles *Aquila chrysaetos* feeding on dead Red Deer *Cervus elaphus* or harrying Ptarmigan *Lagopus mutus*.

The invention of chromolithography meant that colour illustrations could be produced in greater quantities than before. One of the earlier bird books to take advantage of this development was Lord Lilford's *Coloured Figures of Birds of the British Islands* (1891–98). The chromolithographs were made from drawings by Keulemans and Archibald Thorburn with a small number by G.E. Lodge and W. Foster. These illustrations must have been seen by hundreds of thousands of birdwatchers, because they subsequently appeared in all 3 volumes of T.A. Coward's *The Birds of the British Isles and Their Eggs*, which was almost continuously in print for 40 years from 1920 and *The Observer's Book of Birds*, published in 1937. Thorburn in his own *British Birds*, published in 4 volumes in 1915–16, produced plates in which several species could be compared. On one plate there might be up to 11 species seen in appropriate habitat.

With his illustrations for the first two volumes of E.D. Cumming's *The Bodley Head Natural History* (1913) J.A. Shepherd suggested that it might be possible to identify birds from illustrations that show them as living and moving animals. No one else has tried to do this as an aid to identification, but Shepherd's work has influenced some of today's leading British illustrators, particularly John Busby.

Generally, North American bird artists of the early part of this century were more adventurous in approach than the Europeans. Louis Agassiz Fuertes, for example, showed great understanding of light and shade and his gallery paintings were the equal of any European contemporary, with the possible exception of Bruno Liljefors.

Fuertes was then, and still is, a major influence on American bird art and his death at the age of 53 in 1927 was a tragedy. At this time other leading North American bird artists included Lynne Bogue Hunt, Bruce Horsfall, Francis Lee Jaques and two Canadians, Allan Brooks and Frank Hennessy. All were among the exhibitors at the Cooper Ornithological Club's 1926 Annual Meeting in Los Angeles. Among the newcomers was an eighteen-year-old who was to revolutionize birdwatching with his system of illustrating for identification. His name was Roger Tory Peterson.

Peterson in *A Field Guide to the Birds* set a pattern which was to be followed for 40 years at least. In this revolutionary book he showed birds in profile with an arrow indicating diagnostic characters. Peterson, with Guy Mountfort and P.A.D. Hollom, did the same for European birds in *A Field Guide to the Birds of Britain and Europe*, published by Collins in 1954. These field guides have set a format for books on birds of various parts of the world as well as for those about other classes of animals.

Although there have been imitators of Peterson, none has been able to better his technique. Two artists, however, have developed further dimensions to illustration for identification by recognizing that not all birds present their watchers with a perfect profile. They are Peter Hayman, whose illustrations for *The Birdlife of Britain* (Mitchell Beazley, 1976) and *What's That Bird?* (RSPB, 1979) show birds in a variety of postures and Lars Jonsson, a Swedish artist, whose *Fåglar i Naturen* series of identification guides, first published in Sweden from 1977 to 1980, effectively capture the jizz of birds.

As well as book illustrations, Thorburn produced paintings for exhibitions. These often portrayed gamebirds and birds of prey, for it was sportsmen rather than ornithologists who made up the greatest market for bird paintings at the beginning of the century. These pictures showing birds in landscapes were much less dramatic (and, despite his reputation, less accurate) than the oil paintings of his Swedish contemporary, Bruno Liljefors, whose knowledge of birds and other animals and creative ability must make him one of the greatest of all wildlife painters. Other excellent bird painters, who both illustrated books and painted pictures for the private collector at this period, included Winifred Austen, G.E. Lodge, Allen W. Seaby and Frank Southgate.

Thorburn died in 1935, Liljefors 2 years later, by which time the paintings of Peter Scott had become popular, both as illustrations to his books and also reproduced as prints. This work as an artist, together with his conservation activities, helped to create a fertile ground in which the post-war interest in birds could grow. Among other books published in the 1930s were R.B. Talbot Kelly's *The Way of Birds* (1937) and Mary Priestley's *A Book of Birds* (1937) with illustrations by C.F. Tunnicliffe, who later wrote and illustrated several significant books of his own, notably *Shorelands Summer Diary* (1957). R.B. Talbot Kelly's distillation of birds to a few lines and flat colours and Eric Ennion's outstanding ability to catch the movement of birds and commit it to paper have influenced several of today's leading wildlife artists.

C.F. Tunnicliffe had first come to notice as an etcher of country subjects and then as a wood engraver, illustrating the nature books of Henry Williamson. Another expert wood-engraver still working is the Swiss, Robert Hainard, all of whose prints, often in several colours, are based on events that he has seen.

Print-making is not popular among bird illustrators today, but Robert Gillmor has made strong lino-cut prints and Robert Greenhalf uses birds in landscapes as subjects for his etchings.

While European bird art has become freer, in North America there seems to be a vogue for minutely accurate, often rather romanticized portrayals of birds. There is certainly work of a high ornithological standard from Roger Tory Peterson, George Miksch Sutton, Don Eckelberrry, Guy Coheleach and Al Gilbert, and Canada has produced two first-class bird artists in Robert Bateman and J. Fenwick Lansdowne. Australasia has produced several artists in the realistic genre; perhaps the most notable are Peter Trusler, William Cooper and Raymond Harris Ching, a New Zealander whose skilful drawing shows to great advantage when he tackles subjects with which he is familiar.

The contribution of bird illustrators to the creation of an interest in birds and their conservation has always been considerable, but in the last 50 years this contribution has been particularly impressive. The wide popularity of the work of Peter Scott and Roger Tory Peterson, the illustrations of Don Eckelberry, the vast commercial output of C.F. Tunnicliffe, the paintings and prints by Keith Shackleton and the book illustrations, calendars and cards by Robert Gillmor have all been notable.

Never has the demand for bird illustrations been so great nor have there been so many illustrators. However, not all the published bird illustrations are as accurate as they might be. The wonderfully detailed studies by David Reid Henry have yet to be matched by any living wildlife artist. While the growth of nature photography has encouraged some artists to adopt a more abstract approach, photographs have had the unfortunate effect of providing a source for other artists to copy. Sadly, some also use as models mounted specimens which they faithfully reproduce with all their unpreened feathers, shrunken soft parts and sometimes unrealistic poses. However, thanks to the Society of Wildlife Artists, whose inaugural exhibition was held in 1964, standards are improving. The SWLA and in the USA the Society of Animal Artists mount annual ornithological exhibitions and, with conservation societies holding exhibitions and a growing number of privately run galleries, there is plenty of opportunity for bird watchers to acquire original work. With an increasing number of bird books being published and the decorative opportunities presented by the use of birds on gifts and cards there has never been such wide scope for bird artists to have their work used. IMAGE-FIGHTING: term used to describe attacks by a bird against its reflection in a window, mirror or other reflecting surface, e.g. the hub-cap of a motor-car. The attacks may be brief and not repeated or become an obsession, persisting over months, and are usually but by no means always made by male birds, presumably against a territorial 'rival'. Attacks by a number of passeriform species, notably crows *Corvus* and wagtails *Motacilla*, are on record; also by game-birds such as the Capercaillie *Tetrao urogallus*. So far the phenomenon has not attracted more than anecdotal attention.

IMITATION: see under COMFORT BEHAVIOUR; FACILITATION, SOCIAL; FOOD SELECTION; HUMAN IMITATION OF BIRD SOUNDS; LEARNING; MIMICRY, VOCAL.

IMMATURITY: see under YOUNG BIRD.

IMMIGRATION: migration into an area (see MIGRATION; and IRRUPTION).

IMPENNES: a superorder recognized by some authorities (see under CLASS; PENGUIN).

IMPERVIOUS: as applied to nostrils, see NARIS.

IMPING: a technique in FALCONRY for mending broken feathers, also useful for rehabilitating flight-impaired birds. There are 3 main methods. (1) The broken feather's calamus is severed at the widest, most distal, hollow part; a whole moulted feather is cut at the same point, and a shaped wooded plug glued into the vane of each to join them. (2) The broken feather's calamus is cut as in (1) and the 'new' feather's calamus is not cut but trimmed to fit inside the original calamus, retained by glue and a thread tie. This method has been used to attach small transmitters (see RADIO-TRACKING AND BIOTELEMETRY). (3) The rachis is severed proximal to the break, a moulted feather cut to match, and a needle, pointed at each end, inserted with glue to make the join. Severely bent but unbroken feathers can be similarly mended by pushing the needle into the distal rachis at the bend, and ventrally slitting the proximal rachis to insert the needle lengthways.

IMPRINTING: a special case of exploratory or latent learning that has particular relevance for the student of ornithology (see also LEARNING). Like latent learning and insight learning, it is characterized by the absence of any reward in the usual sense of something which satisfies one of the primary physiological needs of the animal. The name 'imprinting' ('Prägung' in German) was originally given to a type of learning characteristic of the development of the following response of the young of nidifugous birds such as geese and ducks and rails. Heinroth, in 1910, found that young geese reared from the egg in isolation reacted to their human keepers, or to the first relatively large moving objects that they saw, by following them as they would their parents. In extreme cases it seems that this need happen perhaps for only a few minutes for the young bird to come to accept a human being as its proper associate and to retain for the rest of its life a tendency to regard human beings as fellow-members of its species. Thus a bird, as a result of this first experience, may when it becomes mature—months or years later—be found to be irreversibly fixated sexually to human beings; and Lorenz (1935) assumed from his work on geese that this was characteristic of imprinting. Subsequent investigation seems to show that such fixations based solely on the experience of the first few hours or days of life are extremely rare. Although many examples have been reported, it is evident that in almost all cases there has been a long subsequent history of rearing and attending by human keepers, so that there has been continual opportunity for the bird to learn to respond to human beings as a result of other types of LEARNING. The important point emerges, however, that when the young bird first follows the parent or substitute parent the attachment is not to an individual (although this will usually come later as a result of conditioning) but to the 'species' in a very general manner. Thus, we can sum up the characteristics of the process of imprinting, in the sense originally proposed by Lorenz, as:

(1) A learning process confined to a very definite and brief period of the individual life.

(2) One that, once accomplished, is often very stable and perhaps in some rare cases irreversible.

(3) A process that is often completed long before the various specific reactions to which the imprinted pattern will ultimately become linked are established.

(4) Learning that is generalized in the sense of leading to an ability to respond to the broad characteristics of the species.

On the whole, subsequent research has tended to emphasize the importance of conclusion (1) and to suggest that (2) and (3) apply only in exceptional cases. Recent developments concerning conclusion (4) will be discussed later.

As regards the first point, it has been shown that the critical age for imprinting Mallard *Anas platyrhynchos* ducklings, by the process of following, is between 13 and 16 hours; and that if the first experience is delayed beyond the latter age then the percentage of ducklings that can be imprinted falls rapidly to zero (Figure). It is known, however, that by holding the birds in complete isolation, or by giving doses of drugs such as meprobamate that reduce metabolism and act as muscle relaxants, the critical age for imprinting can be extended (E.H. Hess). Similar evidence for the existence of a critical period early in life has been found in chicks and goslings, as well as in the young of Tufted Duck *Aythya fuligula*, Moorhen *Gallinula chloropus*, Coot *Fulica atra*, and others.

The importance of internal processes of maturation in determining the start of the sensitive period is indicated by the observation that the start is more closely related to developmental age (time since conception) than to time since hatching.

A wide variety of stimuli will elicit a following response in ducklings and domestic chicks, ranging from a slowly walking person to a flashing light. The optimal stimulus in terms of colour and size varies from species to species, and the efficacy of a particular stimulus is influenced by the rearing environment. P.P.G. Bateson, for example, found that exposure of chicks to a colour pattern in their home pens subsequently facilitated imprinting to that pattern.

As the young bird becomes attached to one stimulus, a tendency to avoid other stimuli develops. In part, the onset of avoidance of new stimuli is a consequence of the imprinting process itself: when one object becomes familiar, others, by definition are unfamiliar and avoided. Thus the sensitive period is to some extent self-terminating and by depriving young birds the chance to become imprinted (e.g. by rearing them in diffuse light) the sensitive period can be extended. However it cannot be extended indefinitely, so it seems likely that the endogenous maturation

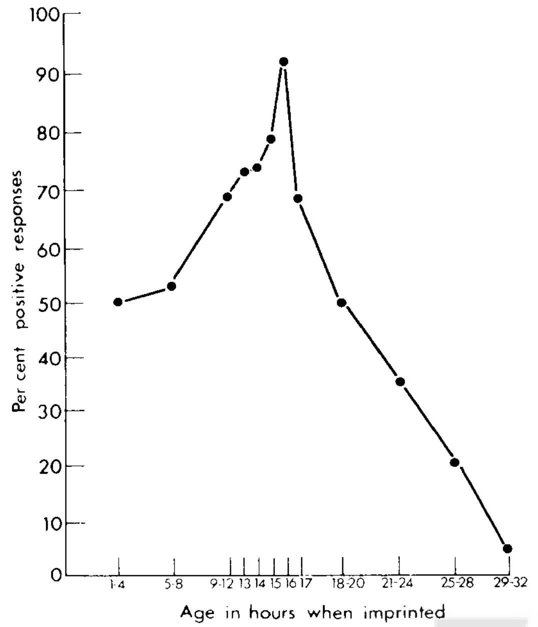

Fig. 1. Critical age for imprinting in Mallards *Anas platyrhynchos* expressed as a percentage of positive responses. (Redrawn from Hess 1957).

of 'fear' also plays a role in terminating it.

More detailed investigations of the stimuli eliciting the following response have shown that in fact the most effective stimulus for an imprinted chick is one that is very slightly different from the original imprinting stimulus; for example a chick imprinted on a yellow flashing light, and then offered the choice between approaching yellow or orange lights, prefers the orange. Thus there is a trade-off between familiarity and novelty and slight novelty provides the optimal stimulus.

Imprinting is not restricted to visual stimuli. In the cavity-nesting Wood Duck *Aix sponsa* exposure to sound signals can lead to a subsequent preference for that sound; further, this imprinted response to sound is not altered or reinforced by visual stimuli. This fits well with the natural life of the Wood Duck, since the first response of the young ducklings inside the dark nest cavity to their mother must be based on auditory rather than visual stimuli.

Sexual imprinting. For Lorenz, one of the key characteristics of imprinting was that later sexual preference could be determined by a rather brief exposure in early life. Subsequent work has shown that sexual imprinting does occur, but that it requires longer exposure to the imprinting stimulus than does so-called filial imprinting of the young bird on its parent. Once established, however, imprinted sexual preference can be very strong. In one experiment Zebra and Bengalese Finches (*Poephila guttata* and *Lonchura striata*) were cross-fostered and then maintained with their own species for a number of years. Even though the cross-fostered birds bred with their own species, when eventually given a choice between their own and their foster species, they strongly preferred to court the latter. Sexual imprinting, does, however, seem to be biassed towards the animal's own species. When the two finch species referred to above are raised by a mixed pair, they always imprint on their own species.

The sexual imprintability of the two sexes may differ in some cases. F. Schütz, for example, reported that in sexually dimorphic duck species only the males show sexual imprinting as a result of cross-fostering, while in the monomorphic Chilean Teal *Anas flavirostris* both sexes imprint.

The biological significance of imprinting. Why should the chancy business of learning be used instead of a fixed genetic instruction to determine filial and sexual preference? One proposal for filial imprinting is that the young bird sees its parent from so many different angles and distances that it would be hard to programme a genetic instruction for recognizing the parent under all conceivable circumstances: learning is more flexible. A second idea refers primarily to sexual imprinting. Recent work with Japanese Quail *Coturnix coturnix japonica* has shown that sexual imprinting is not, after all, simply a matter of learning supra-individual, species-specific chararacters. P. P. G. Bateson has shown that Quail prefer to mate with partners that differ slightly in plumage pattern from those with which they have been reared. This preference for slight novelty may prevent inbreeding, while ensuring that a mate of the correct species is chosen. The flexibility of learning may be better suited to cope with this compromise than a genetically fixed rule.

Other kinds of imprinting. Although most of the research on imprinting has been concerned with filial and sexual imprinting, analogous forms of learning (latent learning in a sensitive period) are known to influence other kinds of behaviour, for example, food preferences and habitat selection.

The concept of a sensitive period also emerges from studies of song development in birds (see VOCALIZATION): young Chaffinches *Fringilla coelebs* are capable of learning songs during their first year of life, but not subsequently. In this case the termination of the sensitive period seems to be under the hormonal control—gonadectomized Chaffinches have a greatly extended learning period. W.H.T. and J.R.K.

INCA: substantive name of some *Coeligena* spp. (for family see HUMMINGBIRD).

INCA-FINCH: substantive name of Andean finches of the genus *Incaspiza* (for family see BUNTING).

INCA-TERN: see TERN.

INCERTAE SEDIS: term used in taxonomy to mean 'of uncertain taxonomic position'.

INCUBATION: the process whereby the heat necessary for embryonic development is applied to an egg after it has been laid. Such heat is usually derived from the body of one or both of the parent birds although species in several groups use foster parents (see BROOD-PARASITISM). The Megapodiidae utilize natural sources of heat such as solar radiation, volcanoes or the heat of fermentation of decaying organic matter (see MEGAPODE).

In the majority of birds heat transfer is effected by the close application to the eggs of the incubation or brood patch. Some birds have a single patch that covers all the eggs whilst others have a discrete patch for each egg. Generally this area on the ventral surface of the bird becomes denuded of feathers, and becomes oedematous and highly vascular through the action of steroid hormones in conjunction with prolactin (for reviews see Lofts and Murton 1973, Drent 1975). The release of these hormones appears to be related to the onset of breeding behaviour, e.g. the manipulation of nest material and stimulation by the mate during courtship. In some species, e.g. pigeons and doves (Columbidae), the incubation patch is an area naturally devoid of feathers and is bare the year round whilst in waterfowl there are no true incubation patches but the feathers in an area on the ventral surface are often plucked out by the parent. There are numerous observations on the way the incubation patch is brought into the right relationship with the eggs. The 'resettling' movements performed when a bird sits on the eggs include ruffling or lowering of the abdominal feathers to expose the patch and a waggling or quivering action as or after the bird lowers itself to adjust the tightness of sit. Some birds lack incubation patches (e.g. pelicans *Pelecanus* spp.) and in the Sulidae (gannets and boobies) the cradling of the egg in the webs of the feet has led to the suggestion that these birds incubate with their feet. The ventral body surface, although lacking an incubation patch, probably contributes to the warming of the egg for, as Drent points out, blood flow through the feet is usually highly variable since the legs and feet are used as heat dissipators for thermoregulation (see HEAT REGULATION).

Kendeigh (1952) surveyed a large body of data collected from all groups on such points as the division of labour between the parents and the patterns of attentiveness and inattentiveness i.e. intervals spent on and off the nest. Almost all the possible arrangements are exemplified from equal sharing of incubation between the sexes (most birds) to either

Magellanic Plover *Pluvianellus socialis* incubating. (*Photo: J.R. Jehl Jr.*).

Double-banded Courser *Cursorius africanus* incubating. (*Photo: G.L. Maclean*).

female (e.g. Galliformes, Strigiformes) or male (e.g. phalaropes, Tinamiformes) taking sole charge. Incubating males generally develop incubation patches (e.g. phalaropes and passerines—Skutch 1957) although several exceptions are listed by Lofts and Murton and by Drent. There are numerous examples of adaptive specialization, for instance, species in which only one member of a pair incubates are in many cases sexually dimorphic; the incubating bird is coloured cryptically and its mate conspicuously.

In bisexual incubation the eggs are generally attended at all times by one or the other parent except, for example, when the weather is mild. In single sex intermittent incubation the time is divided between attending the eggs and inattentive periods usually spent foraging; the nests of these species are usually of complex structure providing good heat retention during the inattentive periods.

Periods spent sitting on the eggs vary enormously between species (Lack 1968), from less than one hour in many passerines e.g. European Robin *Erithacus rubecula*, to a few hours in most seabirds which feed inshore, e.g. gulls and terns, between 2 and 12 days in offshore feeding seabirds, e.g. shearwaters, storm-petrels (Procellariidae), spells of 2½ to 3 weeks in the albatrosses *Diomedea nigripes* and *D. immutabilis* and the 64 days of the male Emperor Penguin *Aptenodytes forsteri*. Incubating birds do not adjust their heat production to regulate egg temperatures, but instead adjust the amount of time they spend in contact with the eggs. Consequently adjustments in the time (number and/or duration of sitting spells) spent attending the eggs are related to the ambient air temperature, degree of nest insulation, and the time required for foraging (White and Kinney 1974). The time spent off the nest foraging is reduced in some cases by the non-incubating member feeding its sitting mate.

When the parent leaves the nest to forage, the eggs lose heat at a rate dependent on their size, arrangement in the nest, degree of nest insulation, ambient temperature, and possibly egg colour. Resistance of the embryo to chilling has been demonstrated clearly in the Procellariiformes and seems to be a feature of bird embryos in general. In the latter half of incubation, when embryonic metabolism is increasing, the heat so produced, whilst not able to maintain the egg temperature, may at least slow its rate of decrease when the parent leaves the nest. Drent points out that in the energy budget for incubation not only is the rate of cooling of the eggs important, but the time required to reheat the eggs when the parent returns may also influence the pattern of foraging.

In birds with open nests on the ground the eggs may be exposed to the danger of overheating due to solar radiation when the parents leave the nest. Many of these species, however, have cryptic egg coloration as a protection against predators, and the pigments responsible for the markings tend to reflect the potentially harmful near-infrared rays and thus minimize solar heating. The bright blue eggs of some tree-nesting species also show high reflectance in the near-infrared. In some instances the ambient/egg temperature may be so high that cooling of the eggs by shading, wetting of the abdominal feathers (see BELLY-SOAKING) or through the brood-patch, with or without accompanying panting or gular flutter, may be necessary. Such species tend additionally to locate their nests to take advantage of prevailing shade and cooling winds and to orient their sitting posture to minimize insulation and maximize cooling by breezes.

The definitive incubation temperature (generally between 34 and 39°C depending on the species) is achieved only after a warm-up period, the length of which may be related to the tightness of sit and the time required for the incubation patch to become fully functional. Maintaining an adequate incubation temperature is, however, only one ingredient in the recipe for successful incubation, for it is clear from a consideration of the artificial incubation of eggs that other criteria must be satisfied through the behaviour of the incubating bird, the particular nest environment or adaptation of the egg. Thus, most eggs irrespective of size lose about 15% of their fresh weight during incubation (due to the loss of water from the contents across the porous shell) which suggests either a regulation of the nest humidity or an adaptation of shell porosity to the humidity conditions characteristic of the species. Control of water loss from the egg may be obligatory if the water content of the hatchling is to be similar to that of the fresh egg and successful hatching maximal. Thus, for example, the eggs of coots *Fulica*, divers (Gaviidae) and grebes have a shell of high porosity as an adaptation to the humidity pertaining in the nest. Species nesting at altitude have a reduced eggshell porosity compared to their sea-level counterparts to compensate for the changes that would result in embryonic respiratory gas exchange and water loss from the egg as a consequence of the lower barometric pressure (for these and other examples see Rahn and Paganelli 1981).

Nest ventilation (achieved presumably during the frequent rising and shuffling by the incubating parent) is important to maintain an optimum gaseous environment and egg turning, 'poking' or 'shifting' behaviour is important for a number of reasons. For example, it helps counteract the temperature gradients which occur in the nest and during early incubation it prevents premature adhesions between the extra-embryonic membranes and the shell membranes. These may result in distortions in subsequent development, with the embryo perhaps dying during incubation or finding itself in a position from which it is unable to escape when hatching. During the latter part of incubation the egg develops an asymmetrical distribution of weight so that in spite of egg-turning by the parent the egg probably resettles in a particular attitude. This may facilitate attainment of a correct pre-hatching position by the embryo (Drent; see HATCHING).

The incubation period is strictly defined as the time which, with regular uninterrupted incubation, elapses from the laying of the last egg in a clutch to the hatching of that egg. Accurate determination of the period of incubation demands marking of the eggs and vigilant observation and many documented periods have not been assessed according to the definition above. Incubation periods vary from 11 days in some of the smaller passerines (egg weight below 1 g) to about 80 days in the Royal

Water Rail *Rallus aquaticus* moving egg during incubation. (*Photo: K.J. Carlson*).

Albatross *Diomedea epomophora* (egg weight about 450 g). There exists a general relationship between egg weight and incubation period: each doubling of species egg weight increases incubation time by 16% on average. However, various factors have been suggested that modulate the relationship. Some of these are the egg temperature during incubation, stage of the development of the chick at hatching, relative risk of predation, type of nest, climate, season and food supply, with the result that there is a wide range of incubation period about any given egg weight. Nice (1954), reviewing these factors, concluded that the crucial one was the rate of development of the embryo. This rate of development is a product of natural selection and ultimate causes may be located in the bird's ecological relationships e.g. the availability of food and growth rate of the young. Thus Lack, commenting on the correlation between the fledging period and incubation period, suggested that the easiest or perhaps the only way to evolve a particular growth rate of the young was to alter the whole rate of development including that of the embryo in the egg (see DEVELOPMENT, EMBRYONIC; GROWTH).

INCUBATOR BIRD: see MEGAPODE.

INDETERMINATE LAYER: species in which the number of eggs laid in a clutch can be altered by the addition or removal of eggs during laying (see LAYING).

INDEX: term sometimes applied to the second digit of the manus, but by a few authors to the first (see WING).

INDIAN REGION: alternative name for ORIENTAL REGION.

INDICATORIDAE: see PICIFORMES; HONEYGUIDE.

INDICATOR SPECIES: species whose ecological requirements are such that their presence more or less guarantees the existence of particular environmental conditions. It may then be easier to observe the presence or the absence of the indicator species than to measure the environmental conditions themselves.

INDIGENOUS: term applied to species, etc., meaning native to the area under reference.

INDIGO-BIRD: substantive name, alternatively 'indigo-finch' or 'combassou', used in East Africa for *Hypochera* spp. (for family see WHYDAH (1)).

INDIGO BUNTING: *Passerina cyanea* of North America (see CARDINAL GROSBEAK).

INDIRECT HEAD SCRATCHING: see COMFORT BEHAVIOUR.

INDIVIDUAL DISTANCE: the minimum distance at which an individual will tolerate the presence of another (usually, conspecific) individual. The term was introduced into ornithology by Conder (1949), who defined it widely so as to include the distance maintained between individuals in various other circumstances; but it is now most often applied to resting, or otherwise inactive, birds. Individual distance tends to be a specific characteristic; it is perhaps most obvious in gregarious birds roosting or perching together, for example on a telegraph line.

Conder, P.J. 1949. Individual distance. Ibis 91: 649–655.

INFECTION: see DISEASE.

INFESTATION: see ECTOPARASITE; ENDOPARASITE.

INFORMATION CENTRE: a phrase coined by P. Ward and A. Zahavi (following J. Fisher) to refer to the idea that birds nesting in colonies or gathering in communal roosts may learn from each other about the location of good feeding sites. The idea is that unsuccessful foragers could follow more successful individuals on their next trip. It has generated a considerable amount of data and theoretical controversy. Most of the evidence pertaining to the idea is inconclusive.

INFRA-ORDER: a systematic category between suborder and superfamily (if used) or family. The use of this category is not obligatory and the grouping of presumed families into a suborder in fact is rather subjective.

INFRA-SOUND: sounds of too low frequency to be detected by the human ear: below 20–30 Hz (waves per second). Recent experiments have shown that pigeons can detect sounds down to 0.05 Hz (1 wave in 20 s). If this proves to be common in birds, it may be related to the presence in their cochlea of a third otolith, the lagena, which has been lost in mammals. It has been suggested that natural infra-sound, which carries for very long distances, may give pigeons cues that help them in homing (see HOMING PIGEON; ULTRASOUND).

INGLUVIES: the crop (see ALIMENTARY SYSTEM).

INHAMBU: name used in Latin America for *Crypturellus* spp. (see TINAMOU).

INHERITANCE: see GENETICS.

INJURED BIRDS: see CARE OF SICK, INJURED AND ORPHANED BIRDS.

INJURY FEIGNING: see DISTRACTION BEHAVIOUR.

INNATE BEHAVIOUR: see BEHAVIOUR, HISTORY OF.

INNER TOE: see LEG.

INSECTICIDES: see TOXIC CHEMICALS.

INSECTIVOROUS: insect-eating; usually assumed to include other terrestrial arthropods.

INSESSORES: former ordinal name, applied to an assemblage of so-called 'perching birds' comprising the Passeriformes of today and various other groups.

INSHORE HABITAT: see under OCEANIC BIRDS.

INSIGHT: see LEARNING.

INSTINCT: an innate capacity for forms of behaviour that do not have to be learnt by the individual—a word falling into disuse as a scientific term because it represents an over-simplified concept and has acquired a variety of meanings.

INSTRUMENTAL SOUNDS: see MECHANICAL SOUNDS.

INTEGUMENTARY STRUCTURES: outgrowths from the skin (see SKIN). Of these the chief are feathers (see FEATHER; PLUMAGE), the rhamphotheca covering the bill, sometimes with horny excrescences or extensions such as casques and frontal shields (see BILL), the podothecae covering the feet (see LEG), and the oil gland (see OIL GLAND); these are dealt with elsewhere, as indicated. So also are the claws growing on the toes and sometimes on the digits of the manus, and the spurs that are present on the tarsus or on the carpal joint in some species (see LEG; WING). There remain to be considered various accessory structures found in certain species, especially about the head and neck; these are of several kinds. See photo BELLY-SOAKING.

Combs, Wattles, and Lappets. These are unfeathered flaps or appendages, usually of a fleshy texture and brightly coloured. Their function must lie in display and recognition; they often show sexual dimorphism; and their state may be subject to hormonal control. They are included in the general term 'caruncle'. A familiar example of a comb—an erect process situated longitudinally on the crown—is that of the domestic fowl, largest in the cock; the name derives from the serrated margin. Wattles are often pendulous from the angles of the mouth ('rictal lappets'), and there may be more than one on each side. Or they may be harder, more warty excrescences, variously situated—rictally, frontally, near the eye, or anywhere on the patches of bare skin found in some species, chiefly on the face and neck. Some of these, as with others adorning the bill, are moulted seasonally (see MOULT). Wattles are found in many species, particularly among the pheasants, turkeys, plovers, jacanas, cotingas, honeyeaters, starlings, and wattle-birds. The Turkey *Meleagris gallopavo* has a varied assortment, comprising a distensible frontal caruncle, tubercles on head and neck, and a throat wattle.

Pouches and Sacs. These are of different kinds. The gular pouches of pelicans and, less markedly, of cormorants play a part in the capture and swallowing of prey. Others are ornamental, such as the long red pouch depending from the almost naked neck of the Marabou *Leptoptilos crumeniferus*; or the inflatable sac, covered with bright red skin, on the front of the throat in male frigatebirds *Fregata* spp. Others again are concealed by feathers and are used in the production of booming calls, such as that uttered in spring by the male Prairie Chicken *Tympanuchus cupido* with the aid of two inflatable sacs on the sides of the neck.

INTELLIGENCE: a term without precise connotation for the study of bird behaviour, its place being taken by 'insight learning' (see LEARNING; also NERVOUS SYSTEM).

INTENTION MOVEMENTS: the incomplete initial phases of a behaviour pattern. For example when a bird is about to take off it crouches, withdraws its head and raises its tail, and then reverses these movements as it takes off. Such incomplete movements may be repeated several times as the bird prepares to take off, in particular if the bird is in a conflict about whether to fly or not. The primary interest of intention movements to students of bird behaviour is that they are thought to be the raw material from which some courtship and threat displays have evolved by RITUALIZATION.

INTERBREEDING: see GENETICS; HYBRID; HYBRIDIZATION, ZONE OF SECONDARY; ISOLATING MECHANISM; REPRODUCTIVE ISOLATION; SPECIATION.

INTERMEWED: term used in FALCONRY.

INTERNATIONAL CODE; INTERNATIONAL COMMISSION: see NOMENCLATURE.

INTERSPECIFIC: between two or more species.

INTESTINE: the posterior part of the gut or digestive tract, comprising the small intestine (duodenum and ileum) and the large intestine (rectum)—see ALIMENTARY SYSTEM.

INTRASPECIFIC: within a single species.

INTRODUCTION, ARTIFICIAL: see NATURALIZED BIRDS.

INTROGRESSION: gene flow between genetically divergent populations, often used technically for gene flow occurring only between species, but that usage begs the question of the exact taxonomic status of the two populations before one can employ the term, and such taxonomic determination is not always easy. In cases of avian hybridization in nature there is frequently little difference between introgression affecting species and that affecting subspecies, although theoretically greater introgession is to be expected between genetically more similar conspecific subspecies than between genetically more divergent species. One complication is that evaluation of hybridization and introgression is usually based upon a few morphological or other traits representing but a small fraction of genetic determinants which may be linked, and hence possibly biased (the fewer the characters studied the more difficult it is to appreciate actual gene flow). Other complications include intrinsic factors such as various reproductive isolating mechanisms, population structure, heterosis, selection for or against certain alien genes and gene combinations, and extrinsic factors such as topography or gene flow in one direction or another (see GENETICS; HYBRID; HYBRIDIZATION, ZONE OF SECONDARY).

Biochemical and other sophisticated techniques applied to cases involving hybridization usually disclose greater introgession than is superficially apparent from analysis of plumage and other morphological traits. Not only are different traits apt to show different degrees of introgression in a given case, but introgression may affect one population more than another. In the Northern Flicker *Colaptes auratus* of North America there is extensive hybridization between the eastern ('yellow-shafted') and western ('red-shafted') subspecies groups: traits such as shaft colour and colour of the facial moustache of males show extensive introgression into the eastern populations, whereas restriction of the nape patch shows little introgression beyond the hybrid zone. Also, the western populations show much more introgression than do the eastern populations. Other notable cases of introgression involve the Yellow-rumped Warbler *Dendroica coronata*, and the Blue-winged Warbler *Vermivora pinus* and Golden-winged Warbler *V. chrysoptera* in North America, the House Sparrow *Passer domesticus* and Spanish Sparrow *P. hispaniolensis* of Europe, and the Pale-headed Rosella *Platycercus adscitus* and Eastern Rosella *P. eximius* of Australia.

Introgression is suspected as a cause of observed variation when hybridization is known to occur between two populations, and the variation encountered shows gradients for traits within each population that involve characteristics of the other population and run toward the area of contact and hybridization between the two populations. Often the gradients in each population, with their gradual increase in characteristics of the other population toward the region of their interbreeding, run counter to all other patterns of clinal variation within each of them.

L.L.S.

INVASION: a term best reserved for an expansion of range into a new area; but sometimes used as synonymous with IRRUPTION.

IORA: substantive name of *Aegithina* spp. (see LEAFBIRD).

IRENIDAE: a family of the Passeriformes, suborder Oscines; LEAFBIRD.

IRIS: a thin, opaque annulus of tissue in front of the lens of the eye, which by its state of contraction determines the size of the aperture (pupil) in its centre (plural 'irides'; see VISION). As in reptiles, but in contrast to mammals, the musculature of the bird iris is striated.

IRIS COLORATION: often a noticeable character of the living bird at close range or of the newly dead specimen, but lost in the museum skin and not always accurately represented by the artificial eyes of mounted exhibits. The character may show SEXUAL DIMORPHISM, and changes with age and sometimes with season. Even more rapid colour changes are reported to occur in the eyes of some species, perhaps corresponding to different emotional states. Although eye colour sometimes matches the coloration of the head, possibly in order to camouflage the eye, brilliant lipochrome pigments in the irides of many birds often make the eye more conspicuous. The function of iris coloration is unclear; as in other vertebrates, the iris of birds is opaque, and its colour can apparently have no effect on vision. In different birds, eye colour may be used for sex or age recognition, in display behaviour, or simply as an integral part of the head plumage coloration.

The pigment of the iris epithelium in birds is brown, but there are nearly always stromal pigment cells (i.e. chromatophores in the stromal connective tissue of the iris) containing various amounts of melanin and/or coloured oils. The iris coloration is the result of both pigmentary factors and differential absorption or reflection by the different layers of the iris (see COLOUR); the red or reddish eyes observed in many species may be due (as in the Rock Dove *Columba livia*) more to richness of the superficial blood vessels than to pigmentation of the iris itself. On close examination, iris coloration may often be seen to be variegated and, interestingly, the iris of most birds has a black edge which may seem to make the pupil appear larger.

Among birds a brown iris coloration, resembling that found in mammals, is very common especially among song birds. In general, the irides of birds of prey are often yellow while many herons, parrots and pheasants have reddish eyes due to oil droplets of different refractions. Dark (brown or black) eyes are even reported to be especially common in birds that fly fast or feed on the wing (Worthy 1978). Despite these generalizations, however, a wide variety of colours occurs in many kinds of birds.

Some examples of birds showing various colours other than brown may be mentioned. Yellow irides are found, for instance, in most owls (Strigiformes), some 'waders' (Charadrii), some pigeons, and some herons, but also in many other groups. The Jackdaw *Corvus monedula* is a familiar example of a species in which the iris is almost white (pearl-grey in the adult). In adult Budgerigars *Melopsittacus undulatus* the iris is white peripherally, and chocolate-brown with white concentric lines in the pupillary part. In the Honey Buzzard *Pernis apivorus* a layer of guanine-containing cells in the yellow iris makes the latter appear brilliant white in reflected light.

An example of a bird in which the irides are green—a relatively infrequent colour—is the Cormorant *Phalacrocorax carbo*. Blue irides are found in, for example, the Oilbird *Steatornis caripensis*, the Blue-eyed Shag *Phalacrocorax atriceps*, the Ariel Toucan *Ramphastos vitellinus ariel*, and the Monkey-eating Eagle *Pithecophaga jefferyi*.

Many groups include red-eyed birds, e.g. rails, pigeons, grebes, herons, coucals (Centropinae), barbets, puffbirds, vireos, and mocking-thrushes; the White-winged Cough *Corcorax melanoramphos* (Grallinidae) has a bright red eye.

Sexual dimorphism in iris coloration is not infrequent. In Brewer's Blackbird *Euphagus cyanocephalus* (Icteridae), the iris is white in the male and dark in the female; whereas in two species of finfoots (Heliornithidae), it is dark brown in the male and bright yellow in the female. In the Wood Duck *Aix sponsa* the iris is orange-red in the male and dark brown in the female. A striking case is that of the Saddlebill *Ephippiorhynchus senegalensis* (Ciconiidae); the brown eye of the male tones with the dark plumage of the head, while the chrome yellow iris of the female is a conspicuous character.

Iris coloration often varies with age. The iris usually begins as blue, grey, grey-brown, brown or yellow, but in many species gradually changes after fledging to reddish-brown, brown, red, orange, yellow, white or green. These age-related changes in iris coloration in birds usually take place over a relatively short period. In the Gannet *Sula bassana*, for example, the iris is dark brown in the nestling, grey-blue in the juvenile, and nearly white—with a fine black outer ring—in the adult. In certain hawks, however, iris coloration may continue to change for several years. There may sometimes be seasonal change; for instance in the Rockhopper Penguin *Eudyptes crestatus* the colour of the iris, with that of the bill, varies from red to yellow with the seasons (see also HERON). As in fish, more rapid changes in iris coloration may sometimes accompany changes in emotional state. For example, the yellow irides of the Eagle Owl *Bubo bubo* are reported to turn red when the bird becomes agitated.

To be distinguished from iris coloration is the colour of the orbital ring of bare (sometimes hardened) skin around the eye in some species, e.g. among the cormorants, or in any circular pattern in the plumage in that position. The white-eyes (Zosteropidae) take their name from a white ring around the eye. J.T.E.

IRRUPTION: a form of MIGRATION in which the proportion of birds leaving the breeding range, and the distance travelled, varies greatly from year to year. Noted mainly in northern regions, irruptions occur in responses to annual, as well as to seasonal, fluctuations in food. Most migrations are regular, taking place at the same season each year, with individuals moving between fixed breeding and wintering areas. In irruptions, individuals may breed or winter in widely separated areas in different years. Regular migrations are associated with regular and predictable food supplies, whereas irruptions are associated with sporadic food supplies, which are much more plentiful in certain years than in others, or are plentiful in one region in one year and in a different region the next (Newton 1972). Strictly the term 'irruption' (or invasion) is applicable only to the region receiving the birds, whereas 'eruption' is often applied to the region losing them, but for general discussion it is convenient to use a single term.

Typically, irruptive species have diets based on one or two food types, which fluctuate from year to year. They include certain finches and other fruit-eating birds of boreal regions, certain raptors and owls that depend on cyclic prey, and a few steppe species, which occasionally experience extreme food shortages through drought (Table 1). All these species appear in strength in particular areas only in certain years.

Seed-eaters. The seed crops of trees vary enormously from year to year, and in some years fail completely. The cropping depends partly on the natural rhythm of the trees themselves, and partly on the weather. Most trees require more than one year to accumulate the reserves necessary to produce fruit, and crop at longer intervals towards the north, where the growing seasons are shorter. Spruce, for example, tends to crop well every 2–3 years in central Europe, every 3–4 years in southern Sweden, and less frequently further north. For a good crop, the weather must also be fine and warm in the preceding autumn when the fruit buds form, and again in the spring when the flowers set; otherwise the crop is delayed for another year. In any one area, most of the trees of a species fruit in phase with one another because they come under the same weather, and often those of a different species also crop in phase. The result is an enormous profusion of fruits in certain years, and practically none in others.

The trees in widely separated areas may be on different cropping regimes, partly because of regional variations in weather, so good crops in some areas may coincide with poor crops in others. Usually each productive area extends over thousands or millions of km^2, and is separated from the next by terrain which, in that year, is almost devoid of seeds. In some years, moreover, the productive patches are plentiful and widespread, and in others few and far between, so that the total production of seeds over a continent varies greatly from year to year.

The birds that depend on such seeds generally concentrate wherever their food is plentiful at the time. The majority of individuals migrate regularly in spring and autumn, but may breed and winter in different areas in successive years. Their local populations therefore fluctuate greatly from year to year in parallel with local seed crops. In winter quarters, too, populations range between total absence in years when appropriate tree seeds are lacking, to thousands of birds per km^2 in years when such seeds are plentiful. The bird species involved seem to move each autumn only until they find areas rich in food, then settle there. In consequence, the distance travelled by the bulk of the migrants varies from year to year, according to where the crops are good, and only when the migrants are exceptionally numerous, or their food is generally scarce, do they reach the furthest parts of their wintering range, as an irruption. Often several species irrupt in the same years, coinciding with the simultaneous failure of their respective food-plants (Bock and Lepthien 1976).

The food shortage which leads to a long and heavy migration is accentuated if the birds are especially numerous at the time. This situation is frequent, because good seed crops are usually followed by poor ones. The good crops in the first year lead to high survival among the birds over winter and to a large breeding population the next summer, and these same birds and their young then encounter the widespread poor crops in the next autumn, so have to move further than usual then. How far irruptive species move northward in spring also depends partly on how much food they meet on the way. The Mealy Redpoll *Carduelis f. flammea* provides the most striking example, for this subspecies curtails its usual migration by up to several hundred km to breed in southern Fennoscandia in years when the spruce crop there is good.

Compared with other migrants in autumn, irruptive finches tend to show more spread in their departure directions, and birds from a particular breeding area may spread over a large part of Europe on migration. Bullfinches *Pyrrhula pyrrhula* ringed in Fennoscandia have been recovered the following winter anywhere between south-west, through south, to east of their breeding place in the previous summer, and similar but less marked trends have been noted in other species. Individuals breeding or wintering in widely separated areas in different years have been confirmed by ringing. For example, one Siskin *Carduelis spinus* was found in successive breeding seasons at places 120 km apart, and 2 Mealy Redpolls were found at places 280 and 550 km apart. Wintering recoveries are even more striking, and Bramblings *Fringilla montifringilla* and Siskins have been caught in Belgium in one winter and as far east as Turkey and the Balkans in a later one. Another Siskin was ringed in Germany one February and recovered 2,200 km to the east in Russia the next, and a Bullfinch was recovered one winter in Russia 2,000 km to the west of where it had been ringed in the winter of the previous year. Three Mealy Redpolls are known to have wintered in different years at places 1,300, 1,500 and 1,800 km apart. Similarly, a Waxwing *Bombycilla garrulus* ringed in Poland one February was recovered in the next winter 4,500 km further east in Siberia, and a Cedar Waxwing *B. cedrorum* ringed in California in April was recovered in Alabama 3,000 km to the east two years later. Presumably all these birds had returned to the breeding range in the meantime, and took quite different directions in the two years.

The extent to which an irruptive finch will wander for food is well shown by the North American Evening Grosbeak *Hesperiphona vespertina*, which breeds in conifer forests and moves south or south-east in autumn. This species feeds mainly on large, hard tree-fruits, but also visits feeding trays for sunflower seeds, a habit which makes it easy to catch. Over 14 winters, 17,000 Grosbeaks were ringed at a site in Pennsylvania. Of these, only 48 were recovered at the same place in subsequent winters, yet 451 others were scattered among 17 American states and 4 Canadian provinces. Another 348 birds that had been ringed elsewhere were caught at this same locality, and these had come from 14 different states and 4 provinces. These recoveries show both how widely individual Grosbeaks range and how weak is their tendency to return to the same place in later years.

The wide wintering range, less rigid directional tendencies, and the poor homing shown by irruptive species are all ways of coping with a sporadic food supply. They contrast with the marked directional tendencies, narrow migration routes and strong homing shown by birds which feed on more predictable food supplies.

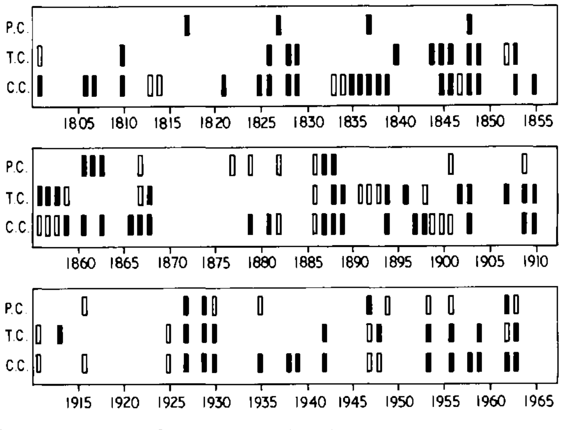

Fig. 1. The dates of crossbill invasions into south-west Europe. Filled blocks show large invasions, open blocks small ones. P.C., T.C. and C.C. refer to Parrot Crossbill *Loxia pytyopsittacus*, Two-barred Crossbill *L. leucoptera* and Common Crossbill *L. curvirostra*.

The most famous of the irruptive migrants are the crossbills, which feed almost entirely on conifer seeds, and leave the boreal region in large numbers only in exceptional years. Between 1800 and 1965, Common Crossbills *Loxia curvirostra* irrupted into south-west Europe at least 67 times; sometimes they came in successive years, and at other times at intervals up to 11 years (Newton 1972). Parrot *L. pytyopsittacus* and Two-barred Crossbills *L. leucoptera* often came in the same years as Common Crossbills, though less frequently. The ultimate cause (adaptive value) of mass emigration is presumably to avoid food shortage on the regular range, but while some authors have speculated that food shortage is the proximate factor releasing the flight (Svärdson 1957), others believe that over-population and crowding present the stimulus to leave (Lack 1954). The hypothesis that best fits the facts is that high numbers are necessary for eruptive migrations of crossbills, but the size of the food crop modifies this (Newton 1972). Once the population is high, emigration probably occurs in response to the first inadequate crop, and only an exceptionally good crop over a wide area will prevent the flight.

Once on the move, some birds reach the extreme south-west of Europe, some 4,000 km from their breeding range. Such mass movements by crossbills were formerly regarded as 'death-wanderings', because most birds failed to find areas of suitable food. However, ringing has now confirmed that some individuals return successfully to the boreal forests in a later year. Moreover, those emigrants which find areas with conifers often stay for a year or two and breed, if the cone crops permit.

In many irruptive species, the young predominate in invading flocks, and among the adults females outnumber males. This has given rise to the ideas (a) that irruptions follow good breeding seasons, (b) that the young emigrate in greater proportion than the adults, and (c) that more adult hens than cocks leave. In general, this is probably true, as in many regular migrants, but recent information on the composition of irruptive flocks is conflicting. While some certainly contain a high proportion of young, others do not, suggesting that not all movements follow good breeding. Some authors have suggested a cyclic rhythm to the irruptions of seed-eating species, but in most cases there is little evidence for this. This is in contrast to the owls and raptors discussed below.

Owls and raptors. Irruptive movements are known from those species which feed on cyclic prey, mass emigration occurring in the 'low' years, when prey are scarce (Newton 1979). Two main cycles are recognized: (a) an approximately 4-year cycle of small rodents on the northern tundras and temperate grasslands; and (b) an approximately 10-year cycle of Snowshoe Hares *Lepus americanus* in the boreal forests of North America. Some grouse-like birds are also involved, but whereas in some regions they follow the 4-year rodent cycle, with peaks in the same years, in others they follow the 10-year hare cycle. The populations of these various animals do not reach a peak simultaneously over their whole range, but the peak may be synchronized over tens or many thousands of km^2. Why such prey species fluctuate with fairly regular periodicity is uncertain, but there is no question that they cause mass movements by their avian predators. Among owls and raptors, the majority of individuals stay in the north of the wintering range in years when prey is plentiful there, and move further south in years when prey is scarce. As in the finches, the food shortage caused by a crash in the prey population is often accentuated because the predators themselves tend to be numerous at such times, as a result of good breeding and survival in the previous few years, when prey was abundant.

The main invasions by the Rough-legged Buzzard *Buteo lagopus* occur at about 4-year intervals, whereas those of the Goshawk *Accipter gentilis* in North America occur roughly every 10 years, corresponding with the 4-year and 10-year prey cycles respectively. Invasions may occur in only one autumn, or in two successive ones if prey remains sparse. Invasions by Rough-legged Buzzards often occur in the same years as those by Snowy Owls *Nyctea scandiaca* (both species eat rodents), while in parts of North America the invasions by Goshawks show a similar periodicity to those by Horned Owls *Bubo virginianus* (both eat hares and grouse). Since the lows in prey populations are not synchronized over the whole range, invasions by any one species tend to come in different years in different regions. Those by the Rough-legged Buzzard and Snowy Owl are also more marked in North America than in Europe, presumably because the birds are more numerous in North America, having a greater area of breeding habitat (tundra) on that continent.

Some Irregular Migrants of the Northern Hemisphere	*Preferred Food*	*Distribution*
SEED-EATERS		
Great Spotted Woodpecker *Dendrocopos major*	Spruce, Pine and other seeds	Palearctic
Waxwing *Bombycilla garrulus*	Berries, especially Rowan	Holarctic
Cedar Waxwing *B. cedrorum*	Berries	Nearctic
Pine Grosbeak *Pinicola enucleator*	Conifer seeds, berries	Holarctic
Fieldfare *Turdus pilaris*	Berries	Palearctic
Coal Tit *Parus ater*	Spruce seeds, insects	Palearctic
Black-capped and Boreal Chickadees *Parus atricapillus* and *P. hudsonicus littoralis*	Various seeds, insects	Nearctic
Nuthatch *Sitta europaea* (Siberian populations)	Spruce seeds	Siberia
Red-breasted Nuthatch *S. canadensis*	Pine, Spruce seeds	Nearctic
Brambling *Fringilla montifringilla*	Beech seeds	Palearctic
Siskin *Carduelis spinus*	Birch, Alder and Conifer seeds	Palearctic
Pine Siskin *Carduelis pinus*	Conifer, Birch and Alder seeds	Nearctic
Northern Bullfinch *Pyrrhula pyrrhula*	Various tree-seeds and berries	Palearctic
Evening Grosbeak *Hesperiphona vespertina*	Maple and other tree-seeds	Nearctic
Redpoll *Carduelis flammea*	Birch seeds	Holarctic
Arctic Redpoll *C. hornemanni*	Birch seeds	Holarctic
Purple Finch *Carpodacus purpureus*	Various tree-seeds	Nearctic
Crossbill *Loxia curvirostra*	Spruce and other Conifer seeds	Holarctic
Two-barred Crossbill *L. leucoptera*	Larch and other Conifer seeds	Holarctic
Parrot Crossbill *L. pytyopsittacus*	Pine seeds	Europe
Jay *Garrulus glandarius*	Oak fruits	Palearctic
Thick-billed Nutcracker *Nucifraga caryocatactes macrorhynchos*	Hazel fruits	Scandinavia
Thin-billed Nutcracker *N. c. caryocatactes*	Arolla Pine seeds	Siberia
Clark's Nutcracker *N. columbiana*	Whitebark Pine and other Conifer seeds	Nearctic
RAPTORS AND OTHER PREDATORS		
Goshawk *Accipiter gentilis*	Various Grouse and Hares	Palearctic
Rough-legged Buzzard *Buteo lagopus*	Lemmings, Voles	Holarctic
Snowy Owl *Nyctea scandiaca*	Lemmings, Voles	Holarctic
Horned Owl *Bubo virginianus*	Varying Hares	Nearctic
Short-eared Owl *Asio flammeus*	Voles	Holarctic
Great Grey (or Northern) Shrike *Lanius excubitor*	Voles	Holarctic
STEPPE BIRDS		
Pallas's Sandgrouse *Syrrhaptes paradoxus*	*Agriophyllum gobicum*	Central Asia
Rosy Pastor *Sturnus ('Pastor') roseus*	Locusts (in breeding season)	Turkestan

Many individual raptors must winter in widely separated areas in different years, as in the finches. On their breeding grounds, too, some rodent-eating species concentrate to breed wherever food is plentiful at the time, so that their local populations fluctuate greatly from year to year. This implies that at least some individuals breed (as well as winter) in widely separated areas in different years. So far, however, ringing recoveries of owls and raptors lend no support to this idea because they nearly all refer to birds handled only once as adults.

Steppe species. The Rosy Pastor *Sturnus roseus* is a regular migrant to India from the Asian steppes, but it is sporadic in its breeding, as thousands of birds may settle in a suitable locality, breed and then desert it again. It feeds its young on locusts, and its irruptions occur in spring and early summer, presumably on occasions when it returns on its normal spring migration to find a failure of the locust hatch. The movements of Pallas's Sandgrouse *Syrrhaptes paradoxus* are probably caused by prolonged drought. Major invasions of sandgrouse into western Europe occurred in 1863, 1872, 1876, 1888 and 1908, and there have been a few other occurrences. Breeding was recorded in Britain in 1888–89 following an irruption.

It seems probable that irregular migration is far more widespread than is generally supposed. There is every gradation between irruption and conventional migration, and even species which are normally fairly sedentary perform irruptive movements on occasion. Unexpected movements of this type have been noted, for example, among Blue Tits *Parus caeruleus* and Bearded Tits *Panurus biarmicus*. They tend to occur when the birds are especially numerous, or in obvious imbalance with their food-supply. I.N.

ISCHIUM: a paired bone of the pelvic girdle, partly fused with the other elements (see SKELETON, POST-CRANIAL).

ISLAND BIOGEOGRAPHY: see DISTRIBUTION, GEOGRAPHICAL.

ISOCHRONAL LINE: a line joining geographical localities at which the same event occurs simultaneously; applied, notably, to the mean date of arrival of a given migratory species (see MIGRATION).

ISOLATING MECHANISM: a difference between species, or populations of a species, that tends to prevent cross-mating and so to maintain reproductive isolation; such differences are often in factors concerned in recognition, i.e. in appearance (plumage) or behaviour (display, voice). An isolating mechanism is said to be 'specific' when it is adaptively built up between two populations that are genetically capable of interbreeding and of producing fertile hybrids; this can occur only when there is some contact between the two populations, with the production of hybrids that are at a selective disadvantage as compared with the parent stocks. Such specific isolating mechanisms often play an important part in speciation (see SPECIATION; also HYBRID; HYBRIDIZATION, ZONE OF SECONDARY; RECOGNITION; REPRODUCTIVE ISOLATION; VOCALIZATION).

ISOPHENE: a geographical line along which a character of a polytypic species has the same value; 'a line of equal phenotype'. Isophenes run roughly at right angles to the direction of a CLINE.

ISOTHERM: a line connecting points of equal air temperature (commonly in terms of the mean temperature for a stated day or month of the year)—see WEATHER AND BIRDS.

ITALICS: as regards their use in printing scientific names of birds (represented by single underlining in manuscript or typescript), see NOMENCLATURE.

ITINERANT BREEDING: a series of breeding attempts by the same individual in two or more different geographical areas during the course of the same annual reproductive period, and recurring year after year as a normal event in the annual cycle of the species. The seasonal movement between the successive breeding areas has been termed the 'breeding migration'.

Conclusive proof of itinerant breeding, e.g. from ringed individuals, is still lacking but circumstantial evidence points to its occurrence in several tropical and temperate species. The phenomenon was first recognized in the European Quail *Coturnix coturnix*, where females arriving in Italy in June and July, apparently to breed, often showed regressing incubation patches from a recent breeding attempt and were frequently accompanied by young no more than 2 months old. These young must have hatched from clutches begun in March but at so early a date breeding could have been possible only in North Africa. Reports of a general exodus of Quail from Tunisia in spring after breeding support this and birds ringed there in May and early June have been recovered in Italy and Albania 2–3 months later. It has been suggested that late clutches laid in Britain and northern Europe in August and September could result from an influx in midsummer of birds that have already bred around the Mediterranean.

Among tropical species the most suggestive evidence for itinerant breeding is for the Red-billed Quelea *Quelea quelea* of Africa. The different races of queleas perform migrations whose patterns are determined by the movements of rainfronts across the continent. The birds congregate during the dry season in certain areas where they subsist on the dry grass seed produced during the previous rains. When the next rains break, however, this abundance of dry seed suddenly germinates and is unavailable as food, forcing the birds to leave the area. Queleas are normally able to perform an 'early-rains migration' to areas over which the rainfront has already passed some two months previously and where the new grass has already set seed. The new seed and insects associated with the growing vegetation enable some birds to begin their first breeding attempt straight away, while others begin the slow return movement, the 'breeding migration'. This follows the course taken by the rainfront at the start of the wet season, in the wake of which is now developing a 'front' of seeding grasses. By remaining within this slowly shifting zone of seeding grass all birds soon reach breeding condition, halt the migration, and establish colonies. Feeding conditions suitable for rearing young do not last long, however, and despite an abbreviated breeding schedule of only 5 weeks, there is not time to rear 2 broods in the same place. The adults abandon the young at 3 weeks old with enough fat reserves to ensure their survival, and continue the 'breeding migration'. On catching up once more with the zone of seeding grasses it is thought that the adults can begin a second breeding attempt, perhaps some hundreds of km from the site of the first, and almost certainly with a different mate.

The evidence is circumstantial but compelling; many females begin developing the yolks of a second clutch while still feeding the first brood, yet do not breed again in the vicinity, and in those regions where colonies are likely to contain a majority of birds breeding for the second time on the 'breeding migration', most adults arrive in already very worn plumage, consistent with a previous breeding attempt. In West and southern Africa there is time in wet years for up to 3 broods to be raised in different places along a 'breeding migration' and in East Africa up to 5, though it is unknown if these maxima could often be achieved.

It is likely that itinerant breeding will be found amongst other birds living in seasonal environments which offer local opportunities for breeding for too limited a period for more than one brood to be reared. Such species may nevertheless be multibrooded if, by performing a 'breeding migration', they can utilize in turn adjacent regions that become suitable at different times during the annual reproductive period. Prerequisites for such a breeding strategy would be a short breeding schedule with early independence of the young. Species that require a long period of territorial establishment, or which undertake prolonged postfledging parental care, would not be expected to be itinerant breeders. P.J.J.

J

JABIRU: *Jabiru mycteria* of South America; in the Old World the name is sometimes applied to the Saddlebill *Ephippiorhynchus senegalensis* or the Black-necked Stork *E. asiaticus*. For all these species of Ciconiidae see STORK.

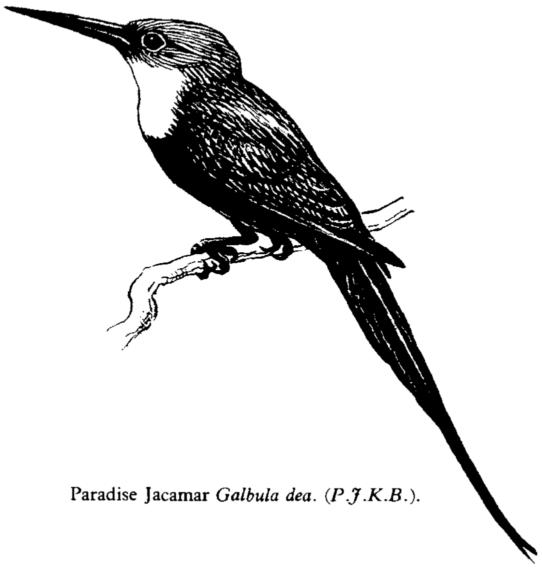
JACAMAR: substantive name of species of Galbulidae (Piciformes, suborder Galbulae): in the plural, general term for the family. This consists of 5 genera and 15 species of small or middle-sized birds (15–31 cm long).

Characteristics, distribution and habitat. Jacamars are confined to the wooded regions of continental tropical America, chiefly at low altitudes. Jacamars have long, pointed, usually slender bills. Their legs are short, and in the 4-toed species 2 toes are directed backward. The inner hind toe of the Three-toed Jacamar *Jacamaralcyon tridactyla* has been lost. The more typical species have glittering metallic plumage and, with their long, thin bills, are reminiscent of overgrown hummingbirds. Perhaps even more than hummingbirds, they seem charged with vitality and intensely alive. They are among the most exciting of all birds to meet.

One of the most widespread and familiar members of the family is the Rufous-tailed Jacamar *Galbula ruficauda*, which ranges from southern Mexico to north-eastern Argentina. Its upper plumage, including the wings and central feathers of the long tail, is glittering metallic green, over which play golden, coppery, and bronzy glints. A broad green band across the chest separates the white throat from the rufous-chestnut of the posterior underparts and the outer tail feathers. The female differs from the male only in having the throat pale buff instead of white. In both sexes, the long, sharp bill is black. *Galbula*, the largest genus, contains 7 other species, including the lovely Paradise Jacamar *G. dea*, distinguished by narrow, greatly elongated central tail feathers.

The stoutest member of the family is the Great Jacamar *Jacamerops aurea*, a long-tailed bird (in all 30 cm in length) that ranges from Costa Rica to the Amazon valley. The top of the male's head is bright metallic green, which merges into rich metallic golden or reddish-bronze on the back and shoulders; this in turn becomes bright golden-green on the rump and central tail feathers. The outer tail feathers are violet–blue. The sides of the head and upper throat are metallic green, the lower throat is white, and the remaining under plumage is rufous-tawny. The female is like the male, except that her throat is tawny instead of white. The black bill is only moderately long and slightly curved.

A less graceful and glittering member of the family is the Chestnut Jacamar *Galbalcyrhynchus leucotis* of Amazonia. Its plumage is largely dark chestnut, with white or chestnut ear coverts. A long, thick, pink or whitish bill and short tail give it a topheavy aspect. Plainest and smallest of the jacamars are the 4 species of *Brachygalba*, which have largely brown or dusky plumage with white on the under parts, short tails, and long, sharp, usually black bills.



Paradise Jacamar *Galbula dea*. (*P.J.K.B.*).

Food. Jacamars appear to be wholly insectivorous and, at least in the best-known genera, *Galbula* and *Brachygalba*, their prey is captured on the wing. They rest on an exposed perch, turning their heads from side to side, until they spy a suitable flying insect, which they overtake by means of a rapid sally. Morphos and large swallow-tails *Papilio*, which most flycatching birds eschew, are often captured by jacamars. With the victim fluttering in its slender bill, the captor returns to its perch, against which it beats the insect long and loudly until the brilliant wings flutter earthward, after which the body is swallowed. Skipper butterflies (Hesperiidae), dragonflies (Odonata), wasps and bees (Hymenoptera), beetles (Coleoptera), and other insects are also captured in large numbers; heliconian butterflies (Heliconiinae) are avoided. The feeding habits of jacamars have been compared to those of Old World bee-eaters.

Voice. The Rufous-tailed Jacamar is a voluble bird whose sharp calls, sounding afar through the woodland, suggest that it lives at a high pitch of excitement. When mated birds are together, and especially when two males compete for a female, their animated vocal performances include an accelerated series of high-pitched notes that may merge into a prolonged, clear, soft trill. The Pale-headed Jacamar *Brachygalba goeringi* has a similarly elaborate song, but in a weaker voice. At their best, jacamars' songs are delightfully melodious.

Behaviour and breeding. Solitary rather than colonial, jacamars nest chiefly in burrows, which they dig in roadside or streamside banks, in steep wooded hillsides, or in the wall-like root-plate of a great fallen tree. Breeding in cavities in termites' nests has been observed in the Great Jacamar and several species of *Galbula*, including the Rufous-tailed Jacamar, which usually nests in earthen burrows. Both sexes of this species loosen the soil with fine-pointed bills, and remove it from the tunnel by kicking vigorously backwards as they enter. The Rufous-tailed Jacamars' burrows range from about 28–50 cm in length. At the inner end, they dilate into a chamber that is not lined. The same burrow may be occupied in successive years.

The Rufous-tailed Jacamar lays 2–4 white, glossy eggs. Few records are available for other species. The Rufous-tailed female incubates through the night, and by day she and her mate sit alternately. Intervals of neglect are short, and the eggs are almost constantly attended. While sitting, the parents regurgitate many shards of beetles and other chitinous parts of insects, which accumulate on the floor of the chamber. The incubation period is 20–23 days.

In contrast to the perfectly naked nestlings of most piciform birds, newly hatched jacamars bear copious, long, whitish down. Their heels are covered with prominent callous pads that are nearly smooth instead of strongly papillate like those of woodpeckers, toucans and other birds that breed in unlined holes in trees. Both parents bring the young a variety of insects, but they fail to clean the nest. As they grow older, the loquacious nestlings repeat weak-voiced versions of their parents' calls, including pleasant little trills.They leave the burrow when from 19 to (in wet weather) 26 days of age, wearing plumage much like that of adults of the same sex. Fledgling Rufous-tailed Jacamars seem never to return to their natal burrow; but 4 juvenile Pale-headed Jacamars continued for several months to return each evening to sleep with both parents in their 79 cm-long burrow in a vertical bank. JACANA: name applied to species of the Jacanidae (Charadriiformes, suborder Charadrii). African and Australian forms are also called lily-trotters or lotus-birds. The name Jacana is an Anglicized form of the Portuguese name 'jaçaná' a transliteration of a native Brazilian name for the bird. The precise systematic relationship of the Jacanidae to the other Charadrii is not clear. Superficial resemblances to the Rallidae are due to convergence.

African Jacana *Actophilornis africanus.* (*C.E.T.K.*).

Characteristics. Conspicuous adaptations for walking on floating vegetation include long, mostly bare tibia and extremely elongated toes and nails. Jacanas are of moderate size (16.5–53 cm). Adult Northern Jacanas (*Jacana spinosa*) weigh only 80–170 g, but their feet cover an area as large as 12 × 14 cm. In the Northern Jacana sharp spurs on the wrist commonly reach 16 mm; other jacanas also have carpal spurs or knobs. In breeding populations Northern Jacana females average 161 g while males average only 91 g. Sexes are monochromatic in all species. The plumage is basically dark reddish or blackish-brown. Five species have white or pale yellow on lower neck, throat and head. Several have pale yellowish primaries and secondaries. The African Jacana *Actophilornis africanus* reportedly moults its flight feathers simultaneously, but the Northern Jacana has a gradual moult and is never flightless. Several species have fleshy frontal shields and/or lappets. The downy chicks are striped.

Habitat. Jacanas are never found on salt water. All species establish territories and breed on floating, low profile, aquatic vegetation in swamps, marshes, and along streams. In addition to feeding in their territories they may feed in dense emergent aquatic vegetation, wet meadows and short-grass uplands. Outside the breeding season jacanas may form flocks of up to several hundred birds that feed in meadows, irrigated farmland or other wet areas.

Distribution. This circum-tropical family occasionally extends into the sub-tropics (Houston, Texas; Peking). Jacanas are found from sea-level to 2,400 m in Kenya, 3,600 m in outer Himalayas. The African Jacana occurs throughout sub-Saharan Africa; *A. albinucha* is found only on Madagascar. The Lesser Jacana *Microparra capensis* is found in eastern Africa. The Bronze-winged Jacana *Metopidius indicus* occurs from India through south-eastern Asia, while the Pheasant-tailed Jacana *Hydrophasianus chirurgus* is found from Pakistan east into south-east Asia, southern China, Taiwan, and the Philippine Islands. The Comb-crested Jacana or Lotus-bird *Irediparra gallinacea* occurs in Indonesia and Australia. The Northern or American Jacana, which occurs from western Panama northward into Mexico, southern Texas and the Caribbean Islands, is regarded by some as conspecific with the Southern or Wattled Jacana *Jacana jacana* found from western Panama south to northern Argentina.

Populations. Local breeding populations vary from one pair to several hundred. Territory sizes vary depending on the quality and shape of habitat. Territories along streams tend to be linear. Territories of the Northern Jacana average 0.15 ha for males and 0.35 ha for females.

Movements. No regular migrations or patterns of movement have been reported. In some areas jacanas occupy territories year-round and breed in any month. In areas with prolonged dry seasons movement to permanent wet lands must occur but no detailed reports are available. In western Costa Rica flocks of 200 to 300 jacanas arrive on the breeding marshes at the beginning of the season; absence of reports of regular movements suggest these are local birds.

Food. Jacanas feed primarily by gleaning insects from floating vegetation. They also take small frogs, fish and invertebrates from just beneath the surface. Sometimes they turn rooted, floating plants upside down and remove invertebrate prey from amongst the roots. Stomach contents often include plant matter. Northern Jacanas occasionally feed on the ovules of water-lilies.

Behaviour. Four species of jacanas are polyandrous. Mating systems in the other species remain unknown. In the Northern Jacana, the best-known species, males defend small territories from which they exclude all other males. Females defend the territories of one to four adjacent males (polyandrous populations average 1.8–2.4 males per female). The pair co-operates in excluding intruders of both sexes, but the small males cannot exclude persistent females without help. Where jacanas breed year-round, both sexes are replaced by new birds on an individual basis. Deserted territories are promptly occupied by new, previously non-breeding birds. Neighbouring females sometimes take over an abandoned male and his territory. A new female that attacks and drives a territory owner from her territory is invariably larger than the female she replaces. Where Northern Jacanas breed seasonally, courtship and territory establishment occur simultaneously. Initial bonding occasionally occurs between one female and two adjacent males; additional males settle next to existing pairs or interpolate themselves between existing territories and become bonded to the already established females. In continuously breeding populations young sometimes stay on parental territory for more than a year. Where the marsh dries, young and adults leave when the chicks are 4–5 months old.

Over short distances the flight appears slow and laboured, with the feet dangling. Sustained flight is stronger and smoother with the legs extending out behind. Although capable of swimming, adult African and Northern Jacanas climb out of water as soon as possible. Small chicks of the Lotus-bird regularly dive beneath the surface to hide from predators.

Voice. Northern Jacana chicks give simple peeps similar to domestic chicks. Adults produce a relatively soft call consisting of very short, wide-frequency notes clustered in repeated groups of 3 to 4 notes. This call is used in non-threatening situations. In response to intruders or predators, adults produce a wide variety of squawks and calls that vary greatly in duration and inter-note interval.

Breeding. Breeding continues throughout the rainy season and may be year-round under uniformly wet conditions. Where they occupy territories, year-round bonds between females and their one to four males persist. Where suitable breeding sites are occupied only during the rainy season, new bonds are established each year. Courtship consists primarily of female aggression and male submission and is relatively subtle. Pre-copulatory displays include calling, posturing, nest building, wing raising and other conspicuous acts. Nests are built on floating vegetation, and construction by the Northern Jacana is primarily by the male. He grasps aquatic vegetation in his bill and either tosses it over his shoulder or backs up over the nest site where he drops it. Material is packed in place with the feet. Nests vary but are usually flimsy. Incubation is by the male and lasts 28 days in Northern Jacana. The clutch of 4 eggs is laid on consecutive days in the nest of one male. The eggs are glossy with dark markings on a brownish or bronze background, unmarked in Pheasant-tailed Jacana. The female may start laying a replacement clutch or a clutch for one of her other males 7 days after completing the first clutch. A polyandrous female Northern Jacana may copulate with all her mates in less than half an hour, but she does not copulate with a male who is incubating or caring for young chicks. Although females feed in and help defend the territories of all their males they do not necessarily visit every male every day. In the Pheasant-tailed Jacana similar interactions occur between the sexes and they are probably also simultaneously polyandrous. Bronze-winged and African Jacanas are less well known, but polyandrous mating groups have been reported. Mating systems in other species are not known, but the larger female size suggests polyandry.

Male Northern Jacanas usually provide all direct care for chicks. Male African, Northern and Comb-crested Jacanas all pick up young chicks

between the wings and body to shelter them from heavy rains. African and Comb-crested males also carry chicks under their wings. In the Northern Jacana the female occasionally broods the young. While the male is away feeding, females often stay near chicks where they can detect potential predators. The precocial chicks develop slowly and are dependent on the male for 3–4 months. Young chicks feed when accompanied by their male parent and may actually starve in his absence.

JACANIDAE: see under CHARADRIIFORMES; JACANA.

JACKASS, LAUGHING: alternative name of the Kookaburra *Dacelo novaeguineae*, while the Blue-winged Kookaburra *D. leachii* is sometimes called the 'Howling Jackass' (see KINGFISHER).

JACKDAW: *Corvus monedula*; also applied to one related species (see CROW (1)). See photos CARE OF SICK, INJURED AND ORPHANED BIRDS.

JACOBIN: substantive name of *Florisuga mellivora* and *Melanotrochilus fuscus* (for family see HUMMINGBIRD).

JAEGER: substantive name, in American usage, for skuas of the genus *Stercorarius* (as contrasted with *Catharacta*—not separated by all authors)—see SKUA.

JAW: see BILL; SKULL.

JAY: substantive name of many species of Corvidae, in various genera; used without qualification, in Britain, for *Garrulus glandarius* (see CROW (1)). 'Blue Jay' is a misnomer in India for *Coracias benghalensis* (see ROLLER). For 'jay-thrushes' (*Garrulax*) see BABBLER. See photo BROODING.

JERY: substantive name of *Neomixis* spp. (see BABBLER).

JESS: term (plural 'jesses') used in FALCONRY.

JEWELFRONT: substantive name of the HUMMINGBIRD *Polyplancta aurescens*.

JIZZ: combination of characters which identify a living creature in the field, but which may not be distinguished individually. A word coined by T.A. Coward (1922. Bird Haunts and Nature Memories. London).

JOURNALS: see ORNITHOLOGICAL SOCIETIES.

JUGAL: a paired bone of the SKULL.

JUGGING: sleeping place of Partridge *Perdix perdix*, where they jug or nestle together; also used of their call when jugging (Oxford English Dictionary).

JUGULUM: the foreneck (see TOPOGRAPHY).

JUNCO: substantive name of *Junco* spp. (see BUNTING).

JUNGLE BABBLER: substantive name of the tribe Pellorneini (see PASSERIFORMES; BABBLER).

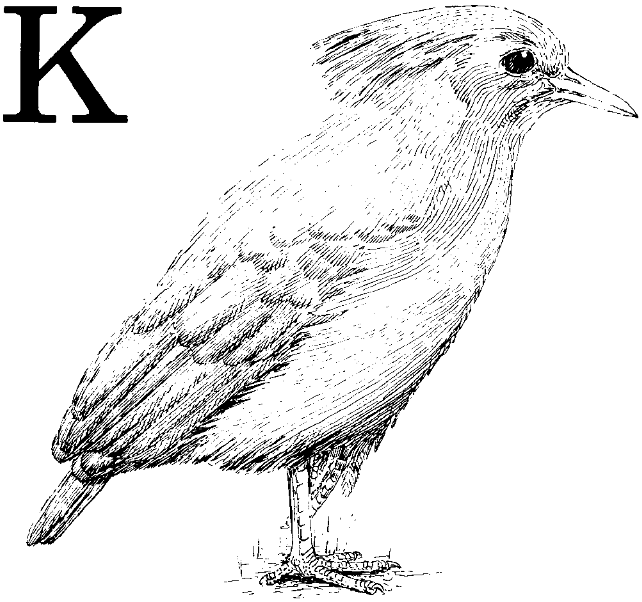
JUNGLEFOWL (1): substantive name of *Gallus* spp. (see PHEASANT; DOMESTICATION).

JUNGLEFOWL (2): name used in Australia for *Megapodius freycinet*; in the plural, serves as a general term for this and allied genera (some also called 'scrubfowl')—see MEGAPODE.

JUVENAL; JUVENILE: term of which the first spelling is usual in America, the second in Britain (see under YOUNG BIRD).

JYNGINAE: see under WOODPECKER.

K



Kagu *Rhynochetus jubatus*. (*C.J.F.C.*).

KAGU: native name, adopted as English, for the monotypic species *Rhynochetos jubatus* endemic to New Caledonia and sole member of the Rhynochetidae (Gruiformes, suborder Rhynocheti). Although some have considered it close to the Ardeidae, it is probably more closely allied to the Eurypygidae (see SUNBITTERN) or to some other gruiform group (Sibley 1972).

Characteristics. The overall colour is slate grey but there is a conspicuous pattern of white, reddish and black bars on the broad, rounded wings (length 29 cm) which is visible when they are spread. The head has a long loose crest which is raised during threat displays. The powerful bill (length 6.3 cm) is slightly decurved and reddish-orange. The reddish-orange legs and feet are strong, enabling it to run fast. Although flightless, the bird is able to glide down slopes. The sexes are alike but females weigh less than males. The total length is about 60 cm.

Habitat. The few hundred remaining birds survive in forests which have well developed undergrowth. These are found mainly in the central mountains on the eastern (wetter) side of the island, between 400 and 1,000 m, often close to rivulets. Only occasionally is the Kagu found in primary forest and in savanna.

Food. The Kagu eats invertebrates, particularly earthworms. It searches for food by tapping the surface of the ground. When a food item is located under the soil, the Kagu digs it up using its strong bill.

Behaviour. Birds move in loose flocks in search of food. Prior to breeding, prs move to higher altitudes. Contrary to earlier reports, the Kagu is active during the day and is only nocturnal when incubating. It has a characteristic habit of running rapidly and then standing motionless; captive birds have been observed whirling round holding the tip of the tail or wing in the bill, but the significance of these antics is unknown.

Voice. The Kagu has a variety of harsh, rattling call notes and, in addition, a powerful and solemn predawn 'song' which is a beautiful, melodious succession of notes and pauses; the female answers the male's song.

Breeding. The nest consists of a thin layer (10 mm) of dead leaves carefully placed on the ground. Occasionally 3 or 4 active nests per ha have been ocated. The single egg has red-brown and grey blotches on a yellow or creamy ground colour. Eggs are laid in the drier months (May to December); the incubation period is 35 days. The downy young is cryptically marked with black and yellow streaks. The young bird is strong enough at 15 days of age to run rapidly for short distances, and shows some independence in about the 10th week of life when it has half the body weight of an adult (about 900 gm); but the semi-dependent phase lasts until the 14th week or even later. At this age young birds compete partially with the parents for food and the latter begin to be aggressive towards their progeny. Family units break up when the young Kagu is between 6 and 12 months old. Young Kagus defend a territory and seek a mate when they are about 2 years of age.

KAKA: Maori name used for *Nestor meridionalis* (see PARROT).

KAKAPO: alternative name (Maori) of the Owl Parrot *Strigops habroptilus* (see PARROT).

KAKARIKI: substantive name used for the *Cyanoramphus* spp. (Psittacinae, Platycercini) (see PARROT).

KAKELAAR: alternative name of *Phoeniculus purpureus* (see WOODHOOPOE).

KALIJ: substantive name of some *Lophura* spp. (see PHEASANT).

KEA: Maori name used for *Nestor notabilis* (see PARROT).

KEEL: the carina of the sternum (see SKELETON, POST-CRANIAL; and CARINATE).

KERATIN: the main structural protein found in the horny parts of the skin, scales, beaks and feathers of birds. It is also found in the skin and epidermal structures of mammals, reptiles and to a lesser extent lower vertebrates. There are two main types of avian keratin: hard keratin, found in claws, beaks and feathers, and soft keratin, found in the skin. Most research into avian keratin has used hard keratin, especially feathers.

Structure. Keratin is a generic name for several groups of closely related proteins which are characterized by their strength, flexibility and resistance to most common solvents and proteolytic enzymes. Avian hard keratins are extremely small and light; they comprise chains of about 100 amino acids, and have molecular weights (MWs) of *c.* 10,500 daltons (feather keratins) or 14,500 daltons (beak and claw keratins). By comparison, mammalian hard keratins are larger and much more variable; they are usually divided into two main groups, one with a high sulphur content and MWs of 10,500–28,000 daltons and the other with a low sulphur content and MWs of 45,000–50,000+ daltons. Reptile scales appear to be made up of two layers, one mammal-like and the other avian-like, with MWs in the range 10,000–85,000 daltons. All hard keratins are unusually rich in the di-amino acid cystine, which comprises two molecules of the amino acid cysteine. The strength and relative insolubility of keratin structures are due to the formation of strong disulphide bonds between the cysteine molecules in adjacent keratin chains. Sections of feathers studied using the electron microscope show an ultrastructure of parallel rod-like microfibrils in an amorphous matrix. The best model for the molecular structure of feather keratin suggests that the central third of each keratin molecule is folded into a pleated sheet, and that two chains of these pleated sheets are wound helically around a central axis, forming the microfibrils seen with the electron microscope. The ends of the keratin molecules (the other two-thirds) contain most of the cysteine amino acids and are believed both to form the amorphous matrix of the feather structure and to be the sites of the inter-molecular disulphide bonds.

Development and keratinization. Keratin is not detectable in chicken embryonic feathers until about the 12th day of incubation, by which stage the feathers are nearing completion of their morphological development. Keratins rapidly then become more abundant and account for most protein synthesis in the feather at 14 days. By 19 days nearly all the protein present in the feather is keratin. The onset of keratinization and the rate of its progress appear to be limited by the amount of keratin messenger-RNA (mRNA) in the embryonic feather cells. Keratinization begins within the cell cytoplasm with the formation of bundles of microfibrils which increase in size until they start to coalesce. Other cellular materials are then reabsorbed from the cells and the bundles finally pack together, trapping a certain amount of cellular debris in the matrix as the cell shrinks and dehydrates. The fully keratinized cell is a totally dead, solid structure.

Heterogeneity. Feather keratins are usually made soluble for chemical analysis by reducing (breaking) the disulphide bonds with thioglycollic acid and preventing them reforming with iodoacetic acid, giving *S*-carboxymethyl keratin (*S*CMK). Using electrophoretic techniques the *S*CMK produces a pattern with many bands showing it to be a complex mixture of many different *S*CMK molecules (monomers). There is good evidence that each *S*CMK monomer is a separate gene product; up to 35 different types have been found in many of the feather keratin electrophoretic patterns examined. This agrees well with an experimental estimate of 25–35 keratin mRNAs in chick embryonic feathers. There are believed to be 100–240 keratin genes in the whole chick genome. Such a multiplicity of genes probably arose following repeated duplication of an ancestral keratin gene and a subsequent slight divergence in the sequence of the coding nucleotides in the original DNA and the resulting copies. This has given rise to a large family of slightly different genes, each producing a slightly different protein. Some of the protein amino acid sequences within a species differ by only one in the hundred or so amino acids that make up the keratin monomers. Different parts of each feather (e.g., rachis, barbs) contain different subsets of the complete pool of keratin monomers and therefore give different electrophoretic patterns, but the way these monomers combine to produce the complex structure of a feather is unknown. Corresponding parts of different feathers of the same main type (e.g., flight, contour) from the same bird share the same subsets of *S*CMK monomers, and there is little or no intra-specific variation in electrophoretic patterns of *S*CMK from comparable feather parts from different individuals. However, using techniques of adequate resolution, differences have been found between all the species and some of the subspecies examined so far. These differences are of use in taxonomic studies. For example, analysis of *S*CMK electrophoretic patterns has been used to investigate the relationships of the African *Halcyon* kingfishers, suggesting, among other things, that the morphological similarity between *H. chelicuti* and *H. pyrrhopygia* is probably due to convergence and that the former is more closely related to the *H. albiventris–leucocephala–pileata* subgenus. Other studies have shown that *Bonasa bonasia* and *B. umbellus* (Tetraonidae) are not at all closely related despite being treated as congeneric, and that the Palm Cockatoo *Probosciger aterrimus* is an extremely aberrant member of the subfamily Cacatuinae. The technique has also been used to show that a unique museum skin of a cotinga belonged to a new species and to suggest affinities with other taxa.

The availability in museums of feather samples of practically all the extant and many extinct species of birds of the world, together with the refined analytical techniques now available, has made feather keratin a potentially important source of taxonomic information. A.G.K.

KESTREL: substantive name of certain *Falco* spp.; used without qualification, in Britain, for *F. tinnunculus* (see FALCON). See photo FLIGHT.

KIDNEY: see EXCRETORY SYSTEM.

KILLDEER: *Charadrius vociferus* (see PLOVER (1)).

KINESIS (1): movement of the upper mandible in relation to the SKULL (see BILL).

KINESIS (2): 'locomotory behaviour not involving a steering reaction but in which there may be turning, random in direction' (Thorpe)—compare TAXIS.

KINGBIRD: substantive name of *Tyrannus* spp. (see FLYCATCHER (2)).

KING-CROW: *Dicrurus macrocercus* (see DRONGO).

KINGFISHER: substantive name of all species (except kookaburras *Dacelo*) of Alcedinidae (Coraciiformes, suborder Alcedines); in the plural, general name for the family; applied without qualification in Britain to *Alcedo atthis*. A diverse family of 86 species, almost cosmopolitan, but with most species in the Paleotropics and only a few in the Palearctic and the New World. Most are generalized predators of arthropods, small lizards and fish, and inhabit rainforests and woodlands, usually near but often far from water. Three subfamilies are customarily recognized on the basis of morphological (Miller 1912) and biological (Fry 1982) characteristics: Daceloninae (tree-kingfishers, 55 species), Alcedininae (22 small species of insect- and fish-eaters), and Cerylinae (9 species, most large and piscivorous). Generic boundaries have been controversial, but the following genera and numbers of species are now recognized.

Daceloninae: *Tanysiptera*, 6, Papuan subregion; *Actenoides* (formerly *Halcyon*), 6, Malaysia to Solomon Is.; the monotypic *Cittura* (Sulawesi), *Lacedo* (Thailand to Wallace's Line), *Melidora* and *Clytoceyx* (both New Guinea); *Dacelo*, 4, New Guinea and Australia; and *Halcyon* (including *Pelargopsis*), 35, Paleotropics.

Alcedininae: *Ceyx*, 8, Paleotropics; *Corythornis*, 3, Afrotropics; and *Alcedo*, 11, Old World.

Cerylinae: *Chloroceryle*, 4, Neotropics; *Megaceryle*, 4—one Oriental, one African, one Neotropical and one Nearctic; and the monotypic *Ceryle* of the Paleotropics.

Characteristics. Kingfishers range from 10 cm in length and 8 g in weight (*Ceyx lecontei*) to 46 cm and 500 g (*Dacelo gigas*), but the majority of species weigh between 20 g and 100 g. They are large-headed birds with long, strong beaks, the maxilla straight and pointed (hooked in some) and the mandible straight and narrow or deep, wide, and recurved. They are short-necked, short-tailed, and round-winged; the legs are short and the feet weak and syndactyl—the second, third and fourth toes being united basally and the third and fourth for much of their length. The second toe is vestigial in *Ceyx fallax* and absent in some species of *Ceyx* and *Alcedo*. The Alcedinidae is rather a distinctive family, and all of the members show an unmistakable general similarity. The most aberrant is *Clytoceyx rex*, a large drab bird probably distantly allied with kookaburras (and like them having a shining azure rump); it eats earthworms and the beak is short, broad and deep with scoop-shaped mandibles. Plumages are generally striking and colourful, dominantly non-iridescent dark blue and rufous, with shining azure rumps, and black or scarlet beaks and legs. Cerylines have no blue, but are pied or rufous with grey or oily green. The sexes are alike or nearly so, but in cerylines and a few dacelonines they differ recognizably in the field. Juveniles are generally like adults, but duskier. Kingfishers are territorial, and only 3 are at all gregarious. Dacelonines have loud songs and conspicuous territorial displays; otherwise many kingfishers are rather quiet and inconspicuous birds,, seen mainly in fast, direct and non-undulatory flight.

Habitat. The interior of tropical rainforest in all strata, its canopy and edges; mangroves; lowland forests with a few species as high as 2,000 m; tropical savanna woodlands, farms and gardens; swamps, paddyfields, wooded or grassy margins of rivers and lakes; arid thorn-bush; seashores in tropical and temperate zones, from wooded estuaries to treeless beaches and coral islands. The few species in the Palearctic and Nearctic can be found by almost any waters, particularly in winter (*Megaceryle alcyon*, *M. lugubris*, *Alcedo atthis*) or in any open countryside and woodland (*Halcyon pileata*, *H. coromanda*). They perch freely in vegetation, often concealed from view, but also on treetops and any open vantage points from which they can scan the ground or water for prey. A few species regularly forage on the ground, rooting in litter and topsoil for invertebrates, but most perch on the ground only transiently when feeding or nesting. Fishing species use such man-made vantage points as posts, boats and quays.

Distribution. The greatest number and diversity of dacelonine species is in the Papuan subregion, and of alcedinine species in that subregion with the adjoining part of the Oriental region. The Papuan subregion has 16 dacelonines of which 13 are endemic there, including some of the most remarkable kingfishers, such as *Clytoceyx rex* and *Melidora macrorhina* which have unusual feeding habits (see below). Both subfamilies extend north to Japan and south to Tasmania; alcedinines do not occur east of the Solomon Is. but several dacelonines are endemic to Pacific islands, from the Caroline Is. to the Marquesas Is. To the west alcedinines range to the Atlantic seaboards of Europe and Africa and dacelonines to the Near East and Africa including the Cape Verde Is. Of the cerylines, the 4 green kingfishers *Chloroceryle* are sympatric in the Neotropics, and *Ceryle rudis* is widespread in Africa and the Orient (for the range of *Megaceryle*, see above). Several species are endemic to a small island; for instance *Halcyon gambieri* is restricted to Niau Is. in the Tuamotu Archipelago and numbers only 400–600 birds. The most widespread kingfisher is *Alcedo atthis*, breeding from the Baltic to the Cape (treating *A. semitorquata* as conspecific) and from Morocco to Japan and the Solomon Is.

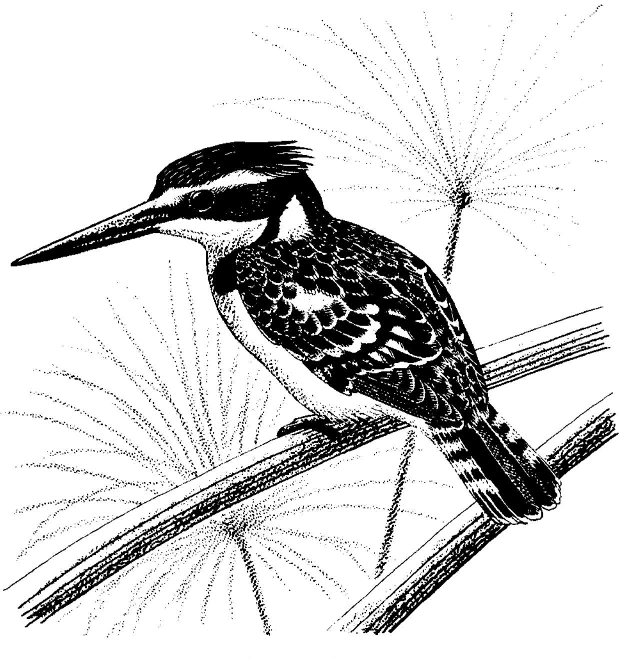
Movements. Most kingfisher species are sedentary, but the temperate-zone ones are migratory at least from more northerly latitudes, and several insectivorous species are intra-tropical migrants. *Halcyon leucocephala* is migratory throughout its African range and in Nigeria has a two-stage vernal movement northwards (pre-breeding and post-breeding), and one return migration after the rains. Its allospecies *H. pileata* in the Orient migrates from Korea to equatorial latitudes.

Food. The dacelonines are all sit-and-wait predators on a variety of arthropods and small vertebrates taken from the ground, tree-trunks and foliage and the surface of water. They eat insects, spiders, centipedes, scorpions, shrimps, frogs, lizards and, among *Halcyon* species, some fish, occasionally taking insects by flycatching, and in some cases evidently specializing on crabs (*Halcyon (Pelargopsis) capensis*) and snails (*H. coromanda*). *Clytoceyx rex* subsists largely on earthworms and other invertebrates caught at the surface of the forest floor by foraging in leaf-litter, worms being extracted in the manner of thrushes. *Melidora macrorhina*, which is evidently nocturnal or at least crepuscular, and at least 2 species of *Halcyon* sometimes feed on worms likewise, ploughing loose soil with their beaks. These kingfishers, and in particular the largest 2 of the 4 kookaburras, are formidable predators of vertebrates and catch snakes and some birds.

Among the Alcedininae, *Ceyx* species are dry-land insectivores but also take some prey from water. *Corythornis* (a genus of 1 forest and 2 savanna species intermediate between *Ceyx* and *Alcedo*) eat small dry-land and aquatic arthropods and vertebrates; and *Alcedo* feed almost entirely from water, on arthropods nearly as much as on fish. In the Cerylinae, *Chloroceryle* and *Ceryle* are almost exclusively piscivorous, *Megaceryle maxima* subsists largely on river crabs and *M. alcyon* takes fish and in addition mussels, clams, oysters, salamanders, young landbirds, mice, a variety of insects (including butterflies taken on the wing) and even, exceptionally, plant matter.

Dacelonines capture land prey by swooping down to seize it in the beak and alighting on the ground or a perch to immobilize it by beating. They usually take aquatic prey in much the same way, a splash-and-grab at the surface with subsequent beating at a perch. Species of alcedinines and cerylines (closely related subfamilies) can be arranged in a sequence suggesting evolutionary change from such swooping to more proficient diving and ultimately to reliance on more specialized diving. Evident correlates are a shift from forest floor to forest waterway to open-water habitats and from insectivory to piscivory. Moreover, those species which hunt farthest from the shore are the ones which eat the most fish, and the fish are caught in dives not only from perches but also from hovering flight: *Alcedo atthis*, *A. semitorquata*, *Chloroceryle amazona*, *C. americana*, *Megaceryle alcyon*, the marine *Halcyon saurophaga*, and—the extreme case—*Ceryle rudis*. No kingfisher other than these 7 is known to hover; and no other species regularly fishes open waters. *M. alcyon* and *C. rudis* are spectacular fishers; they scan the water by hovering as high as 12 m and make a straight or spiral dive directly downward, but how far they can submerge is not known. *Ceryle rudis* fishes up to 3 km offshore and in choppy conditions it makes 4 times as many dives from hovering flight as from perches. It can catch 2 fish at once, and swallow a small fish without having to return to a perch to beat it.

Voice and behaviour. Detailed accounts have been published for some dozen species; little is known about most others and nests of a few have not yet been described. Breeding biology is apparently rather uniform. Kingfishers are monogamous and territorial. A group of African and Asian *Halcyon* species maintain their territories by the frequent repetition of a far-carrying song delivered from a tree-top—a loud initial note and a series of evenly-spaced notes on the same or a falling pitch—accompanied by a highly conspicuous display. The bird perches erect with cocked tail, and flicks the wings to show a bold ventral pattern of chestnut, black and white. *H. senegalensis* pivots rapidly from side to side, holding the wings fully outstretched and vibrating. Mates may display and call together, and duetting occurs in *H. chelicuti*, an African arid-zone bird in which 20% of territories are occupied and defended by a mated pair with a helper. Helpers occur also in *Ceryle rudis* and *Dacelo gigas*. Nearly all other kingfishers live in pairs or, after dependent fledglings have dispersed, solitarily; but *C. rudis*, with up to 5 adult helpers at a nest, is quite gregarious and *D. gigas*, with helpers at more than half the nests, lives in pairs or perennial groups of 3–6. Kookaburras are obtrusive on account of their permanent occupancy of a socially defended territory and of their infectious 'laughing jackass' song. Alcedinines and cerylines are much less conspicuous in defence of their territories; cerylines are vocal, but songs and displays among alcedinines are weak or non-existent.



Pied Kingfisher *Ceryle rudis*. (*N.A.*).

Breeding. All kingfishers are hole-nesters, lay sub-spherical white eggs and have no nest sanitation. Dacelonines nest in tree-holes, often expropriated from other birds, remodelling the chamber, and they commonly use holes in termitaria on the ground or high in trees; some, notably the African and Asiatic halcyons, regularly nest also in earth banks, excavating the tunnel themselves. Alcedinines excavate their own nest holes in earth banks by water. Soil is loosened by the beak and kicked out backwards by the legs. The tunnel is horizontal, straight or a little curved, 0.75–1.5 m long, and ends in an oval egg-chamber.

Kingfishers never line the nest chamber. Incubation begins with the first egg laid, so the brood is staggered in size. The sexes incubate alternately in a cycle varying from 3–24 hours (*Chloroceryle amazona*, with the female incubating all night) and even 48 hours (*Megaceryle torquata*, with each sex taking 24-hour spells of incubation). During incubation the egg chamber becomes fouled with the pungent, watery excrement and with trodden-down pellets of regurgitated insect sclerites or fish bones. Clutches vary from one egg (rarely in *Dacelo gigas*) to 10 (rarely in *Alcedo atthis*), with specific means of about 3 to 4 eggs in the tropics and 6 to 7 in the temperate zone. Many species lay second and replacement clutches. The hatchling is naked and prognathous, the mandible projecting up to 2.5 mm beyond the maxilla. Nestlings stand on the heel, not the toes, and have rugose heel-pads. In most species fledglings have the same plumage as their adults, and they continue to be fed by adults for 10 weeks or more. Incubation and nestling periods are not known; incubation has been estimated as 14–16 days for *Corythornis*; 10–21 days for *Alcedo*; and about 14 days for *Halcyon*. The nestling period for *Corythornis* is at least 25 days.

Reyer, H.-U. 1980. Flexible helper structure as an ecological adaptation in the Pied Kingfisher (*Ceryle rudis rudis* L.). Behav. Ecol. Sociobiol. 6: 219–227.

KINGLET: in American usage, substantive name of *Regulus* spp. (see WARBLER (1)).

KINKIMAVO: substantive name of the Madagascar endemic *Tylas eduardi* (for family see BULBUL).

KIN SELECTION: the operation of natural selection, not directly on the individual under consideration but indirectly, on related individuals who share a proportion of his genes. Kin selection is one of the mechanisms that have been invoked to explain the evolution of ALTRUISM (see also SOCIOBIOLOGY).

KIOEA: the Hawaiian HONEYEATER *Chaetoptila angustipluma.*

KIRITIKA: substantive name of the endemic Madagascar warbler *Thamnornis chloropetoides* (for family see WARBLER (1)).

KISKADEE: substantive name of *Pitangus* spp. (see FLYCATCHER (2)).

KITE: substantive name of species of Milvinae, and used also for members of the Elaninae (for both these subfamilies of the Accipitridae see HAWK).

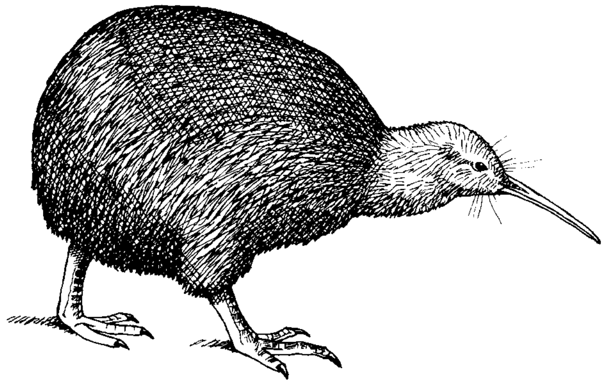
KITTIWAKE: substantive name of 2 species of Laridae; used without qualification in Britain for *Rissa tridactyla* (alternatively, Black-legged Kittiwake), the other species being the Red-legged Kittiwake *R. brevirostris* of the Bering Sea (see GULL).

KIWIS: the smallest and most aberrant of the RATITES and endemic to New Zealand. They are generally regarded as being most closely related to the MOAS (also endemic to New Zealand), each group being given the status of an order, or—as here—together making up the suborder Apteryges, one of the 4 suborders of the Struthioniformes. There are yet other alternative schemes for classifying the ratites, perhaps the most common recent ground for agreement being that they are monophyletic in origin. Both kiwis and MOAS are regarded as being descendants of the Gondwanaland fauna and thus the most ancient elements of New Zealand's recent avifauna. There are 3 species: *Apteryx australis* the Brown—or Common—Kiwi (subspecies, *A. a. australis* South Island, *A. a. mantelli* North Island and *A. a. lawryi* Stewart Island); *Apteryx oweni* the Little Spotted Kiwi (North and South Islands, no subspecies); *Apteryx haasti* the Great Spotted Kiwi (South Island only, no subspecies). No recently exinct species are known and the earliest fossil kiwi (*Pseudapteryx gracilis*) dates from the Quaternary. However, footprints attributed to the family have been found in Upper Miocene mudstone.

Characteristics. Kiwis are 35–55 cm long. Distinctive features include a long and slightly decurved bill with nostrils near the tip, a cone-shaped body tapering markedly to a strong neck and comparatively small head, small eyes, large ear apertures and many long tactile bristle-like feathers about the face and base of the bill, powerful muscular legs (which make up about one-third of the body weight), large feet with stout claws, and very small virtually bare wings (4–5 cm in length) which end in a claw and are hidden in the plumage. There is no external tail. The plumage is brown or grey, loose and hair-like, and does not change in form throughout life. Its neotenous characteristic of having weak barbs and lacking aftershafts gives the birds a shaggy appearance. The largest kiwis (the Stewart Island race) have females weighing at least 3.5 kg, the smallest (Little Spotted) about 1.2 kg. Females are about 20% heavier than males and their bills 25–30% longer.

With the exception of the Stewart Island race (which is also active during the early morning and evening) kiwis are nocturnal and uncomfortable in broad daylight.

Habitat. Though primarily birds of the indigenous forests (kauri, podocarp or southern beech), kiwis may also occur in scrub, native grasslands and even in exotic forests and pastures. Among critical environmental factors may be soil texture, its humus content, atmospheric humidity and dense vegetation overhead; certain combinations of which may be essential for kiwis to burrow and feed in and for the development of a suitable soil fauna for food. Nothing reliable is known about differences in habitat requirements that separate the 3 species.



Brown Kiwi *Apteryx australis.* (*N.W.C.*).

Distribution and populations. Originally Brown and Little Spotted Kiwis had a wide distribution on both main islands and D'Urville Island (which is separated from the South Island by a shallow strait only about 1 km wide and of post-glacial origin). Apart from the Stewart Island race of *A. australis*, they are not known to have occurred on any other islands. Now, they have gone from the east coast of the South Island (subfossil records only) and the southern and south-eastern parts of the North Island. The Little Spotted Kiwi has apparently been extinct in the North Island for about a century and is thought to be extinct in the South Island and survives only on Kapiti I. where it was introduced in 1913. The Great Spotted Kiwi is now found, apparently in good numbers, on the western side of the Southern Alps, mainly north of 43°S. More detailed information is needed on the distribution of all kiwis, especially to determine the extent to which overlap, spatial as well as ecological, occurs.

Kiwis have been successfully introduced to offshore islands and will readily breed in captivity, so the ultimate survival of all species and subspecies seems assured. They have no native predators, and do not seem to be unduly sensitive to predation by the various introduced mammals (rats, mustelids and cats), though the Little Spotted Kiwi may be an exception. However, many are maimed or killed by being caught in traps set for the introduced Australian possum or by being burnt or crushed in forestry or land-clearing operations. Nevertheless, kiwis have long been fully protected by law and have added protection where they occur in national parks or similar reserves.

Food. All 3 species have the same general food habits but little is known in detail. Earthworms are the principal item of diet, though woodlice, millipedes, centipedes, slugs, snails, spiders, a wide range of insects, seeds and berries are also taken. The highly developed sense of smell is apparently important in finding food.

Voice. Although each species and subspecies has contact calls of characteristic quality, all are essentially similar—males utter a shrill and prolonged whistle with a slightly ascending and then brief descending pitch (from which the species' name is derived); females have a hoarser and lower cry. These are heard at dusk, during the night and near dawn. When alarmed or aggressive, kiwis growl, hiss and loudly snap their mandibles. The other common noise is a loud snuffling made by expelling air forcibly through the nostrils while feeding.

Breeding. It is not known what stimulates breeding—the egg-laying period extends from July (late winter) to February (late summer). A functional right ovary is always present but only the left oviduct. The age of sexual maturity is unknown, but is likely to be at least 2 years. Studies of captive kiwis have shown that after about 2 months of burrowing or otherwise preparing a nest site, mainly by the male, the first egg is laid. Captive females may lay up to 5 eggs in a continuous series with a mean interval of 33 days between each; but in the wild clutches contain 1, 2 or rarely 3 eggs (each 18–25% of the female's body weight, depending on the species). The heavily yolked (61%) white-shelled egg is incubated almost entirely by the male for some 74–84 days before the chick hatches active, open-eyed and fully feathered. G.R.W.

KLEPTOPARASITISM: see FEEDING HABITS; PIRACY.

KNEE: for both the true knee and for a popular misconception on the subject see LEG.

KNOT: substantive name of *Calidris canutus* and one congener (see SANDPIPER).

KOEL: *Eudynamys scolopacea* (see CUCKOO).

KOKAKO: *Callaeas cinerea* (see WATTLEBIRD (2)).

KOKLASS: *Pucrasia macrolopha* (see PHEASANT).

KOLOA: alternative name (indigenous) for the Hawaiian Duck *Anas wyvilliana* (for family see DUCK).

KOOKABURRA: substantive name of *Dacelo* spp. (see KINGFISHER).

KORHAAN: substantive name of some South African species of *Eupodotis* (see BUSTARD).

KORI: *Ardeotis kori* (see BUSTARD).

KRONISM: see CRONISM.

K-SELECTION AND r-SELECTION: see ECOLOGY (final paragraph).

L

L. LINN. LINNAEUS: see NOMENCLATURE.

LABYRINTH: part of the ear (semicircular canals)—see HEARING AND BALANCE.

LAGENA: part of the cochlea, in the inner ear (see HEARING AND BALANCE).

LAGGAR: *Falco jugger* (see FALCON).

LAMELLAE: in birds, fine hair-like structures lining the bills of some species, enabling them to filter small food particles (see BILL; FEEDING HABITS).

LAMINIPLANTAR: having the horny sheath of the tarsus undivided on its posterior surface, although scutellate on the anterior surface (see LEG); compare BOOTED.

LÄMMERGEIER: name, alternatively 'Bearded Vulture', of *Gypaetus barbatus* (see VULTURE (1)).

LANCEBILL: substantive name of *Doryfera* spp. (for family see HUMMINGBIRD).

LANCEOLATE(D): spear shaped.

LAND-BRIDGES: see GEOLOGICAL FACTORS.

LANDRAIL: alternative name (probably obsolescent) for the Corncrake *Crex crex* (see RAIL).

LANGERHANS, ISLETS OF: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

LANIIDAE: a family of the PASSERIFORMES; suborder Oscines; SHRIKE.

LANNER: *Falco biarmicus* (see FALCON).

LAPAROTOMY: the minor surgical process used to assess the state of the internal organs of an animal. Typically involves making a small opening (1–2 mm) between the ribs and then using a powerful light source to look into the body cavity. General or sometimes a local anaesthetic is used. Valuable in sexing birds.

LAPPET: a wattle, particularly one at the gape (see INTEGUMENTARY STRUCTURES).

LAPWING: substantive name of some *Vanellus* spp., others being called 'plover'; used without qualification for *V. vanellus*; in the plural, general term for plovers of this genus (split by some authors into several genera constituting a subfamily Vanellinae)—see PLOVER (1).

LARDER: a collection of prey items impaled on thorns or barbed wire by shrikes (Laniidae) and some other birds.

LARI: see under CHARADRIIFORMES.

LARIDAE: see under CHARADRIIFORMES; GULL.

LARK: substantive name of the species of the family Alaudidae (Passeriformes, suborder Oscines).

Characteristics. Larks are small (11–19 cm) ground-feeding birds of open spaces. They rarely perch on vegetation to feed although some species do so regularly to sing. Like pipits and some buntings which also spend much time on the ground, larks have long, generally straight claws on their hind toes. Larks differ structurally from other Passeriformes in lacking an ossified pessulus in the syrinx and in having the posterior surface of the tarsus covered by scutes rather than an unbroken lamina. Most larks have cryptic brown or buff plumage with dark streaks. The sexes are usually similar in appearance though in a few cases (e.g., *Melanocorypha yeltoniensis*, some *Eremopterix*) they differ, with the male being more strikingly marked though not in bright colours. Many species have a marked size dimorphism, the males being larger than females.

Habitat. Larks live in open country including hot and cold deserts, tundra, moors, grasslands, steppe, savanna and farmland. Nests are always on the ground so the abundance of trees and bushes is not important in determining the availability of nesting cover. However, sympatric species often differ in the preferred density of trees and bushes in the habitat. Skylarks *Alauda arvensis* tend not to feed near tall hedges or woodland even when food is abundant there. Woodlarks *Lullula arborea* are superficially similar but are less averse to feeding near cover and live in areas with scattered trees or by woodland edges.

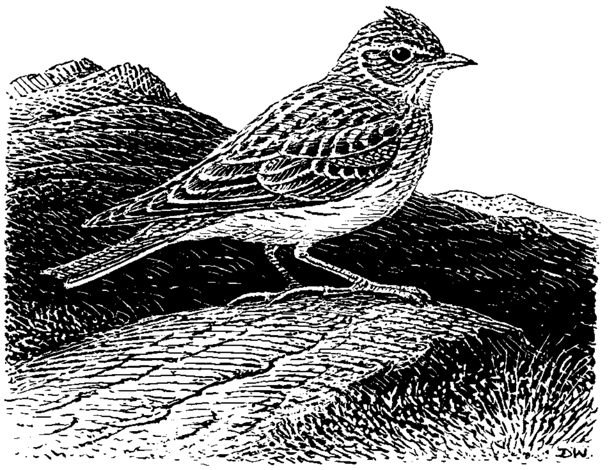
The colour of the soil is an important habitat feature for some desert-dwelling larks (*Ammomanes*, *Mirafra*, *Certhilauda*, *Eremopterix*) which tend to live in areas with soil similarly coloured to their plumage. In some species birds avoid landing on ground with contrasting soil colour even when driven over it. This matching is presumably an adaptation providing concealment from avian predators (see COLORATION, ADAPTIVE).

Distribution. A predominantly Old World family with one species, the Shore Lark *Eremophila alpestris*, in the Americas. Three-quarters of the 76 species occur in Africa and over half are only found there. Only one species (*Mirafra javanica*) occurs in Australia and New Guinea.

Populations. Larks generally occur at lower population densities than are typical of similarly sized woodland or scrub-dwelling passerines, which is probably due to the simple vegetation structure and low productivity of their preferred habitats. However, suitable habitat often covers vast tracts of land (e.g., deserts, tundra, arable farmland) so total populations may be very large. For example, the tundra dwelling Shore Lark is one of the world's most numerous birds. Population densities of Skylarks are 10–50 pairs/km^2 on arable farmland in England and up to 70 pairs/km^2 on coastal dunes. Woodlarks also occur at fairly low densities with territories 5 ha or more in extent. Population densities of desert-dwelling larks are very variable in space and time, since many species are nomadic, and are also usually low, though pockets with densities up to 1,250 pairs/km^2 can occur in *Eremopterix* spp. where rain has fallen. The average annual mortality rate for adult Skylarks is about 33% which is low for a temperate small passerine.

Movements. The family includes long distance and partial migrants and sedentary species. All North Temperate larks are at least partially migratory. Some species living in arid areas are nomadic, moving between areas of localized rainfall and abundant food. In the Kalahari desert granivorous species such as *Calandrella conirostris* and *Eremopterix* spp. are nomadic, while larks which include more arthropods in their diet are mainly sedentary. In the short term, frequent movements are made by some larks (e.g., *Eremopterix*) to waterholes to drink while other desert species appear to derive sufficient water from dew and food. There may be a correlation with diet; species feeding on arthropods and green vegetation being less likely to need to fly to water than those taking dry seeds.

Food. As a family, larks feed on a great variety of foods including seeds, flowers, buds, leaves, seedling cotyledons, molluscs and arthropods. A large proportion of species take a broad range of foods but some are specialized in feeding on insects or seeds. Omnivorous species have a conical, straight bill (e.g., *Alauda*, *Galerida*) while seed-eating specialists such as *Eremopterix*, *Melanocorypha* and *Calandrella* have deeper, finch-like bills. The Hoopoe Lark *Alaemon alaudipes* and some other species have thin decurved bills which they use to dig for soil arthropods. All larks search for food by walking. The Skylark is an omnivorous species with an unspecialized bill. On arable farmland it feeds on grain, weed seeds, leaves and cotyledons and insects, particularly beetles. Grain and seeds are not hulled as they are by finches and buntings since the bill lacks the grooves within the upper mandible used to hold the seed by these groups. Although Skylarks may feed almost entirely on leaves of cereals in midwinter, they have a short intestine and lack the large caeca of larger



Skylark *Alauda arvensis*. (*D.W.*).

herbivorous birds. Larks which take green leaves probably select plant species and growth stages rich in nutrients. Skylarks feed on weed and crop seedlings with high-protein levels. Stark's Lark *Spizocorys starki* in the Namib desert feeds on grass seedlings soon after germination. Gray's Lark *Ammomanes grayi* and Stark's Lark also select the tender basal node of grasses, discarding less digestible parts. Most larks feed their young on insects though some feed seeds by regurgitation (e.g., *Eremopterix leucotis*). On arable farmland Skylarks collect weevils, click beetles, grasshoppers, caterpillars and sawfly larvae for their young from rough grass and weeds at field edges. Desert-dwelling larks in southern Africa exploit ant and termite colonies, particularly when these are producing sexuals, and also locust nymphs.

Behaviour. Most larks breed on dispersed territories and are monogamous. Breeding territories are defended by song and chasing. Skylarks sing and visit the territory for much of the year in England as do some *Mirafra* larks in southern Africa. Nomadic desert species such as Stark's Lark may only be territorial and sing when breeding. Song and territory may function more to attract a mate than to maintain a feeding area which may be more important in sedentary species. Skylarks tend to remain faithful to a breeding site from year to year. In the Namib desert Gray's Lark lives in small groups throughout the year; territoriality is not strongly developed, with courtship and mating sometimes taking place within the group. Many lark species associate in flocks when not breeding. In southern Africa nomadic species form the largest and most cohesive flocks. Skylarks and Shore Larks migrate in flocks.

In hot deserts larks show behavioural adaptations to avoid overheating. Karroo Larks *Certhilauda albescens* and Stark's Larks become inactive and sit in shade during the hottest part of the day while Spike-heeled Larks *Certhilauda albofasciata* and Gray's Larks, foraging partly in the shade around the entrance of rodent burrows, are able to remain active. Larks roost on the ground and do not roost communally.

Voice. Song is well developed and long in many species, often delivered during a song flight or from a prominent perch. The song flight incorporates a rapid dive to the ground in several species. The wings and sometimes the tail are used in sound production in some larks, especially *Mirafra*, though these also sing. Flight calls are uttered by single and flocking birds. In the Skylark single birds usually call *chir-r-rup* while those in cohesive flocks call *seep*.

Breeding. All larks nest on the ground. Often the nest is a scraped cup but on hard substrates a foundation may be built to support the sides of the cup. The cup is often lined with grass or grass fibre. Sand larks (*Ammomanes*) and finch-larks (*Eremopterix*) build a rampart of pebbles on the windward side of the nest. This may act as a windbreak and prevent the nest filling with sand. Shore Larks also collect pebbles and other objects around the nest. In hot deserts lark nests are often built close to a stone or tuft of grass which shades the nest during the hottest part of the day. Nest ramparts may also contribute to shading the nest as well as perhaps partly concealing the nest from predators at ground level. The eggs are usually cryptically streaked or spotted. Clutch-sizes are larger in arctic and temperate larks (average about 4 eggs) than in tropical Africa (2–3 eggs). In Africa clutch-size tends to be larger in species living in more arid, less wooded habitat. Skylarks in England show a seasonal variation in clutch-size with mid-season clutches being larger than those at the beginning and end. Incubation is for 10–12 days by the female alone or by both sexes in some species. The young are fed by both parents and leave the nest well before they can fly, usually at about 10 days old. The down of the nestlings is cryptically coloured. Leaving the nest early is probably an anti-predator adaptation, reducing the risk of loss of a whole brood collected at one place, although movement of the young may also be beneficial in reducing the distance the adults have to carry food; the feeding areas are sometimes far from the nest. Losses of nests and young to predators are often high, 80% of eggs failing to produce fledglings for 7 species in the Kalahari and 90% of eggs failing to give rise to independent young for Skylarks on coastal dunes in England. Breeding is annual in temperate and arctic larks but is initiated after rainfall in many desert species. Skylarks begin to breed in the year after hatching.

LARK, SONG-: see SONGLARK.

LARO-LIMICOLAE: Stresemann's order equivalent, in the classification here followed, to the order Charadriiformes less the families Jacanidae, Thinocoridae, and Alcidae.

LARYNX: see RESPIRATORY SYSTEM; SYRINX; TRACHEA.

LATEBRA: core of fluid white yolk at the centre of an EGG.

LATENT LEARNING: see LEARNING.

LATEROSPHENOID: a paired bone of the SKULL.

LATIN NAME: see NOMENCLATURE.

LATIPLANTAR: having the hinder aspect of the tarsus flat (applied to oscine Passeriformes); opposite of ACUTIPLANTAR (in general, see LEG).

LAVEROCK: archaic name for the Skylark *Alauda arvensis* (see LARK).

LAYING: the deposition of the egg; the act of oviposition.

Oviposition. At ovulation the ovary releases a yolk (ovum) into the body cavity. Within half-an-hour it is engulfed by the upper end of the oviduct, the infundibulum, and it then passes through three further regions of the oviduct (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM). In the 'magnum', the chalazae and the thick albumen are added; in the 'isthmus', inner and outer shell membranes are formed; and in the 'uterus' or shell-gland, where the egg remains for 20–24 hours, it undergoes a 25% osmotic increase in volume, the chalky shell is deposited, and (mainly in the last hour before laying) pigment and the cuticle may be formed (see EGG). The times given apply to the domestic hen, in which the whole process from ovulation till laying takes about 24–27 hours.

The method by which the egg is carried through the oviduct has not been demonstrated conclusively. Some maintain that it is moved entirely by ciliary action, and others that it is propelled by peristaltic movements of the oviduct (Gilbert 1971). In the oviduct the egg lies with its pointed end towards the cloaca and in many species, e.g., domestic pigeon, eggs are correspondingly laid pointed pole first. In other species, e.g., Black-headed Gull *Larus ridibundus*, domestic hens and ducks, eggs are quite often laid blunt end first; this happens in 29% of the eggs of Khaki–Campbell domestic ducks. By using X-rays, it has been shown that such eggs undergo a quick 180° rotation (in a horizontal plane) an hour before they are laid. On rare occasions this rotation precedes the formation of pigment spots; the latter then collect round the pointed pole of the egg. Rotation is more frequent in some individuals than in others, and its incidence increases with age, presumably because the uterus wall becomes more stretched with repeated layings.

How the egg is actually released from the body has for long been a matter of controversy. Some maintained that the whole uterus (with contained egg) prolapses through vagina and cloaca to the exterior, where the uterine wall everts, thus unwrapping the egg and leaving it outside. Sykes (1953), however, observed, in laparotomized hens, that the uterus is not everted during oviposition; instead, the egg passes from the uterus into the vagina and is then pushed out by peristaltic action of the vaginal muscles. In intact birds he showed, also, that the distension of the vagina by the egg evokes a ventroflexion of the legs and erection of the feathers surrounding the vent, as well as 'bearing down' contractions of the abdominal muscles and increased respiratory movements causing a rise in the abdominal pressure. The egg may be expelled after a period of bearing down lasting 1–3 minutes. In social parasites, e.g., cowbirds *Molothrus* spp. and cuckoos (Cuculinae), the process is a matter of seconds. A Bobwhite Quail *Colinus virginianus* needs from 3–10 minutes at the nest to lay an egg, whereas Turkeys *Meleagris gallopavo* and geese *Anser* spp. are reported to labour for 1–2 hours. A bird that cannot lay its egg is called egg-bound; this condition may be caused by inflammation, stricture, or tumour in the oviduct; sometimes a malformed, oversized, or soft-shelled egg may be responsible.

An egg that is ready for laying can be held back; a Cuckoo *Cuculus canorus* is thus able to wait until the nest-owner has left the nest (see BROOD-PARASITISM). Many song-birds postpone laying while quickly constructing a new nest when the old one has been damaged or removed. For review of the hormone and neural control of oviposition, see Gilbert (1971), Sturkie and Mueller (1976).

Age of bird. Captive Quail *Coturnix coturnix* reproduce at 6 weeks of age, some individuals laying as early as 38 days (*Science* 129: 267). Most breeds of domestic hen begin laying at 5–7 months; most passerines, pigeons (Columbidae), and ducks *Anas* spp., etc., many gallinaceous birds, and some owls (Strigiformes) at one year; geese, many gulls (Laridae), and birds-of-prey, some waders (Charadriidae), and a few passerines at 2 years; cormorants (Phalacrocoracidae), divers (Gaviidae), and the larger gulls at 3 years; the large birds-of-prey and storks (Ciconiidae) when 4–6 years old, and the Royal Albatross *Diomedea epomophora* not until it is at least 8 years old. In many of these species the age at which breeding first occurs may vary with the individual. These differences are often explained by stating that larger birds require longer to mature than those of smaller size. More convincing is Lack's suggestion that breeding imposes a strain on the parents that may have been too great for the young individuals in some species, thus leading to adaptive retardation of the breeding age (Lack 1968). This is particularly the case for species with specialist feeding techniques, for themselves or for their young. For example, neither Arctic Tern *Sterna paradisaea* nor the Puffin *Fratercula arctica* breed before 3 years, rather later than do land birds of equivalent size. Breeding also takes place earlier in low-density populations with little adult competition than it does in more crowded ones, as expected if inexperienced females find it easier to collect enough food for egg formation when fewer birds are present.

Time of year. Like other reproductive activities, egg-laying is restricted to particular seasons of the year in most birds (see BREEDING SEASON). In general it is so timed that the young grow up when their food is most abundant, or when the female can find enough food to form eggs (Perrins 1970). In temperate and cold climates, the proximate factors controlling the time of egg-laying are increase in day-length in late winter and warm temperatures in early spring. In the tropics the rainy season determines the onset of breeding in many passerines. In special cases other factors and adaptations may be involved; thus the Great Crested Grebe *Podiceps cristatus* does not normally breed until the vegetation supporting its floating nest has grown up. Eiders *Somateria mollissima*, Common Gulls *Larus canus*, and Herring Gulls *L. argentatus* in the Arctic are reported to postpone breeding on islets until the surrounding ice has melted, which may be an adaptation against robbing by Arctic Foxes *Alopex lagopus*. The date of laying of the first egg varies somewhat from year to year and between individuals; in many species, birds laying for the first time tend to do so a few days later than older ones. According to one view, birds of a colony influence one another's reproductive activities in such a way that bigger colonies lay earlier in the season and within fewer days, i.e., are more closely synchronized, than small ones. Other studies do not support either statement, but it appears that small colonies may lay later in the season because they include a larger proportion of young birds than bigger colonies.

Time of day. Some birds lay only at a particular time of day; many song-birds such as finches (Fringillidae), wrens (Troglodytidae), tanagers (Thraupinae), wood-warblers (Parulidae), and hummingbirds (Trochilidae) around sunrise; pigeons (Columbidae) early in the afternoon; pheasants (Phasianidae) in the evening. In a flock of domestic hens, 56% of the eggs were laid between 9 am and 1 pm.

Successive eggs may not be laid at the same time of day; in the domestic pigeon the second egg appears 44–46 h after the first and is thus laid earlier in the day. The laying pattern, i.e., the time interval between the laying of successive eggs, is characteristic for a species. This interval is 20–24 h for most but not all passerines and for many ducks; 24–28 h for the domestic hen; 24–72 h, with an average of 40 h, for the Black-headed Gull; 2 days for the Raven *Corvus corax*, Ostrich *Struthio camelus*, and Rhea *Rhea americana*; 3 days for cassowaries *Casuarius* spp; 5 days for the Condor *Vultur gryphus*; and for the Masked ('Blue-faced') Booby *Sula dactylatra* a 6–7 day interval has been reported.The interval probably corresponds to the time necessary for the formation of the various layers of the egg. It is known that in the domestic hen ovulation usually follows the laying of the previous egg within about 30 minutes, except when the previous egg is laid late in the afternoon—in which case ovulation is delayed until the next morning.

Number of eggs. Most birds lay eggs in a clutch—they lay a few eggs in sequence, then stop and incubate. The domestic hen is a notable exception, laying continuously for a large part of the year. Here cycles of 3, 4 or more days of uninterrupted laying are separated from one another by one or a few days of non-laying. The annual output declines steadily with increasing age and so does the length of the laying season; 351 eggs in one year and 1,515 eggs laid within 8 years by a single hen have been recorded.

The number of eggs in a clutch (clutch-size) varies with the species. Some lay only 1 egg; others regularly have clutches of 2, 3, or 4; others show more variability, especially where the number is large (such as 10–20 for the Partridge *Perdix perdix*). In many species clutch-size varies between populations, with the individuals of a population, and even for one individual in different years. The average clutch-size of a population has been shown to be delicately adjusted to yield the maximal number of successfully reared young (Lack 1968). It is influenced by such factors as the age of the parents, seasonal influences responsible for the availability of food later in the year, and population density (see EGG; CLUTCH-SIZE).

Determinate and indeterminate layers. Little is known about how the regulation takes place—what are the climatic (or other) indicators of abundance of food later in the season, and by what means they affect the activity of the ovary. A further complication arises from the fact that 2 types of egg-laying mechanism may have to be distinguished; in some birds (indeterminate layers) the number of eggs laid can be changed by adding or removing eggs during or just before the time of laying; in other birds (determinate layers) this has no influence. In the latter case, presumably, the ovary produces only as many yolks as eggs will be laid. Experimental addition of eggs to the first egg of the clutch may reduce the number of eggs laid subsequently, e.g. in the Tricolored Blackbird *Agelaius tricolor* of North America. In many other species, e.g., Swallow *Hirundo rustica*, pigeons, gulls, and the Lapwing *Vanellus vanellus*, this has no effect; but if eggs are presented a few days earlier in some of these, egg-laying may be suppressed fully or partially—thus a Black-headed Gull sitting on model eggs for 2–8 days before laying its first egg may lay only 2 or 1. Removal of eggs, so as to leave only one or a few in the nest, increases the number to be laid in many species. Such protracted laying occurs, e.g., in the Yellow-shafted Flicker *Colaptes auratus* (where one female laid 71 eggs within 73 days) and in other woodpeckers (Picidae); a Mallard *Anas platyrhynchos* is reported to have laid 80–100 eggs when one was removed daily, and a House Sparrow *Passer domesticus* laid up to 50 eggs in succession (of which 12–19 were laid on consecutive days) instead of the usual clutch of 4–5. These and many other birds thus qualify as indeterminate layers. In a few others, e.g., Swallow, Magpie *Pica pica*, Gentoo Penguin *Pygoscelis papua*, Lapwing, and gulls, this procedure has no influence on the number of eggs laid. Nevertheless some of these have been shown to be indeterminate layers; they will lay additional eggs at normal intervals if the first egg is taken as well, i.e., if all eggs are removed as soon as they are laid. In these circumstances the Lapwing and Gentoo Penguin will lay one and gulls 3 more additional eggs. In pigeons, egg-laying could not be protracted in this way (Poulsen 1953).

In the ovary of an indeterminate layer more oocytes may enter the final phase of growth than are normally laid, and tactile or visual stimuli from the eggs in the nest are responsible for the cessation of laying. In some species, e.g., gulls, the end of laying is determined not by a definite number of eggs in the nest but by the opportunity for the bird to incubate. Only a limited number of eggs are laid after the onset of incubation, which causes all oocytes under a critical size in the ovary to degenerate. In species that do not incubate before the clutch is complete this explanation cannot apply. Here it is the critical number of eggs in the nest that stops the growth or causes the degeneration of superfluous oocytes. In neither case can laying be protracted once the reserve follicles have started to degenerate, i.e., one or more days after the onset of incubation.

Number of clutches. Many wild birds normally lay only one clutch in each year, but there are others that have two or more broods in a season. The domestic pigeon may lay up to 10 clutches a year. In most species (but not the domestic pigeon) the number of eggs tends to decrease with each successive clutch.

In Megapodiidae there may be no clutch in the ordinary sense; the eggs, often very numerous, are laid at intervals throughout several months, and there is no synchronization of incubation and hatching (see MEGAPODE).

Most birds with only one brood annually, and all of those with more than one, are able to replace the clutch when it is lost (repeat laying); a Black-headed Gull will lay again 8–12 days after the loss. Exceptions are some big vultures (Aegypiinae) and most Procellariiformes. Repeat clutches tend to be smaller than the first one. (U.W.) S.G.T.

LEAFBIRD: substantive name of the species of the genus *Chloropsis* of the Chloropseidae (Passeriformes, suborder Oscines). Members of a second genus, *Aegithina*, are called ioras. There is no accepted collective in English.

Characteristics. Small to medium-sized, wholly arboreal passerines 12–19 cm long in the weight-range 10–40 g, with small toes, tarsi slender in ioras, short and thick (similar to bulbuls) in leafbirds; bill medium to fairly long and slender, terminally decurved to hooked and finely notched; wing and tail of moderate length. All have ample, fluffy body plumage, long on the rump. Leafbirds resemble fairy-bluebirds (Irenidae) and bulbuls (Pycnonotidae) in profusely shedding feathers when handled. During flight the white flank feathers of some ioras conspicuously overlay the rump, and all except *A. lafresnayei* also have two white wing-bars.

All chloropseids are predominantly green or green and yellow (or orange). Most male leafbirds combine intense black and glossy blue on the throat and a proportion of the males of some ioras (not *A. viridissima*) tend to be black rather than green above, which character often varies clinally. Black is lacking in the body plumage of most females and apart from some south-east Asian island leafbirds most chloropseids show well-marked sexual dichromatism. Juveniles resemble females, and some populations of non-forest ioras acquire a brighter breeding plumage by moult.

Leafbirds superficially resemble and behave like some bulbuls, with which all chloropseids have at times been merged. A possible link with Meliphagidae has also been suggested.

Distribution and habitat. The 12 species constitute 1 of only 2 bird families endemic in the Oriental biogeographical region, chloropseids being found to its full limits. Northern congeners tend to be segregated by biotope and maximum co-occurrent diversity is reached in Sundaic dipterocarp forests where up to 5 species in both genera can be found together. Philippine congeners are allopatric by island.

Only *Aegithina* has non-forest representatives. The familiar *A. tiphia* everywhere inhabits thinly wooded environments (locally also mangrove), its range being almost that of the family. In evergreen forests of the Sunda and Indochinese subregions it is replaced respectively by *viridissima* and the larger *lafresnayei* (which also occurs in the Malay Peninsula but is scarce there away from forest-edge). A close relative, *nigrolutea*, replaces it in the driest scrub of north-west India and Pakistan.

Leafbirds are purely forest dwellers. *C. aurifrons* inhabits northern deciduous forest, others evergreen forest though *C. cochinchinensis* comes to quite open edge. The continental montane species is nearly everywhere the colourful *C. hardwickii*. Its place in the mountains of Sumatra is taken by an isolated form of *aurifrons* (possibly with the little insular endemic, *venusta*), and in Borneo by an upland subspecies of *cochinchinensis*.

Movements. Non-migratory, but in its Himalayan range *C. hardwickii* makes seasonal shifts of altitude.

Food. Ioras are mostly insectivorous. Leafbirds have mixed insect/fruit diets and some at times visit flowers, reputedly for nectar. A role in the pollination biology of certain forest trees is conceivable. The main foraging mode of both genera is leaf-searching, often acrobatic and frequently in dense foliage. Non-forest and forest-edge species hunt at all levels, forest species largely in the continuous canopy (from which *A. viridissima* regularly visits the crowns of tall emergents).

Behaviour. Ioras and leafbirds forage alone, in pairs or small, loose groups, and in forest frequently attend mixed-species gatherings. At flowerings or fruitings in extensive forest the northern leafbirds congregate in considerable numbers but show no flock cohesion, such gatherings being strictly temporary.

Voice. *A. tiphia* has numerous sharp or drawn-out and repeated whistles, loud and with spectacular shifts of pitch. Leafbirds have liquid, whistling songs, most sustained and melodious in *C. hardwickii* and *C. aurifrons*. Some are also considerable mimics of other birds.

Breeding. Some ioras have elaborate courtship displays involving vertical leaps and parachuting flight by males. *A. tiphia* builds a neat compact cup of fine grass and plant fibre felted into a branch fork with cobweb. The few known leafbird nests are loose cups of fine twigs variously mixed with grass and bryophytes, felted with cobweb and suspended by the rim from outer branchlets.

A. tiphia eggs are pale pinkish with purple–brown blotches zoned in some populations round the longest circumference. Known leafbird eggs are pale buff–cream to pinkish-white speckled, or speckled and hairlined, reddish or purple–black. Chloropseid clutches average 2 eggs, rising to 3 only in some outer tropical forms. *A. tiphia* fosters the cuckoo *Cacomantis sonneratii* (see BROOD-PARASITISM). D.R.W.

LEAFLOVE: used as a substantive name for some species of Pycnonotidae (see BULBUL).

LEAFSCRAPER: substantive name of *Sclerurus* spp. (see OVENBIRD (1)).

LEAF WARBLER: see WARBLER (1).

LEAP-FROG MIGRATION: migration by a northern breeding population to winter quarters which lie further to the south than those occupied by a southern breeding population of the same species; or the corresponding return migration to the breeding quarters.

LEARNING: best defined as 'the production of adaptive changes in individual behaviour as a result of experience'. There has been considerable difference of opinion as to whether the term 'adaptive' should be included in the definition (Thorpe 1956); the word is used here to prevent the term 'learning' from including such changes in behaviour as those resulting from fatigue, sensory adaptation, and the effects of injury (surgical or otherwise). This is important, because it is generally agreed that learned behaviour is to be carefully distinguished from changes in behaviour caused by physiological or structural damage to the system.

Many workers have considered that a more or less frequent repetition of a stimulus or of a changed situation is necessary for learning, but so many examples are now known of learning as a result of a single experience that this contention can no longer be maintained. There are 6 different categories of learning that are found to be useful in describing behaviour of birds and the higher vertebrates generally, one of which is discussed in a separate article (see IMPRINTING; see also BEHAVIOUR, DEVELOPMENT OF).

Habituation. This is, in some respects, the simplest type of learning found in the Animal Kingdom. It consists of 'the waning of a pre-existing response as a result of repeated stimulation when this is not followed by any kind of reward or punishment' (*reinforcement*). It is most evident in nature in relation to avoiding action to more generalized and simple stimuli such as loud sounds, sudden movements, any stimulus or situation that is strange, and any familiar stimulus at an unusually high intensity. Many species of birds, also, have the inborn ability to recognize, and immediately take appropriate avoiding action or other response in regard to certain types of predator, such as hawks and owls that are particularly dangerous to their species; but such an inherited response is hardly likely to have been evolved except in response to dangers that are of primary significance to the particular species. To have such an instinctive response to every kind of predator, and to every and any danger, would be out of the question. Therefore instead of, or in addition to, such specific responses, practically all animals show this ability to become habituated to stimuli that experience shows to be harmless. Obviously, if the response to such stimuli as sudden movements and sounds were completely automatic and unvarying, the life of the animal would become impossible since it would be continually taking cover from the flicker of a leaf and from every passing shadow. Habituation is thus that very simple form of learning which saves an animal from wasting its energies in response to stimuli that experience shows to be of no significance. Habituation is obviously of prime importance in the process of taming birds and other animals, constituting as it does the first step in accepting the abnormal conditions of captivity. The term 'habituation' is used in a general way for any type of response decrement shown by animals.

It is, however, important to distinguish between habituation and the alternative processes, *sensory adaptation* and *muscular fatigue*. An example of how these can be distinguished refers to the withdrawal response of the marine worm *Nereis pelagica*. This animal, which lives in a burrow, withdraws into its home in response to a stimulus such as a shadow or a touch from a small rod, but repeated presentations of such stimulus lead to a waning of the withdrawal response. The worm's muscles are not fatigued, because a change in stimulus immediately elicits complete withdrawal. Nor have the worm's sense organs adapted to the stimulus (in much the same way as we adapt to bright light after emerging from a dark room), because the worm, even though it does not withdraw when prodded, shows other responses such as turning towards the rod. Therefore the change in the withdrawal response is due to habituation. In vertebrates, habituation is probably a result of a process in the central nervous system, although not many examples have been studied at the neurophysiological level.

Associative learning. The great majority of studies of animal learning by experimental psychologists have focused on two kinds of associative learning, in which the animal learns an association between a reward or *reinforcement* and another event. Two main categories of associative learning are recognized.

(a) *Classical or Pavlovian conditioning* (named after the great Russian scientist I. Pavlov) in which the animal learns an association between two *stimuli*. One stimulus is motivationally significant, such as the sight of food (this acts as the reinforcer) and the other is a neutral arbitrary stimulus such as light or a buzzer. In Pavlov's classic experiment a dog learned to associate the light or buzzer with food, so that eventually it would respond by salivating whenever the light or buzzer was presented.

(b) *Operant or instrumental* conditioning, in which the animal learns an association between a *reward* and a *response*. In a typical experiment an animal has to perform a response (e.g., pecking at a key), to get a reward in the form of food. In both kinds of associative learning, then, the experimenter arranges a set of contingencies—in classical conditioning between a stimulus and reward, in operant conditioning between a response and reward.

Adaptive value of operant and classical conditioning. The two kinds of associative learning obviously play a major adaptive role in the life of birds. The ability of birds to learn to go to good feeding sites and to stay away from places where predators are likely to attack are examples of operant conditioning. An adaptive advantage of classical conditioning is that it allows an animal to anticipate the onset of a biologically significant event: by learning to associate the start of a rain shower with the emergence of worms birds might get to the feeding site ahead of competitors.

The role of associative learning can also readily be seen in the process of DEVELOPMENT OF BEHAVIOUR. For example, pecking movements of young chicks, or the ability of young Great Tits *Parus major* to deal with food items held under the feet are both examples of feeding skills that improve with performance. A chick's first pecks are poorly co-ordinated and inaccurate, but within a few days precision and control has improved greatly; the young Great Tit is clumsy and inept when it first handles food with its feet, but it soon learns to do the job skilfully and without errors. In these cases the process of instrumental conditioning is serving to modify the animal's natural behaviour to improve efficiency at obtaining rewards. In this kind of learning the animal gradually selects successful (in terms of reward-getting efficiency) manoeuvres and rejects less successful ones, suggesting an analogy between natural selection over many generations and learning within the lifetime of an individual. Both processes involve the selection of successful variants and discarding others. A similar point is made by K. Lorenz who has dubbed instrumental associative learning 'trial-and-success' (as opposed to the more usual term 'trial-and-error').

Although animals in the laboratory can be taught rather arbitrary responses to obtain food (e.g., raising a leg, pressing a lever, putting a coin in a slot), such instrumental conditioning proceeds more readily if there is some natural association between the response and the reinforcer. In fact what appears to be an arbitrary response to get food may be based on a natural feeding movement: rats 'pressing a bar' to get a food reward may often, on closer inspection, be gnawing at the bar as though engaged in normal appetitive behaviour for feeding.

Latent learning and perceptual learning. In the types of learning so far described the performance is established or stereotyped as a result of the attainment of some kind of reward, e.g., food, drink, effective nest building, or control of flight movements. It has long been recognized that in some animals another type of learning can be discerned which is independent of reward in the ordinary, physiological sense of the term. The classical experiment is as follows: a litter of young rats is divided into two groups, one of which is placed for a period every day for 10 days in a particular maze of a particular pattern and allowed to explore this maze at random; the others are given no such experience. If, then, both groups of rats are given identical training in such a maze by being rewarded in the normal manner by finding food in the food box on completion of the run, it will be found that those rats which had had the chance to explore the maze previously (but without being rewarded in it) had, in fact, learnt a great deal about its layout and showed a striking decrease both in errors and time of running as compared with the control group. A simple maze may in this way be entirely mastered through random exploration, but this learning is latent in that it cannot be demonstrated until the introduction of a reward. Latent learning can thus be defined as 'the association of indifferent stimuli or situations (i.e. situations without reward)'. One cannot conveniently train pigeons in mazes, but there is little doubt that latent learning is a laboratory version of what is a very general feature of animals that in nature have to find their way about. There is no doubt that a great deal of the learning displayed by birds in getting to know territory, individual habitat, migration routes, and so on, resembles latent learning in that the learning achieved is not immediately rewarded in the ordinary physiological sense. Also, like latent learning, it implies a tendency to explore the environment and to learn as a result the characteristic features and their special relation to one another.

Perceptual learning is essentially similar to latent learning: prior exposure to a stimulus improves later learning abilities. For example, rats reared with circles and triangles on the walls of their cages may subsequently be able to learn to discriminate these stimuli more rapidly than control animals. Perceptual learning, therefore, involves building up a set of descriptions of the critical features of a stimulus situation. Song learning in birds (see VOCALIZATION) and IMPRINTING are examples of perceptual learning.

Insight and other complex forms of learning. There are some examples of learning which at least at first sight appear to go beyond the processes of habituation and associative learning. In the early part of this century the psychologist W. Köhler made the classic observations of *insight learning* in Chimpanzees *Pan troglodytes*. He saw that they could pile boxes on top of one another to make a 'ladder' to reach bananas hanging from the ceiling, and piece together sections of bamboo pole to make a 'rake' which they used to collect food outside their cage. According to Köhler the chimpanzees were perceiving objects in their environment in a new way—in a flash of *insight* the animals saw that sticks could be used as a rake, boxes as a ladder. An analogous form of learning is the ability of some animals to work out a short-cut through a maze, having been taught only a devious route.

The extent to which these examples of learning should be viewed as qualitatively different from associative learning is not clear. For example, during the course of their normal play behaviour Chimpanzees will manipulate sticks and even fit them together or pile boxes up and climb on them without using the behaviours to obtain food. What Köhler saw as a flash of insight may in fact have simply been a reflection of the Chimpanzees' normal behaviour patterns. Among birds there are examples, along the same lines, of tool using in the normal process of food acquisition (see TOOLS, USE OF).

Imitation is another class of learning which has sometimes been viewed as being more complex than associative learning. In birds a famous example is the ability of titmice Paridae to peck open milk-bottle tops to drink the cream. It is likely that relatively few individuals learned the trick *de novo* and that others acquired the novel feeding method by watching those that had already learnt it. In this way milk-bottle opening spread as a cultural behaviour tradition. The ability of birds to learn by watching others seems widespread. Experiments have shown that an individual can learn to avoid certain distasteful foods, to obtain food from a novel hiding place, and to mob an artificial 'predator' stimulus simply by observing another bird doing the same thing.

It is sometimes suggested that the various learning abilities of animals can be expressed in terms of a single dimension of *intelligence*. However, as yet this term is not very useful to the student of animal behaviour since it is hard to define precisely and as we have seen, learning phenomena are diverse in nature. It is also becoming increasingly apparent that different species may have different specialized learning abilities to cope with their particular way of life. W.H.T. and J.R.K.

LEATHERHEAD: substantive name, alternatively 'friar-bird', of *Philemon* spp. (see HONEYEATER).

LECTOTYPE: see TYPE SPECIMEN.

LEG: the paired hind limb; but the term 'leg' is variously used, in different contexts, for the whole limb or for the ordinarily visible part of it and to include or exclude the 'foot', itself an inexact term for the extremity. The main components are the thigh, the lower leg (equivalent to shin), the so-called tarsus, and the toes—corresponding osteologically with the femur, the tibiotarsus plus fibula, the fused tarsometatarsus (with one free metatarsal where there are four toes), and the digit phalanges (see SKELETON, POST-CRANIAL). The joints between these components are the knee, the inter-tarsal joint or ankle, and the joints of the toes; as most birds stand on their toes, the raised ankle is often popularly mistaken for a knee (the real knee being concealed in the plumage) although it bends in the reverse direction.

Birds are dependent upon their limbs for locomotion on land or on water, and there are a number of adaptations to meet these varying conditions. When the bird is standing, the leg is situated just behind the bird's centre of gravity, balance being maintained by the toes. The legs are set farther back in swimming species; this is particularly true of the divers (Gaviidae), in which walking becomes almost impossible, so that on land they rest on their tarsi and wriggle on their stomachs—as sometimes do penguins (Spheniscidae), although these can also walk or hop in the upright position; the grebes (Podicipedidae) can run on their toes in emergency.

The thigh, knee, and upper part of the lower leg are completely hidden by the flank feathers and it is only the lower part of the lower leg, the ankle joint, the tarsus, and the toes that are visible. The relative length of the limb is extremely variable. Birds that walk or run, such as the Ostrich *Struthio camelus*, have long legs, whereas most small birds hop and have relatively shorter legs (see LOCOMOTION, TERRESTRIAL). In passerine birds that run, e.g., larks and wagtails, the young initially hop. Similarly, wading birds, particularly flamingos and the Stilt *Himantopus himantopus*, have long legs and can thus go far into the water without wetting their plumage. The Secretary-bird *Sagittarius serpentarius* is an example of a long-legged hawk-like bird that both evades snakes and preys on them by springing in the air and killing them by striking. The shortest legs are seen in those species that seldom walk, such as the swifts and the kingfishers; but such short legs are capable of digging—the Bee-eater *Merops apiaster* leans on its wings while it digs with its feet.

Relative strength depends upon function. Birds-of-prey possess powerful limbs for striking and holding their quarry; swimming species, particularly those that are not assisted in the water by their wings, possess massive thighs (see SWIMMING AND DIVING); whereas those that scratch the ground for food, such as the gallinaceous birds, have heavy tarsi and toes. See also CARRYING; HOLDING; PERCHING.

Covering of tarsi and toes. In some birds, the tarsi and even the toes are covered with feathers or bristles. This may be protective against the cold, e.g., Pallas's Sandgrouse *Syrrhaptes paradoxus*, in which the feathers extend to the upper surface of the toes only, and the Ptarmigan *Lagopus mutus*, in which the under surface of the toes is also feathered. Feathering in other species, including the owls (Strigiformes) and the House Martin *Delichon urbica*, cannot be accounted for in this way. Feathering may therefore be primitive, a scaly covering being a secondary transformation of feathers. These scales may be shed annually (see MOULT), and occasional variants of the Buzzard *Buteo buteo* possess feathered tarsi, similar to those of the Rough-legged Buzzard *Buteo lagopus*. Man has produced feathered tarsi by selective breeding in domestic pigeons and fowls.

The part of the limb lacking feathers is covered with a thickened, hardened structure, the podotheca. This may be corneous (horny) as in land birds or softer and more 'leathery' as in water birds. The surface may be scutellate (scaly), reticulate (covered with polygonal plates), granulate (covered with small tubercles), cancellate (covered with cross lines, as on the webs of water birds). If the podotheca is undivided or has only a few scales close to the toes, the bird is said to be 'booted' or holothecal, a condition found in most passerines (but when young these have scutellae that disappear by fusion). The young of certain Piciformes, Coraciiformes, and Trogonidae possess 'heel' pads, at the back of the intertarsal joint, that are shed when the birds leave the nest. These pads are in most cases strongly papillate, but smooth in Galbulidae. In some grouse (Tetraonidae) with unfeathered toes these are laterally pectinated (for pectinate claws see below). (See also FOOT PAPILLAE AND PADS.)

Tarsal shape. In most species the tarsus is rounded in cross section, but in many swimming species it is compressed laterally to reduce water friction when the leg is brought forward, the foot folding neatly to the same shape. This is most highly developed in divers and grebes, where the tarsus resembles a knife blade.

Spurs. These consist of a bony core covered with a pointed horny sheath and are situated on the posterior and inner surface of the tarsus. They are used with skill in battles that can well prove fatal, and are possessed by cock birds of polygamous species such as pheasants and peacocks and turkeys. The peacock-pheasants *Polyplectron* spp. have up to 4 full-sized spurs on each leg (see also COCK-FIGHTING).

Number and arrangement of toes. No bird has more than 4 toes; some have only 3, the hallux having been lost (vestigial in some others), and one species has only 2, as noted below. Their arrangement depends upon function. The majority have 3 forward toes and one, the 1st toe or hallux, behind (anisodactyl). This was the position in *Archaeopteryx* of the Jurassic period (see ARCHAEOPTERYX). Exceptions are as follows:

(*a*) All 4 toes may point forwards, as in the swifts.

(*b*) The 1st toe may be capable of turning backwards or forwards, as in

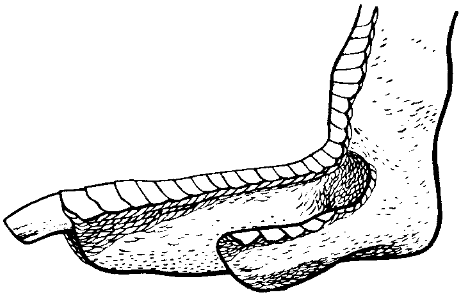

Fig. 1. Foot (right) of Ostrich *Struthio camelus*, with toes uniquely reduced to two. One-fifth natural size. (*M. Yule*).

the mousebirds (Coliidae); this and the preceding case have been termed the pamprodactyl foot.

(*c*) The outer forward toe (4th) may be capable of turning backwards or forwards, as in most owls (Strigiformes) and the Osprey *Pandion haliaetus*.

(*d*) The toes may be permanently in pairs, 2 in front and 2 behind—the zygodactyl or 'yoke-toed' foot. This occurs in woodpeckers, toucans, cuckoos, parrots, and others. These have the 1st and 4th toes pointing backwards, but in the trogons it is the 1st and 2nd that do so (sometimes called 'heterodactyl'). In some Picidae, e.g. the Three-toed Woodpecker *Picoides tridactylus*, the 1st toe has been lost; in a few others (*Campephilus* etc.) the 1st and 4th toes are, during climbing, rotated into an external lateral position (ectropodactyl).

(*e*) The 3rd and 4th toes may be partly united, with a single broad sole—the syndactyl foot of the kingfishers, hornbills, and the Cock-of-the-rock *Rupicola rupicola*.

In swift-running species it may be advantageous to lessen the surface of contact with the ground. Thus the 1st toe becomes raised and tends to disappear, as in some plovers (Charadriidae). The extreme is seen in the Ostrich, which has only 2 forward toes, one poorly developed and both possessing a soft elastic cushion on the sole to prevent sinking into soft sand. In sandgrouse the 3 forward toes are united by a membrane holding them close together.

Claws. Claws are specialized scales, and in ptarmigan *Lagopus* spp. are moulted in winter. Their shape is variable; sharp, well-curved claws are used for gripping firmly and are seen in such birds as the treecreepers (Certhiidae), the Wallcreeper *Tichodroma muraria*, woodpeckers, and the birds-of-prey (excepting the carrion-feeding vultures (Aegypiinae) and the Honey-buzzard *Pernis apivorus*, in which the claws are weaker and straighter). The claws of oxpeckers *Buphagus* spp. are extremely sharp. Strong, blunt claws are associated with species that scratch the ground in search of food, while exceptionally long claws, such as the hind claws of some larks and pipits *Anthus* spp., and the long 2nd claw of the One-wattled Cassowary *Casuarius unappendiculatus*, may be concerned with balance when running. In the jacanas all 4 claws are long, in association with long thin toes; this remarkable adaptation enables the birds to walk over floating vegetation. In grebes the claw is flattened and is incorporated into the paddle.

The herons, nightjars, and pratincoles *Glareola* spp., have a serrated edge or 'comb' on the inner border of the 3rd claw, which, in the herons at least, has a special function in plumage-maintenance (see COMFORT BEHAVIOUR).

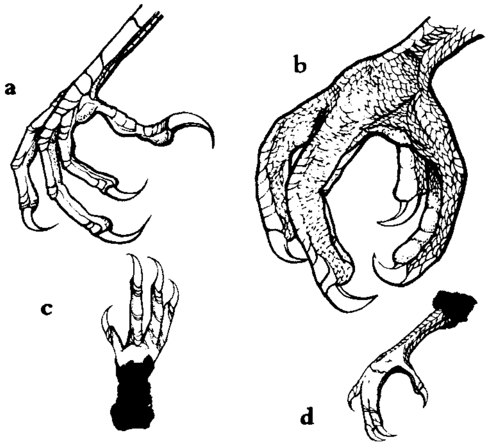

Fig. 2. Some perching and clinging feet (right): (a) Starling *Sturnus vulgaris*, anisodactyl; (b) Senegal Parrot *Poicephalus senegalensis*, zygodactyl; (c) Swift *Apus apus*, with all 4 toes directed forwards; (d) Kingfisher *Alcedo atthis*, syndactyl. Natural size. (*M. Yule*.)

Types of foot. Although there are many transitional forms, three main functional patterns have been evolved.

1. *Perching*

(*a*) In the passerine foot all the toes are free and mobile, the hind toe being highly developed and 'opposable' to produce a firm grip. (For an exception see PARROTBILL (1).)

(*b*) The zygodactyl foot with 2 'opposable' toes provides an even surer grip. Parrots use the foot like a hand in feeding. The 'semi-zygodactyl' variant, typified in *Turacus fischeri*, has been defined by R.E. Moreau 'as having a fourth (outside) toe that can be brought back to form an angle of about 70° with the first toe, and forward until it almost touches the third toe, but normally is held at right angles to the main axis of the foot'.

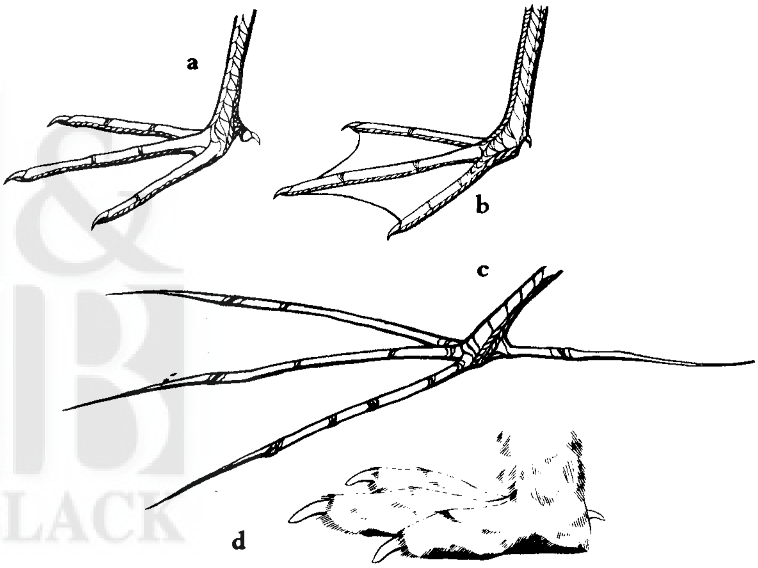

Fig. 3. Some walking and wading feet (right); (a) Lapwing *Vanellus vanellus*; (b) Avocet *Recurvirostra avosetta*, webbed; (c) Lesser Lily-trotter or Jacana *Microparra capensis*; (d) Ptarmigan *Lagopus mutus*, in winter plumage with feathered toes ('snowshoes'). Two-thirds natural size. (*M. Yule*).

(*c*) In the raptorial foot the toes are widely spread and possess sharp, highly curved claws. The under surface of the toes has bulbous and roughened pads, which in the Osprey carry spines to fix the slippery fish. This type of foot has great grasping and holding powers.

2. *Walking and wading*. In general the foot has tended to lose its power of gripping. The hind toe may become elevated to lose contact with the ground and has become reduced in size—or it may be lost, as in the Kittiwake *Rissa tridactyla*. In some wading birds the toes are partially or completely webbed, for example the flamingos, storks, and avocets *Recurvirostra* spp.; walking over soft ground is thus facilitated, and such species can swim well on occasion.

The rails have developed long toes and claws as an adaptation for walking over soft ground; this type reaches its extreme form, as already mentioned, in the jacanas, which are thus able to distribute their weight over a large surface area.

The feathered foot of the Ptarmigan increases the weight-bearing surface when walking on snow in winter. The American Ruffed Grouse *Bonasa umbellus* in winter develops 'snow shoes' in the form of a row of scales along each side of the toes.

3. *Swimming*. Many unrelated birds such as the petrels, gulls, auks, ducks and geese, have developed along similar lines to transform the foot into a paddle.

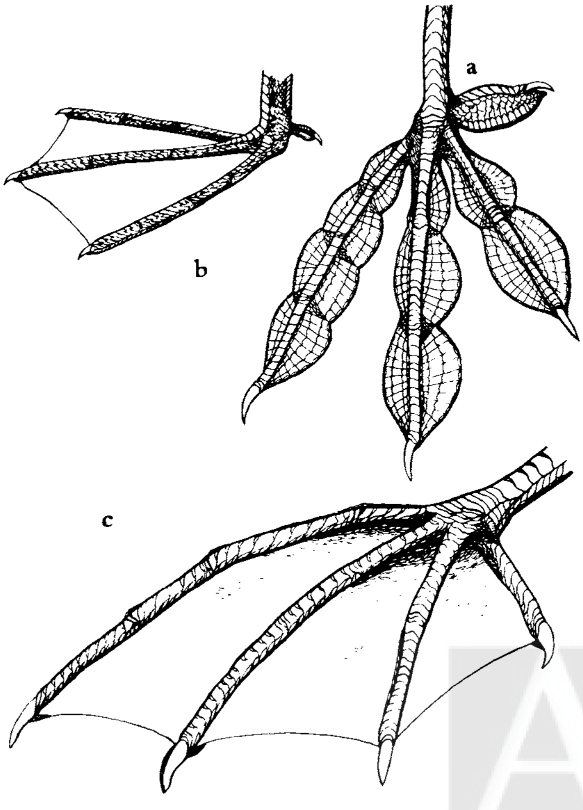

Fig. 4. Some swimming feet (right): (a) Coot *Fulica atra*, lobate; (b) Mallard *Anas platyrhynchos*, palmate; (c) Cormorant *Phalacrocorax carbo*, totipalmate. Half natural size. (*M. Yule*).

In the lobate variation, each toe carries independent webs, examples being the coots *Fulica* spp., phalaropes, the grebes, and the three remarkably grebe-like species of finfoot, thought to be of gruiform affinity. In grebes, the tibiotarsus is held in extreme external rotation when the bird is swimming; the foot is pale on its inner surface and dark on its outer surface, so that, as the latter is uppermost in swimming, the normal countershading is maintained.

In the palmate variation the 3 forward toes are united by a web, typical examples being the gulls, petrels, and ducks. The hind toe is free, poorly developed, and unmodified except in diving ducks, in which it is lobulate. The Hawaiian Goose *Branta sandvicensis* possesses a partially palmate foot and is an example of a goose that has reverted to a more terrestrial life.

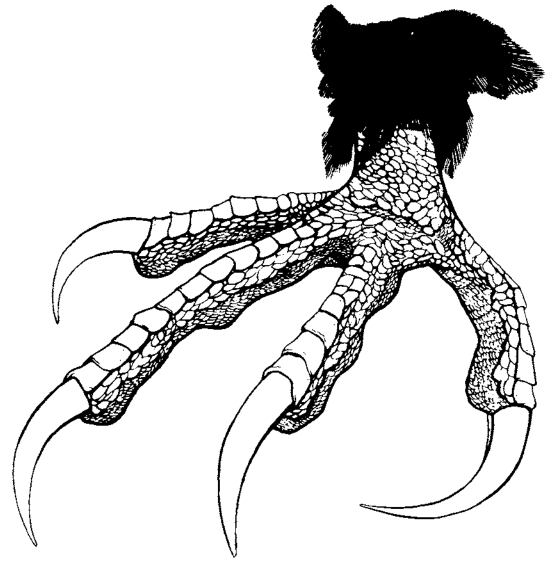

Fig. 5. Foot (right) of Golden Eagle *Aquila chrysaetos*, adapted for grasping. Half natural size. (*M. Yule*).

In the totipalmate variation characteristic of the Pelecaniformes, all 4 toes are webbed to provide the perfect swimming foot, the outer toe being the longest and the hind toe pointing slightly forward.

Unfeathered legs and feet, particularly webbed feet, are a potential source of heat loss. Irvine and Krog have shown in gulls *Larus* spp., however, that there is not only a reduced blood flow at low external temperatures but also some kind of vascular heat exchange, so that blood flowing into the unfeathered part of the leg does so at a very low temperature. This can be appreciated by feeling the cold web of any water bird. Serious heat loss is thus eliminated; and, in extremes, loss can be further reduced if the bird sits on its legs, covering them with its feathers (see also HEAT REGULATION).

Abnormalities. Supernumerary limbs and toes occur as genetic variants (except in domestication, the Dorking Fowl possessing a constant supernumerary toe on each foot). Very rarely a toe may be missing due to a congenital defect; frequently the toes are crooked, in association with inbreeding. Survival has been recorded in a wild Pheasant *Phasianus colchicus* after both feet had been accidentally amputated through the tarsi. Partial or total loss of one or both feet is not uncommon in water or wading birds and there is evidence that this is caused by fishes and molluscs. Loss of toes in a Moorhen *Gallinula chloropus* has followed a tuberculous arthritis. Normal embryonic development may be altered by radiation or drug administration. J.G.H.

LEITLINIE: original German term, best translated as ‘leading line’ (see MIGRATION).

LEK: a communal display ground (sometimes called ‘arena’) where males congregate for the sole purpose of attracting and courting females and to which females come for mating. The term is sometimes applied to the group of males congregating at such an area, and seems to be derived from Swedish ‘leka’, ‘to play’, which can have a sexual connotation. In resident species leks are usually traditional, their location remaining unaltered year after year; but in some migratory species the position of leks may change yearly, and even within seasons.

Lek displays constitute one of several categories of polygynous mating systems (see MATING SYSTEM; POLYGYNY), their most important distinguishing feature being that the males do not defend any resource needed by the female (nest-site or food) but compete directly among themselves for the attention of females, those of the highest status doing most of the mating. It is the rule for each male to occupy and defend his own display area (a cleared or trampled area, usually known as a ‘court’ if it is on the ground, or a special perch or group of perches if it is in a tree) within the lek. Mating normally takes place at the lek, on the successful male’s court or display perch, after a stereotyped display sequence. Detailed studies of lek displays have shown that some males, usually those whose courts are centrally placed within the lek, attract most females and do most of the mating, while peripheral males are relatively or completely unsuccessful. It is assumed that even peripheral males nevertheless have a better chance of mating than they would have if they attempted to court females away from the lek, and that this is so for two reasons. First, because the males stimulate and enhance each other’s displays, a group of *n* males will be more than *n* times as effective in attracting females as a single male displaying alone, and secondly, peripheral males have a chance to succeed to central positions in a lek when these fall vacant. Evidence for the first of these assumptions, which are crucial to explaining the evolution of lek displays, is very difficult to obtain; but there is a considerable amount of evidence that peripheral males in a lek take every opportunity to claim more central positions and regularly succeed in doing so.

It is not always possible to draw a clear distinction between true leks (in the sense used above) and those in which males display in a looser group within a circumscribed area, often out of sight but within earshot of one another. The term 'dispersed lek' or 'exploded lek' has been used for such cases. In some species the spatial organization of displaying males probably varies according to population density. Closely related species within the same genus (e.g. manakins of the genus *Pipra*) may show examples of different degrees of spacing.

In many species with lek displays the intense inter-male competition has led to the evolution of striking male ornamentation; display postures and movements are typically both striking and highly stereotyped. In some groups of lek birds, however, most notably the hermit hummingbirds, male and female differ hardly at all in plumage. It is noteworthy that the most refined elaborations of plumage, as in the Great Argus Pheasant *Argusianus argus*, Peacock *Pavo cristatus* and Lyrebird *Menura novaehollandiae*, are found in species in which the males display solitarily or in 'dispersed leks'. There is generally a clear distinction between displays which serve to attract females from a distance (loud calls, and very striking visual displays, especially flight displays) and those that presumably stimulate females at close quarters (the more elaborate and refined, often static, visual displays).

Lek displays, being performed by birds belonging to several different families in which monogamy is probably the primitive condition, exemplify evolutionary convergence in behaviour. An important predisposing condition is that the male is emancipated from nest-attendance and parental care. This probably explains why lek displays have evolved only in birds with precocial young and, among birds with altricial young, only in some fruit-eating, nectar-eating and seed-eating groups (for further explanation, see MATING SYSTEM). The following is a systematic summary of the main known cases of lek behaviour.

Male Ruffs *Philomachus pugnax* displaying and fighting at a lek with (lower photo) females, 'reeves', in attendance. (*Photos: A. Christiansen*).

Game-birds. The grouse family (Tetraonidae) includes several species with highly developed lek displays, the Black Grouse *Tetrao tetrix* and Sage Grouse *Centrocercus urophasianus* being well-studied examples. True lek displays apparently do not occur in the largest of the game-bird families, the Phasianidae, but males of the Great Argus and some other species occupy isolated display areas within earshot but not within sight of one another ('dispersed leks').

Bustards. The Great Bustard *Otis tarda* has a lek display; in other species, so far as known, the males display solitarily.

Waders. The Ruff *Philomachus pugnax* is one of the most outstanding and best known of lek birds. Ruffs are unique in having highly polymorphic male display plumage, no two individuals being exactly alike. There are two main types of male: independent males, with mainly dark display plumage, which occupy and defend courts within the display grounds (known, in this species, as 'hills'); and satellite males, with largely white display plumage, which lack aggressive behaviour and are tolerated at the courts of the independent males. The Ruff is exceptional among lek birds in being silent at the 'hill', but the courts may be only *c.* 0.5 m from each other, the area is open and frequented year after year, and conspicuousness is increased by corporate flights. Two other waders, the Buff-breasted Sandpiper *Tryngites subruficollis* and the Great Snipe *Gallinago media*, have lek displays. Unlike the Ruff, they show little sexual dimorphism in plumage. The display of the Great Snipe, which takes place mostly at night, is accompanied by loud vocalizations; the Buff-breasted Sandpiper's displays are made conspicuous by showing off the satin-white underside of the raised wings.

Parrots. It is reliably reported that the little-known, and gravely endangered, Kakapo or Owl Parrot *Strigops habroptilus* of New Zealand is a lek species. The males congregate in restricted display areas, where each bird advertises itself with a booming call.

Hummingbirds. Many, perhaps all, of the hermit hummingbirds of the genus *Phaethornis* display in leks. They are dull-coloured for hummingbirds, and the sexes are nearly or quite alike in plumage. The males advertise themselves on their display perches by constant singing; displays directed towards intruding males and females are similar, mating being elicited by appropriate behaviour on the part of receptive females. Singing assemblies of some other tropical hummingbirds, which may qualify as leks, have been less studied. It seems that the evolution of lek behaviour in the hermit hummingbirds is connected with the fact that they are 'trap-lining' hummingbirds and do not defend their nectar sources (see HUMMINGBIRD). A 'resource-based' mating system, such as is found in some other hummingbirds, is therefore not possible, and males establish their status by direct competitive interaction.

Manakins (Pipridae). This Neotropical family of small forest-living birds contains a number of species with highly developed lek displays, notably the White-bearded Manakin *Manacus manacus* (and its near relatives), several species of *Pipra*, and the 4 species of *Chiroxiphia*. *Manacus* species display on cleared courts on the forest floor, *Pipra* species on perches in under-storey trees, and *Chiroxiphia* on low, more or less horizontal vines and other stems within a few metres of the ground. The display behaviour of *Chiroxiphia* is unique in that 2, or in one species 3, males take part in a perfectly coordinated joint dance in front of a female but only one, apparently the dominant male of the group, mates with her. In one closely related group of *Pipra* species, including the Wire-tailed Manakin *P. filicauda*, the owning (or dominant) male on a display perch is regularly joined by a visiting (or subordinate) male in the absence of a female, and the two birds carry out an elaborate series of coordinated display flights and other movements.

Cotingas. This family, closely related to the manakins but containing mainly larger forest birds and, like the manakins, largely frugivorous, contains many species with extravagantly ornamented males which have elaborate displays, but only a few of them are known to display at leks, most notably the 2 cocks-of-the-rock *Rupicola* spp. Several species, including the bellbirds *Procnias*, have dispersed leks. The Screaming Piha *Lipaugus vociferans* parallels the hermit hummingbirds in that the sexes are alike and dull-coloured, and the males advertise themselves by persistent calling from their display perches within a well-defined lek.

Jackson's Whydah *Euplectes jacksoni* male displaying at a lek, showing development of 'ornamental' features often found in birds with this type of behaviour. (*Photo: J.F. Reynolds*).

Weavers. Among weavers, Jackson's Whydah *Euplectes jacksoni* is unique in having a lek display, the females nesting away from the display area (not within the male's display territory, as in the typical polygynous weavers).

Birds-of-paradise. Several of the birds-of-paradise, notably the species of *Paradisaea*, display at leks; in others the males have a system of dispersed leks or display solitarily. In all these, the males are extravagantly ornamented. Other species are monogamous, and show much less sexual dimorphism. As in the manakins and cotingas, the evolution of lek displays seems to be related to frugivory. D.W.S. (1)

LENS: part of the eye (see VISION).

LEPTOSOMATIDAE: see CORACIIFORMES; CUCKOO-ROLLER.

LESSER COVERTS: see TOPOGRAPHY.

LEUCISM: see PLUMAGE, ABNORMAL.

LEUCOCYTE: see BLOOD.

LEYDIG CELLS: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

LICE: see ECTOPARASITE.

LIFE, EXPECTATION OF: see AGE.

LIFE ZONE: an area defined, for ecological purposes, in terms of temperature and humidity rather than of nature of ground and vegetation (contrast BIOME).

LIGAMENT: band of connective tissue, tough and flexible, uniting two bones (see SKELETON, POST-CRANIAL) or supporting an organ.

LIGHT: considered as an environmental factor—see PHOTOPERIODISM; also under BREEDING SEASON; MIGRATION; NOCTURNAL HABITS; RHYTHMS AND TIME MEASUREMENT; ROOSTING; VISION.

LILY-TROTTER: substantive name most commonly used for African species of Jacanidae (see JACANA).

LIME, BIRD: a viscous substance (made from holly bark, etc.) used for smearing on twigs or other perches in order to catch small birds. The term is sometimes popularly misapplied to the residual excrement adhering to trees, rocks, buildings, and the like much frequented by birds.

LIMICOLAE: formerly used as the name of an order equivalent to the suborder Charadrii of the Charadriiformes (see also LARO-LIMICOLAE).

Limpkin *Aramus guarauna*. (*C.J.F.C.*).

LIMPKIN: *Aramus guarauna*, sole species in the New World family Aramidae (Gruiformes, suborder Grues). It has certain osteological and pterylographical characters that are crane-like (i.e. as in Gruidae) and a digestive system like that of the rails.

Characteristics. In general appearance the Limpkin is like a very large rail (length 58–71 cm). The sexes are similar in size and appearance. The bill is long, laterally compressed, and slightly decurved. The neck is long and slender; the wings are very broad and rounded; the tail is short and broad; the legs are long, with tibiae partly bare. The general coloration is glossy brownish olive, quite finely streaked with white on the neck and with broader broken streaks on the body. Fledged young closely resemble adults, but have shorter bills. Nestlings are dark brownish, evenly coloured. The feet are not webbed, but it is an efficient swimmer. It is seldom seen in flight. It stands on the ground or perches at any height, including the tops of tall trees.

Habitat. Although it is a wading bird, usually occurring in wooded swamps or shaded places where there is a lush growth of woody or herbaceous vegetation, it has been found in areas of arid brush in the West Indies.

Distribution and movements. The Limpkin is a sedentary species. It occurs from Georgia and Florida through Central America and on various islands, south in South America east of the Andes to central Argentina. Four subspecies are recognized.

Food. The Limpkin feeds almost exclusively on large snails, mainly *Pomacea* (*'Ampullaria'*), obtained in water of wading depth. The bird walks ashore or to very shallow water with its prey, extracts the snail, and discards the undamaged shell; a perching place is sometimes littered with these.

Behaviour. Although, where not protected, it is considered to be crepuscular and nocturnal in its habits, it is notably unwary and diurnal (as well as nocturnal) at certain localities in Florida where it is responding to full protection.

Voice. The Limpkin is best known for its voice and is often called 'wailing bird' or 'crying bird'. Its varied wailing, screaming, and assorted clucking notes are heard most frequently at night.

Breeding. Relatively little is known about its breeding habits. The rather flimsy shallow nest, of sticks and dry vegetation, is built in a shaded spot on the ground near water or even as high as a few metres up in a bush or tree. The 4–8 eggs are pale buff, spotted or blotched with various light browns. Incubation is by the sexes in turn for an unknown period. Both parents tend the precocial young for an unknown length of time. Either the nesting season (in Florida) is very prolonged or else the species is double-brooded. The young out of the nest, even for some weeks after they have attained flight, approach from behind and reach forward between a parent's legs for food; the snail (in shell) is taken from the bill of the parent and swallowed whole. LINCOLN INDEX: the formula of a sampling method used in population studies (and see PREDATION), viz.:

$$\text{Population} = \frac{\text{M} \times \text{S}}{\text{m}}$$

where 'M' is the number of marked animals released in a given area; 'S' is the number of animals captured in a sample taken after the dispersal of the marked animals from the release point; and 'm' is the number of marked animals in the sample S.

Lincoln, F.C. 1930. Calculating waterfowl abundance on the basis of banding returns. Circ. U.S. Dept. Agric. no. 118: 1–4.

LINE TRANSECT: see CENSUS.

LINKAGE: see GENETICS.

LINNET: *Carduelis cannabina* (see FINCH).

LIOCICHLA: substantive name sometimes used for laughing thrushes of the genus *Liocichla* (for family see BABBLER).

LIVER: a large unpaired organ associated with the digestive tract (see ALIMENTARY SYSTEM). In addition to secreting bile into the duodenum by way of the hepatic duct or ducts (gall-bladder present or absent), it is the site of important metabolic changes in substances brought to it by the portal vessels (see VASCULAR SYSTEM) and also to some extent a storage depot, e.g., of glycogen (see METABOLISM).

LIVER (with long 'i' as in 'diver'): name derived from that of the city of Liverpool and applied since the 17th century to a bird imaginatively portrayed in the municipal coat-of-arms, originally intended to be the eagle of St John the Ecclesiastic but now changed out of recognition (see, in general, HERALDIC BIRDS).

LLANO: an environment of savanna type characteristic of parts of tropical South America (see SAVANNA).

LOAFING: see ROOSTING.

LOBATE; LOBED: having the toes separately fringed by lobes, as distinct from webs connecting the toes (see LEG).

LOCAL ENHANCEMENT: see FACILITATION, SOCIAL.

LOCOMOTION, TERRESTRIAL: birds use three gaits, the walk and run in which the feet move alternately and the hop in which they move together. In walking, each foot is on the ground for more than half the stride so there are times when both are on the ground. In running, each foot is on the ground for less than half the stride so there are times when both are off the ground.

Gait and energy cost. Turkeys, ducks, rheas and probably many other birds use the gait known as the stiff walk, which is also used by man. In it, energy is saved by the principle of the pendulum. The potential energy of a pendulum increases and decreases as the bob rises and falls, and its kinetic energy increases and decreases as the bob accelerates and decelerates. Very little work is needed to keep the pendulum swinging because kinetic energy increases as potential energy decreases and vice versa: energy is shuttled back and forth between the two forms. In the stiff walk, the leg is kept rather stiff while the foot is on the ground so the bird's centre of mass rises as it goes from position (a) to position (b) (Fig. 1). At the same time the force exerted by the ground on the foot, acting along the leg, slows the bird down a little. Thus potential energy increases and kinetic energy decreases as the bird goes from (a) to (b). The reverse changes occur between (b) and (c). There is a maximum speed which depends on the length of the leg, above which it is impossible to make the potential energy changes compensate for the kinetic energy changes, and the stiff walk loses its advantage. The Wild Turkey *Meleagris gallopavo* uses the stiff walk at speeds below 1.5 m/s but runs to go faster.

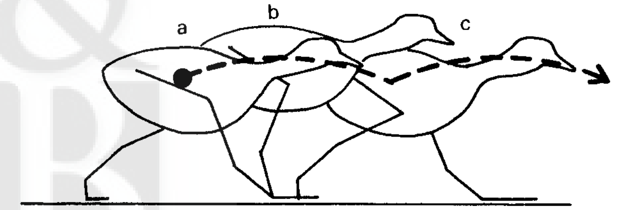

Fig. 1. Successive positions of a bird performing the stiff walk. The broken line represents the path of the centre of mass.

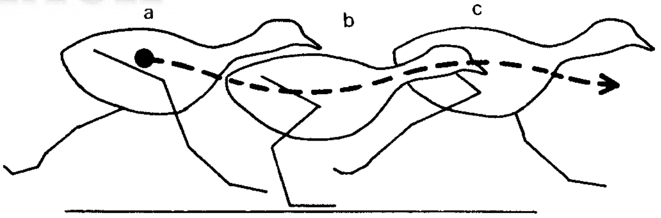

Fig. 2. Successive positions of a running bird. The broken line represents the path of the centre of mass.

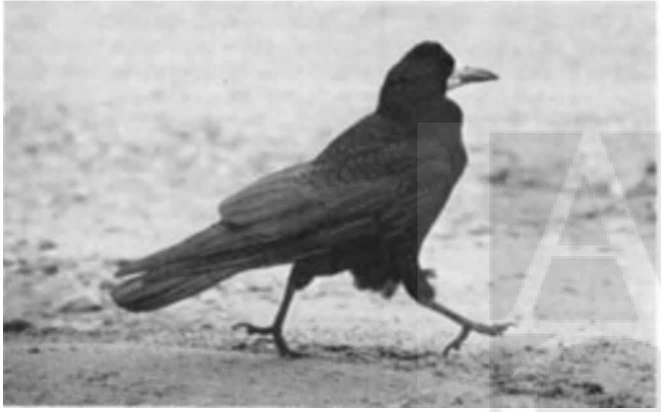
In running, energy may be saved by the principle of the bouncing ball. The centre of mass is lowest when the bird is moving most slowly (Fig. 2b) so kinetic and potential energy have their lowest values at the same time. However, the force on the foot is largest at this time and tendons in the leg are stretched, storing elastic strain energy. Kinetic and potential energy are converted to elastic strain energy between (a) and (b), and restored by elastic recoil between (b) and (c). This mechanism is most effective at high speeds, when the feet are on the ground for only a small fraction of the stride and the forces on them are correspondingly large. Calculations based on films and dissections seem to show that tendon elasticity saves a lot of energy in the fast running of Ostriches *Struthio camelus*, but it is not certain that it is important in smaller birds. It may also save energy in hopping.

Most small passerines and some other birds hop. Most of those that do are small or arboreal in habits or both. Hopping seems a particularly

Sanderling *Calidris alba* in winter plumage, running. (*Photo: J.B. & S. Bottomley*).

Large Pied Wagtail *Motacilla maderaspatensis* walking. (*Photo: T. Shiota*).



Rook *Corvus frugilegus* walking. (*Photo: H.E. Grenfell*).

Lesser Yellowlegs *Tringa flavipes* wading. (*Photo: J.B. & S. Bottomley*).

useful gait in trees where supports for the feet are sparse (in comparison with solid ground) but where the feet can always be placed side-by-side on the branch. Some families (for instance, the Corvidae) include species which hop and others which walk or run. Some species (for instance the Blackbird and American Robin, both species of *Turdus*) sometimes hop and sometimes run. The Magpie *Pica pica* walks to travel slowly and hops to go faster, but its hop is a peculiar asymmetrical gait with the left and right feet out of phase. Vultures use a similar asymmetrical hop.

Birds have been trained to run on a conveyor belt, so that they remain stationary while the belt moves under them. This technique has made it possible to measure the rate at which they use oxygen as they run, and so to estimate their energy consumption. Ostriches use oxygen at about the same rate as ponies of the same weight, running at the same speed. Similarly roadrunners *Geococcyx* use oxygen at about the same rate as ground squirrels of similar weight at the same speed. However, birds whose style of walking looks clumsy (for instance, geese and penguins) use oxygen up to three times as fast as more graceful species of similar weight at the same speed. Ostriches seem to run a little faster than typical antelopes but most birds are slow runners, compared to mammals of similar size. Ostriches have a much larger proportion of leg muscle in the body than flying birds.

Measurements of oxygen consumption of kangaroos have shown that their hopping uses more energy than the running gaits of other mammals of similar size, except at high speeds. Measurements on smaller hopping mammals (for instance, kangaroo rats) show that they use oxygen about as fast as similar-sized running mammals, at all speeds. There is no evidence that hopping can give any energetic advantage, for any size of mammal, and no measurements seem to have been made on birds.

Penguins slide down slopes on their bellies and presumably save energy that way, but this technique of locomotion seems not to have been closely studied. The mechanics of wading have also been neglected by zoologists.

Balance. The hips of birds are far posterior to the centre of mass of the body, but standing and walking without overbalancing are only possible if the average position of the feet is directly below the centre of mass. Most birds stand and walk with the thighs nearly horizontal, so that the knees are alongside the centre of mass. They move their thighs only a little as they walk or run, and swing the legs mainly from the knees. Penguins and auks have thighs too short for this, and bring the centre of mass over the feet by standing with the trunk erect.

Head bobbing. A bobbing movement of the head is characteristic of the gaits of many birds, including pigeons. The head moves backwards and forwards relative to the body in every step. There is a stage in the step when the head is moving backwards relative to the body and is more or less stationary relative to the ground. It is believed that having the head even briefly stationary relative to the surroundings may make it easier for the bird to detect moving objects visually. In support of this idea, pigeons do not bob their heads when walking on a conveyor belt so as to be stationary relative to their surroundings. R.McN.A.

LOCUS: of a gene (plural 'loci')—see GENETICS.

LOCUST-BIRD: name applied in parts of Africa to various species of birds that congregate to feed on locust swarms, e.g. the Black-winged Pratincole *Glareola nordmanni* as an off-season visitor to South Africa.

LOGGERHEAD: name applied in the Falkland Islands to steamer ducks *Tachyeres* spp.; and in North America to the Loggerhead Shrike *Lanius ludovicianus*.

LOGRUNNER: substantive name of *Orthonyx* spp. (see RAIL-BABBLER).

LONGBILL: substantive name of the 2 New Guinea HONEYEATERS of the genus *Toxorhamphus*.

LONGCLAW: substantive name of *Macronyx* spp. (see under WAGTAIL).

LONGEVITY: see AGE.

LONGSPUR: substantive name, in North America, of *Calcarius* spp., including the Lapland Bunting *C. lapponicus* (see BUNTING).

LONGTAIL: substantive name of *Urolais epichlora*, and an alternative substantive name for prinias *Prinia* spp. (see WARBLER (1)).

LOOMERY: term which has been applied to breeding colonies of guillemots (*Uria*)—see AUK.

LOON: substantive name used in North America for all the species of Gaviidae (see DIVER).

LOOP MIGRATION: see MIGRATION.

LORE: the area between the base of the upper mandible and the eye, on each side (plural 'lores'; adjective 'loral')—see TOPOGRAPHY.

LORICULINAE: see PARROT.

LORIINAE: see PARROT.

LORIKEET: substantive name used sometimes for the smaller species of lories (Loriinae) (see PARROT).

LORY: substantive name of the species of the Loriinae; in the plural (lories), general term for the subfamily (see PARROT).

LOTUS-BIRD: name in Australia for *Irediparra gallinacea* (see JACANA).

LOURIE: alternative substantive name of some species of Musophagidae (see TURACO).

LOUSE-FLIES: see ECTOPARASITE.

LOVEBIRD: substantive name of the African *Agapornis* spp. (Psittacinae, Psittaculini); sometimes applied to the Budgerigar *Melopsittacus undulatus* (Psittacinae, Platycercini) (see PARROT).

LOWAN: name, alternatively 'Mallee Fowl', of *Leipoa ocellata* (see MEGAPODE).

LUMPER: a taxonomist who prefers a nomenclature that recognizes broad groupings, and hence emphasizes relationships—in contrast to a SPLITTER, who prefers a nomenclature that recognizes fine distinctions. Workers interested primarily in wider evolutionary problems tend to be lumpers, while specialists in narrower fields of research tend to be splitters; but this distinction should not be pushed too far.

LUNG: see RESPIRATORY SYSTEM.

LURE: instrument used in imitating bird-calls to attract birds of the particular species within range; also a form of bait used by falconers to recover their charges (see FALCONRY).

LUTEIN: a yellow, fat-soluble, carotenoid pigment ($C_{40}H_{56}O_2$) found in many plant and animal materials; for example, in yolk of eggs, fat cells, corpus luteum, and feathers.

LYMPHATIC SYSTEM: much of the fluid part of blood, with its protein, that escapes from the blood capillaries into the tissue spaces is retrieved by lymphatic capillaries, collected in lymphatic vessels and ultimately returned to the venous system. Thus the lymphatic vessels function in the maintenance of the fluid balance of the body. Throughout the body are accumulations of lymphoid tissue, the cells of which provide immunity to antigens such as microorganisms, toxins, foreign cells and tissues. Embryologically, lymphoid tissue and lymphatic vessels originate independently.

Lymphatic vessels. The lymphatic capillaries are blind endothelial tubules forming plexuses which drain into collecting vessels that are tributaries of the main transporting lymphatic vessels. Lymphatic vessels accompany blood vessels, usually veins. Generally the lymphatics are paired and flank their veins. Most of the lymph flow of the body converges on the 'venous angles' at the confluence of the jugular and subclavian veins where the major transporting trunks (thoracoabdominal, jugular, and subclavian) empty individually, their orifices guarded by valves.

Dual thoracoabdominal trunks (thoracic ducts) are tightly applied to each side of the descending aorta, and communicate extensively with one another. The jugular trunks, usually two on each side, descend the neck adherent to the jugular veins. Lymph is propelled by compression of the vessels brought about by muscle contraction and body movements, backflow prevented by the valves interspersed along the vessels. In most mature birds lymph hearts are absent. A pair of contractile hearts have been reported in some ratites, anseriforms, storks, and grebes, located in the pelvic region. In birds lymph vessels, especially cutaneous vessels, and their valves are more sparse than in mammals. Most of the lymph is produced by the alimentary canal and the liver.

Lymphoid tissue. Most of the lymphoid tissue is found in the wall of the alimentary canal, cloacal bursa, thymus, spleen as well as in numerous small nodules and foci scattered throughout many organs and tissues, including the lymphatic vessels themselves. The lymphoid tissue is in the form of solitary or aggregated nodules, consisting largely of lymphocytes and organized into diffuse masses with germinal centres.

Birds generally lack lymph nodes which function as filters of lymph. Avian lymph nodes somewhat resembling those of mammals are reported to occur in adults of some anseriforms, the Coot *Fulica atra* and the Herring Gull *Larus argentatus*. In these forms only 4 nodes are present: a pair of cervicothoracic nodes located on the jugular lymphatic trunks and a pair of lumbar nodes located on the thoracoabdominal trunks in the pelvic region. The avian node is a fusiform structure grafted on to the vessel with an irregular central sinus, a central zone of lymphoid tissue, and a peripheral meshwork of reticular fibres into which the sinus spaces open, allowing some filtration of the lymph. The main sinus space is central rather than peripheral as in mammalian nodes.

Accumulations of lymphoid tissue occur abundantly on the lymphatic vessels of all species examined so far. These are the mural lymphoid nodules which are embedded in one side of the vessel, protruding into the lumen. Nodules apparently have no filtration capacity.

Birds, especially the chicken, have been important research subjects in the elucidation of much basic information on adaptive immunity since it was discovered that the cloacal bursa possesses an immunological function. The bursa and the thymus are intimately connected with the development of immunity. In the early life of these organs are found the primary sources of immunologically competent cells which are seeded to other connective and epithelial tissues, where they form secondary centres of lymphoid tissue. The bursa and thymus programme the cells, which are sent elsewhere to proliferate and respond to antigens.

The *cloacal bursa* (of Fabricius) is unique to birds. A diverticulum of the proctodeal part of the cloaca, it rests on the dorsal wall of the cloaca. The bursa has a central space; its walls contain numerous lobules (follicles) of lymphoid tissue. The bursa begins to regress with onset of sexual maturity, diminishing in size and undergoing fibrosis. The bursa-dependent line of cells is represented morphologically by larger lymphocytes of the germinal centres and by plasma cells. These cells bear surface immunoglobulins which appear to function as antibody receptors for various antigens.

The *thymus* consists of a series of lobes stretched out along each jugular vein. Each lobe contains lobules of lymphoid tissue which also regress at onset of sexual maturity. The thymus-dependent line of cells is represented morphologically by the smaller lymphocytes of the circulation and the diffuse type of lymphoid tissue. These cells which carry no antibodies on their surfaces are concerned with the development of cellular immunity such as graft-versus-host, homograft, and delayed hypersensitivity reactions.

The *spleen* is a small, brownish-red organ located near the junction of proventriculus and gizzard. The spleen of birds has little or no function as a blood reservoir. It produces red blood cells only in foetal life and lymphocytes throughout adult life. As a lymphoid organ the spleen contains both thymus-dependent (diffuse) lymphocytes and bursa-dependent (germinal centres and plasma cells) lymphocytes in the white pulp and loose lymphocytes in the red pulp. The main functions of the adult spleen are destruction of red blood cells in the red pulp, production of lymphocytes in the white pulp, and uptake of antigens and antibody production by lymphocytes in both types of splenic pulp. LYREBIRD: name applied to the 2 species of Menuridae (Passeriformes, suborder Oscines). The name stems from the supposed close resemblance of the male Superb Lyrebird's tail to a Greek lyre. Lyrebirds rank among the largest passerines and are renowned for their spectacular courtship display and vocal mimicry.

The origin, affinities and even the specific name of one of the species are controversial. On the basis of their simple syringeal musculature, the aberrant lyrebirds and their distant relatives the SCRUB-BIRDS, Atrichornithidae, have long been considered suboscine and grouped together in the suborder Menurae. Lyrebirds and scrub-birds have 3 pairs of intrinsic syringeal muscles whereas the suborder Oscines usually have 4. This suboscine classification has naturally led some authors (e.g. Cracraft 1973) to propose a southern, Gondwanaland origin for the Menurae, even though most of the extant Australian avifauna, except possibly the ratites, is probably of northern origin.

Recently, C.G. Sibley proposed on the basis of a review of anatomical and egg white protein comparisons that lyrebirds and scrub-birds are oscine and allied to the bird-of-paradise–bowerbird assemblage. He advocates dropping the suborder Menurae and placing lyrebirds and scrub-birds next to Ptilonorhynchidae in Passeres. He thus considers lyrebirds part of the 'corvine assemblage' and probably of Asian origin. While the morphology of the stapes (see SKULL) also supports the affinities with the oscines (Feduccia 1975), the alleged close relationship with bowerbirds and birds-of-paradise is not reflected in the appendicular myology (Raikow 1978). Nonetheless a more distant sister-group relationship with this assemblage remains possible.

Characteristics. Lyrebirds have weak powers of flight but run swiftly. Flying is limited to downhill gliding and short, clumsy flights of a few metres between tree branches. Despite this, they roost high in the forest canopy (especially males), ascending by jumping from branch to branch and gliding. They are very 'shy' and difficult to approach and observe.

The Superb Lyrebird *Menura novaehollandiae* is mainly dark brown dorsally and grey-brown ventrally. The Albert Lyrebird *Menura alberti* is more rufous-brown above and has rufous rather than grey undertail coverts. Both species have long legs and large feet equipped with big claws, and are sexually dimorphic in size and tail plumage. Male Superb Lyrebirds (80–90 cm long) have highly modified rectrices comprising 2 outer lyrates, 2 medians and 12 filamentaries. The lyrates are 's'-shaped with one vane greatly reduced; their upper surfaces are dark brown edged with black, their under surfaces white (except in the race *edwardi*). The broad vane has a black tip and many transparent notches edged with rufous on the underside. The medians have very narrow vanes, while the filamentaries, black above and white below, have widely spaced distal barbs which lack barbules. The smaller female has unspecialized rectrices, except for the outermost 2 which have transparent notches like male lyrates. Male Albert Lyrebirds also have unspecialized lyrates but their tails are otherwise like those of male Superb Lyrebirds.

Superb Lyrebird *Menura novaehollandiae*. (*N.W.C.*).

Distribution and habitat. Lyrebirds are endemic to Australia and restricted to the mountains and foothills of the south-eastern seaboard. The Superb Lyrebird ranges from southern Victoria to south-eastern Queensland, inhabiting mainly wet sclerophyll eucalypt forest and temperate rainforest dominated by beeches *Nothofagus*. However, it also occurs in sub-tropical rainforest and the *edwardi* race is restricted to drier, open forest in the granite country of southern Queensland. The Albert Lyrebird has a much more restricted range, occurring only in subtropical rainforests in a narrow belt in north-eastern New South Wales and southern Queensland. In 1934 the Superb Lyrebird was introduced to Tasmania where it now has a restricted range in wet sclerophyll and temperate rainforest.

Food. Lyrebirds eat mainly soil-dwelling invertebrates which they expose by digging with powerful feet capable of removing large obstructions such as stones and roots with comparative ease. In southern Victoria, Superb Lyrebirds typically catch about 13–17 prey per minute of foraging and dig to a maximum depth of approximately 12 cm. Invertebrates living in fallen, rotting logs are also secured by ripping away the covering bark and outer layers with the claws. The adult diet has not been quantitatively documented, but widely overlaps that of the nestling whose principal foods are earthworms, amphipods, spiders, millipedes, centipedes, isopods and fly and beetle larvae. Superb Lyrebirds regularly drink from streams and surface pools.

Behaviour and mating system. Both lyrebird species probably exhibit sexual bimaturism (deferred male maturity). Male Superb Lyrebirds gradually acquire adult-type rectrices from age 2–5, 6 or 7 years. They frequently associate in pairs or trios characterized by much mutual aggression and display during their early development. Shortly before or when the full adult tail has developed, they become territorial and begin to show courtship behaviour; females are thought to commence breeding at a much earlier age. Adult males occupy marginally overlapping territories averaging 2.5–3.5 ha throughout the year and defend them by displaying, chasing and singing. In southern Victoria, males are fairly evenly dispersed throughout suitable habitat. However, they often have a preferred singing area within the territory, and since those of some neighbours are commonly adjacent across a shared boundary, temporary clustering sometimes occurs during display and countersinging.

Lyrebirds exhibit arena behaviour. Male Superb Lyrebirds clear and maintain many earth mounds 1–1.5 m in diameter on their territories and spend up to 50% of daylight singing and displaying on them, as well as on the ground, on fallen trunks and in trees, during the mating season. Male Albert Lyrebirds display on well-concealed platforms of criss-crossing vines and/or fallen branches on scratched ground (Curtis 1972). Copulation is probably largely restricted to the mounds and platforms.

Male Superb Lyrebirds are polygamous, probably promiscuous, and take no part in caring for the young (see POLYGAMY). In southern Victoria, 2–3 female breeding territories lie within or partially overlap each male territory and some females visit more than one displaying male immediately prior to laying. Heterosexual association between adults is limited and typically brief (Lill 1979a), so that pair-bonding seems to be absent. However, some hens have been recorded copulating with the same male in successive seasons (see Reilly 1970 and Kenyon 1972 for other interpretations of the parental care and mating systems).

Voice. The territorial song of the Superb Lyrebird contains a loud, species-typical component lasting about 5–6 s, audible from 1 km under minimal wind conditions and exhibiting marked local dialects. But up to 80% of territorial song is composed of extended bouts of mimicry of the vocalizations of a wide range of co-habiting bird species (see MIMICRY, VOCAL). There is some evidence that these are learned in part from conspecifics rather than the models themselves. The mimicked sounds include the antiphonal duetting of whipbirds *Psophodes*, kookaburras *Dacelo* and magpies *Gymnorhina* and the wing-beats and calls of flying flocks of *Rosella* parrots. A quieter type of singing occurs during close pursuit and courtship of hens away from the mounds. This often contains mimicked bird calls rarely heard in territorial song, as well as mimicry of dogs barking and, reputedly, occasionally sounds made by inanimate objects. Females can produce full territorial song including mimicry but do so infrequently. Superb Lyrebirds also give 3 distinct species-typical calls during courtship display and emit loud whistles when alarmed. The Albert Lyrebird also has a loud territorial song and a softer courtship song, but its mimicry is restricted largely to only 4 or 5 avian models (Smith 1976).

Display. In full courtship display, the singing male Superb Lyrebird holds the rectrices horizontally over the back so that they form a fan spread over and in front of the bird. The white undersurfaces of the lyrates and filamentaries are thus strikingly exposed. When a female visits the mound, however, the rectrices are held forward but close together and rapidly quivered. Courtship climaxes in rapid circling and jumping displays. Away from the mounds and main display area, courtship involves quiet song, wing-lowering and tail-shaking. The display of the male Albert Lyrebird has been less well described but is broadly similar.

Breeding. Both species commence breeding in winter. The nest of the Superb Lyrebird is a large chamber with a side entrance and averages 14 kg. The base and sides are built of sticks, the interstices being packed with moss and bark strips. The chamber is lined and roofed with fine rootlets and sometimes a little green vegetation is placed on the roof. Immediately before laying, some body feathers are added to the chamber floor. Nests are constructed from ground level to 22 m, the preferred range being up to 2 m. The principal nest sites are on earth banks and rock faces, in trees and grass and sedge clumps, and on boulders. Nestbuilding is usually protracted over several months (Reilly 1970, Lill 1980).

The clutch-size is one and re-laying is uncommon. The egg is grey with dark brown markings and averages 62 g when fresh. The full incubation rhythm takes up to 18 days to develop and even then daytime attentiveness averages only 45%. Throughout incubation the egg is continuously deserted for 3–6 hours each morning, during which time embryonic temperature falls to and remains at the prevailing ambient level of less than 10°C and development is presumably interrupted. Consequently the incubation period is unusually long, averaging 50 days (Lill 1979b).

The newly-hatched chick with its incomplete dorsal cover of black down is brooded for a gradually diminishing percentage of daylight hours until it is effectively homeothermic at about 10 days old. However, it also chills appreciably during maternal absences in the first few days after hatching. In the post-brooding stage, the nestling is fed about 3 times per hour, the mother storing collected food in a gular sac. During the 47-day nestling period the chick's weight increases roughly 12-fold to an average fledging weight which is 63% of adult female body weight. Available nesting success estimates vary widely from 11–20% to 65–79% and introduced mammals and native birds have been implicated as the major nest predators (Lill 1980). Fledglings leave the nest in October and November and accompany and are partly fed by the mother for up to 8 months. Although the breeding biology of the Albert Lyrebird is less well known, the main features are similar.

Lyrebirds were slaughtered in great numbers in the 19th century for their tail plumage. Nowadays both species have protected status and are quite common in suitable habitat. The impact of introduced predators on recruitment is difficult to assess; probably the main threat to lyrebirds' survival is continuing large-scale clearance of wet forests for commercial purposes. M

MACAW: substantive name of the Neotropical *Ara* spp. and *Anodorhynchus* spp. (Psittacinae, Arini). (see PARROT).

MACHAERAMPHINAE: see HAWK.

MACHAIR: florally rich turf on leeward side of dunes on north-west Scottish coast and especially in the Hebridean islands.

MACROCHIRES: name formerly used for the order APODIFORMES; SWIFT.

MACROSMATIC: having a highly developed olfactory sense (see SMELL).

MADAGASCAR: see MALAGASY REGION.

MAGELLANIC PLOVER: *Pluvianellus socialis*, sole member of the Pluvianellidae (Charadriiformes, suborder Charadrii).

Characteristics. The superficially dove-like Magellanic Plover is a small grey wader, *c.* 20 cm long, with a white belly. It has a short straight bill, stout legs and feet, and a bright coral red iris. Though formerly classified with the plovers (Charadriidae), its closest relatives are the sheathbills (Chionididae).

Habitat and distribution. It breeds along gravel shores of small fresh-water ponds in Patagonia and northern Tierra del Fuego, and winters in sheltered bays and estuaries on the coast of Argentina north to Chubut Province. During the breeding season it is sparsely distributed and the entire population may not exceed several hundred individuals.

Food. Magellanic Plovers feed exclusively on invertebrates which they obtain by walking slowly along the shore or upper beach and pecking at the surface. In a unique behaviour, they also stand in one spot and spin, phalarope-like, using their feet to excavate shallow holes in areas of rotting vegetation where fly larvae are common.

Breeding. During the breeding season, they are invariably found in pairs, whereas in winter they form small flocks and often associate with Two-banded Plovers (*Charadrius falklandicus*) and other waders. Although at least 10 distinct vocalizations have been documented, the birds are quiet and inconspicuous at all seasons.

Nesting begins in September. Linear territories are established along the lake shore and are defended in a complicated display involving both members of the pair. The clutch consists of 2 relatively small unspotted eggs, laid in a nest-scrape lined with a few pebbles and incubated by both parents. Apparently only one chick is raised. Both parents feed the chick by regurgitation. The chick grows slowly and makes its first flight at 28 days of age. It remains with the parents, and is still being fed by them, at least until day 40.

MAGNETIC SENSE: see NAVIGATION.

MAGPIE (1): substantive name of the two species in several genera of Corvidae; used without qualification, in Britain, for *Pica pica* (the 'Black-billed Magpie' of North America)—see CROW (1).

MAGPIE (2): substantive name of the two *Gymnorhina* spp. in the family Cracticidae (Passeriformes, suborder Oscines).

Characteristics. These similar crow-like birds of upright stance, about 25 cm high, have boldly pied plumage, with black underparts, wings (with white flashes) and head; the tail is white with a terminal black band. In the Black-backed Magpie *Gymnorhina tibicen* the back is black and the male has a white nape and rump, which are variably greyish in the slightly smaller female. The males of the White-backed *G. t. hypoleuca* and Western *G. t. dorsalis* are pure white-backed and the females are mottled grey-backed, darker in *dorsalis*. In first-year birds the pied effect is reduced by grey or buff fringes to all the feathers; this varies in degree so that some individuals are much lighter and others darker than average. Most second-year plumages resemble the adult, but some lighter individuals are difficult to distinguish from darker one-year-olds. The bill of first-year birds is dark and the pale bluish base develops in the second year until only a dark tip remains in the fully adult bird. The Western Magpie is longer-billed than the others.

Habitat. The preferred habitat is open savanna woodland, with pasture for feeding and trees for nesting, roosting and shelter. Australian magpies are most abundant, and prominent visually and vocally, in settled areas, rural and urban.

Distribution. The Black-backed Magpie occurs throughout New South Wales (except the southern border) and Queensland, becoming sparse across the north into Western Australia and southern New Guinea. The White-backed Magpie covers Tasmania, South Australia into the centre of the continent, Victoria and across its northern border into New South Wales, with further penetration and increasing scarcity northward along the Great Dividing Range and Pacific coast, finally petering out in south-eastern Queensland. Black-backed and White-backed forms interbreed, producing plumage intergrades which breed successfully. The White-backed Magpie is well established by introduction to both islands of New Zealand, where variable dark-backed birds also occur. The Western Magpie is confined to the south of Western Australia.

Food. Magpies are versatile ground feeders, taking mainly beetles and other insects, earthworms, ants and spiders, and a few frogs and lizards; they hawk for adult scarabs and grasshoppers in season, and survive on grain during frost and drought.

Voice and behaviour. The loud melodious carolling throughout the year, with social groups calling in antiphonal chorus between neighbouring territories, especially at dawn, is one of the most popular Australian bird sounds. The birds often become quite tame, and the adult male can be embarrassingly aggressive to humans near the nest. By contrast, in the outback they are shy and distant.

The habitat is divided into permanent territories of about 8 ha strongly held all year by small social groups of Black-backed and White-backed Magpies; larger groups of Western Magpies hold larger areas. In the first two, non-territorial and therefore non-breeding birds form loose flocks, which feed in open treeless pasture by day and roost in denser woodland up to several km distant; in Western Magpies, all birds are in territorial groups. Top-quality habitat contains all requirements for survival and breeding within each territory, often in excess of needs; it is held most strongly and permanently, and birds so ensconced never leave their territory so long as the group remains intact to defend it. At all seasons there is intense competition by groups and individuals to improve their habitat and social status; groups pre-formed in the flock continually seek entry to breeding habitat, and familiarity with the voices of neighbouring birds enables vacancies to be exploited at once. In dry country, where food may be less abundant or seasonally unreliable, territories are enormous.

Breeding. In treeless country, magpies nest on telegraph poles, low bushes, and even the ground. The nest of twigs lined with grass or wool contains 3–5 mottled eggs during July to October, and is usually obvious in the outer canopy of a gum tree. The hen does all the building and incubation, and often alone rears the nestlings for 4 weeks, while their plaintive insistent food-begging calls can be heard for another 2 months or more. The males police the territory, and the females assist to repel invaders of their own sex. Polygamy is common, and a sex hierarchy of dominance within the group leads to subordinate hens breeding later or not at all. In exceptional cases, where older hens are unusually tolerant or the younger ones can escape their attention, one-year-old females have bred, but most are 2 or 3 years old at first breeding. They are single-brooded and productivity is low; only 1 young for every 2 adult hens in permanent territories survives to independence, and none at all in poorer territories. A detailed large-scale study of individually-marked Black-backed Magpies during 1955–1966 (Carrick 1972) showed that social groups of 2–10 birds consisted mainly of monogamous and bigamous adults plus immatures, but all ratios up to 3 adults of each sex occurred. Territory boundaries and size remain fairly constant despite wide fluctuations in the number of occupants. Individual advancement takes precedence over group loyalty. Birds established in good territories are long-lived, and the main mortality occurs in the slightly nomadic flocks. Australian magpies are aggressive capitalists, and very sedentary birds indeed; even non-breeding individuals move only a few km throughout life. R.C. (1)

Robinson, A. 1956. The annual reproductory cycle of the Magpie, *Gymnorhina dorsalis* Campbell, in south-western Australia. Emu 56: 235–336.

MAGPIE-LARK: substantive name of *Grallina cyanoleuca*, one of the 2 species in the family Grallinidae (Passeriformes, suborder Oscines), the other being the Torrentlark *G. bruijni* of New Guinea (see Schodde 1975 and CHOUGH (2)). Alternative English names for the group are 'mudlark' and 'mud nest-builders'.

Characteristics. The Australian Magpie-lark, 26–30 cm long, is a medium-sized boldly pied bird, showing conspicuous sexual dimorphism in head and throat patterning. The relatively long legs are black, the beak and iris creamy white. The male's crown and throat are black, with white eyebrow and cheek patches. The female's crown and breast are black, but a black vertical stripe runs through the eye and joins them; forehead, throat and sides of the head are white. Juveniles have the black forehead and white eyebrow of the male and the white throat and chin of the female. They moult into adult plumage after about 3 months.

Distribution and habitat. Widespread throughout mainland Australia, but rare in Tasmania. It prefers open areas such as water margins, open woodland and cleared paddocks and rarely penetrates closed forest or dense scrub. Agricultural development, with the provision of water in dams and bores, has led to considerable extension of the bird's original range. Its wide distribution, conspicuousness and the readiness with which it has adapted to city suburbs have made it among the best known Australian birds.

Food. Magpie-larks are ground-feeders, their varied diet consisting mainly of insects, but also spiders, pond snails, small frogs and seeds.

Behaviour. Adult Magpie-larks live in monogamous pairs in all-purpose territories of 4–8 ha. Both partners actively defend the territory and share nesting duties. The pair-bond and territory probably endure for the lifespan of the birds. Aggression is mostly confined to encounters between birds of the same sex, and is most intense against single intruders. This suggests that year-round territoriality not only protects resources but, with the persistent pair-bond, has adaptive advantage for a species so dependent on rainfall for opportunistic breeding.

Unlike the adults, young birds are relatively wide-ranging. After leaving the parental territory at about 3 months old, they join local flocks of their peers, moult into adult plumage, develop song and eventually form pairs. These leave the flock, which may number from 50–3,000 individuals, at the start of the next breeding season, and set up their own territories. Ringing studies have shown that adults are sedentary and that flocks are mainly composed of first-year birds.

Voice. Magpie-larks communicate through a large and varied repertoire of strident calls, often accompanied by striking displays. These are used for communicating with the mate, while a few universal calls are reserved for contact with the young, with rivals or to warn of predators. The most interesting feature of the vocal behaviour is antiphonal singing in exact alternation. This helps to keep the partners together and the territory intact.

Breeding. The local distribution of the Magpie-lark is related to the availability of fresh surface water, since breeding depends on a source of mud for nest-building. A typical bowl-shaped mud nest was 15 cm across, 9 cm deep, with walls 2 cm thick and weighed 950 g (Serventy and Whittell 1967). Nests are built far out on bare horizontal branches often over water. Wads of grass are collected with the mud to strengthen the construction and the finished nest is lined with dry grass, feathers or wool. Clutch-size ranges from 1–4, commonly 3 eggs, white with violet or purplish brown blotches. Breeding takes place during the wet season (summer in the north, winter in the south and at variable times inland) and its success seems to depend upon an adequate spell of favourable rainfall conditions. Breeding may be stopped or interrupted in dry or unusually wet years, but birds will rear 2, or rarely 3, broods if the wet season is consistent and long-lasting. Also, rainfall outside the normal nesting season can stimulate successful breeding (Serventy and Marshall 1957). Both parents incubate and tend the young, which are downy when hatched and fledge in *c.* 20 days.

Magpie-lark *Grallina cyanoleuca*, juvenile (top), adult female and male (bottom). (*N.W.C.*).

Torrentlark. The Torrentlark has a pied plumage like the Magpie-lark and also shows marked sexual dimorphism. The legs are blackish, the iris dark brown and the bill greyish white. The male has a black face, chin, throat and upper abdomen, with a white superciliary stripe. The female is distinguished by her white forehead and breast and a more pronounced eyebrow. The Torrentlark is restricted to montane habitats where it feeds on insects along fast-flowing streams. The cup-shaped nest is made of mud and rootlets. Little is known of the species' biology and behaviour. (A.K.) S.T.

MAGPIE-ROBIN: substantive name of *Copsychus* spp. (see THRUSH).

MAINTENANCE ACTIVITY: see COMFORT BEHAVIOUR.

MAJOR MITCHELL: the Australian cockatoo *Cacatua leadbeateri*, formerly known as Leadbeater's Cockatoo (see PARROT).

MALACONOTINAE: see SHRIKE.

MALAGASH: alternative name of the Cape Gannet *Sula capensis* (see GANNET).

MALAGASY REGION: the faunal region formed by Madagascar (adjective Malagasy) and outlying islands, east to the Mascarenes, north to the granitic Seychelles. Although Madagascar, the putative main source of the avifauna of the outlying islands, is separated from Africa at the nearest point by only some 400 km, its fauna is so unique that it is now widely accepted as distinct from the AFROTROPICAL REGION. Madagascar was probably separated from Africa in the late Cretaceous. If the fossil remains found in Africa are correctly attributed to the Aepyornithidae, which is questionable (see ELEPHANT-BIRD; FOSSIL BIRDS), it would follow that their dispersal to Madagascar pre-dated this separation. Most of the remainder of the avifauna may have arrived later by flying and, as might be expected, has an African origin. Nevertheless, there is a distinct Asian element, including 3 genera unknown in Africa, viz. *Ninox*, *Hypsipetes* (=*Ixos*) and *Copsychus*.

Apart from the Aepyornithidae, which may have survived until 400 years ago, there are 3 families endemic to Madagascar, the Mesitornithidae (3 species in 2 genera), Brachypteraciidae (5 species in 3 genera) and the suboscine Philepittidae (4 species in 2 genera): see MESITE, GROUND-ROLLER and ASITY. The Leptosomatidae (1 species) are only otherwise known from the Comoros: see CUCKOO-ROLLER. The Vangidae (14 species in 11 genera, including the Coral-billed Nuthatch *Hypositta corallirostris*, formerly placed in its own family, the Hyposittidae) are only represented outside Madagascar by one of these species in the Comoros: see VANGA. Of the *c.* 180 breeding land birds (including 2 only discovered since 1970), 67% are endemic, even 94% in the passerines. Specific differentiation is so marked that the genera average less than 1.3 species each (in passerines as low as 1.1 as against 3.5 for the Afrotropical Region). Nevertheless, there is striking evidence of evolutionary radiation in the Vangidae and in the endemic genus *Coua* (see CUCKOO), with 10 species.

Ecological diversity is strongly marked. Eastern Madagascar is very wet (rainfall per annum up to 350 cm in the north-east); the original vegetation dense evergreen forest, much of it cleared for cultivation, but perhaps 3,000 km^2 still standing. A spine of highlands runs down the middle, mostly at 1,600 m, but rising in places to *c.* 3,000 m. This area, where habitat destruction has been worst, has largely degenerated into eroded grassland. The much drier west consists of more or less wooded savannas, with subdesert scrub in the south-west (rainfall less than 50 cm per annum). While some species range practically throughout (but often showing well-marked subspecific differentiation), others are very restricted. Thus, of the 10 *Coua* spp., 4 are only known from evergreen forest, one from subdesert scrub.

A figure of 180 breeding land birds is small in comparison to the Afrotropical Region. The comparable figure for Zambia exceeds 600. The water birds make up 30%, as against 16% Afrotropical (some not even subspecifically distinguishable between the two regions, but 1 in 3 in the former is endemic). Yet the Malagasy passerines account for 34% only, as against 48%. They are deficient in fruit eaters—only 1 starling (Sturnidae) and 1 bulbul (Pycnonotidae, but 6 others possibly wholly insectivorous)—and in seed-eaters, 1 lark (Alaudidae), 4 weavers (Ploceidae) and 1 mannikin (Estrildidae).

According to Cheke (1985), the volcanic Mascarenes developed a highly endemic and bizarre avifauna in the absence of any native mammalian ground predators. The Dodo and solitaires (see DODO), and the large rails *Aphanapteryx* spp. were flightless. There were also several endemic genera of parrots and starlings, and endemic species of ducks, raptors, pigeons, owls, swifts, and at least 8 families of passerines. The introduction of rats, monkeys, pigs, cats and other animals by man took their toll of the flightless birds soon after the islands were discovered and settled (16th and 17th centuries), and hunting followed by extensive habitat destruction has left only 16 survivors from the 40–45 known endemic species. The affinities of the Mascarene avifauna are with Madagascar and Asia, a pattern also shown by the native bats and reptiles.

The 4 Comoro Islands, also volcanic (Grand Comoro, still active, rising to 2,560 m), have an avifauna predominantly Malagasy, but with some Afrotropical transitional elements. The number of species of land birds (excluding water birds, few in number) is *c.* 30 per island. Endemism is considerable (1 genus, *c.* 8 species). North-eastward, towards the granitic Seychelles, there are many low-lying islets, some important for breeding sea birds, but few with more than 2 species of land bird. By far the largest and least disturbed is the elevated limestone atoll of Aldabra, rising 10 m above sea level, and 36 km long. The number of species of land (excluding water) birds attains the relatively high figure of 12, including 2 endemics, while even among the 7 water birds there are 2 endemic subspecies (6 among the land birds), one of the 2 being a flightless form of rail. The Aldabra avifauna is predominantly Malagasy-derived.

The Seychelles, possibly a continental relic, are nevertheless oceanic from the ornithological aspect. At the height of a glacial epoch *c.* 18,000 years ago, with sea levels *c.* 150 m lower than now, they would have formed a single land mass. There were at least 14 species of land bird, and 4 water birds (3 herons, Moorhen *Gallinula chloropus*) still breed. Endemic, very well marked, subspecies of parakeet *Psittacula eupatria* and white-eye *Zosterops mayottensis* apparently became extinct in the 1890s. Several of the 12 surviving land birds, under special protection, are on the upgrade from near extinction. There is no endemic genus, but 7 endemic species. As to be expected, the Asian element is more pronounced than in Madagascar and the Comoros. C.W.B.

MALAR: pertaining to the area on the side of the throat immediately below the base of the lower mandible (see TOPOGRAPHY).

MALEO: Dutch name (sometimes used as English) in Indonesia for *Megacephalon maleo* (see MEGAPODE).

MALIA: *Malia grata*, an endemic BABBLER of Celebes (Sulawezi).

MALIMBE: sometimes used as substantive name of certain *Malimbus* spp. (see WEAVER).

MALKOHA: substantive name of *Rhopodytes* spp. (see CUCKOO).

MALLARD: *Anas platyrhynchos*, the common 'wild duck', but originally applied only to the male (a usage now obsolete)—see DUCK.

MALLEE: an environment, consisting of *Eucalyptus* scrub, characteristic of Australia.

MALLEE FOWL: name, alternatively 'Lowan', of *Leipoa ocellata* (see MEGAPODE).

MALPIGHIAN BODY: see EXCRETORY SYSTEM.

MALPIGHIAN LAYER: the basal layer of the epidermis (see SKIN).

MALURIDAE: family of PASSERIFORMES, suborder Oscines; WREN (2).

MAMMALS, ASSOCIATION WITH: occurs as a regular habit of various avian species, chiefly in relation to the quest for food (see FEEDING HABITS). The most frequent role of mammals, wild or domesticated, is that of a beater, disturbing insects or other prey for birds, as they move through the herbage or foliage. Cattle Egrets *Bubulcus ibis* find food more rapidly when they are associated with mammals than when they hunt alone. Similar associations are shown by such familiar birds as the Starling *Sturnus vulgaris* associating with cattle in Europe, or by the Piapiac *Philostomus afer* with domestic stock and wild grazing mammals in tropical Africa; its habit of perching on the Elephant *Loxodonta africana* is well known, and most remarkable, because elephants do not tolerate the attentions of oxpeckers *Buphagus* spp. Examples of such associations between birds and mammals of many species, in various parts of the world, are too numerous to cite at length.

Often, the attendant bird will perch on the mammal. Aquatic and wading birds of many species habitually perch on the backs of an almost submerged Hippopotamus *Hippopotamus amphibius*: cormorants (*Phalacrocorax* sp.) are characteristic in this role. Sometimes the animal provides the bird with a vantage point for fishing, as in the case of

Great Tit *Parus major* attacking field mouse *Apodemus*. (*Photo: M.S. Wood*).

White Wagtail *Motacilla alba* and pig. (*Photo: F. Pölking*).

Hamerkop *Scopus umbretta* on the lookout for frogs; in other instances, it may be no more than a convenient resting place.

Sometimes birds find some part of their food on the beast itself, as the Common Sandpiper *Actitis hypoleucos* on the hippo's hide. The 2 oxpeckers have a closer, rather symbiotic, relation with the mammals that they frequent, feeding upon the ticks in the hide (see OXPECKER). Another special case is the strange association on the part of HONEYGUIDES (Indicatoridae) with Ratels *Mellivora capensis* and man.

In tropical forests, association of mixed bird parties with squirrels is frequent, sometimes to mob a snake or an owl, more often to catch the insects which the mammal flushes out of the foliage. The same type of association exists with duikers *Cephalophus* and various rodents. The most remarkable case is the constant association of the Hornbill *Tropicranus albocristatus* with *Cercopithecus* monkeys in tropical Africa. *Tropicranus* apparently possesses anatomical and behavioural adaptations which have evolved in connection with its constant association with monkeys.

Nesting associations with mammals are rare. The only perfect case seems to be that the Miner *Geositta cunicularia* of South America, which nests only in the burrow of the Vizcacha *Lagostromus trichodactylus*.

All associations between birds and mammals are initiated by the birds, and are for their own benefit. Nevertheless, in some cases, the presence of the birds obviously favours the security of the mammals; for example, at the approach of a potential enemy, the roving troop of *Cercopithecus* is alerted by a special call of *Tropicranus*, which is followed by modification in the behaviour of the monkeys.

For associations with mankind, see also TAMENESS. A.B.

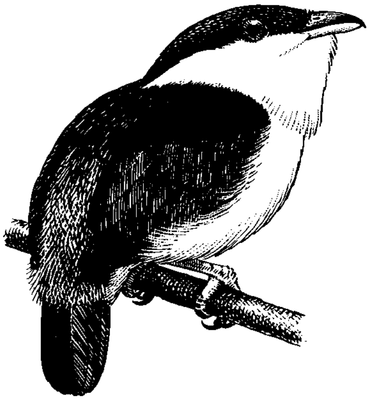
MAMMAL SIMULATION: also 'rodent run' (see DISTRACTION BEHAVIOUR).

MANAKIN: substantive name of species of Pipridae (Passeriformes, infraorder Tyranni)—not to be confused with MANNIKIN; in the plural, general term for the family. This Neotropical group of some 50 species is allied to the cotingas (Cotingidae) and, less closely, to the tyrant-flycatchers (Tyrannidae).

Characteristics. Manakins are small, stocky birds the size of tits (Paridae) 9–15 cm long, usually with short wings and tail, and with short bills rather broad at the base and slightly hooked at the tip. In most species the sexes are strikingly different, the males being predominantly black with patches of brilliant red, orange, blue and other colours, and the females greenish. In several species the males have some of the flight feathers modified for making mechanical sounds. In one species, the Wire-tailed Manakin *Pipra filicauda*, the tail feathers are prolonged into curved wire-like structures. In a few species, supposed to be primitive, the sexes are alike and mainly green or brown. It is, however, doubtful whether some of these, for example the Thrush-like Manakin *Schiffornis turdinus*, are really closely related to the typical manakins.

Habitat and distribution. Manakins are distributed throughout the lowland forests of South and Central America; few of them extend up into subtropical montane forests. Most are birds of primary forest, but some species are regular in secondary growth. They feed mainly on small fruits which they pluck on the wing; insects are also taken in small quantities by the adults, and form a major part of the food of the young. As far as known, all species are sedentary.

Behaviour. Manakins are especially notable for their elaborate courtship behaviour, which appears to have evolved under conditions of intense sexual selection. They are polygynous, the males taking no part in attending the nest. In the White-bearded Manakin *Manacus manacus* (a member of a widely distributed assemblage of forms, including Gould's Manakin which is sometimes treated as a separate species, *M. vitellinus*), the males display in LEKS. Each clears for itself a small 'court' on the floor of the forest, taking away all leaves and twigs that are small enough to be carried, and dropping them a few metres away. Each court contains a vertical sapling that serves as the main display perch, and one or more other saplings. On and around his court the male executes astonishing jumps and evolutions of a highly stereotyped nature. Various loud snapping and whirring noises are made with the wing feathers, the secondaries having much thickened shafts and a special musculature, while the outer primaries are thin, stiff and curved. The females visit the males at their courts and take part in a joint dance with them. Mating in



White-bearded Manakin *Manacus manacus*. (*R.G.*).

this genus, as in the other species studied, takes place on the main display perch.

Several *Pipra* species that have been studied display on horizontal perches between about 2 and 15 m up in trees or saplings, below the main forest canopy. Their displays consist of various elements: a swift flight to the perch from a distance, often accompanied by vocal or mechanical sounds; 'sliding' movements along the perch (in fact, very short and rapid steps); raising of the wings and spreading of the tail; rapid about-turns on the perch; and quick to-and-fro flights between the main perch and an adjacent perch, accompanied by mechanical wing-noises. Some *Pipra* species, e.g., the Golden-headed Manakin *P. erythrocephala*, display in typical leks, while in others the males are dispersed more widely, within sound but not in sight of one another. In a group of 3 closely related species that includes the Wire-tailed Manakin, the owner of a display perch is regularly joined by a visiting, or subordinate, male, and the two perform beautifully coordinated joint displays. The Wire-tailed Manakin has a unique display that makes use of its modified tail: the male faces away from his display partner, elevates his tail, and with a rapid twisting movement of his body brushes the other bird's throat with the wire-like tips of his tail-feathers. This display is little used in the joint displays of males (mentioned above), but is the main element of the male's display to a female.

The displays of several species are remarkable, but little known. In 2 species of *Machaeropterus* the male hangs head downwards on a vertical perch and rapidly turns the body from side to side while making a grasshopper-like reeling sound. It is noteworthy that, in *Machaeropterus* and some other species, observers have found it extremely difficult to determine whether certain sounds accompanying the displays are vocal or mechanical in origin. In *Corapipo gutturalis* the male is described as crouching on the ground and, with wings fully spread, moving towards the female in a laboured undulating crawl, an action strikingly like that described for the bowerbird *Archboldia sanfordi* (see BOWERBIRD).

The 4 species of *Chiroxiphia* have perhaps the most remarkable behaviour in that 2, or in *C. caudata* 3, males take equal parts in various joint displays that serve to attract and stimulate the female, after which one male only (apparently always the dominant male of the group) takes part in the final phase of courtship and copulation. The most striking of the joint displays is a 'catherine wheel' dance. When a female comes to the display perch the males face her; the front bird then jumps up and, hovering, moves backwards through the air while the other (in *C. caudata*, the next) bird hops up into his place and in his turn jumps as the first bird lands. The dance is accompanied by a rhythmic twanging, consisting of alternating calls uttered by each bird as it hovers.

Breeding. Except for *Schiffornis*, which builds a bulky cup nest composed chiefly of leaves (and may not be at all closely related to the typical manakins), all manakins whose nests are known build thinly woven cup nests slung in a horizontal fork of a tree branch, sapling or fern, at heights ranging from less than a metre to as much as 15 m above the ground. The clutch normally consists of 2 eggs. The eggs are pale grey, brown or beige in ground colour, mottled and spotted with darker brown. Recorded incubation periods are mostly 17–19 days, and fledging periods 13–15 days. The female alone builds, incubates, and cares for the young. D.W.S. (1)

MANDARIN: substantive name, often used instead of Mandarin Duck, of *Aix galericulata*, a highly ornamental Chinese duck now naturalized in Britain (see DUCK).

MANDIBLE: term sometimes used without qualification for the lower jaw (compounded of several bones—see SKULL) and its horny covering (see BILL), and in this sense contrasted with 'maxilla'; in another usage applied to either jaw, with the adjective 'upper' or 'lower' (see also MAXILLA; MUSCULATURE).

MANGO: substantive name of *Anthracothorax* spp. (for family see HUMMINGBIRD).

MANGROVE SWAMP: a specialized type of environment widely distributed in tropical parts of the world and bordering areas of the sea, tidal rivers, or saline marshes; it consists of mangrove trees (several species) growing closely together out of water and liquid mud, presenting a most formidable obstacle to human ingress.

MANNIKIN: substantive name of various *Lonchura* spp.; in the plural, general term for a tribe (Amadini) of the Estrildidae (see ESTRILDID FINCH). Not to be confused with MANAKIN.

MAN O' WAR BIRD: sailors' name for *Fregata* spp. (see FRIGATE-BIRD).

MANTLE: see TOPOGRAPHY.

MANUBRIUM: forward process of the sternum (see SKELETON, POST-CRANIAL).

MANUCODE: substantive name of species of *Manucodia* and *Phonygammus* (see BIRD-OF-PARADISE).

MANUS: the 'hand' (see SKELETON, POST-CRANIAL; WING).

MAO: *Gymnomyza samoensis*, a HONEYEATER endemic to Samoa.

MAPPING: see CENSUS.

MARABOU: also 'Marabou Stork', *Leptoptilos crumeniferus* (see STORK).

MARGARORNITHINAE: see OVENBIRD (1).

MARGINAL COVERTS: see TOPOGRAPHY.

MARISMA: Spanish word applied to marshy country, notably in the delta of the Guadalquivir (an important bird habitat).

MARKING: a term initially confined in its application to what is now known as 'bird ringing' or 'banding', but conveniently extended as a comprehensive term for all techniques used to mark birds. All forms of

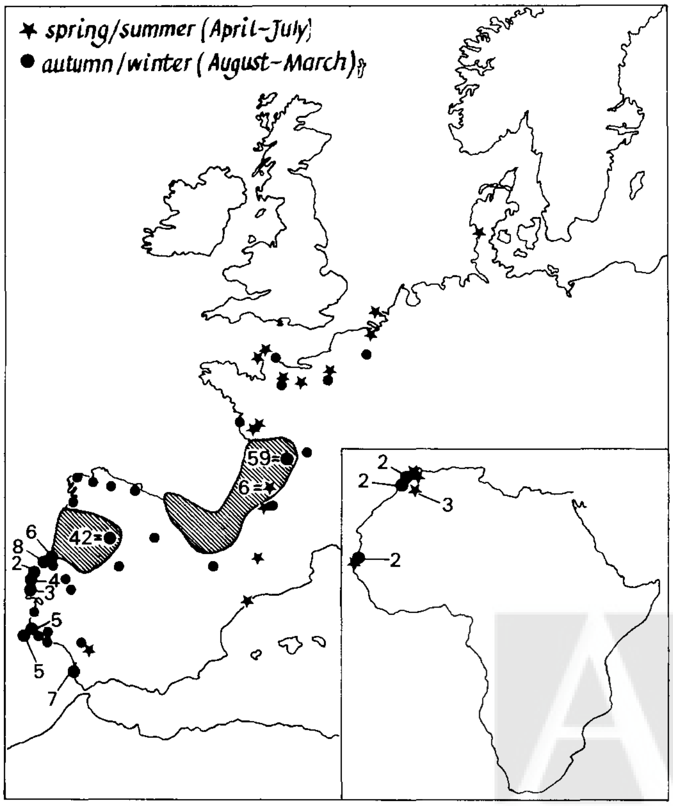

Fig. 1. Recovery localities of Common Whitethroat *Sylvia communis* ringed in Great Britain. The British population of this species migrates slightly west of south to its wintering area in West Africa. There is a major autumn stop-over area in northern Portugal.

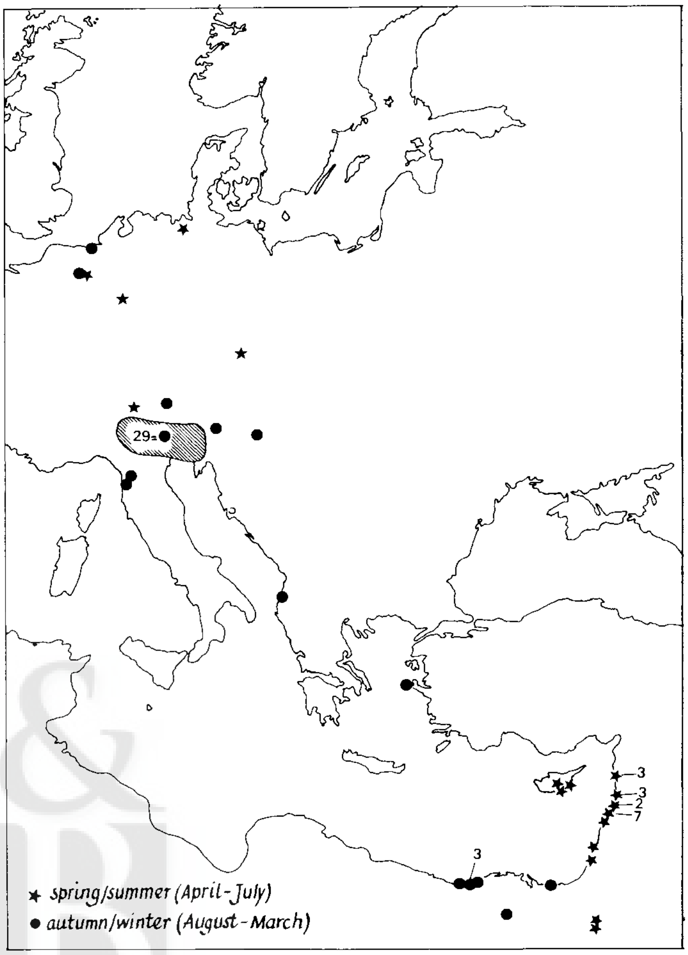

Fig. 2. Recovery localities of Lesser Whitethroat *Sylvia curruca* ringed in Great Britain. The British population migrates south east to winter in East Africa. The recoveries indicate staging posts in northern Italy and, probably, the Nile Delta in autumn and in Asia Minor during the spring.

marking have in common a basic purpose: to make a bird recognizable, either as an individual or else as a member of a class, e.g., a brood, a colony or an age group. The many techniques now in use may be divided into two categories: the extensive system, generally organized on a national or even Continental basis, in which public co-operation is normally important or essential, and the intensive or private systems, in which the marks are meaningful only to the operator, or to those he initiates.

The main—almost the only—extensive technique is known as bird ringing, the term 'banding' being preferred in North America and Australasia. The private or intensive techniques include colour ringing or marking in various forms, tagging, radiotelemetry, undertaken for reasons of research, and closed ringing for captive birds (see CAGE BIRD).

Bird ringing. The essential feature of bird ringing, as here defined, is that each ring carries, in addition to a unique serial number, a postal address to which any finder of the ring is invited to write. Usually both number and address appear on the outside of the ring, but in North America, on the smallest sizes, the return address may be on the inside.

The rings are bands of metal which are fixed around the tarsus (or, occasionally, tibia) of the bird. They range in size from an inside diameter of 1.8 mm to one of 30 mm. Aluminium or aluminium alloys are used for small sizes. Large sizes are frequently of modern alloys such as monel, incoloy or stainless steel. Most rings are supplied in the shape of a 'C', which is closed to form a circle round the leg. In some countries the largest rings are secured by having the two ends brought together and bent over to form a clip.

The rings may be fitted on nestlings, as soon as the legs and feet are sufficiently developed, or on fully-grown birds caught specially for ringing (see TRAPPING). As a part of their bird-ringing scheme, certain issuing authorities have also used wing-clips. These resemble small safety-pins, the pin being passed through the PATAGIUM and secured in the cap, upon which are marked the usual inscriptions of address and serial number. Wing clips are especially used for marking young Anatidae, which may be very difficult to catch by the time their legs have grown sufficiently to retain an ordinary ring (but see next paragraph). Their chief disadvantage is that they are inconspicuous when partly concealed by the feathers and hence produce proportionately fewer recoveries than do rings.

A technique developed in Latvia temporarily reduces the inside diameter of rings with soft plasticine or florist's wax, thus permitting ducklings to be marked at a much earlier age and obviating the need for wing tags. The growing tarsus squeezes out the plasticine or wax so that the inside diameter is automatically adjusted to the diameter of the tarsus.

The details of species, race, age, and sex (if ascertainable), date and locality are recorded for each ring used and the bird is released or returned to the nest. The ringing data are entered on schedules which are filed at the headquarters of each scheme for reference.

Objects. Two broad categories of study may be recognized, migration and vital statistics, including life histories. The more spectacular nature of migration studies attracted attention from the outset (see MIGRATION), whereas the use of ringing for population studies and similar investigations began rather later and new methods of interpretation are still being developed.

Results. Ringing data, based on the accumulation of individual case histories, provide generally more precise information than other migration study techniques. Limitations arise from the small proportion of birds recovered and the fact that the geographical distribution of these recoveries may not be fully representative. Effectiveness in determining the summer and winter distribution of migratory species tends to bear a close relationship to the density of the human populations in the areas concerned, their literacy, and their hunting traditions. Thus, for the Anatidae wintering in Britain, with a breeding range extending northwards and eastwards across Europe, the recovery rate may exceed 20% for some species and is generally over 10%. In contrast, small passerines wintering in Africa may show a recovery rate of less than 0.5%. Common British garden birds have recovery rates in the range 1–4%, although the figure for particular species may vary appreciably between rural and suburban areas. Because of the high human population and the high level of ringing activity, ringers operating in countries like Britain and the Netherlands tend to enjoy much higher recovery rates for non-quarry species than do ringers in other parts of the world. Furthermore, improved catching efficiency, associated especially with mist nets and cannon nets (see TRAPPING), is leading to further improvement. For many species, ringers can now rely on re-capturing far more of their ringed birds than will be reported by the public—a factor of obvious importance in the development of population studies.

For species with low recovery rates, there are generally still too few records to permit detailed analysis of summer and winter distribution. Recoveries providing data about migration are more numerous and may be used to determine such features as the direction and sometimes the speed of migration, and time of arrival of passage migrants in given areas. Only ringing can provide quantitative data for the study of partial migration and abmigration, and the presence of ringed birds in 'wrecks' and other weather movements is often a valuable guide to the origin of the populations involved. For species which may be at risk, as for example, auks from oiling, raptors from pesticides, terns from persecution, the policy of keeping a proportion of the population ringed at all times provides a sensitive monitoring system. Locally, ringing has proved effective as a means of studying the gathering area for communal roosts and the feeding ranges of colonial nesters.

In the study of population dynamics, ringing data have been used to establish the age at which breeding begins; age structures of populations; annual, seasonal, and regional variations in mortality; common causes of death. The value of such data depends on the fate of the recovered birds being representative of what happens to all birds. This may be almost impossible to prove, but allowance can be made for recognized sources of bias, and recovery data are generally regarded as valid (see ECOLOGY).

In long-lived species, including many seabirds, longevity studies were for a time handicapped by the weakness of the aluminium rings. The harder modern alloys, first introduced in the late 1950s, are beginning to produce more realistic survival figures (see AGE).

History. Although there had been sporadic attempts and a few schemes (in Great Britain from 1890) of limited scope, the first ornithologist to undertake systematic large-scale ringing was Christian Mortensen of Viborg (Denmark), who commenced his experiments in 1899. Germany was quick to take up the study (1903) and the pioneer 'Vogelwarte' at Rossitten, on the Baltic, did much to establish the value of ringing. The practice soon gathered impetus: Hungary (1908), Great Britain (1909), Yugoslavia (1910), Holland (1911), Sweden (1911), Denmark (1914) and Norway (1914) all had effective schemes before the 1914–1918 war. Between the two World Wars there was a rapid growth in the number of ringing schemes, especially in Europe, at least 15 being established between 1918 and 1930, and a further 8 by 1939. In North America the start was later, for although an American Bird Banding Association was founded in 1909 (and Jack Miner was marking wildfowl before 1914 with rings carrying Biblical quotations instead of serial numbers), the two main centres, at Washington and Ottawa, were not established until 1920 and 1922 respectively; but the growth of activities was rapid and the scale of ringing soon outpaced work of individual European centres. Outside Europe and North America, ringing has been on a small scale, and generally of recent development, as is shown by the following dates of commencement: Japan (1924), Egypt (1937), New Zealand (1947), Tasmania (1947), Union of South Africa (1948), Australia (1953), and Zaire (1954). Marking has also been done in the Antarctic (e.g., by the UK, USA, France, Australia and New Zealand) and from time to time on various oceanic islands.

In Britain, H.F. Witherby in London and A. Landsborough Thomson in Aberdeen both started comprehensive schemes in 1909. The latter scheme came to an end during the First World War, but the former developed steadily under the guidance of its founder until 1937, when responsibility for the organization was handed over to the British Trust for Ornithology, and a special Bird Ringing Committee was appointed to control activities, with headquarters at the British Museum (Natural History). Although the scheme was for many years financially self-supporting, since 1954 it has required a subsidy, currently from the Nature Conservancy Council. In 1963, the headquarters moved to Tring in Hertfordshire (see also OBSERVATORY, BIRD).

In Europe a major obstacle to full use of ringing data has been the dispersed housing of the results, with over 30 different ringing schemes holding data and working autonomously. To meet this problem EURING, the European Union for Bird Ringing, was established in 1963 to standardize both methodology and terminology throughout the continent. The advent of computer facilities permitted the inauguration of an international data bank of European recoveries, at Arnhem in the Netherlands. This now stores recovery data for more than half the birds ringed in western Europe. Even in western Europe not all countries contribute to the Data Bank, while data from eastern Europe are as yet very unevenly represented.

In North America a single banding scheme covers the entire continent. The main direction of effort has been towards birds of economic importance and the high annual intake of recoveries necessitated early use of computers to facilitate analysis. Sophisticated capture–recapture techniques have been evolved for use in population studies, while in the field of passerine migration annual corporate studies were introduced under the code name 'Operation Recovery'.

Intensive or private techniques. The aim of most intensive marking techniques is to permit the recognition of individual birds at a distance, and there is little point in so marking birds unless the research worker is prepared to spend long hours of observation or to publicize widely a request for sightings. National and international discipline in the launching of colour marking programmes is essential to prevent inadvertent duplication of codes, but is too often lacking.

Most early studies used celluloid rings, but these rarely incorporate light-fast pigments so that the colours fade in a year or two. For a time anodized aluminium was used, but modern plastics such PVC and Darvic have proved more satisfactory. 'Traditional' colour ringing usually involves the use of several different rings on each bird: for example yellow over blue left leg, yellow over red right leg. On bigger birds this has generally been superseded by the use of large laminated plastic rings engraved with large figures and/or letters. On geese, in favourable conditions, the detailed combination of letters and numbers may be read by telescope at distances up to 300 m.

Other devices. For species which spend much time in the water, engraved leg rings may be of limited use. This has led to the development of neck collars, chiefly used on geese and swans, of nasal discs, used on ducks and of small plastic patches temporarily cemented to the plumage of head or wing. For the easier identification of birds on the wing, tags have been developed. Most are attached by a stainless steel pin, passed either through the patagium or elsewhere in the wing; some wrap round the wing, overlying the scapulars. Tags may be colour-coded or carry a combination of letters and figures.

Radiotelemetry has been used to facilitate the tracking of birds by aeroplane, but is chiefly (and increasingly) employed for very intensive local studies. The equipment permits detailed, round-the-clock monitoring of movements, but despite advances in the miniaturization of both transmitter and battery, the weight factor still renders the technique unsuitable for use on small birds. The high unit cost of the equipment, which is often lost, means that few individuals can be marked in any one programme (see RADIO TRACKING AND BIOTELEMETRY).

Radio-isotopes, bonded to conventional metal rings, have been used to obtain round-the-clock records of the incubation roles of male and female seabirds.

Web tags. In detailed studies of Anatidae it may be important to recognize the young as individuals from soon after hatching, at which stage their legs and feet are much too tiny to take a ring appropriate to a fully-grown bird. As an alternative to the wing clip already described, which is used as a permanent mark, small tags may be passed through the web of the foot, a conventional ring being substituted at a later date. Work in the United States has demonstrated that the same end can be achieved by the use of a variously placed tiny hole in the web.

Plumage dyeing has been much used on pale-coloured birds ranging in size from small waders to swans. Dye offers a short-term approach, being lost with the first moult, but because of its conspicuousness at long range it has proved invaluable in tracing the migratory paths of birds such as Bewick's Swan *Cygnus columbianus bewickii*.

Close ringing. This technique differs from the others in that the rings are not split but are true rings. Their use is confined to nestlings, which are marked while the foot is still small enough to permit the rings to be slipped on; once the foot is fully grown the ring cannot be removed. Close rings are of little value to ornithologists, but aviculturists and pigeon-fanciers use them extensively to establish individual identity and ownership; and in the law of several countries a correctly fitted close ring is taken as proof that the bird was bred in captivity (see CAGE BIRD).

In recent years the high-value, often illegal, trade in birds of prey has led to much research into a tamper-proof ring which can be 'locked' on to the leg of a bird for life. It is too soon to say whether designs evolved will successfully fulfil their function. R.S.

Mead, C.J. 1974. Bird Ringing: BTO Guide 16. Tring.
Stonehouse, B. (ed.). 1977. Animal Marking: Recognition Marking of Animals in Research. London.

MARROW: see BLOOD; SKELETON, POST-CRANIAL.

MARSH-BIRD: substantive name of 2 South American icterids of the genus *Pseudoleistes* (for family see ORIOLE (2)).

MARTIN: substantive name of some species of Hirundinidae (see SWALLOW).

MARTLET: archaic and heraldic name for a bird which may have been either the House Martin *Delichon urbica* (or other hirundine) or the Swift *Apus apus*, perhaps used for both (see HERALDIC BIRDS).

MATE: either member of a pair in relation to the other (see PAIR).

MATING: see COPULATION.

MATING SYSTEM: that part of the social organization of a species that involves the relationship between the sexes, especially copulation and the subsequent events of the breeding cycle.

In the great majority of birds—over 90% of all species—more or less long-lasting pairs are formed (see PAIR FORMATION), which usually persist through the breeding season and in some birds for life. The minority, which do not form simple pairs, show a great variety of mating systems, mostly involving some form of polygamy. Because of its prevalence in most families of birds it is generally thought that monogamy is the primitive condition in birds, and that polygamous systems are later specializations. There are two main forms of polygamy: polygyny (the mating of one male with two or more females) and polyandry (the mating of one female with two or more males). Both polygyny and polyandry may be simultaneous, when a bird has several mates at the same time, or successive (serial), when a bird has several mates in quick succession. A clear-cut classification of mating systems is difficult because they are not necessarily mutually exclusive; thus in some species polygyny is combined with successive polyandry.

Some species, especially those with LEK displays, seem to be promiscuous in their mating; but detailed study is needed in order to establish this, and it is unlikely that both sexes will be equally promiscuous. Thus in some lek species which had been thought to be promiscuous, observation of marked birds indicates that females show well-marked attachments to particular males. In general it will be expected that males will be more promiscuous than females, because of the very different parental investment in each mating by the male and female. Males invest very little in each mating, and there is no great disadvantage to them in a mating which is unsuccessful in its outcome; but females invest a great deal in each reproductive attempt, and choice of a suitable mating partner is important.

Some ecological correlates of the different mating systems are clear. Monogamy is usual when the conditions in which a species breeds are such that both parents are needed for the successful rearing of the young; polygamy and promiscuity are possible only when one parent is able to rear the young single-handed. Hence, polygamy and promiscuity are found mainly in birds with precocial young, especially if the young find their own food, and in birds with altricial young if their food is plentiful or easily found. It is probably for this reason that polygyny is found in several groups of seed-eating, fruit-eating and nectar-eating birds, and very rarely in insectivorous birds. Other factors are, however, important. For instance frugivorous birds that nest in holes tend to live strictly in pairs, probably because both parents are needed to guard the nest-hole.

Another predisposing condition for the evolution of polygyny is that a proportion of the males can occupy all the suitable nesting territories, the other males being relegated to suboptimal or unsuitable territories. If females of such species make their choice mainly on the basis of the quality of the male's territory, a small proportion of the males may acquire most of the females. This kind of system has been demonstrated in some American marsh-breeding icterids (see ORIOLE (2)) and may also apply to some weaver-birds and in less extreme form to some arctic sandpipers. A related system, apparently rare, involves the male's domination over an essential food resource. Male Orange-rumped Honeyguides *Indicator xanthonotus* defend the huge combs of the honey-bee *Apis dorsata*: the females mate only with comb-holding males, and they and their offspring have access to the combs of the males with which they have mated. In some hummingbirds a similar system probably obtains, the resource in this case being a clump of flowers held by a territorial male.

Several species of waders that breed in the far north, or in montane areas, have mating systems ('rapid multi-clutch systems'—Graul 1974) enabling them to make the fullest possible use of the short period that is suitable for nesting. The essence of such a system is that the female lays two or more clutches in quick succession; it may be combined with monogamy, the male incubating the first clutch and rearing the young and the female taking charge of the second clutch (e.g. Temminck's Stint *Calidris temminckii*, Mountain Plover *Charadrius montanus*), or with serial polyandry, the female laying clutches for two or more males (e.g., Dotterel *Eudromias morinellus*, Spotted Sandpiper *Actitis macularia*).

For details of the various forms of polygamy, and of the groups in which they occur, see POLYGYNY and POLYANDRY (see also CO-OPERATIVE BREEDING). D.W.S. (1)

MATURATION: literally 'ripening'; in physiology, applied particularly to completion of the development of the germ-cells (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM); in ethology, the development of a behaviour pattern in a young bird without performance, i.e., without learning through practice (see BEHAVIOUR, DEVELOPMENT OF).

MATURITY: attainment of the age at which the bird is capable of reproduction (although breeding condition is a seasonal phenomenon); in practice, the criterion is usually the acquisition of full adult plumage (for immaturity see under YOUNG BIRD). In highly seasonal environments many small species first breed in their first summer, when they are just under a year old but in non-seasonal environments they may start breeding at 6–8 months of age, e.g., Zebra Finches *Poephila guttata* in Australia (see under LAYING).

The term has occasionally been restricted to mean the age at which maximum breeding capability is attained, usually one or more years after the age of first breeding.

MAVIS: popular name, in Britain, for the Song Thrush *Turdus philomelos* (see THRUSH).

MAXILLA: osteologically, a slender paired bone of the SKULL, between the jugal and the premaxilla; sometimes used more generally as a term for what is otherwise called the 'upper mandible', i.e., the upper jaw (of which the premaxillae are the chief bones) and its horny covering (see BILL); in the latter usage the term mandible is restricted to the lower part (see MANDIBLE).

MEADOWLARK: substantive name of *Sturnella* spp. (see ORIOLE (2)).

MEAN, ARITHMETIC: equivalent to 'average' in the sense in which the latter word is most exactly used—the sum of the recorded values divided by the number of observations in the sample. In a perfectly symmetrical distribution the arithmetic mean coincides with the median and modal values (see BIOSTATISTICS).

MEASUREMENT: here confined to the sense of recording the lengths of external features of birds. Measurements may be used to give a general indication of size or for a variety of taxonomic, ecological or other purposes (see also SIZE). Within a population of a species, significant differences in measurements may occur between the sexes, age classes or seasons, the latter reflecting feather growth and wear. Differences between populations may correlate with local environmental factors and over the range of a species may vary clinally or disjointedly according to subspeciation. Individual birds from the same population and age/sex group vary in size and correlated behavioural features may be found. Similar species can sometimes be separated most reliably by measurement (see also WING FORMULA).

For scientific purposes, millimetres are conventionally preferred to centimetres, but centimetres are often used in general descriptions. Care should be taken to avoid measuring feathers shortened by undue abrasion and fracture or not fully grown during moult. Innumerable features of birds can be and have been measured but the 6 described below are in most common use.

Wing. This is the most widely taken measurement, being a fair indicator of size of an individual within a species. It is easy to measure on a live bird. Wing-length is taken on the naturally folded wing from the carpal joint to the tip of the longest primary using a ruler with an end-stop. If the curvature of the wing is not corrected in any way, a 'minimum chord' is obtained. One of the two curvatures can be eliminated by pressing at the greater coverts to flatten the wing on to the ruler to give a 'flattened chord'. Most of both curvatures can be removed by flattening the wing as above and then straightening the primaries along the ruler with a firm stroking action to give a 'maximum chord' wing-length. Maximum chords can be measured most reliably and repeatedly and are to be preferred. The difference between the maximum and minimum chord can easily be 10% and thus as great as most other differences that might be being studied, so beware of published wing-lengths without the method stated. Beware too of measurements of skins which might, apart from the effect of shrinkage, be harder to flatten and straighten if this has even been attempted. In Britain, the maximum chord method is advocated by the British Trust for Ornithology for use by bird-ringers.

Tail. Tail-length is generally taken as the measurement from the point of emergence of the feathers to the tip of the longest, but may instead be of a stated pair. Measurement can be made with an unstopped ruler, dividers or vernier callipers and taken from above or below the tail. The roundedness or forkedness of a tail is taken as the distance between the tips of the central and outer feathers measured directly from an unfanned tail.

Bill. Bill-length is probably the second most widely used measurement after wing-length and is of particular interest in some seabirds, wildfowl and waders which show intraspecific variation with race and latitude. Bill-length can be measured to the cere (owls and birds of prey), to the start of the feathering, to the base of the skull or less commonly to the nares or the gape, so it is vital to note the method used in any published data. Other bill dimensions may be of ecological interest.

Tarsus. The bone is measured from the depression at the rear of its upper joint to the end of the last complete scale before the toes diverge at the front. Dividers or callipers may be used.

Total length. This is taken from bill to tail by laying the live or freshly dead bird on its back along a ruler and straightening it out. The measurement is difficult to take consistently, is of no taxonomic or ecological use and consequently is often expressed in inches in British literature. Total length is used in identification books to convey a general impression of size, though as such it is not very helpful because of the misleading influence of long bills or tails.

Wing-span. Wing-span is measured from tip to tip by straightening the wings of a live or freshly dead bird as far as they will go without undue force. Like total length, it is not easy to measure consistently and is mainly used to give an approximate idea of size especially of larger birds. Wing-span is, however, of use in flight performance models derived from aerodynamic theory (see FLIGHT).

Documentation. Measurements quoted in standard reference works are generally of museum skins which because of shrinkage will be lower than those obtained, as most now are, from live birds in the field. Many such published data are further inadequate because the method by which they were taken is not stated and the statistical necessity of giving the sample size and standard deviation is overlooked (see BIOSTATISTICS). There is thus an outstanding need for the collection and publication of standard measurements even of species which are common and frequently handled by bird-ringers. C.J.B. (2)

MEATUS: an opening, particularly of the ear (see HEARING AND BALANCE).

MECHANICAL SOUNDS: non-vocal sounds, made by the bill, wings, or tail, as contrasted with vocal utterances (see VOCALIZATION). The 3 types may be considered separately.

Bill sounds. Some of these, perhaps to be regarded as adventitious, are made by two birds together. Various clattering noises are made in the course of bill-fencing and bill-sparring in a wide range of birds, such as grebes, herons, auks, pigeons, kingfishers, woodpeckers, waxwings, thrushes, crows, and some finches. Bill-crossing and bill-tapping are common in the sexual display of albatrosses (Diomedeidae); the whetting together of the bills of a pair of Laysan Albatross *Diomedea immutabilis* has been described as producing a whistling sound.

Bill-rattling by a single bird, producing a noise like that of a nutmeg-grater, occurs among frigatebirds as an alarm note, and also as an entreaty for food on the part of the chicks. The bill-clapping of storks is well known. In the White Stork *Ciconia ciconia* it is a sign of recognition between members of a pair or group; the head is thrown down and back between the legs, to the accompaniment of raising and flapping of wings and spreading of tail. The chick, when sufficiently strong, exhibits similar behaviour towards its parents, recognizing them and soliciting food. Other species of stork also clap, but less loudly. The Shoebill *Balaeniceps rex* clatters its massive mandibles, but without posturing, as a note of alarm and an entreaty for food.

Bill-snapping as a defensive threatening sound is made by most owls and is particularly loud in such large species as the Eagle Owl *Bubo bubo* and the Snowy Owl *Nyctea scandiaca*.

In a different category are sounds made by the bill in contact with various objects. Some of these are adventitious effects of feeding or nesting actions, for example among tits, nuthatches and woodpeckers. On the other hand, specialized bill-drumming—beating a tattoo on the wood of a tree—is practised by many woodpeckers and has been most studied in the Great Spotted Woodpecker *Dendrocopos major*. In this species both sexes produce a loud, harsh vibrating sound by an extremely rapid rain of blows at a selected point, most commonly near the end of a broken or dead branch, but exceptionally on some quite different sort of sounding-board such as the lead-covered top of a wireless mast. The sound produced depends upon the resonant properties of the branch; the normal duration is about a second, and the normal frequency may exceed 20 blows per second. At the higher rates the human ear runs the sounds together to form a continuous vibration which may be audible at distances up to 1 km. The strength diminishes after the first or second blow, and the rate accelerates steadily from 15 per second to 25 per second so that the sounds tend to die away and rise in pitch. The drumming period extends in Britain from the end of February to the first week in May; the sound serves to attract mates, and both birds drum before coition. In the Lesser Spotted Woodpecker *D. minor*, the sound tends to be less powerful and higher in pitch, and may last for 2 s at a frequency of 22 blows per second; both sexes drum before performing the sexual 'butterfly dance'. The Northern Flicker *Colaptes auratus* of North America beats a rolling tattoo on dead branches in spring, and sometimes uses metal telegraph poles for the purpose.

Wing Sounds. The normal flight of some birds is inaudible except when there is a dense flock within close range. Owls are particularly silent, even at ultrasonic frequencies audible only to their prey, due to special adaptations of their feathers (these are absent in the fishing owl, *Scotopelia peli*). The flight of other birds may make a considerable noise. Ducks produce rather musical sounds with their wings when flighting; the audible intensity of the sound depends to a great extent on atmospheric conditions and wildfowlers are agreed that it reaches its maxi-

White Storks *Ciconia ciconia* bill-clappering at nest. (*Photo: E.J. Hosking*).

mum effect on still, frosty mornings. Teal *Anas crecca*, especially in planing down, make a metallic-sounding 'swoop', and among other surface-feeding species the Shoveler *Anas clypeata* stands out for the amount of sound emitted during level flight—as, in a different group, does the Shelduck *Tadorna tadorna*. On the whole, however, it is the diving ducks that make most sound, and notably the Goldeneye *Bucephala clangula*—commonly known in America as the 'Whistler' because of the penetrating sound made by its wings, especially in the case of old drakes. The Mute Swan *Cygnus olor*, alone among its kind, produces a high-pitched harp-like note from its primaries on the downbeat.

Various gallinaceous birds have noisy flight. Flying Pheasants *Phasianus colchicus* create a musical high-pitched whistle with their wings; and the 'whirr' of wings of Red Grouse *Lagopus lagopus scoticus* and Partridge *Perdix perdix* are familiar. The American Wood Stork *Mycteria americana* makes a most amazing noise as the air rushes through the wings when it dives from a height to its feeding grounds. The Rhinoceros Hornbill *Buceros rhinoceros* has been described as making a sound 'like that of a chugging steam locomotive' with its wings.

Hummingbirds are so called because of the sound made by the extremely rapid vibration of their wings; it reminded Salvin of a piece of machinery actuated by a powerful spring. The humming sound is produced by wing-beats as fast as 80 to the second (although the largest species, the Giant Hummingbird *Patagona gigas* beats its wings only 8–10 times per second). As originally noted by Darwin, different species produce a different 'hum'. In the male Broadtail *Selasphorus platycercus* the primary feathers taper at the tips and the air filtering through the openings produces a distinctive rattling whistle, whereas the female has normally shaped feathers and hovers with the usual humming or buzzing sound.

The foregoing examples relate to ordinary flight, although the sounds are in some cases not heard under all conditions. There are other instances where a characteristic sound is emitted only at special times, and usually as an element of display; these include cases where the sound is the result of wing-clapping, although that can happen also in other circumstances. This last point is particularly relevant to the pigeons; wing-clapping is common in domestic pigeons, notably tumblers, and many wild species start with a few clapping strokes when taking off—the sound varies considerably from one species to another. In the Woodpigeon *Columba palumbus* the male, near the top of its display flight, makes 1–3 vigorous claps with its wings; the sound has been attributed to forcible downstrokes analogous to the crack of a whip, but as in other cases it is more likely to be due to the wings striking each other.

Even the silent-flying owls do this. In the breeding season the Short-eared Owl *Asio flammeus* will circle on extended wings with only occasional beats, and from time to time will drop like a stone for some distance clapping its wings 4–6 times in rapid succession beneath its body; the wing-tips appear to meet only at the first clap, but contact at the carpal region is said to take place throughout the clapping. Clapping is also used when the nest is threatened. The Long-eared Owl *A. otus* performs zig-zag flights between the tree-trunks, and then rises above the tree-tops clapping its wings beneath the body at the end of each beat; both sexes do this, the female less frequently, and again the action is also used when the nest is threatened. Similar habits have been described for other owls.

In the breeding season the male Nightjar *Caprimulgus europaeus* produces a series of wing-claps; the tips do not appear to meet, but possibly the carpal joints do. The male may clap as many as 25 times in succession while gliding with tail spread and wings raised obliquely. The female also claps, and apart from the mating season has been observed to do so when accompanied in flight by her two young in early September. In America the Common Nighthawk *Chordeiles minor* indulges in 'sky-coasting', and, when the bird makes the turn, the air rushing through the primaries produces a booming sound such as one might imitate by blowing across the bung-hole of an empty barrel.

The Ruffed Grouse *Bonasa umbellus* of North America 'booms', while at rest, by striking its wings against its breast. It is a great performer in the mating season, and both sexes 'boom' before coition. The sound has been described as a deep-toned thump, like the muffled beating of a great heart, followed by a quickly accelerating drumming roll like distant thunder. Various other gallinaceous birds have similar, if less notable, performances; for instance, the crowing of the cock Pheasant *Phasianus colchicus* in spring is associated with flapping and thumping.

Both sexes of the Red-throated Diver *Gavia stellata* produce a loud rushing noise with their wings when, in May and June, they volplane down to the loch uttering wild raucous cries. The American Woodcock *Scolopax minor* has the first 3 primaries modified and attenuated as a musical instrument used during the nuptial flight; the writer observed this at twilight in March, when the birds produced a cadence of musical whistling during the rapid descent following the upward spiral. Various plovers in the breeding season make wing noises during flight; thus the male Lapwing *Vanellus vanellus* makes a 'zooming' noise.

Among the passerines, mention may be made of the birds-of-paradise; those species with specialized wings and drooping tails, such as Princess Stephanie's Bird-of-paradise *Astrapia stephaniae*, produce an attractive sound comparable with rustling silk. The Neotropical manakins (Pipridae) perform peculiar dances with both buzzing sounds and clashes that resemble loud thumb-snappings; their outer primaries are strikingly attenuated in some species, and some also have modified secondary feathers (see MANAKIN). Other examples include the wing sounds made by flappet larks *Mirafra* spp. and todies *Todus* spp.

Finally, a case of wing-sound made by two birds: in courtship flight the drake Pintail *Anas acuta* passes beneath the duck so closely that their wings clatter together with a loud noise like a football rattle.

Tail sounds. Of these the chief are the 'drummings' or 'bleatings' of snipe *Gallinago* spp. during aerial evolutions in the breeding season. The Common Snipe *G. gallinago* produces a resonant, tremulous sound lasting about a couple of seconds and sometimes frequently repeated; both sexes do it, but chiefly the male. The sound accompanies a rapid descent at an angle from a considerable height. Experiments have provided definite proof that the sound is a result of vibration of the outer pair of rectrices, which—when the tail is spread fanwise—are detached from the remaining 6 pairs; but that the wavering element is due to the action of the wings in intermittently deflecting air against the tail. The sound can be artificially reproduced by various devices, such as attaching the musical feathers in the appropriate position to a cork and whirling it at the end of a string; the latter imparts a vibratory motion and serves (as a rigid stick will not) to simulate the tremulous effect naturally derived from wing movements.

The musical feathers, the outermost rectrices (7th pair), show a specialized structure, the essential features of which are comparable with those of a harp. The outer web is narrow and formed of stiff rami that can be easily separated. The inner web is very broad and formed of long, stiff rami making an acute angle with the shaft and having radii and hamuli so arranged that the whole web is strongly locked together. The adjacent feathers (6th pair) show something approaching the same structure, whereas the 5 central pairs are soft and unmusical.

In some other species of snipe that make similar sounds the total number of rectrices is greater—16, 18, 20, or even 26–28; this last occurs in the Pintail Snipe *G. stenura* of Asia, in which 8–9 on each side are attenuated, the outermost so much so that they resemble pins. The number showing specialization varies considerably with species; in *G. nobilis* of northern South America there are 3 on each side. The quality of the sound also varies; in Latham's Snipe *G. australis* it is more voluminous—a tremendous rushing noise—and in the Auckland Island Snipe *Coenocorypha aucklandica* the bleat is high-pitched. The Great Snipe *Gallinago media* and Jack Snipe *Lymnocryptes minimus* possess no musical feathers, and the same is true of the European Woodcock *Scolopax rusticola* and the American Woodcock *S. minor*.

A sound made by the Lyre-tailed Honeyguide *Melichneutes robustus*, in the course of elaborate flying evolutions, is thought to be produced by vibration of the outer rectrices, as in the Snipe. P.M.-B. (J.D.P.)

MEDIAN COVERTS: see TOPOGRAPHY.

MEDULLA: for that of the adrenal glands see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

MEDULLA OBLONGATA: part of the hindbrain (see NERVOUS SYSTEM).

MEGAGEA: see under ARCTOGAEA; DISTRIBUTION, GEOGRAPHICAL.

MEGAPODE: substantive name of species of Megapodiidae (Galliformes, suborder Galli); in the plural, general term for the family. Alternative English names, given to species found in Australia, are 'Scrubfowl', 'Brush-turkey'—and in one instance 'Mallee Fowl' or 'Lowan'. Such general terms as 'mound-birds', 'mound-builders', and 'incubator birds'—this last a common American usage—have been applied to the group. The family is a small one. The members are characterized by their habit of not incubating their eggs. Instead they lay them in holes in the ground or in mounds of rotting vegetable matter and leave them to be incubated by natural heat.

The family comprises 6 genera, which can be divided into 3 ecological groups, viz., scrubfowl (*Megacephalon* and *Megapodius*), brush-turkeys (*Alectura*, *Aepypodius*, and *Talegalla*), and the Mallee Fowl (*Leipoa*). Of these *Megacephalon*, *Alectura*, and *Leipoa* are monotypic, the species being *M. maleo*, *A. lathami*, and *L. ocellata*. The genus *Aepypodius* includes 2 species, *A. arfakianus* and *A. bruijnii*; and *Talegalla* includes 3, *T. cuvieri*, *T. fuscirostris*, and *T. jobiensis*. Peters recognized 9 species, including 28 subspecies, of *Megapodius*, but E. Mayr reviewed the genus and reduced these to 3 species—*M. freycinet*, *M. laperouse*, and *M. pritchardii*. Some later authors have increased the number of species but not convincingly.

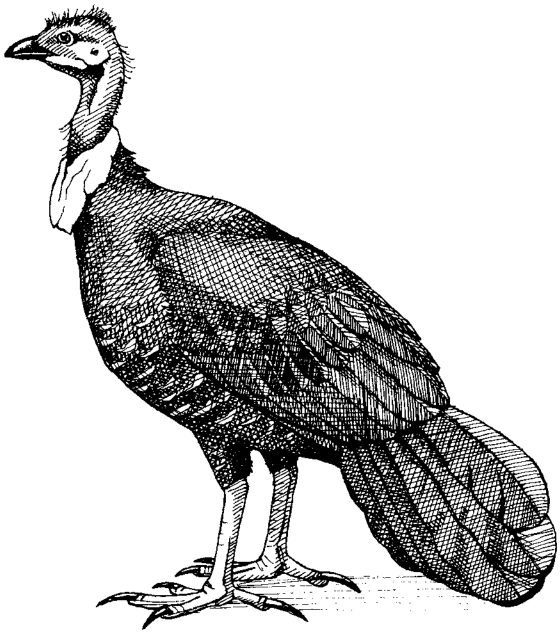
Characteristics. With the exception of *Megacephalon maleo* which is more colourful, scrubfowl are dull brownish birds with sombre plumage and small crests. *M. maleo* is distinguished by having a black tail, black wings, and pink underparts, and its head bears a prominent casque. All are about 50 cm in total length.

The brush-turkeys are black, with vertically folded tails, and are longer than scrubfowl, being 66–71 cm in total length. Their heads and necks are bare, except for numerous coarse hairs. Similar in size to the brush-turkeys, the Mallee Fowl is coloured brown in keeping with the red-brown soils of its habitat, and each feather of the wing coverts bears a prominent white spot edged with black.

Megapodes are ground-living birds. Scrubfowl and brush-turkeys are very active, although secretive, and seldom fly unless hard pressed. They are quite vocal, particularly in the evenings. According to K.H. Bennett, the Mallee Fowl's 'actions are suggestive of melancholy, for it has none of the liveliness that characterizes almost all other birds, but it stalks along in a solemn manner as if the dreary nature of its surroundings and its solitary life weighed heavily on its spirits'.

Habitat. The brush-turkeys are generally restricted to tropical rain-forest, both lowland and highland, but in a few places in Australia *Alectura* extends into drier, more inland scrubs. The scrubfowl are also mostly found in rain-forest but also are common in monsoon forest and gallery forest in riverine locations.

The Mallee Fowl is unique in inhabiting a semi-arid environment. It is confined to the dry scrubs of inland Australia; it is characteristic of, but by no means confined to, mallee scrub, which consists of several species of dwarf eucalyptus. The only extension of its range from the inland area occurs in Western Australia, where it is found in a narrow strip of heathland on the south-western coastline.



Brush Turkey *Alectura lathami*. (*N.W.C.*).

Distribution. Of the brush-turkeys, *Aepypodius* spp. and *Talegalla* spp. are confined to New Guinea, and *Alectura lathami* to the eastern coast of the Australian mainland.

Megapodius freycinet, with many subspecies, extends from the Nicobar Islands in the west to central Polynesia in the east, and from the Philippines in the north to the tropical northern coasts of Australia. Included in this range are coral islands with little vegetation, heavily vegetated continental islands, and mainland jungles. The birds are found in all these habitats but rarely extend far inland. *M. pritchardii* and *M. laperouse* have a similar habitat, but more restricted ranges, in central Polynesia and the Mariana Islands respectively. The Maleo *Megacephalon maleo* is found in Sulawesi.

Populations. Eggs of megapodes are used as food by indigenous peoples and, in places, traded for other goods in the markets. In New Britain and some other places the harvesting of eggs of *M. freycinet* is the prerogative of certain clans and age-groups and some ceremony is attached to it. Prayers are said to ensure that the birds return in good numbers to the breeding ground each season. In some cases, because of access to firearms and to a cash economy involving the eggs, the traditional methods are now upset and predation could be a serious population problem, but in the past the rituals were, in effect, a primitive but effective programme of harvest regulation and management.

The present position is that due to habitat destruction, perhaps accelerated utilization of the birds and their eggs and also perhaps because of declining volcanic heat in some regions, some megapodes have declined in this century. Concern has been expressed especially for *Megacephalon maleo* and *Megapodius pritchardii* but detailed data are lacking. The 3 species in Australia, *Leipoa ocellata*, *Megapodius freycinet* and *Alectura lathami*, are still in a strong position despite clearing of habitat in the interests of agriculture and, in *Leipoa*, the competition for food imposed by grazing stock and rabbits.

Movements. Australian populations of *Megapodius freycinet*, *Alectura lathami* and *Leipoa ocellata* are sedentary. There are no precise data on other species but, although some populations make roosting flights to off-shore islands, there seems to be no doubt that all are essentially sedentary.

Food. There are no precise data on the food of any megapode, but general observations suggest all are omnivorous. The food mostly consists of insects, small animals, seeds and fruits. The food of the Mallee Fowl is better known than that of other members of the family and consists largely of the seeds of the *Acacia*, *Cassia* and *Beyeria*, and the flowers of several ephemeral herbs as well as ground-living insects and small lizards. The Mallee Fowl is apparently independent of free water, but will drink if water is available.

Behaviour. The brush-turkeys and the Mallee Fowl are solitary to the extent that, except when eggs are to be laid, the male drives the female from the mound. The other species, where there have been observations, live in pairs and, with mound-building species, two or more pairs can use the one mound but visit it at different times so that confrontation is avoided.

Voice. There is no detailed description of the repertoire of sounds of any megapode. The male Mallee Fowl possesses a very loud, booming call and the female a high-pitched crow. The brush-turkeys have gobbles and loud grunts and the scrubfowl loud cries that are likened to gurgles and shouts.

Breeding. The simplest type of incubation is found in *Megacephalon*, and some populations of *Megapodius freycinet*. The birds simply lay each egg in a pit dug on a beach or in sandy soil exposed to the sun. The hole is filled in and the eggs are hatched by heat conducted from the soil surface. The site is not visited again, and so no temperature control is exercised. A suitable incubation temperature is apparently achieved by careful selection of the location of each egg-pit. On some islands in the Pacific, the Solomons and in New Britain, the egg-pits of *Megapodius* species are dug into soil heated by volcanic action, the eggs being incubated by that agency. On Dunk Island, off the Queensland coast, some *M. freycinet* lay their eggs in fissures in rocks exposed to the sun, the heat-retaining capacity of the rock ensuring a relatively constant temperature by day and night.

In other places, particularly in denser jungles, *Megapodius freycinet* constructs large mounds of earth up to 11 m in diameter and 5 m high, including a variable amount of vegetable material which, by fermentation, supplements the heat of the sun. The eggs are laid in tunnels up to 1 m long dug into the mound. The amount of vegetable material in the mound varies according to its location. Some mounds are built of almost pure soil and others of almost pure vegetable material, and all intermediate stages exist. Several pairs of birds participate in the construction of these mounds. Apparently the exact composition is determined by the local air temperature and amount of insolation; heavily shaded mounds require a greater supplement of heat of fermentation than those exposed to direct sunlight.

Studies of *M. freycinet* in north Queensland have shown that in a large leafy mound the temperature fluctuated from 30–38°C but the egg was always laid in the warmer parts of the mound. There was evidence that the birds were conscious of the temperatures in the mound but it cannot be said if they exercised any control over it.

There is no such variation in the nesting mounds of the brush-turkeys, all of which construct mounds composed mainly of plant material; these are commonly about 4 m in diameter and 1 m high. In the warm, moist jungles the mound ferments rapidly and generates much heat. The males regularly test the temperature of the mound by probing with their bills; the temperature-perceiving organ is not known but is possibly the tongue. In the first burst of fermentation the temperature of mounds rises to a high level, and the male exercises some control over it by digging into the top and turning over and mixing the material. Not until the temperature is declining does he permit the female to approach and lay eggs.

Throughout the incubation period the male remains in charge of the mound. In captive birds it has been shown that the temperature does fluctuate but the egg is always placed in the warmer parts of the mound. It is suspected, but not proved, that the male exercises some control over mound temperature. It has also been suggested that digging in the mound is important in controlling the oxygen supply available to the embryo.

In its arid inland habitat the Mallee Fowl must adopt more complicated methods to secure a suitable incubation temperature. The air temperature fluctuates widely during the day and the year; accordingly, the soil does not keep a suitable constant temperature. Leaf mould does not form on the ground, litter is sparse, and fallen leaves dry and wither and do not ferment.

To provide the proper constant temperature, the birds dig a hole in the ground up to 5 m in diameter and 1–1.5 m deep. During the winter they fill the hole with vegetable material swept up from the ground over a radius of some 45 m, and when it is moistened by a shower of rain the whole is covered by a layer of sandy soil 50 cm or more thick. Sealed from the dry air, the vegetable material ferments and generates heat, which later in the season is supplemented by solar heat.

It has been shown that in the spring fermentation heat is the more important and the birds need to open the mound frequently to allow heat to escape, so as to maintain the incubation temperature of 34°C. In midsummer the thickness of the soil cover is increased so as to slow the penetration of the sun's heat into the mound; by then the sun is the most important source of heat and is greater than is needed. In autumn the sun's heat is less and the fermentation heat has been exhausted. Then the birds open and flatten the mound daily to allow the sun's rays to penetrate it and warm the eggs. The result of all of this is a very uniform temperature in the mound for several months.

Details of egg laying have been recorded for only one megapode, the Mallee Fowl. The number of eggs laid varies from 5 to 35. Variation in clutch size is very great, both between different females in one year and in the same female in different years. The eggs are laid at intervals of several days, the length of the interval being apparently determined by the nutritional state of the female. As many as 35 eggs have been laid by a female *Alectura lathami* in captivity. Up to 20 eggs have been taken from pits of *M. freycinet* in New Britain, but in north Queensland one female, watched quite regularly, laid 12 or 13 in the one season.

Each egg begins to incubate as soon as it is laid and, as the eggs are laid throughout a period of several months, the first eggs are hatched and the chicks have left the mound long before the last eggs are laid. The chicks, on hatching, dig their way unaided to the surface of the mound and run into the scrub. They are capable of running very swiftly within a few hours of hatching and can fly within 24 hours. They never see their parents and live completely independent and solitary lives. H.J.F.

MEGAPODIIDAE: see GALLIFORMES; MEGAPODE.

MEGASUBSPECIES: a subspecies or group of subspecies which is considered almost to deserve the status of an ALLOSPECIES. The status of such a geographically representative form may be represented typographically. For instance, if the Red Grouse of Scotland, *scoticus*, is considered to be merely a distinct subspecies of the continental Willow Grouse *Lagopus lagopus*, it is represented by a simple trinomial, *L. lagopus scoticus*. As a megasubspecies it may be shown as *L. (lagopus) scoticus*. As an allospecies it may either be represented simply as a species *L. scoticus*; or its relationship to *L. lagopus* may be indicated by the use of square brackets, *L. [lagopus] scoticus*.

Amadon, D. & Short, L.L. 1976. Treatment of subspecies approaching species status. Syst. Zool. 25: 161–167.

MEIOSIS: division of a germ-cell involving reduction in the number of chromosomes (see CELL; GENETICS).

MELAMPITTA: substantive name of the 2 species of *Melampitta* of New Guinea (for family see RAIL-BABBLER).

MELANIN: see COLOUR.

MELANISM: see PLUMAGE, ABNORMAL.

MELEAGRIDINAE: see under GALLIFORMES; and TURKEY.

MELIPHAGIDAE: a family of the Passeriformes, suborder Oscines; HONEYEATER; SUGAR-BIRD (1).

MELIPOTES: substantive name of the 3 species of *Melipotes* of New Guinea (for family see HONEYEATER).

MEMBRANE BONE: one that, in the course of development, ossifies directly without going through a cartilaginous stage (see SKELETON, POST-CRANIAL).

MEMBRANES, FOETAL: see DEVELOPMENT, EMBRYONIC.

MEMBRANES, SHELL: see EGG.

MENDELIAN INHERITANCE: see GENETICS.

MENTUM: chin (see TOPOGRAPHY).

MENURAE; MENURIDAE: see PASSERIFORMES, suborder Oscines; LYREBIRD.

MERGANSER: substantive name of *Mergus* spp. (see DUCK).

MERGINI: see DUCK.

MERISTIC: a statistical term for data values that vary in whole units, such as the number of eggs in a clutch. In contrast, 'linear' values vary continuously, as in the measurement of wing length, where precision is limited only by the precision of measurement (see also BIOSTATISTICS).

MERLIN: *Falco columbarius* (see FALCON).

MEROBLASTIC: the type of embryonic development found in birds (see DEVELOPMENT, EMBRYONIC).

MEROPES; MEROPIDAE: see CORACIIFORMES; BEE-EATER.

MERRYTHOUGHT: the FURCULA; and see SKELETON, POST-CRANIAL.

MESENTERY: a fold of peritoneum in the abdominal cavity, enclosing part of the intestine together with blood vessels and nerves supplying it (see ALIMENTARY SYSTEM).

MESETHMOID: bony interorbial septum (see SKULL).

MESIA: substantive name of the Silver-eared Mesia *Leiothrix argentauris* (see BABBLER).

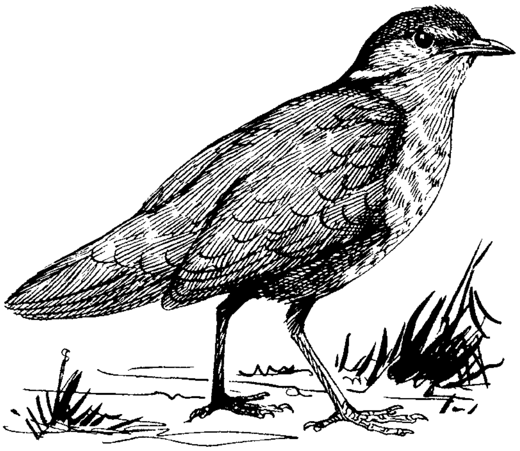
MESITE: name used for 2 of the 3 species (*Monias* being the other) of the family Mesitornithidae, sole member of the order Mesitornithiformes.

The family is endemic to Madagascar. Although placed here in its own order, its systematic position is by no means certain. At one time or another it has been considered as galliform, gruiform, ralline or even passerine, specimens reminding at least one student of ground-babblers of the genus *Eupetes* (family Timaliidae, subfamily Orthonychinae).

Characteristics. The 3 species are *c.* 30 cm long, with long and broad tails, short wings and moderate-sized feet. The bill is short and straight in *Mesitornis*, longer and curved in *Monias*. There are 5 pairs of powder-down patches. The Brown Mesite *Mesitornis unicolor* is rufous brown above, with a single white stripe along the sides of the neck, somewhat paler, more greyish below. The sexes are alike. The White-breasted Mesite *M. variegata* is longer billed, but with a shorter tarsus. It also differs in having the sides of the head streaked with whitish, rufous and blackish, the throat and chest whitish spotted with black. The Monias (alternatively Bensch's Rail) *Monias benschi*, unlike the 2 *Mesitornis* spp., shows well-marked colour dimorphism. Both sexes are greyish above, with a white superciliary streak. The male, however, is whitish on the throat and chest, the latter spotted with black, whereas the female has this whole area heavily marked rufous chestnut.

Habitat. All 3 species are strongly terrestrial. *Mesitornis unicolor* inhabits evergreen forest; *M. variegata* thick woodland relatively clear of underbrush; and *Monias benschi* subdesert scrub with a shady substrate covered thickly with leaf litter.

Distribution. *Mesitornis unicolor* is known from widely scattered localities in the humid east, but *M. variegata* is only known from Ankarafantsika, some 100 km south-east of Majunga, and from near Tsarakibany, in the extreme north. *Monias benschi* is confined to the coastal south-west, from north of Tulear to the Mangoky River.



Brown Mesite *Mesitornis unicolor*. (*C.E.T.K.*).

Populations. Due to habitat destruction, the status of all 3 species is a matter for deep concern; particularly of *Mesitornis variegata*, so localized.

Movements. All may be assumed to be extremely sedentary.

Food. Nothing is known about the diet of the *Mesitornis* spp., but *Monias benschi* feeds on fleshy fruits and insects.

Behaviour. *Monias benschi* runs with quick, pigeon-like steps, bobbing the head and depressing the tail at each step. It is capable of flying short distances, but does so only rarely. It tends to be gregarious, and has even been recorded in groups of up to 20. There is no information regarding *Mesitornis unicolor* or *variegata*, except that the latter has been recorded in pairs. Probably in all respects they resemble *Monias benschi*.

Voice. A variety of calls, including a 'choral song', have been described for *Monias benschi*, but the most typical one is *nak-nak-nak-* - -; hence the local name 'naka'. *Mesitornis variegata* is said to emit a brief *tsik*, but nothing at all is on record for *unicolor*.

Breeding. The nest of all 3 species is placed in a shrub or small tree within 2 m of the ground, in such a situation that it could be reached without flying (in the case of *Monias benschi* a kind of inclined 'ramp' has been noted). It is a flat, thin platform of twigs with some lining of grass, leaves and other soft material, scantily constructed. The eggs are nearly oval, whitish, somewhat glossy, spotted with brown, tending to form a wreath at one end. The chicks are covered with down at the time of hatching. In *Monias benschi* the down is rufous brown on the upperparts, white on the underparts, but in the *Mesitornis* spp. it is said to be entirely black. All 3 species have been claimed to be nudifugous, although for *Monias benschi* the age at which the young leave the nest is positively stated to be unknown.

Two nests of *Mesitornis unicolor* each contained a single egg being incubated by a female, which allowed herself to be caught on the nest. For *M. variegata*, however, the clutch-size is said to be 2 or 3, and possibly more than one female is involved. At all events, one nest of *Monias benschi* contained 2 eggs, apparently laid by different females, associated with a single male. Incubation was by the male and at least one female. In the case of another nest, the family consisted of one male, one female and 2 young, which were fed by both parents. (A.L.R.) C.W.B.

MESITORNITHIDAE: see MESITORNITHIFORMES; MESITE.

MESITORNITHIFORMES: an order, comprising the sole family Mesitornithidae (see MESITE). In Wetmore's system treated as a suborder Mesitornithes of the order Gruiformes.

MESOBLAST: the middle layer of the embryo, developing between the epiblast and endoblast that are formed at a very early stage (gastrulation)—see DEVELOPMENT, EMBRYONIC.

MESOENATIDES: alternatively 'Mesoenades' and 'Mesitornithes' (see MESITORNITHIFORMES).

MESOGYROUS: see ALIMENTARY SYSTEM.

MESOMYODI: see PASSERIFORMES.

MESOPTILE: term applied to the second of two nestling down plumages, in cases where there is such a sequence, the first then being called 'protoptile' (see PLUMAGE).

METABOLISM: the processes of biochemical breakdown and synthesis of nutrients that take place within the cells of all body tissues. Catabolic processes provide the energy necessary for the maintenance of body temperature and for muscular work, as well as supplying precursor compounds for the anabolic processes of growth and body maintenance. The central metabolic reactions (often called intermediary metabolism) are those involving carbohydrates, fats and proteins (Fig. 1) but we may also speak of the metabolic reactions of individual elements, especially of minerals, e.g. calcium metabolism (see EGG). Metabolic reactions are all catalyzed by specific enzymes under hormonal control (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

The biochemical breakdown of carbohydrate and fat (and in some circumstances protein) liberates energy partly as heat, which contributes to thermoregulation (see ENERGETICS; HEAT REGULATION), and partly as chemical energy by the formation of a high-energy compound, adenosine triphosphate (ATP), which fuels many other metabolic reactions and is itself utilized directly by muscle cells to perform work.

Carbohydrate metabolism. The breakdown of carbohydrates ultimately involves their complete oxidation to carbon dioxide and water but the initial stages of this process (glycolysis) can occur anaerobically (in the absence of oxygen) to yield small but useful amounts of energy as ATP. Under anaerobic conditions the end point of glycolysis is lactic acid. Cells cannot tolerate excessive amounts of lactic acid, however, so that heavily working muscle can obtain sufficient energy from ATP produced in this

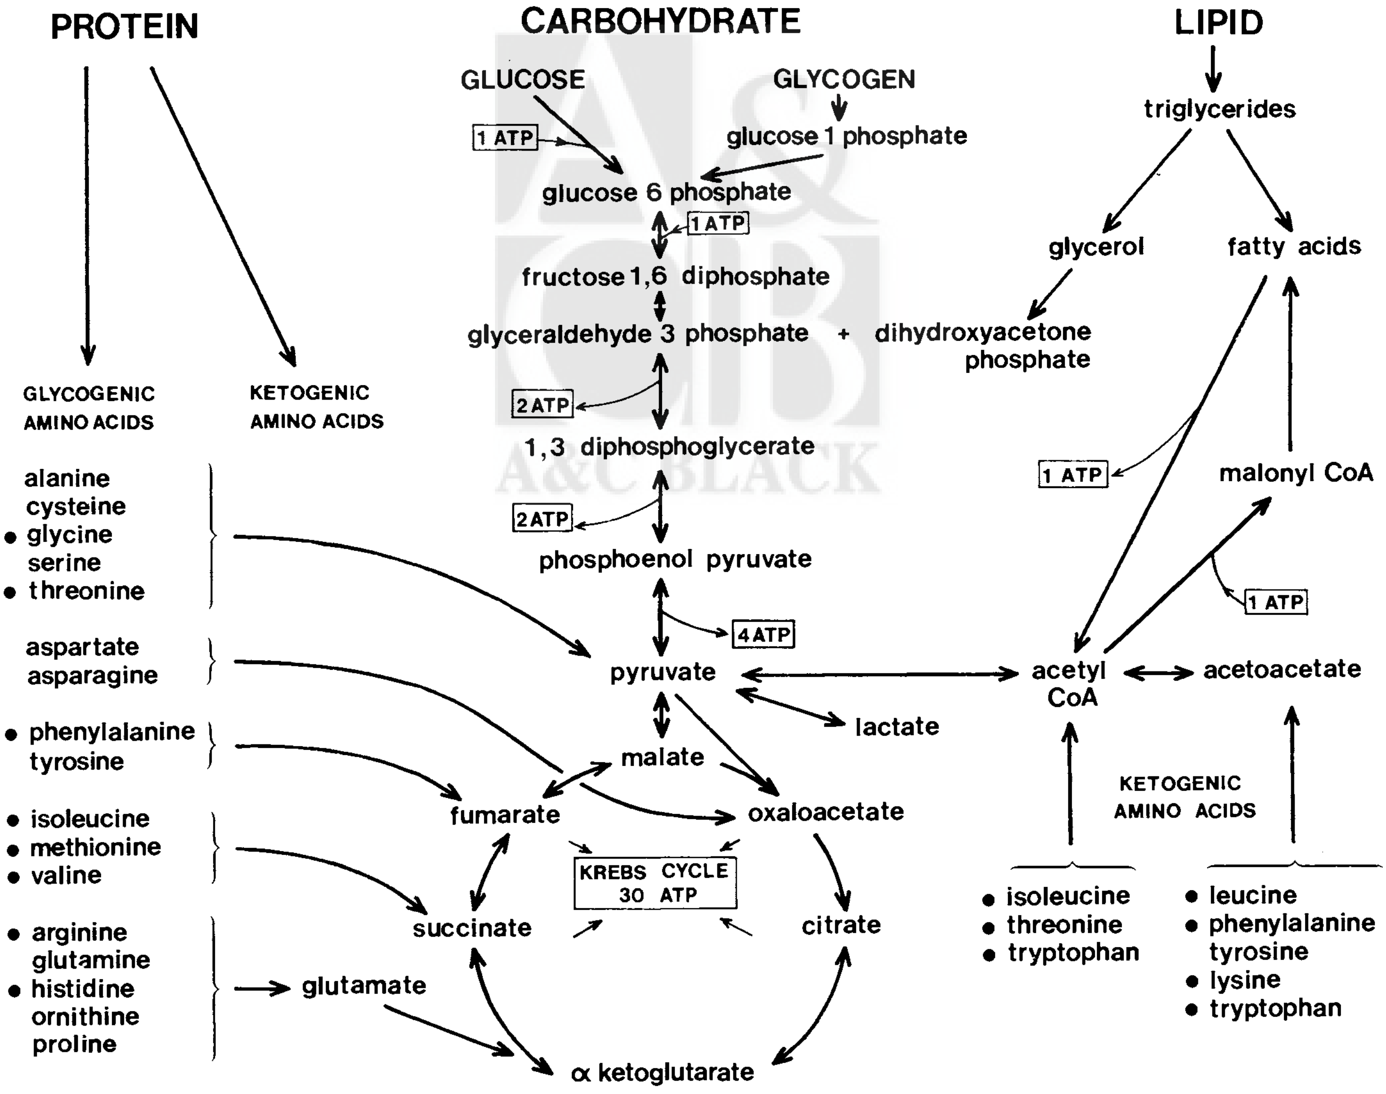

Fig. 1. Biochemical pathways of intermediary metabolism. Essential amino acids are marked •.

pathway for only a limited period before fatigue due to lactic acid build-up develops. The lactic acid accumulation constitutes an 'oxygen debt' since it must eventually be removed by oxidation. Anaerobic glycolysis with lactic acid as an end-point releases only 7% of the energy of a glucose molecule. However, in the presence of oxygen, lactic acid is not formed and complete oxidation can occur, trapping some 37% of the total energy of one glucose molecule as ATP. The remainder is liberated as heat.

Glucose or other intermediate stages of glycolysis essential for energy production must sometimes be provided from non-carbohydrate sources. The enzymes for this occur primarily in the liver and are particularly important in the embryo because yolk contains very little carbohydrate. These enzymes decrease markedly after hatching in granivorous birds with a high carbohydrate diet, but carnivorous species retain them.

Carbohydrate metabolism is controlled by the pancreatic hormones insulin, glucagon and avian pancreatic polypeptide. Insulin lowers blood glucose, promoting the synthesis of glycogen in the liver, while glucagon stimulates the breakdown of liver glycogen.

Fat metabolism. Birds store lipid as an energy reserve for overnight metabolism and in large amounts for long-distance MIGRATION. Lipid has almost twice the energy value as the same dry weight of carbohydrate and, unlike carbohydrate, can be stored without large amounts of additional water. The weight saving is obviously advantageous for flight.

Some fat is taken in the diet but birds also convert large amounts of dietary carbohydrate to lipid before use, which is consistent with the low Respiratory Quotients (RQ values of 0.75–0.80) measured in birds (see ENERGETICS). In birds the liver is the main site of lipid synthesis and is 20 times more active than other sites in the body, whereas in mammals adipose tissue itself is important in lipid synthesis. A product of glycolysis, pyruvate, is the normal starting point for lipid synthesis, being converted first to fatty acids and then to triglycerides. Since the liver has only limited storage capacity, the triglycerides are liberated into the bloodstream to be transported either to target tissues and metabolized, or to fat depots and stored. Mobilization of stored fat involves hydrolysis to free fatty acids and glycerol. Fatty acids are readily oxidized inside muscle cells, the later stages of oxidation occurring along the same pathways as the breakdown of carbohydrate. The complete breakdown of fatty acids enables 41% of the total energy stored as lipid to be trapped by ATP and then used by the muscle cell, a figure agreeing well with that obtained by the complete combustion of carbohydrate.

The structure of bird flight muscle reflects which metabolic pathway normally provides energy. 'White' muscle has few mitochondria (cell structures where oxidation occurs), few lipid inclusions, and is poorly oxygenated. It is, however, rich in carbohydrate (glycogen) which can be rapidly metabolized anaerobically. Such muscle is adapted to short-duration bursts of hard work, for example during take-off. In contrast, 'red' muscle has little glycogen but is rich in fat, myoglobin (the oxygen-carrying pigment responsible for the red colour), mitochondria and the enzymes for fatty acid oxidation, all of which enable the muscle to sustain energy output for steady prolonged flight.

Protein metabolism. Proteins enter the metabolic pathways as amino acids. Two processes, transamination and deamination, are central to protein metabolism. Transamination involves the transfer of an amino group, $-NH_2$, to another carbon skeleton, so that all amino acids, other than a few 'essential' amino acids (see NUTRITION), can be interconverted. The deaminated carbon chains of some amino acids may be metabolized by pathways leading to intermediates in carbohydrate metabolism and so take part in carbohydrate synthesis or oxidation (the glycogenic amino acids); others may take part in fatty acid synthesis (ketogenic amino acids). Glutamate plays a central role in regulating nitrogen metabolism; it can be deaminated or synthesized without involving a receptor or donor amino acid and it can give up an amino group as waste ammonia, NH_3. In mammals this waste ammonia is detoxified by conversion to urea. However, this requires the enzyme carbamylphosphate synthetase, which birds lack. Instead birds form uric acid (see EXCRETORY SYSTEM), a nearly insoluble compound whose particular advantage is that, as the waste product of embryonic metabolism, it can be stored harmlessly within the egg.

Protein metabolism is under hormonal control; indeed, hormones are often classified as anabolic or catabolic with respect to protein. Adrenal corticosteroids increase protein mobilization and insulin and glucagon also directly affect amino acid transport and metabolism. P.J.J.

Sturkie, P.D. (ed.). 1976. Avian Physiology. New York.

METACARPUS (adj. metacarpal): name of certain bones of the 'hand' (see SKELETON, POST-CRANIAL).

METAL-TAIL: substantive name of HUMMINGBIRDS of the genus *Metallura*.

METAPATAGIUM: a membranous fold of skin between the body and the posterior margin of the upper wing (see MUSCULATURE; WING).

METATARSUS (adj. metatarsal): name of bones of the foot, 3 of them fused together in birds, and at their upper ends with the distal row of tarsals, to form the TARSOMETATARSUS (see also LEG; SKELETON, POST-CRANIAL).

METEOROLOGY: see BIRDS AND WEATHER.

MEW: archaic or poetic name, also 'sea-mew', for a gull (Laridae sp.), cf. German 'Möwe'; also, in American usage, adjectival name of *Larus canus* (see GULL).

MEWS: term used in FALCONRY.

MICROECA: substantive name of most species of *Microeca*, a genus of Australasian flycatchers (see FLYCATCHER (1)).

MICROPODIFORMES: name formerly used for the order APODIFORMES; SWIFT.

MICROPSITTINAE: see PARROT.

MICROSMATIC: with poorly developed olfactory sense (see SMELL).

MIGRATION: term used hitherto in ornithology for only those movements of bird populations occurring at predictable times of each year, between breeding and one or more non-breeding areas, and therefore involving flights in predictable directions. Movements which do not include an obligatory return journey or preferred directions of flight have been classed as 'DISPERSAL', 'nomadism', 'emigrations' and 'IRRUPTIONS' rather than 'true' migrations. But the functions of all these types of movement may be similar: to allow exploitation of different geographical areas at different stages of the annual cycle and in response to seasonal changes in population density and in the environment (see below). They may also follow from vegetational changes in an area, resulting from plant succession.

This long-established classification has resulted from emphasis on populations rather than individuals. Thus DISPERSAL has been distinguished from migration because only the latter need involve a change in the geographical centre of distribution of the population. Each individual, however, that takes part in the outward dispersive movement, from e.g., a seabird colony, might in fact fly in a preferred direction rather than at random; but different individuals would have to move in different preferred directions if the centre of distribution were not to change. Since dispersals usually occur at predictable times of year, and since, especially in seabirds, the individuals of the species concerned may reassemble at the breeding locality in the following year, the difference from 'true' migration lies only in the degree of unanimity amongst individuals concerning the preferred direction of departure.

In the more specific terminology of Berndt and Sternberg (1968), dispersals are movements that lead to observed dispersions (locations in space) of individuals of a population. Their terminology was developed for comparisons of the locations of individuals in successive breeding seasons, later termed 'natal dispersal' and 'breeding dispersal' by Greenwood (1980). Such studies consider only the resultant distances and directions involved, and not the routes by which the changes in breeding locations occur, which may or may not involve long-distance return migrations between breeding seasons.

Even in 'true' migrations, the routes, and therefore directions, by which individuals of a species return to their breeding areas are not necessarily the reverse of those followed on the outward journey. For example, the Pied Flycatcher *Ficedula hypoleuca* returns from Africa to its northern breeding range by a more easterly route. Fidelity to a previously used breeding site occurs commonly in long-distance migrants, and fidelity to a wintering site is found regularly in some wildfowl, especially geese, and estuarine waders. Some marked individual passerines have returned to the same 'wintering' area in Africa (Moreau 1972), but fidelity to a non-breeding locality may be the exception rather than the rule amongst passerines. This is especially true for species whose foods outside the breeding season occur unpredictably either in space (e.g., fruit and berry crops) or time (e.g., mass emergence of insects). Indeed, although some northern European thrushes, such as the Redwing *Turdus iliacus*, are generally considered to be 'true' migrants, the movements of individuals within the wintering range are best described as itinerancy (*sensu* Moreau 1972). It is but a short step further to include within the class of 'true' migrants species that may shift their breeding localities, within a year, e.g., Quail *Coturnix coturnix*, or between years, e.g., Crossbill *Loxia curvirostra*, and which also move about within their 'wintering' range. The difference from nomadism, which refers to movements of species that do not normally revisit either breeding sites or non-breeding areas, is thus one of degree and not kind.

Migration has also been defined in terms of a change of habitat, but in birds this does not always occur, e.g., Oystercatchers *Haematopus ostralegus* may move several hundred km between coastal breeding sites on sandy beaches in northern Britain and similar wintering habitats in southern Britain. On the other hand, the definition adopted by Baker (1978) in an attempt to find one which applies to individuals of all animal species—namely 'the act of moving from one spatial unit to another'—is too general, although it avoids the need to define habitat boundaries. It would be better to exclude unintentional movements (birds blown outside their normal range) and those used in everyday foraging and roosting behaviour by restricting the term migration to movements leading to a change of home range.

In bird species whose migrations involve long non-stop flights, physiological as well as behavioural changes usually occur before departure. The most marked behavioural changes occur in nocturnal migrants, particularly small passerines, which develop an additional activity rhythm during the hours of darkness, when they normally roost.

Methods of observation. Information on the daily and seasonal timing of migration of species, populations and individuals, on directions, routes and distances of flight, and on flight performance has been collected by the following methods.

(1) Direct observation usually of visible migration but sometimes of audible movements also (especially at night). Under favourable weather conditions for migration, many birds pass too high to be seen with the naked eye, but flights at moderate altitudes can be detected with the aid of binoculars, a method pioneered in the Netherlands to study diurnal migration of Chaffinches *Fringilla coelebs*. The directions of flights at lower altitudes are often influenced heavily by topography and thus may change frequently; hence it is difficult to establish preferred directions with accuracy from direct observations.

(2) Seasonal timings of migration may be established by noting dates of arrival at, and departure from, the breeding and non-breeding areas. This method gives reliable information on first arrivals and last departures, but continued passage through possible breeding or wintering areas may not be detected. However, at intermediate stopovers on migration routes it has been used successfully for determining the duration of passage, particularly of night migrants.

(3) Radar observations using long-range surveillance equipment, have proved complementary to those visual observations which record only low-altitude flights. They have been particularly useful for measurements of flight directions over long distances and uninfluenced by topography. Data on seasonal patterns of movement have been established chiefly for groups of species with similar flight characteristics. Recognition of individual species has not often been possible. The most detailed studies of the influence of weather on migratory departures and flight behaviour have been made with the aid of RADAR.

(4) Direction of flight can be determined by watching the silhouettes of migrants crossing the face of the full (or nearly-full) moon. The method demands prolonged observation of the moon's disc through a telescope or binoculars. Identification of migrants to the specific level is rarely possible. As the method can be used effectively for at most 7 days each month, it cannot provide much information on seasonal patterns of movement and has been largely superseded by the use of radar. It has been used most successfully in the USA (Lowery and Newman 1966). In northern Europe, cloud associated with the flow of maritime air from the Atlantic often renders observation at full-moon periods impossible.

(5) Marking of birds, with numbered metal rings, combinations of coloured rings, or plumage dyes, all of which can be used on a large scale, has provided a considerably quantity of data on migration routes, destinations and (less precisely) timing of movements. Bias in the regularity and reliability of reports from different parts of the world, however, requires results to be interpreted with caution. Nonetheless, the results can be assigned unambiguously to particular species.

(6) Radiotelemetry has given detailed information on the flight tracks and movements of individual birds. By the early 1980s, the weight of transmitter and power pack had been reduced sufficiently to permit attachment to birds of the size of Starlings *Sturnus vulgaris* for migration studies, and further miniaturization of transmitters and batteries is to be expected. Because of the restricted range of frequencies that may be used and the high cost of radio-tags, most studies to date concern only 20–30 individual birds. Limited detection range also restricts the value of the technique for migration studies, but radio-tags promise to give useful data on the behaviour of migrants immediately before departure, even if the birds cannot be followed thereafter (see RADIO TRACKING AND BIOTELEMETRY).

(7) Automated recordings of daily activity patterns of captive migrants can show when nocturnal migratory behaviour develops and for how long it continues. When the directional components of total activity have been separated, information has been obtained on preferred directions of departure of different species, and on cues for obtaining compass information (see NAVIGATION).

Patterns of migration

1. Time of day. Most long-distance passerine migrants, travelling from temperate or arctic breeding areas to tropical non-breeding areas, depart an hour or two after sunset, as recorded by radar in several parts of the Northern Temperate Zone. Although they fly chiefly at night and usually land at dawn, some make non-stop flights of several days' duration over inhospitable habitats, e.g., Blackpoll Warbler *Dendroica striata* from North to South America over the Western Atlantic Ocean. Many primarily nocturnal migrant passerines are insectivorous during the breeding season, but they may also feed on fruits before and, in daytime pauses, during autumn migration.

Most short-distance passerine migrants travelling chiefly within the Northern Temperate Zone, fly by day, often departing slightly before sunrise. But, in contrast to nocturnal migrants, they move for only a few hours in a morning before stopping to feed, unless they are aerial feeders such as Swallows *Hirundo rustica*, which may continue to migrate all day, feeding as they travel. Many diurnal migrants are primarily seed- or fruit-eating species, especially outside the breeding season in northern latitudes. A few of these species also migrate by night, e.g., Brambling *Fringilla montifringilla*. Soaring birds, including the White Stork *Ciconia ciconia*, and birds of prey such as the Black Kite *Milvus migrans*, move chiefly during the middle of the day when thermals which assist their flight are most active. Shorebirds (Charadrii) may depart at any time of day or night, since their activity patterns are also governed by the tidal cycle. Their departures often coincide with those times when they would normally fly to high-water roosts.

Exceptionally, nocturnal migrants may not leave until the middle of the night. Wave-like migratory departures from roosts several hours after dusk have been recorded by radar; they refer to Starlings leaving Britain in spring to return to breeding areas in continental Europe.

Several advantages have been suggested for migration at night: the availability of more than one astronomical cue to assist navigation so that migrants may obtain directional information from fixed patterns of stars, rather than from the changing position of the sun in the sky; reduced likelihood of predation, particularly important at the end of a flight when the migrant's speed may have fallen; and improved atmospheric conditions for detection of sound signals, which may give information about terrain below the bird, or about the positions of conspecifics; also the daylight hours become available for feeding.

2. Patterns of migration in species, populations or individuals moving each year.

2a. Distances and directions. The most prominent and extensive movements of land birds occur in a north–south direction. Most passerines breeding at high latitudes in the western Palearctic move towards equatorial regions of Africa during the Northern Hemisphere autumn, whereas those breeding in eastern Siberia move chiefly towards south-east Asia and Australasia (Moreau 1972). In the New World, extensive southward movements occur in autumn towards central and South America, though many species do not travel further than the southern states of the USA. The same pattern is broadly true of waterfowl movements in the New World, whereas in the Palearctic most species move further west than south to spend the (northern) winter in countries bordering the North Sea and the Mediterranean, and in West Africa. Autumn movements of several arctic-breeding wader species in the New World involve long south-eastward flights overland to the east coast near the Canadian/USA border, followed by southward flights to South America; others migrate southwards along the west coast of North America or make long overwater flights to 'wintering' areas on the Pacific Islands, the most spectacular flight being that of the Lesser Golden Plover *Pluvialis dominica fulva* from Alaska to Hawaii, a distance of about 4,000 km. Waders from Greenland fly south-east to Europe and then southwards to West and South Africa; many from Siberia, even from longitudes far to the east, move westwards in autumn to the western European seaboard. Some then continue southwards to north-west Africa. Others may fly overland from Siberia via the Caspian Sea to South Africa, whereas yet other species from eastern Asia move southwards to Australasia. Many of these long-distance routes approximate to great circles—the shortest distance between two points on the earth's surface.

Seabird movements are more complex still. Within the Atlantic region, many species move primarily on a roughly north/south axis, which may also involve crossing from the western side of the North Atlantic off Canada to the western side of Africa (Arctic Tern *Sterna paradisaea*), or from the eastern side of the North Atlantic off the British Isles to the eastern coast of South America (Manx Shearwater *Puffinus puffinus*). The tern continues its movements beyond southern Africa into the Antarctic Ocean, thereby flying some 25,000 km on the round-trip from and to its breeding grounds. Conversely some seabirds breeding in the southern Atlantic spend the non-breeding season in Northern Hemisphere waters, e.g., the Great Shearwater *Puffinus gravis*, which breeds on the Tristan da Cunha group of islands and congregates during the northern summer to moult off the Newfoundland coast. Similar extensive movements occur within the Pacific, e.g., those of the Mutton Bird or Short-tailed Shearwater *Puffinus tenuirostris* from breeding sites in southern Australia to moulting areas in the Bering Straits. This migration follows an almost circular route, at first north and westwards to Japan and later south and eastwards along the western coast of the USA before crossing back to Australasia.

Migrant land birds breeding at mid-latitudes in the Northern Hemisphere often do not move as far south in autumn as those from higher latitudes. In western Europe, the directions of most movements of passerines lie between south and west, to wintering areas in the British Isles, the Iberian Peninsula and the Mediterranean coasts and islands. In the Southern Hemisphere, which lacks extensive ice-free land masses further south than those at mid-latitudes in South America and southern Africa, most migrant species move northwards after breeding but rather few cross the Equator and none enter the Northern Temperate Zone. Some of the most extensive movements are made by aerial feeders, such as the Brown-cheeked Martin *Phaeoprogne tapera* from Argentina to Venezuela and central America.

Within the tropics, generalizations about directions of migration are hardly possible, since many movements are associated with the alternation between wet and dry seasons. These result from the seasonal movements of air masses and accompanying belts of rains, often in different directions in different parts of the tropics. Associated with each of these weather systems, which affect flowering and fruiting of plants, may be a separate migration system, as has been documented by Ward (1971) for *Quelea quelea* in different parts of Africa.

Short-distance movements between different altitudes also tend to occur in a variety of directions, dependent on the alignment of mountain ridges such as the Andes and the Alps. For example, the Grey-flanked Cinclodes *Cinclodes oustaleti* nests in the Chilean Andes above an altitude of 3,500 m and spends the non-breeding season along the sea coasts nearby.

2b. Time of year. Amongst species that migrate every year, major differences in seasonal timing occur, according to the feeding requirements of each species on the breeding grounds, the climatic zones crossed during their migrations and the timing of other events, such as moult and reproduction, in their ecophysiological cycles. Generalizations are difficult to make. Land-birds nesting in the high Arctic, north of the tree-line, usually depend upon the emergence of insects for successful reproduction; they must arrive in the Arctic late in the spring (May or June) and so pass through the lower latitudes well after many, including their own, species have begun nesting there. The lower-latitude breeding species usually do not move such long distances after the breeding season, and may still be present on their breeding grounds when the higher-latitude species return in late summer and early autumn. The lower-latitude species often have protracted migration periods.

Of more general relevance are situations leading to variations in timing of movements within a species. An observer may notice the occurrence of several periods of passage of the same species during a single season through a refuelling area on the migration route. These can arise in autumn in several different ways: (1) Different breeding populations may reach the same place at different dates, e.g., Dunlin *Calidris alpina* from Iceland and Greenland pass through the British Isles in August and September, en route for north-west Africa, whereas those from northern Russia reach the end of their migration route in the British Isles, arriving from mid-September onwards. (2) Young birds, particularly of species deserted by their parents soon after hatching, may leave arctic breeding areas many weeks after the adults. Adult Grey Plovers *Pluvialis squatarola* move from their breeding areas in Siberia to moulting grounds in western Europe 4–5 weeks before their juveniles reach the same areas. (3) Males and females may migrate at different times. This occurs in many shorebirds, in some of which males (and in others females) leave the breeding grounds first; also amongst certain wildfowl in which males take no part in care of their young and desert their mates once they have begun incubation, e.g., Eiders *Somateria mollissima*, in which males move to moulting grounds well before females. (4) Young of later broods may migrate later than those from first broods, e.g., House Martins *Delichon urbica*, whose second broods may not fledge until September. Indeed a higher proportion of young from later broods may be migratory, as in Great Tits *Parus major* in northern parts of continental Europe. (5) In single-brooded species with long periods devoted to incubation and care of the young, failed breeders may migrate earlier than successful breeders, e.g., European Shelduck *Tadorna tadorna* moving to their moulting grounds in north-west Germany.

In addition to these situations which lead to several waves of passage, the duration of a single migratory wave may be prolonged in species with a wide spread in dates of laying, particularly those in which birds breeding for the first time do so later than experienced breeders.

Some of these temporal patterns of movements are noticeable also in spring. Different breeding populations often occur at a locality on passage on different dates. Indeed, departures of different populations from a common wintering ground may take place in different months, as in the case of the races of Yellow Wagtails *Motacilla flava* wintering in Zaire. Males of species that defend territories during the breeding season usually return to the breeding grounds before females. Birds attempting to breed for the first time may migrate later than older birds. Indeed in some waders, e.g., Bar-tailed Godwit *Limosa lapponica*, immature birds may migrate towards the breeding grounds not only later than potential breeding birds, but also without completing the journey. Migrations of species within the tropics may be less predictable on a calendar basis, since the timing of the wet and dry seasons is also less predictable than that of the seasons at higher latitudes.

Amongst the smaller insectivorous passerines, several species contain partially migratory populations, particularly at higher latitudes. These comprise some individuals that leave their breeding grounds each autumn and return each spring and others that are resident. In mild winters, the residents survive better than the migrants, which suffer mortality not only on the more southerly wintering grounds but also during migration; in cold winters on the breeding grounds the residents survive worse (e.g., Goldcrests *Regulus regulus* in Finland). Partial migrants tend to move south later in autumn but return earlier in spring than long-distance migrants breeding in the same areas (e.g. Willow Warbler *Phylloscopus trochilus*).

3. Patterns of migration in species, populations, or individuals moving only in some years. Amongst the types of migrants falling into this category, the most prominent are those taking part in IRRUPTIONS. Others include those populations in which certain individuals are partial migrants, moving in some years but not in others, or different distances in different years, albeit along the same preferred direction. The British race of Redpolls *Carduelis flammea cabaret*, which utilizes the seeds of birch *Betula* in winter, comes into this category.

Large seabirds, such as albatrosses, that attempt to breed only every other year but move away from the breeding colony between attempts, may also be considered as irregular migrants.

Finally, some species, particularly those that feed by probing in damp earth or picking prey from the surface in short grasslands (see PLOVER) may move in response to the onset of freezing conditions. These 'hard-weather migrants', like the Lapwing *Vanellus vanellus* and Skylark *Alauda arvensis*, move in directions most likely to lead them to unfrozen feeding areas, i.e., between west and south. In mild winters, no such movements take place; in other years, their timing is dictated by the occurrence of the severe weather.

Functions of migration. Successful migration enhances the lifetime reproductive output of an individual, either by increasing its chances of survival or by allowing it to breed where it can rear more young than if it remained resident in another site, or for both reasons. In some species migration allows colonization of areas in which individuals could not survive throughout the year.

In relation to increased reproductive performance, migration to higher latitudes provides longer hours of daylight, between the spring and autumn equinoxes, in which young can feed or be fed. This is particularly important to species such as the passerines that forage visually and not by touch, and thus are dependent upon daylight feeding. Disturbance and predation pressures from mammals may also be less at higher latitudes, since few predatory mammals can survive there through the winter. This may permit greater nesting success for ground-nesting species, e.g., shorebirds.

The chances of survival of migrant individuals during the breeding season are greater in temperate and arctic areas than they would have been in the (often tropical) non-breeding areas, for reasons considered above and later. Against this must be balanced the costs of the journey. A similar equation can be drawn up for seasonal movements within tropical regions according to the timing of wet and dry seasons. In many cases, food is more abundant or more predictable in the breeding area, particularly once nesting has begun, than it would have been in the non-breeding area at the same time of year.

'Moult migrations' are also concerned with enhancing the chances of survival of the individual—in this case, normally a waterfowl. Aggregations of certain species, or sex- or age-groups, of ducks and geese occur in areas of plentiful food and/or improved protection from mammalian predators when they are at their most vulnerable, having shed all their flight feathers in rapid succession.

For many species breeding in the North Temperate or Arctic regions and migrating southwards in autumn, the clemency of weather they face in the non-breeding area increases, the further it lies from the breeding area. Taken to its extreme in trans-equatorial migration, movement can eliminate the hazards of severe weather, except on the flight itself, by taking birds from the northern summer to the southern summer and back again in a single year. In species whose average life expectancy is more than a few years, individuals would be expected to produce most offspring during their lifetimes by devoting resources chiefly to survival in the early years of life and to reproductive efforts later. The longer-distance migrations of young, of species such as Black-headed Gulls *Larus ridibundus* from central and northern Europe, to less severe winter conditions than encountered by adults agree with such a prediction. Theoretical considerations of reproductive investments by males and females may explain why the non-breeding areas of the two sexes sometimes differ. For example, in waterfowl, females often move to safer places; in some terrestrial species, males may attempt to stay on or close to breeding territories whilst females migrate to more favourable climates.

Dingle (1980) has suggested that most migrants may be 'fugitive' species, which cannot compete successfully with residents, and are displaced into marginal habitats, whose resources are less predictable in space and time than are those occupied by the residents. As in insects, successful utilization of marginal habitats can be achieved only by mobility (a biological response to adversity), so fugitive species of birds have been pre-adapted to take advantage of seasonally available resources in mid- and high-latitudes. The habitats occupied by passerine migrants in the non-breeding season tend to have transient resources—hence the itinerancy reported by Moreau (1972) in Africa.

Evolution. Long-distance migration must have evolved many times in many species. Most of the migration patterns seen today, in all their variety and complexity, must have altered considerably in the last 10,000 years, since the last glaciations. (Intra-tropical movements may, however, have existed relatively unaltered for a much longer period.) The glaciations were not responsible for the origin of migrations, only for modifying distances moved. Many existing routes bear no relation to the geographical patterns of advance and retreat of the glaciers. However, the movement patterns of several species appear conservative. For example, although the Wheatear *Oenanthe oenanthe* has spread as a breeding species from the Palearctic eastwards into Alaska and westwards into Greenland, the non-breeding area has remained within Africa and birds from the outlying breeding areas rejoin those from the Palearctic on their way south in autumn.

Although easier achievement of energy balance, by migrating from severe climates, may be an important advantage for some present-day migrants from high-latitude breeding areas, other species have evolved adaptations which permit survival through the worst weather in those same areas, e.g., the resident Scandinavian Yellowhammers *Emberiza citrinella* have thicker plumage than the migratory Ortolan Buntings *E. hortulana*. Hence, migration need not have evolved solely for energetic reasons.

In Africa, central America and other areas used by non-breeding passerine migrants, resident and migrant species are often segregated by habitat or microhabitat. This has been taken as evidence for competition and shortage of food in the non-breeding areas, but such a deduction ignores the differences in the types of habitat used by the two groups of species. Migrants are usually found in habitats where they can utilize superabundant but erratically distributed food resources, both in time and in space. These habitats are probably unsuitable for breeding attempts for most species, unless food concentrations remain for long enough to enable completion of a breeding cycle at least once every few years.

Migration may thus have evolved in the non-breeding areas by colonization of, or displacement of species into, habitats that provided adequate food for survival of nomadic individuals but were insufficiently predictable for successful reproduction; followed by further movements to temperate and higher latitudes where productivity at certain seasons was sufficiently great and predictable.

These generalizations may apply only to passerines. Myers (1981) points out that both migrant and resident shorebirds present during the southern summer in coastal areas of Argentina use dependable food resources, albeit erratically distributed in space. He suggests that the migrant sandpipers that evolved in the Northern Hemisphere have failed to establish themselves as breeding species in Argentina chiefly because their densities there are so high that behavioural and competitive interactions do not allow sufficient time and resources for successful breeding. The few local breeding species of shorebirds are taxonomically and ecologically distinct from the migrants.

Preparation for migration. In longer-distance migrants, two distinct phases of preparation can be identified. The first, termed *Zugdisposition*, is concerned with physiological preparation for the energy demands of migratory flight. The second, *Zugstimmung*, leads to the behavioural changes needed to initiate and maintain prolonged flight. It may involve a change in the daily rhythm and orientation of activity, under hormonal control. In caged birds, *Zugstimmung* is expressed as *Zugunruhe* (migratory restlessness), a phenomenon which has been exploited in studies of orientational preferences. Field studies of the behaviour of migrants at a refuelling area (Rappole and Warner 1976) have highlighted differences in behaviour between birds in *Zugdisposition* ('feeders') and those in *Zugstimmung* ('flyers') within the same species. Feeders attempted to acquire territories and did not gain weight unless they did so; flyers foraged in groups and gained little weight. Flyers flocked to assist in synchronizing their departures.

Physiological preparation. Fat is the main fuel used for extended flights by birds. Weight for weight, it provides more than twice as much energy when oxidized as does glycogen, the carbohydrate fuel used by many (but not all) species of migrant insects. Before migration, fat is stored chiefly in subcutaneous and visceral deposits, sometimes known as fat pads. Increase in the mass of a pad results from accumulation of fat within existing adipocytes (fat storage cells), rather than from proliferation in the number of such cells. In general terms, the mass of fat stored before a migratory flight is related to the distance to be flown, especially in terrestrial birds making obligatory sea- or desert-crossings. In species, such as the Ruby-throated Hummingbird *Archilochus colubris*, that migrate across the Gulf of Mexico, fat may form about 50% of the total mass of a bird before its departure. A similar load is carried by some Sedge Warblers *Acrocephalus schoenobaenus* migrating from the British Isles towards West Africa in autumn and by some waders leaving Britain for the high Arctic in spring. The extent, if any, of the safety margin of fat carried by different species, above that required for flight to the destination in calm air, is not known. Possibly some species rely on flight with following winds to make a successful journey.

Not all species begin migration with the maximum fat load they are known to carry. In spring in the North Temperate areas, many songbird migrants that move up to a few thousand km in a series of relatively short flights may set out from their 'wintering grounds' with rather small deposits of fat. This may be an adaptation to link the rate of their movement northwards with the timing of improvement in weather conditions. In autumn, long-distance migrants begin to move southwards from their breeding grounds with small fat stores, but build up reserves en route towards geographical barriers. For songbirds that change diet to include ripe berries in late summer, it becomes progressively easier for them to increase their rate of food intake, as they move south, if they start soon enough, since most fruits ripen earlier at lower latitudes.

Glycogen is not an important source of energy for long flights. The chief storage organ is the liver, and the maximum quantity that has been recorded represents less than 1% of the total mass of a bird. However, although this and other components of the lean mass of a migrant—skeleton, water and protein (chiefly muscle and gut)—do not change measurably during fat deposition in some migrant species, there are definite increases in flight muscle mass before migration in a few passerines and shorebirds, e.g., Dunlin, and of decreases in flight muscle mass, to below 'normal' levels, in several shorebirds after flights from Europe to Mauritania, W. Africa (Dick and Pienkowski 1979). Such changes in muscle mass would be expected if migrants attempted to fly at optimum speeds (see below), which should be high when they first depart and are heaviest, but decrease as they use up their fuel during flight (Pennycuick 1978). A reduction in flight speed without a change in wing-flapping rate could be achieved by reducing power output, i.e., by reducing muscle mass.

Control of fat deposition. In birds, fat is synthesized in the liver and transported to the storage sites in the blood as low-density lipoproteins. The source of the increase in the rate of fat synthesis before migration is chiefly an increase in daily food intake. If food is restricted, fat deposition can be prevented in captive birds. Metabolic changes which would allow greater availability of materials for fat storage without an increase in food intake—namely, a reduction in maintenance energy, more efficient assimilation of the normal diet, or change to an 'energy-rich' diet—are not of general importance, though they have been claimed as important additional factors for a few species. Most laboratory studies have revealed that an increase in food intake precedes, or is independent of, the timing of onset of nocturnal activity in captive migrants, so that an independent means of control of food intake must be sought. Prolactin has been implicated as the hormone most heavily involved both in stimulating appetite and in increasing the rate of fat synthesis in the liver. Its effects are dependent on the time of day at which it is administered to captive birds, and circadian rhythms of prolactin release are known to occur in free-living birds.

Once fattening has begun, it may produce gains of body weight of as much as 5% per day in small warblers *Acrocephalus* (Gladwin 1963). However, rates of use of fat during flight are much faster. Hence, unless migration is accomplished in a single non-stop flight, pauses for 'refuelling' must separate periods of flight by several days at least.

Control of the timing of migration.

1. Ultimate factors. Migration must be timed to bring individuals to potential breeding areas at the most appropriate times (see BREEDING SEASON). Movement away from the breeding area may be timed by the need to moult at a particular site, or to reach a certain refuelling site as soon as possible before its food resources have been depleted, or to establish a feeding site in the non-breeding area.

Thus the timings of movements are ultimately controlled by the influence of seasonal fluctuations in the availability of food on reproductive success and survival.

2. Proximate factors. Since long-distance movements cannot be undertaken without adequate preparation, both physiological and behavioural, certain timing factors must operate to initiate these processes in advance of the dates when migration 'should' take place.

For transequatorial migrants, the timing of start of fat deposition and migratory restlessness at the end of the non-breeding season and after breeding is controlled chiefly by an internal circannual rhythm, synchronized perhaps by changes in daylength on the breeding grounds (see RHYTHMS AND TIME MEASUREMENT). For migrants wintering in the Northern Temperate Zone, preparation for spring migration is initiated chiefly by the increase in daylength beyond a certain threshold. Preparation for autumn migration in these species may be timed as a 'carry-over' effect from the spring, since many species lose their sensitivity to photostimulation in late summer after breeding. Alternatively, they may rely on a circannual rhythm for timing of fat deposition and changes in behaviour in autumn, as presumably must the juveniles of such species. Once initiated, the rate of development of migratory condition can be modified by secondary timers such as temperature, particularly in spring.

In intra-tropical migrants, whose movements are related to the alternation between wet and dry seasons, rainfall, or its indirect effects on food abundance, is most likely to act as the proximate timer.

Once adequate levels of fat deposition have been achieved, weather conditions provide the 'fine tuning' to the timing of a migratory flight. There exists an interplay between the degree of physiological preparedness and the favourability of the weather in determining whether or not a migrant will depart. The effects of weather on migration have been reviewed by Richardson (in Alerstam *et al* 1978). Particularly in spring, the rate of advance of passerine migrants is closely correlated with the northward movements of certain isotherms, which suggests that temperature, as well as the presence of following winds, may exert an important influence on departures. Once migration is underway, if migrants then land with low fat reserves, their migratory behaviour may be suppressed temporarily whilst they regain weight. However, such physiological inhibition of migration in individuals may be over-ridden by social factors in species that fly in flocks by day or that feed upon the wing.

Flight performance. Pennycuick (1969, 1975) has predicted from models of the mechanics of bird flight that each individual should migrate at a speed which maximizes the range it can achieve for each gram of fat oxidized. For migrants carrying large loads of fat on departure, the maximum-range speed should decrease as fuel is used up. This awaits confirmation by radar observations. So also do a series of predictions concerning rates of climb and altitudes of flight, published by Pennycuick (1978).

Body temperatures of flying birds normally lie above those of resting birds, so that cooling of the bird during migration can be considered a major problem. This is achieved by two routes—direct loss of heat by convection from the surfaces of the flight muscles and underwings, and evaporative cooling via the respiratory system. It has been claimed that water requirements rather than the size of energy reserves may limit the flight range of many migrants, but conclusive evidence is lacking. Migrants may alter the relative importance of the two routes of heat loss by adjusting the altitude at which they fly: direct convective loss increases at the lower temperatures found at higher altitudes. However, many other features are involved in choice of flight altitude.

Most passerines fly at altitudes of less than 1,500 m, but at the end of a long flight over the western Atlantic birds have been recorded as high as 6,800 m above the sea. It is not known whether they had adopted a 'cruise-climb' strategy on the flight from the north-eastern USA. Migrant shorebirds have been recorded at greater altitudes. Canada Geese *Branta canadensis* have been seen by radar to fly over the Canadian Rockies on migration. The altitudes chosen by passerines may be affected by the favourability of the wind direction if this varies with height above ground (see also FLIGHT; FLIGHT, SPEEDS OF).

Most migration of songbirds takes place on a broad front, especially by night. By day, concentrations of migrants may form along 'leading lines'—topographical features marking the boundaries between habitats. Particularly effective are coastlines, if the preferred migration directions would lead landbirds over the sea. Such 'leading lines' are followed primarily when migration occurs into a headwind, for birds fly low under these conditions. Other concentrations may occur along escarpments, which may provide shelter for small passerines, or mountain ridges which provide updrafts to assist soaring birds on migration. Other groups of species may follow narrow migration routes because their areas of origin are restricted. For example, shorebirds congregate on estuaries as refuelling areas during migration. These are often well separated geographically. They then depart on narrow routes for the next section of their long-distance journeys.

Flocking of migrants occurs chiefly by day—possibly as an anti-predator adaptation. Although large numbers of birds migrate by night, evidence for tightly-bunched flocks is scarce, though individuals of many species call in flight, which may serve to keep loose groupings together, perhaps to assist in maintenance of the preferred direction.

Even if migrants prepare adequately for flight, choose appropriate weather conditions for departure, and fly at suitable altitudes, long-distance migration will be successful for an individual only if it chooses an appropriate direction of flight. The mechanisms of orientation and navigation are dealt with elsewhere (see NAVIGATION). Two points are relevant here: (1) weather conditions at the time of departure restrict the orientational cues available for use—for example, the stars are obscured by total cloud cover; and (2) weather conditions during flight determine whether or not a migrant can maintain its preferred flight track. Strong side or headwinds may force a small slow-flying songbird to abandon its track and allow itself to be blown off course (see DRIFT).

MIMESIS: same as MIMICRY (adjective 'mimetic').

MIMICRY: the resemblance, by evolutionary convergence, of one species to another for mutual or one-sided benefit. This phenomenon is widespread among insects but rare in birds where, however, it has not been searched for in a systematic manner.

Mimicry in birds commonly involves plumage and shape, sometimes also posture, movements or voice. Cases of alleged mimicry must be carefully evaluated before drawing conclusions regarding their functional and evolutionary basis. Interspecific resemblance may be simply the expression of close relationship, or of parallel adaptations to a common environment and shared specializations.

Defensive mimicry. A docile and palatable animal may evolve a resemblance to a pugnacious or unpalatable one in order to achieve protection from enemies (Batesian Mimicry). From encounters with the unpleasant species, predators learn to avoid it and, in the process, will avoid similar species, whether unpleasant or not; avoidance may also be innate. The two African forest flycatchers *Stizorhina* resemble almost to perfection the two ant-thrushes *Neocossyphus*, presumably shunned by predators because of the smell of formic acid transferred to them from their food. The 'snake mimicry' of cornered Wrynecks *Jynx* includes 'scaly' plumage pattern, undulating movements of the extended neck, and hissing. Brooding titmice *Parus* may move their necks, feign attacks and hiss like snakes toward an intruder from the darkness of their nest cavity (hence no plumage mimicry is required).

In other cases, association with a pugnacious model may be a prime selective force. Examples are 5 Moluccan–New Guinea orioles *Oriolus* which are more dull-coloured than their continental congeners but which resemble, species for species, 5 pugnacious honeyeaters *Philemon* with which they share feeding sites; and 2 African black flycatchers *Melaenornis*, which resemble 2 pugnacious drongos *Dicrurus* with which they frequently associate.

The benefit obtained by a mimic will increase as the model becomes relatively more common. Should a model become rare, the advantage gained by the mimic will decrease, as will selection pressure in favour of resemblance. However, a highly deterrent model need not present itself very often to maintain its beneficial influence on the mimic. Several cuckoos of the genus *Cuculus* have evolved a striking resemblance to specific birds of prey which as a rule do not markedly outnumber the cuckoos. The main purpose of this resemblance is thought to be protection from other raptors. Whether it confers any net advantage to the cuckoos in their parasitic activities remains uncertain.

Another form of defensive mimicry (called Müllerian) implies that several 'unpleasant' species converge in appearance in order mutually to reinforce their deterrent effect on a predator—a situation well known from butterflies but so far not demonstrated in birds. The concept of 'social mimicry' advocated by some authors may, however, include aspects of this kind.

Aggressive mimicry. The model in this case may or may not be a victim of the mimic. Eggs of parasitic cuckoos usually mimic those of locally preferred foster-parents. Nestling whydahs *Vidua* have gape patterns of the same shape and colour as their foster-siblings, species by species, which will elicit feeding by fosterers and prevent the parasite from being ejected. Similarly, nestlings of some parasitic cuckoos (the Drongo Cuckoo *Surniculus lugubris*, the koels *Eudynamis*, the Channel-billed Cuckoo *Scythrops novaehollandiae* and various *Clamator* species) have a plumage resembling their most frequent foster-siblings, usually drongos or crows; and young Parasitic Weavers *Anomalospiza imberbis* are said to mimic the plumage of young *Cisticola* warblers, a frequent host genus.

There may also be cases where a raptor resembles an abundant innocuous species, enabling it to approach its prey unnoticed. The white morph of the Indo–Australian Goshawk *Accipiter novaehollandiae* probably evolved in response to the presence in great numbers of white cockatoos *Cacatua galerita*. On islands where goshawks occur but not cockatoos, the white morph is absent. In this instance, the model presumably is not affected by its role in the interaction between predator and prey, since the latter does not include cockatoos. The occasional adoption by hunting Merlins *Falco columbarius* of a 'passerine' flight mode has also been interpreted as aggressive mimicry. The dangers of interpretation are highlighted by the case of the Zone-tailed Hawk *Buteo albonotatus*, whose resemblance in silhouette, flight, and plumage to the innocuous Turkey Vulture *Cathartes aura* may have originated as an aggressive disguise but may now serve mainly as a means of avoiding being mobbed by passerines (see also BROOD-PARASITISM; COLORATION, ADAPTIVE; MIMICRY, VOCAL). MIMICRY, VOCAL: imitation by birds of sounds other than their specifically characteristic vocalizations. The place that the ability to imitate sounds plays in the development of the vocalizations of a species is dealt with to a certain extent elsewhere (see LEARNING; VOCALIZATION). However, the vocal performances of those birds that can not merely imitate sounds characteristic of their own species or of other species of birds but can even imitate the human voice and other sounds of non-avian origin, pose problems of quite a different order for students of animal behaviour and of phonetics.

Consonant and vowel sounds. Roughly speaking, there are two types of consonant sound in human speech, the plosives (of which p, b, t, and d are examples) and the fricatives (which include f, v, and varieties of s, z, and ch sounds, all on the whole of relatively high frequency). The first group, the plosives, really involve different ways of stopping and starting sounds more or less suddenly, with more or less explosive force, and with greater or less infusion of high frequencies. Since birds in the course of producing their normal vocalizations are obviously capable of stopping and starting their sounds with extreme suddenness, we should expect them to be able to produce something like our consonants; but since their tongue, larynx, and mouth cavity are so different from ours, and since the overall size of the vocal organs of most birds is so much smaller than ours, we should not expect sound-spectrograms of birds' voices to show more than a slight and very general resemblance between the stopped sounds of birds and those which we ourselves produce. Thus we find that the sound-spectrograms of normal bird voices do not give us any very clear evidence of distinguishing between, say, p and b, or t and d. When we come to the fricatives we find that the resemblances are a good deal closer, and we can distinguish in bird vocalizations sounds that are closely similar to a number of our own fricative consonants; it is for this reason that, when we attempt to represent the sounds of small birds in words, we find ourselves making such lavish use of the letters f, v, s, x, and z. Thus, the closest similarities between human consonants and the sounds made by birds as part of their normal repertoire are found amongst those that depend on the range and relative intensity of the higher frequencies present.

When we come to the vowels, the problems posed by bird vocalizations are of peculiar interest to the phonetician. Twenty-three different vowels or vowel-like sounds are recognized in human speech. These are the incidental results of the fact that we have more than one resonator. Vowels occur whenever our throats and mouth cavities are stirred into resonance simultaneously, whether this is due to vocal cords (as in speech and song, when the sound is said to be 'voiced') or whether it is merely due to the airstream passing through both cavities, as in whispering. Four types of modulation occur in speech: (i) start-stop, (ii) vocal cord, (iii) frictional, and (iv) cavity modulation. Of these, (i) and (iii) affect the flow of air from our lungs, (ii) and (iii) convert it into audible sound waves, while (iv), broadly speaking, varies the quality of the sound. The different types of consonants discussed above are produced by differing combinations of these types of modulation but always contain (i) or (iii) or both. When pure vowels or vowel-like sounds are produced in ordinary speech, only (ii) and (iv) occur. The vocal resonances that give the vowel sounds their characteristic qualities are determined by the shapes and sizes of the resonators and are under very precise control by the movements of the lips, jaw, tongue, and soft palate; but it stands to reason that this cavity modulation will affect the sounds produced by the vocal cords very much more than those produced by frictional modulation, since the sounds produced by the vocal cords arise behind the cavities concerned whereas those produced frictionally arise in front.

Talking birds. At first sight the vocal equipment of birds does not appear to have the cavities necessary to enable them to produce anything at all similar to our vowels, and examination of sound-spectrograms of bird vocalizations often shows that when we think we hear a particular vowel we may be deceiving ourselves. In some cases all that the bird seems to be doing is to change the overall pitch of the sound in the same general manner as we may change pitch during vowel production, but without producing the characteristic human resonance patterns. However, there is no doubt that some species of birds, particularly those such as parrots Psittacidae and mynahs *Acridotheres* spp., which can be taught to produce plausible imitations of human speech, do in fact do something more than this and can, in a manner not yet by any means understood, produce a surprisingly accurate copy of the vocal resonances hitherto regarded as peculiar to human speech. A great deal more anatomical and physiological research will be necessary before it will be possible to account fully for the talking abilities of birds, and until this further knowledge is available speculation is apt to be profitless.

Quite apart from the physiological problems arising in connection with bird imitation of human speech, there are other questions concerning the evolution and biological function of this mimetic ability. Talking birds are so familiar to us that the significance of the performance has often been overlooked. No satisfactory evidence is available that either parrots or mynahs ever use their remarkable powers of imitation in the wild; these seem to lie completely latent. Within the primates we find a great variety of vocal mechanism which, it would seem, should enable some of these apes to produce excellent imitations of human speech, yet not even the chimpanzee can be taught to do this. That the birds with their entirely different and apparently much inferior vocal equipment can on occasion overcome almost perfectly the problems of phonation posed by human speech is indeed mysterious.

Why these birds should learn to imitate human speech when kept in captivity is perhaps a little more understandable. Many birds such as Budgerigars *Melopsittacus undulatus* and mynahs learn to talk best when they are kept in close contact with human beings but away from their own kind. This is probably because, as they develop a social attachment to their human keepers, they learn that vocalizations on their part tend to retain and increase the attention that they get, and as a result vocal production, and particularly good vocal imitation, is quickly rewarded by social contact. This seems an obvious explanation of the fact that a parrot when learning will tend to talk more when its owner is out of the room or just after he has gone out—as if he is attempting, by his talking, to bring him back. If this theory about the psychology of talking birds is correct, it makes their process of learning appear very similar to that of the human infant in its first attempts to talk. Mowrer (1950), in advancing this hypothesis, has suggested that birds and babies make their first efforts at reproducing words and other sounds because these sounds seem good to them—they are, in fact, self-stimulatory. Mothers often talk or croon to babies when attending to them, and so the sound of the mother's voice has become associated with comfort-giving measures. So it is to be expected that, when the child, alone and uncomfortable, hears its own voice, this will likewise have a consoling, comforting effect. In this way Mowrer supposes that the human infant will be rewarded for his own first babbling and jabbering without any necessary reference to the effects that these sounds produce upon others. Before long, however, he will learn that if he succeeds in making the kind of sound his mother makes he will get more interest, affection, and attention in return; and so the stage is set for the first steps in the learning of human language. In spite of all the differences, it seems hard not to believe that something of the same sort is happening in the learning of human speech by pet birds.

Mimicry in wild birds. While many birds learn their songs, or at least some phrases of them, by imitation from others of their own species, it is well known that some species incorporate into their songs sounds copied from completely alien species or even sounds of non-avian origin. This tendency to mimic a wide variety of sounds can probably be regarded as a special development of the ability to learn songs from the parents or other conspecifics. It has been shown that some species that show no traces of imitation of alien sounds in their songs nevertheless include quite a number of such sounds in their sub-songs. When these sub-songs are transformed at the beginning of the breeding season into the true songs, all the sounds of alien origin are omitted. This fact will perhaps give a clue to the development of this faculty of general mimicry, for it is significant that sub-songs seem to have little or no communicatory function, whereas the songs themselves, at least in territorial species and probably in many others too, are important in transmitting information to other members of the species about the circumstances of the singer, e.g., whether mated or not, whether established in a territory, and sometimes also constituting an individual recognition mark.

There is no doubt that a very large number of species occasionally imitate alien sounds, but only very few species are good general mimics. Even in those which are renowned for their mimicry, such as the Starling *Sturnus vulgaris*, the Marsh Warbler *Acrocephalus palustris*, and the Mockingbird *Mimus polyglottos*, it is far from easy to make any estimate of how much of the vocal repertoire has been picked up in this way. It is estimated that an average male Marsh Warbler mimics 76 species (range 63–84). Of particular note is the observation that about half the mimicked species are from the Marsh Warbler's breeding area in Europe, while the other half are from its wintering grounds in Africa. As regards the percentage of total song that consists of mimicry, for Mockingbirds estimates are from 5%–18%, for Starlings about 10% and for White-eyed Vireos *Vireo griseus* about 53%.

The robin chats *Cossypha* spp. are said to include some of the best mimics among African birds. *Cossypha dichroa* seems to interact vocally with the models: it tends to match vocalizations of species it mimics in direct response to their songs. In Australia, the bowerbirds Ptilonorhynchidae, the lyrebirds Menuridae, and the scrub-birds Atrichornithidae are all renowned as mimics; and Chisholm (1937) has pointed out that it is the ground-living members of these and a number of other families in Australia that are most skilled and persistent in their mimicry.

Marshall (1950) points out that most vocal mimics in Australia are strongly territorial (although not necessarily using their vocalizations in territorial defence), and that most of them carry out much of their mimicry near the ground in wooded country where visibility is limited. He suggests that the lack of visibility places a premium on communication by sound. A number of hypotheses have been put forward to account for the biological significance of mimicry, all of which may be correct, since mimicry probably serves a variety of functions in different species. (a) *Mimicry is a method of acquiring a large repertoire.* There is some evidence that variety in bird song is attractive to females (an 'acoustic peacock's tail') and mimicry may simply be a way of increasing repertoire size. In one study of Mockingbirds there was some evidence that individuals with larger repertoires paired earlier. (b) *Mimicry is important in interspecific territoriality*. Some species mimic many of their competitors (e.g. *Cossypha dichroa*) and may use their mimicked song in interspecific territoriality. (c) *Mimicry as a form of deception*. The Thick-billed Euphonia *Euphonia laniirostris* is reported to mimic the mobbing calls of other species nesting near its breeding site, thus inducing them to mob predators while the Euphonia retreats to a safe distance. It is possible that there are other examples of mimicry used to deceive competitors, rivals or predators, but as yet there is no convincing evidence for this. (d) *Mimicry in reproductive isolation*. The parasitic Paradise Whydah *Vidua paradisea* learns part of its song by mimicking that of the host species *Pytilia*. Song in *Vidua* plays a role in mate attraction, and it appears that a female prefers to approach *Vidua* males singing the song of the foster-species by which she was reared. Thus song learning ensures that the brood parasites selectively mate with individuals reared by the same hosts, thereby maintaining host-specific reproductively isolated parasite species. W.H.T. MIMICS: sometimes used as a general term for the Mimidae.

MIMIDAE: a family of the Passeriformes, suborder Oscines; MOCKING-THRUSH.

MINER: substantive name of *Manorina* spp. (see HONEYEATER).

MINER (alternatively **MINERA**): substantive name of *Geositta* spp. (see OVENBIRD (1)).

MINERAL REQUIREMENTS: see NUTRITION.

MINIVET: substantive name of *Pericrocotus* spp. (see CUCKOO-SHRIKE).

MINLA: substantive name of the 2 species of *Minla* of south-east Asia (see BABBLER).

MIOMBO: an environment, consisting of sparse leguminous woodland (*Brachystegia*), characteristic of large parts of south-central Africa.

MIRROR: a white spot on the otherwise black wing tip of certain species of gulls (Laridae).

MISTLETOEBIRD: *Dicaeum hirundinaceum* (see FLOWERPECKER).

MIST NET: see TRAPPING.

MITES: see ECTOPARASITE.

MITOSIS: ordinary cell-division, without reduction in the number of chromosomes (see CELL).

MOA: substantive name of the species, all extinct, of the family Dinornithidae, order Struthioniformes, suborder Apteryges.

The moas were wingless, cursorial birds, of moderate to very large size, endemic to New Zealand; a moa bone found in Australia is now believed to have been taken there from a New Zealand site by man (Scarlett 1969); fossil remains are extremely rare, virtually all the abundant material so far discovered being of Post-Glacial age; the living birds were hunted by the prehistoric Maoris, and extinction became complete only within the last few centuries. Examples of the largest species, *Dinornis maximus*, estimated to have stood more than 3 m high, were the tallest, though not the heaviest, birds ever known, being exceeded in mass by the largest Dromornithids and some Aepyornithids.

Discovery. In the early years of European exploration in New Zealand there is no unequivocal evidence that the Maoris had any memory of the former existence of giant birds, or that they had a name for them, although the archaeological record proves that their ancestors were hunting moas only a few hundred years previously. The name 'moa' did feature, but only very rarely, in a few Maori traditions, but there was no clear indication of what it meant, beyond that it implied some kind of monster, man or bird. After Europeans had found bones of giant, extinct birds, the name 'moa' (the widespread Polynesian word for 'chicken') was applied to these birds.

Specimens of moa bones were first exhibited and described by Richard Owen, who was shown, in 1839, the shaft of a femur brought to England by Dr John Rule. Owen's verdict was that the femur indicated the existence in New Zealand of a large struthious bird, probably as large as the Ostrich *Struthio camelus*. With more material received in the next few years, he was soon able to elaborate his descriptions and referred to his genus, *Dinornis*, 6 distinct species. These descriptions were further elaborated over a period of nearly 40 years (Owen 1879). Notable subsequent reviews are those of Hutton (1892), Archey (1941) and Oliver (1949) who listed 27 species in 7 genera. Cracraft (1976) suggested a considerable reduction to 13 in 6 genera. Acceptance of this proposal depends largely on whether marked variations in skeletal size reflect real specific differences or simply sexual dimorphism. More recently Millener (1981, 1982) has merged 2 of the species admitted by Cracraft, thus indicating that only 12 species should be considered valid.

All classifications have agreed in regarding moas as 'ratite' birds (see EARLY EVOLUTION OF BIRDS), and this assumption has not been challenged except by theoretical inference. Despite earlier suggestions of a polyphyletic origin for the group, there is now overwhelming evidence for monophyly (reviewed in Sibley and Frelin 1972). Within the ratites the moas appear to be most closely related to the kiwis (Apterygidae) and perhaps more distantly to the Aepyornithidae (see ELEPHANT-BIRD). Their closest non-ratite relatives are possibly the Galliformes (Cracraft 1973).

Evolution. The ancestry as well as virtually the entire evolutionary history of the moas is largely speculative, as their fossil record is sparse. The most abundant remains are Holocene in age, some are undoubtedly Pleistocene, but none are, other than tentatively, of Pliocene age or older. It can be reasonably assumed, however, that the moas developed from volant ancestors of southern continental (Gondwanaland) distribution and that flightless ancestors of the moas were present (see FLIGHTLESSNESS) on the New Zealand landmass at the time of its late Cretaceous (*c.* 80 million years BP) separation from Gondwanaland.

Adaptive radiation in the moa lineage presumably began in the earliest Tertiary but, as noted by Cracraft (1976), the remarkably diverse Holocene assemblages most probably resulted from a later, Pleistocene, radiation. The changes in landform, climate and vegetation during the Pleistocene, more marked and more rapid than any in the Tertiary, while stimulating adaptive radiation, must almost certainly have effected extinctions amongst the Tertiary forms. The radiation of the moas, obviously strongly favoured by the absence of mammalian predators, is paralleled by the faunas of a number of other oceanic islands and indeed within New Zealand by a number of other avian families, notably the Rallidae.

Deposits. The oldest known moa remains are a very few, isolated bones found in marine deposits of ?Pliocene and Pleistocene ages. The oldest radiometrically dated remains in terrestrial deposits are of late Pleistocene age (McCulloch and Trotter 1979). All recognized species, however, occur in Holocene deposits.

The largest deposits of moa bones are found in situations that indicate death from natural causes, accumulation having continued over a long period. The richest deposits have been found in swamps where huge mixtures of bones prevented much identification of individual skeletons, and attempts to assemble them resulted in many mistakes in the early descriptions of supposed species. An important swamp deposit found in 1937 at Pyramid Valley, Canterbury, has provided numerous individual moa skeletons associated with a considerable variety of other avian remains. Sand dune deposits, especially in the far north of the North Island, have yielded abundant moa and associated faunal remains of Holocene age. Caves have frequently provided well-preserved individual skeletons while those in drier regions have also produced dried integument and feathers (Buller 1888).

Significant finds, especially of moa footprints, have been made in river deposits and in the early days of European settlement, when large areas of forest and scrub were being cleared, skeletons were found on the surface of the ground.

The wealth of material from these predominantly Holocene deposits is such that it is likely that all those species of moa which survived the Pleistocene are now known. We still, however, know nothing of the earlier Tertiary forms.

Moa bones are common in early archaeological sites from one end of the country to the other. They are, however, rarely intact, having been broken up by the Maoris to make bone fishhooks and other artefacts. The largest, and greatest number, of these 'moa-hunting' sites are along the coast, especially at river mouths, but sites also occur inland, even in the high country of the South Island. At least two early prehistoric rock drawings in Canterbury show birds that can be identified as moas with reasonable certainty.

Reconstruction. Interpretation of plentiful bones, quantities of eggshell, a few unbroken eggs, a few feathers and pieces of skin, some gizzard contents, occasional footprints and, of course, associated faunal and floral remains provide substantial clues to the habits and habitats of moas.

The general robustness of the bones of moas and especially the relative lengths of their hind limb elements indicate that most were sturdy and slow-moving. Even the most lightly-built would appear to have been far more ponderous than any of the extant savanna-dwelling ratites. Superficially the birds probably had the looped neck stance of emus *Dromaius* and cassowaries (Casuariidae) rather than the erect carriage of the Ostrich and rheas (Rheidae). Surviving feathers, at least of *Megalapteryx*, are less 'degenerate' than the norm for struthious birds. They have aftershafts but no barbules and some show vane pigmentation (purplish black centres with golden buff edges). Eggshell, which is usually white and occasionally pale green, is not abnormally thick for the size of the eggs. Moa nests, presumed to be those of *Anomalopteryx*, were discovered by Hartree in two North Island districts. All contained single eggs or chicks in scoop nests on sheltered ledges or cavities. Buller, however, produced evidence of a brood of 4 in *Dinornis robustus*.

Ecology. Whenever moa remains have been found, the associated fauna and flora are indicative of a forest habitat, as is only to be expected in the light of New Zealand's vegetational history (see Fleming 1979). Only in alpine and recently active volcanic zones and, during the Pleistocene, in isolated periglacial regions, can there have existed extensive grassland.

Moas appear to have been entirely herbivorous, berries, seeds and shoots of a wide variety of forest trees having been found as gizzard contents (Burrows 1980), suggesting a close analogy to the browsing, forest-dwelling cassowaries of New Guinea and north-eastern Australia. Collections of gizzard stones of various, most frequently quartzose, lithologies have been found.

Distribution. Five of the 6 moa genera, but only 4 of the 20 or so species were common to both North and South islands. This dichotomy, into what are in many cases North Island–South Island 'species-pairs', is doubtless the result of the two islands having been effectively isolated from each other since the Post-Glacial inundation of Cook Strait some 10,000 years ago. On neither island, however, does any one species appear to have been restricted to a particular altitudinal or geographic zone, although both *Megalapteryx* and *Anomalopteryx* have not commonly been found in coastal sites, and some of the larger species are rare in steeper country. Generally, however, moa bone deposits, wherever they occur, yield a considerable variety of species.

The finding of moa remains predominantly in lowland or coastal sites (both natural and archaeological) has led to the assumption that moas were most abundant in these regions. It is more probable that this distribution simply reflects the distribution of sites in which moa remains were most readily preserved. Indeed there were probably few areas in New Zealand, except perhaps the most mountainous, that were not at some time inhabited by moas.

The occurrence of the remains of many different species of moas in a single site has, on the assumption that all were deposited at essentially the same time, been taken to indicate that these many species shared the same habitat. However, the time it may have taken for such deposits to accumulate has been a factor all too often overlooked. As a result, excessive estimates of population density and extravagant theories of catastrophism have often been invoked to explain accumulations which more probably have resulted from prolonged and intermittent deposition.

Extinction and the impact of man. All the moa genera known have been found in archaeological sites, so that moas clearly were widespread when New Zealand was first colonized by prehistoric Man from East Polynesia about 1,000 years ago. All the moas were extinct or extremely rare by the time of European settlement which occurred in the years following Cook's first visit of 1769.

The exact date of moa extinction will always be hard to define, but the latest radiocarbon dates for archaeological sites containing any number of moa skeletons suggest that the 15th century AD was the last time that moas were at all numerous; and that by 1800 AD they were extinct or virtually so.

Because all the known moa genera became extinct in the short period of prehistoric settlement, it is likely that the arrival of man was an important factor in their demise. It is clear from archaeological evidence, particularly in the South Island, that moas were hunted extensively.

Moas must also have been seriously affected by the widespread burning of forest which accompanied the spread of the prehistoric population. However, large areas in the remoter parts were never seriously disturbed by prehistoric hunting or burning, so that the disappearance of the moa cannot everywhere be ascribed to the direct effect of man. It is possible that natural environmental changes were also detrimental, although the fluctuations of the Holocene were never as drastic as those of the Pleistocene, which the moas had previously survived. The prehistoric introduction of the Polynesian rat *Rattus exulans* and the domestic dog may also have affected the moas.

Possible survival into the 19th century. The discovery, in an excellent state of preservation, of bones of an individual *Megalapteryx* in an open fireplace in a rock shelter near Lake Te Anau led to the suggestion that this bird was hunted by Maoris in the period after European settlement. In the absence of radiocarbon dating this conclusion is highly speculative, as the state of preservation of bones cannot be taken as a reliable guide to age.

It is quite clear that none of the largest species were ever seen by Europeans, but there is a possibility that at least one of the smaller ones, *Megalapteryx didinus*, still survived in the southern province of Otago into the early part of the 19th century. Sealers from Foveaux Strait were in the habit of spending many months in the south-western fiords and living off the land. Most of the birds they described to F. Strange in 1852 are recognizable, except a larger one which they called 'the fireman', because of a call reminiscent of the wooden rattles carried by firemen on duty. Maori informants about the same time frequently referred to kiwis and to a larger bird which they called the Roa. European lexicographers have since attached this name to one of the larger kiwis, *Apteryx haasti*, but this species does not and apparently did not occur in the south-western area, and there is a possibility that the Roa was in fact a small moa.

Among reported direct observations by Europeans, one of the most arresting is that given in her later years by a Mrs Alice McKenzie of South Westland. As a child of 7, about the year 1880, she claimed to have seen a large bird of dark bluish plumage standing close to her. It was about 1 m in height, and her clearest recollection was of its large protruding eyes, broad beak, and powerful scaly legs.

Classification. The following classification, adapted from Archey (1941), Oliver (1949), and Scarlett (1972), represents the more traditional diagnosis of the group.

Order DINORNITHIFORMES
Family Dinornithidae
- Genus *Dinornis* Owen—6 species, 3 in each island.

Family Emeidae
- Subfamily Anomalopteryginae
  - Genus *Anomalopteryx* Reichenbach—2 species, the larger in both islands, the smaller only in the North Island.

Genus *Megalapteryx* Haast—2 species, the larger in both islands but very rare in the North Island. The smaller, rare and confined to the South Island.

Genus *Pachyornis* Lydekker—4 species, the largest in both islands although very rare in the North Island; 2 confined to the North Island and the fourth known only from the unique South Island holotype.

Subfamily Emeinae

Genus *Emeus* Reichenbach—1 species, probably confined to the South Island.

Genus *Euryapteryx* Haast—4 species, the largest in both main islands and from cultural deposits only on Stewart Island, the others confined to the North Island.

In the classification proposed by Cracraft (1973, 1976), a single order, Palaeognathiformes, encompasses the tinamous and ratites, with the moas occupying 6 genera within a single family (Dinornithidae). Cracraft admits only 4 species in *Dinornis*, 2 each in *Anomalopteryx*, *Megalapteryx*, *Pachyornis* and *Euryapteryx*, and one in *Emeus*. Millener (1981, 1982) has shown that only the one species *A. didiformis* is admissable in the genus *Anomalopteryx*. (R.A.F.) R.J.S.C. and P.R.M.

MOBBING: term used for collective and noisy demonstration (see DISTRACTION BEHAVIOUR) against a predator by birds of one or several species. This behaviour is typically shown when small passerines surround a perched owl in daytime and when a party of hirundines pursue a hawk. Only rarely is the predator actually struck by the mobbing birds.

Herring Gull *Larus argentatus* mobbing White Storks *Ciconia ciconia*. (*Photo: E.J. Hosking*).

MOCKINGBIRD: see MOCKING-THRUSH.

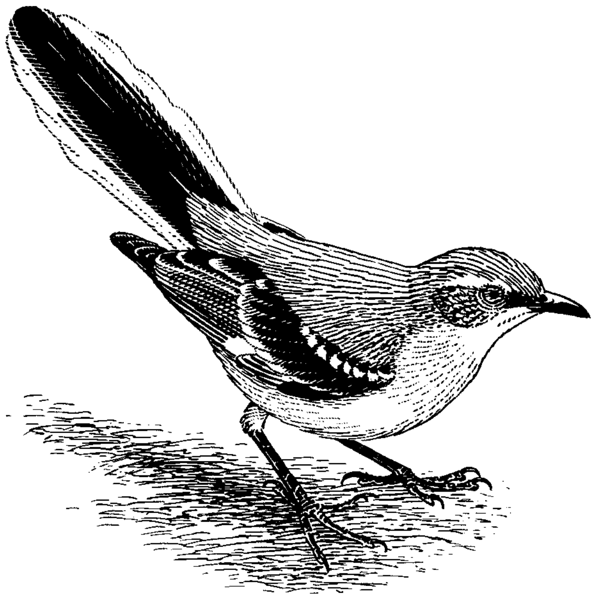
MOCKING-THRUSH: general term for the 33 species comprising the Mimidae (Passeriformes, suborder Oscines), consisting of the mockingbirds and their allies, though not used as the substantive name of any of the species. (*Donacobius atricapillus*, formerly known as the Black-capped Mocking-thrush, is now considered to be an aberrant wren (see WREN (1)). The name 'mockingbird' is used for the 13 members of the genus *Mimus* (including *Nesomimus*), the 2 blue mockingbirds of the genus *Melanotis* and the monotypic genus *Mimodes*. The name 'thrasher' is used for the 10 members of the genus *Toxostoma* as well as the 2 members of the genus *Margarops*, and the monotypic genera *Rhamphocinclus*, and *Oreoscoptes*. The members of the monotypic genera *Dumetella* and *Melanoptila* are known as 'catbirds'. The monotypic *Cinclocerthia* is known as the 'trembler', owing to its habit of vigorously quivering its wings during most intra- and interspecific social interactions.

Characteristics. This New World group is related to the thrushes (Turdinae), and nearly all are suggestive of them in appearance, especially the 2 *Margarops* thrashers and the 2 catbirds. They range from 20–33 cm in length. They have rounded, short wings characteristic of birds that do not fly extensively. The relatively long-winged arboreal *Margarops* thrashers are exceptions. Most have long tails. The bill is strong, medium to long, and in many species, especially the thrashers of the genus *Toxostoma*, is slightly to strongly decurved. Most species are shades of white, grey and/or brown, the exceptions being the blue mockingbirds and the iridescent Black Catbird *Melanoptila glabrirostris*. Many have white areas in the wings and on the tips of the tail feathers. Dark spots are found on the ventral surfaces of various thrashers and several of the mockingbirds. The crissum (under tail coverts) of several species exhibits contrasting coloration, ranging from the chestnut of the Grey Catbird *Dumetella carolinensis* and the Crissal Thrasher *Toxostoma crissale* to various shades of reddish-brown in other thrashers and mockingbirds.

The mocking-thrushes are very varied in ecological adaptation for such a small number of species. Several, notably the 2 catbirds, are structurally quite like many other unspecialized brush-dwelling insectivorous–frugivorous thrushes. However, the group also includes the Trembler *Cinclocerthia ruficauda*, which with its elongated cranial structures, short legs, reduced sternum, narrow interorbital structures, and eyes oriented for close binocular vision, is adapted to probing arboreal epiphytes. The *Margarops* thrashers have developed powerful pectoral systems adapting them for much flying in their arboreal habitat. A particularly interesting group of specializations is found in the 10 *Toxostoma* thrashers. Evolutionary stages leading to powerful pelvic systems, reduction of the pectoral system, including the length of the wings, and modification of skull structural relationships, including lengthening and increased curvature of the bill, have been demonstrated. The species exhibiting the least degree of modification are the Brown, Long-billed and Cozumel Thrashers (*T. rufum*, *T. longirostre*, and *T. guttatum*). The most extreme modifications are found in the Le Conte's, Crissal and California Thrashers *T. lecontei*, *T. crissale*, and *T. redivivum*), species which are weak flyers, and are specialized to search for invertebrates by hoeing soft desert soils and litter with their long decurved bills.

Habitat. Typical members of the group are either largely terrestrial or dwellers of thickets, brush or low trees.

Distribution. The mocking-thrushes can be divided into 2 major groups. The larger includes the mockingbirds of the genus *Mimus*, which range from southern Canada through northern Central America, the West Indies, through non-rain-forest areas of South America to Tierra del Fuego, and the Galapagos Archipelago where the 4-member endemic superspecies *Mimus* (formerly *Nesomimus*) *trifasciatus* is found. This first group also includes 2 monotypic genera, *Oreoscoptes montanus* of western North America and *Mimodes graysoni*, found only on Socorro Island in the Revillagigedo Archipelago off the west coast of Mexico. Evidence suggests that both these species are closely related to *Mimus* and the English name of the latter has been changed to Socorro Mockingbird. Also included in this section of the family are the 10 thrashers of the genus *Toxostoma* which are confined to the United States and Mexico, the



Northern Mockingbird *Mimus polyglottos*. (*R.G.*).

Grey Catbird of North America, and the Black Catbird which is found only in coastal Central America from Yucatan to Honduras.

The second group includes the Blue Mockingbird *Melanotis caerulescens* of Mexico, the Blue and White Mockingbird *M. hypoleucus* of southern Mexico and Central America, and 3 West Indian endemic species, the Pearly-eyed Thrasher *Margarops fuscatus*, the Scaly-breasted Thrasher *M. fuscus* and the Trembler *Cinclocerthia ruficauda*. The endangered West Indian endemic species, *Ramphocinclus brachyurus*, although clearly a mocking-thrush, cannot unequivocally be associated with either of the two major groupings.

Movements. Migration is well developed in some species that breed in temperate zones.

Food. Invertebrates and various fruits are the principal foods.

Behaviour. During the non-breeding season, some species (*Mimus parvulus* and *Ramphocinclus brachyurus*) move about in small groups, possibly families. Group territories are sometimes defended. Individual Northern Mockingbirds *Mimus polyglottos* will often defend a favourite food source during winter months. Mockingbirds are often extremely aggressive in defending the area about the nest, vigorously attacking and striking predators in their efforts to drive them away.

Voice. The mocking-thrushes are renowned for vigorous and versatile song. Nearly all are continuous singers. In most, the songs consist of a wide variety of syllables which are assembled into species-characteristic phrases, the detailed patterns of which are often highly varied. Some members of the group, especially the mockingbirds and notably the Northern Mockingbird, are excellent mimics. The degree of mimicry varies widely among individuals, ranging from slight in many birds to extensive in a few. Mockingbirds typically incorporate mimicked sounds, syllables, and songs into their own species-characteristic song patterns. The Northern Mockingbird, for example, usually repeats the model 2–4 times as it does its own sounds. Night singing is prominent during the breeding season and, in members of the genus *Mimus*, song may continue as the bird flies up and flutters above its song perch. The Sage Thrasher *Oreoscoptes montanus* sings on the wing as it circles over its treelees sagebrush plain habitat.

Breeding. Nests are typically placed in bushes or dense trees and are open cup-like structures, sturdily built of twigs, often incorporating leaves, and lined with rootlets and hair. The Pearly-eyed Thrasher prefers holes in forest trees. Eggs number 2–5, rarely more, the greater numbers occurring in some individuals of species living in high latitudes, the smaller numbers occurring in tropical species. The ground colour of the eggs ranges from pale whitish-blue to intense blue-green. The mockingbirds (*Mimus* and *Mimodes*), the Sage Thrasher, and the *Toxostoma* thrashers generally have spotted eggs. The eggs of all others are unmarked. In most species, incubation lasts about 13 days and is performed by the female. In some, the male assists. Both parents feed the young, which fledge in about 13 days. In some species, nest helpers have been observed. Social organization during the breeding season is monogamous and territorial. (A.H.M.) J.L.G.

MODE: see BIOSTATISTICS.

MOHO: alternative name of the Oriole Babbler *Hypergerus atriceps* (for subfamily see BABBLER).

MOHOUINAE: see WARBLER, AUSTRALIAN.

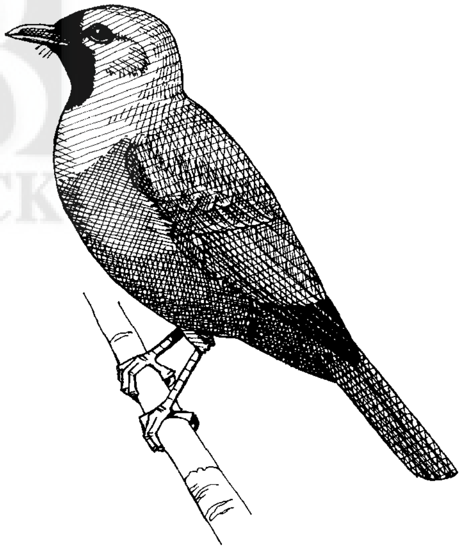
MOLLYMAUK: sailors' name, with several variants, for the smaller species of Diomedeidae (see PETREL); also applied to some other sea birds.

MOLT: American spelling of MOULT.

MOMOTIDAE: see CORACIIFORMES; MOTMOT.

MONAL: substantive name of *Lophophorus* spp. (see PHEASANT).

MONARCH: substantive name of several species of monarchine flycatchers (see MONARCH FLYCATCHER).



Black-faced Monarch *Monarcha melanopsis*. (*N.W.C.*).

MONARCH FLYCATCHER and allies: substantive name of family Monarchidae (Passeriformes, suborder Oscines). This group, though in the main distinctive, remains to be clearly circumscribed and defined, particularly in anatomical terms. Boles (1981) regarded it as a subfamily, Myiagrinae, of the Pachycephalidae, together with the Australo-Papuan robin-flycatchers (*Petroica* spp.) and whistlers, Pachycephalinae.

The nucleus of the group consists of the Indo-Pacific and Australian genera *Monarcha*, *Arses*, *Pomarea*, *Neolalage*, *Clytorhynchus*, *Chasiempis*, *Metabolus*, *Mayrornis*, *Myiagra*, *Hypothymis* and *Philentoma*, the African '*Trochocercus*' (probably an artificial genus) and the Afro-Indian *Terpsiphone*, some 87 species. To these have been added the African fantail-like *Elminia* and *Erythrocercus* (Traylor 1970); the fantails themselves, Rhipiduridae, are here given family status but see Beecher (1953), Boles (1979). Other genera that have been referred to this group include the somewhat drongo-like *Peltops* of New Guinea, the Indo–Malaysian *Hemipus* (currently in the Campephagidae), the mudnest-building *Pomareopsis* and *Grallina* (Grallinidae), and the egregious Fijian Silktail *Lamprolia*. The association with the monarchs of the Australo–Papuan boat-billed flycatchers *Machaerirhynchus* has been questioned by Storr (1958). Certain other African genera included in the Monarchidae have been removed by Traylor (1970), *Platysteira*, *Batis* and relatives to the Platysteirinae, and *Hyliota* and *Stenostira* to the Sylviidae (see also Pocock 1966, and Beecher 1953).

Characteristics. The body is of general passerine proportions (overall length 12.5–20 cm, but see *Terpsiphone*, below), though with a tendency for relatively short tarsi and a relatively long tail. The wings are moderately long and pointed, the tail squared or rounded (strongly graduated in *Machaerirhynchus*, forked in *Peltops*); the tarsal envelope laminiplantar; the bill with a tendency in some species for dorsoventral flattening (pronounced in *Machaerirhynchus* and *Myiagra ruficollis*), with slight terminal hook and subterminal notch usually present on upper mandible, and gape usually armed with rictal bristles. The nostril is rounded, usually exposed, and open (slightly lidded in *Peltops*). Other modifications to external morphology include crests or incipient crests (e.g. *Terpsiphone*, '*Trochocercus*', *Hypothymis*), nuchal frills (*Arses*), long streamer-like median rectrices (*Terpsiphone*) and blue eye-wattles (*Arses*, *Terpsiphone*, *Hypothymis*). The plumage is most often in combinations of grey, blue, black (often glossed), white, rufous and brown, though sometimes largely or wholly one of these; less frequent combinations include black and yellow (*Monarcha chrysomela*), black, white, olive-green and yellow (*Machaerirhynchus*) and black, white and red (*Peltops*). Many species are strongly sexually dimorphic; the young are wholly or largely unspotted. Legs and bills are grey-blue to blackish and blackish-brown, irides usually dark brown (orange or red in *Peltops*).

Distribution, habitat and movements. The typical monarchs inhabit the Oriental, Australasian and Afrotropical regions; they are notably well-represented in the Pacific, where several endemic genera occur. Habitats range from primary rain-forest and second-growth through open woodland to shrub savanna. Tropical and subtropical populations may be sedentary or, in the case of higher-altitude breeders, descend to the lowlands after breeding; some populations of high latitudes migrate to lower latitudes after breeding, e.g., southern Australian populations of the Leaden Flycatcher *Myiagra rubecula* and Black-faced Monarch *Monarcha melanopsis*, and northern Indian populations of the Paradise Flycatcher *Terpsiphone paradisi*.

Food. Chiefly insects: dragonflies, termites, grasshoppers, bugs (including cicadas and lerps), beetles, flies, butterflies and moths (including caterpillars), bees and ichneumon wasps, also spiders. In addition the Shining Flycatcher *Myiagra (Piezorhynchus) alecto* of waterside thickets takes isopod crustaceans, tiny shellfish and crabs, the Restless Flycatcher *M. (Seisura) inquieta* worms and centipedes, and the Spectacled Monarch *Monarcha trivirgata* small snails.

Behaviour. Monarch flycatchers are usually solitary or in pairs, sometimes family groups; some species also noted in mixed feeding parties. Most species hunt by moving briskly through the foliage of trees, shrubs or herbage, flicking wings and fanning tail in the manner of FANTAILS, presumably to dislodge their prey; many also catch flying insects in aerial sallies (a habit not pronounced in *Monarcha*, however). Variations of these methods occur. The 2 species of frilled monarchs (*Arses*), for instance, habitually climb up and down the trunks of trees flushing insects from bark-crevices; the Shining Flycatcher has been observed creeping along near the ground among mangrove roots or swamp-litter; and the Restless Flycatcher hunts mainly by flying slowly over open ground and hovering above its prey before pouncing. As in the fantails, prey too large to be swallowed whole may be held under the foot and eaten piecemeal.

Displays are not well-documented. Species with crests, incipient crests, nape-tufts or nuchal frills will raise these when excited. Courtship display observed in male Paradise Flycatcher consists of a slow rising and dropping flight with long tail-streamers undulating. Group-displays involving repeated chasing or following within a restricted area have been observed in *Arses* and *Machaerirhynchus*.

Voice. Calls are short and simple, the quality variously described as dry, grating, harsh, rasping, buzzing or scolding, the notes often with a rising inflexion. Some species are not recorded as possessing a song (e.g., Azure Monarch *Hypothymis azurea*); songs of others are described as a series of simple whistles (*Myiagra*), slow rattled ringing trills (*Arses*), a musical jumble of loud mellow notes and fluting whistles (*Monarcha*) and a low pleasant rising and falling warble (*Terpsiphone*).

Breeding. Nests are cup-shaped, mainly of vegetable matter, often bound with spiderweb and adorned with cocoons, lichen and bark; usually supported from beneath, on a horizontal branch (e.g., *Myiagra*) or in a vertical fork (e.g., *Monarcha*, *Mayrornis*) at heights from 1–20 m, exceptionally partly or wholly suspended by rim (*Arses*, *Erythrocercus*, and apparently, *Machaerirhynchus* and *Peltops*). The 2–4 eggs are whitish or very pale pastel shades, spotted and blotched with reds, greys and browns, in two chief types of distribution: (a) marked more or less uniformly over the shell, e.g., *Monarcha*, (b) markings concentrated in wreath, e.g., *Myiagra*, *Elminia*. Whether this variation is of taxonomic significance remains to be determined. Incubation lasts 14–17 days; the young fledge after 12–18 days according to species. Where information is available, both sexes build the nest, incubate, and feed the young; in some the female does most of the nest-building and incubating, but the male has been recorded as doing most of the building in *Machaerirhynchus flaviventer*. Traylor, M.A. 1970. Notes on African Muscicapidae. Ibis 112: 395–397.

MONARCHIDAE: family of PASSERIFORMES, suborder Oscines; MONARCH FLYCATCHER.

MONIAS: *Monias benschi*, sometimes misnamed 'Bensch's Rail' (see MESITE).

MONJITA: substantive name of most species of *Xolmis*, a genus of tyrant-flycatchers inhabiting open country in South America (see FLYCATCHER (2)).

MONKLET: substantive name of the small PUFFBIRD *Micromonacha lanceolata* of tropical America.

MONOCULAR VISION: see VISION.

MONOPHYLETIC: of a single evolutionary ancestry (contrasted with POLYPHYLETIC).

MONOSPECIFIC: in reference to a genus containing only one species.

MONOTYPIC: term applied to a taxon that has only one unit in the immediately subordinate category, e.g., a genus comprising only one species, or a species not divisible into subspecies—contrasted with POLYTYPIC.

MONOTYPY: see under TYPE SPECIES.

MONTANE: appertaining to mountains; term applied particularly to the avifaunas of elevated areas in which the bird-life is strikingly different from that of adjacent areas of less altitude. The contrast tends to be especially pronounced at high levels in low latitudes; and it has been one of the puzzles of ornithology that particular sedentary species, sometimes not even showing subspecific differentiation, are found on isolated tropical mountain ranges separated by wide areas of unsuitable country in which such birds are never encountered (see AFROTROPICAL REGION).

MOOD: 'the preliminary state of "charge" or "readiness for action" necessary to the performance of a given course of instinctive behaviour' (W.H. Thorpe).

MOON-WATCHING: see MIGRATION.

MOOR FOWL: antique term (in British game laws) for the Red Grouse *Lagopus lagopus scoticus*; cf. HEATH FOWL.

MOORHEN: substantive name of *Gallinula* spp.; applied without qualification, in Britain, to *G. chloropus* (see RAIL).

MOORUK: native name in New Guinea, sometimes used as English, for Bennett's Cassowary *Casuarius bennetti* (see CASSOWARY).

MOPOKE: popular name, also written 'more-pork', used in Australia for *Podargus strigoides* (see FROGMOUTH), and both there and in New Zealand for subspecies (or related forms) of *Ninox novaeseelandiae* (see OWL). The name purports to represent the call.

MORILLON: British fowler's name (probably obsolescent) for immature Goldeneye *Bucephala clangula*, once thought to be a different species (see DUCK).

MORPH: term introduced (J.S. Huxley 1955) to replace the less precise 'phase', denoting any one of the different forms of a species population subject to polymorphism (including dimorphism, where there are only two morphs)—see POLYMORPHISM.

MORPHOLOGY: literally, the science of form or shape; nowadays commonly extended to cover all external characters, including coloration, or even used synonymously with 'anatomy' (literally, internal structure as revealed by dissection); and it may be applied not only to the study but to its subject matter, as a collective term for the 'morphological' characters of a taxon.

MORTALITY: see AGE.

MOSAIC EVOLUTION: see under ARCHAEOPTERYX.

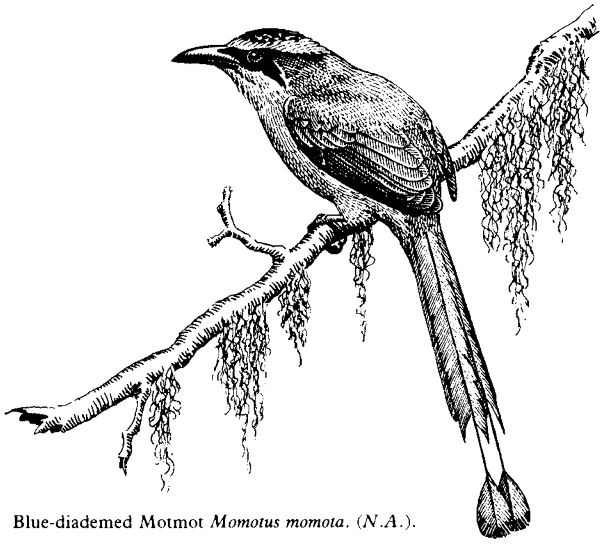
MOSSIE: or Cape Sparrow, *Passer melanurus* (see SPARROW (1)).

MOTACILLIDAE: a family of the PASSERIFORMES, suborder Oscines; WAGTAIL.

MOTHER CAREY'S CHICKEN: sailors' name (from 'Mater cara') for storm-petrels of various species (Hydrobatidae)—see PETREL.

MOTIVATION: see AMBIVALENCE; BEHAVIOUR, HISTORY OF.

MOTMOT: substantive name of species of Momotidae (Coraciiformes, suborder Alcedines); in the plural, general term for the family. The motmots are allied to the kingfishers (Alcedinidae) and even more closely to the todies (Todidae). The 6 genera and 9 species of motmots (*Momotus*, *Electron*, and *Baryphthengus* have 2 each) are confined to continental tropical America, chiefly at low altitudes; but the family was once far more widely distributed, as the fossil bird *Protornis glarniensis* from the lower Oligocene of Switzerland is now ascribed to it.



Blue-diademed Motmot *Momotus momota*. (*N.A.*).

Characteristics, distribution and habitat. At the present time, the Momotidae are best represented in northern Central America and southern Mexico, where in certain regions of lighter vegetation these birds are abundant and conspicuous. Among the noteworthy structural peculiarities of the motmots are the serrated edges of their broad bills, which are about as long as their heads and downcurved at the end, and their feet, of which the outer toe is united to the middle one for most of its length and only one toe is directed backward, as in kingfishers.

These beautiful birds (16–50 cm in total length) are clad in softly blended shades of green, olive-green, and rufous rather than in brilliant spectral colours; although the head is often adorned with bright blue, and a black patch is usually present on the chest or throat. The most arresting feature of motmots is the tail, which is long and strongly graduated. In typical motmots, the central rectrices far exceed the others in length, and, when they first expand, the vanes may be narrower in the subterminal region than elsewhere. In this subterminal portion the barbs are loosely attached and fall away as the bird preens, and probably also in consequence of rubbing against the vegetation through which it moves, leaving a length of naked shaft which supports a spatulate or raquetlike tip where the vanes remain intact. The length of denuded shaft varies considerably from genus to genus, and in some genera it is lacking. While perching, motmots often swing their tails, pendulum-wise, from side to side, and sometimes hold them tilted sideways. When they about-face on a perch, they lift the tail over it with a graceful flourish.

One of the most beautiful members of the family is the Turquoise-browed Motmot *Eumomota superciliosa*, which is found from southern Mexico to northern Costa Rica in semi-arid country and in clearings in rain forest. Well over half of its 35 cm is accounted for by its long tail. As in other motmots, the sexes are alike in coloration. The upper plumage is largely bright olive-green, with a patch of cinnamon-rufous in the centre of the back. Above each eye is a broad band of pale turquoise, the bird's brightest colour. The lores and ear tufts are black; and on the throat is an elongated, wedge-shaped patch of black, bordered on each side with turquoise. The remaining under plumage is greenish olive and cinnamon-rufous. The middle feathers of the greenish-blue tail have a much greater length of denuded shaft than in other motmots, so that the spatulate, blue and black ends hardly appear to be connected with the rest of the bird. This makes the Turquoise-browed Motmot more airily graceful than its relatives.

The largest member of the family is the Rufous Motmot *Baryphthengus martii*, which inhabits heavy forests from Nicaragua to Amazonia and western Ecuador. This 46-cm bird has the head, neck, and most of the underparts tawny, the back and rump and undertail coverts green. There is a black patch on each side of the head and one in the centre of the chest. Each of the central tail feathers has a short length of naked shaft. At the other extreme of size is the Tody Motmot *Hylomanes momotula*, an elusive, little-known inhabitant of forests from southern Mexico to northwestern Colombia. About 17 cm long, clad in dull green and rufous, with black ear-tufts, this small motmot has a short tail without racquet tips.

An aberrant member of the family is the Blue-throated Motmot *Aspatha gularis*, which in northern Central America and extreme southern Mexico inhabits forests of oaks, pines, and cypress from about 1,200 to 3,000 m above sea level. Here it resides throughout the year, despite the severe frosts of the winter months. About 28 cm long, this motmot is almost wholly clad in green, with a blue throat, black ear-tufts, and a black patch on the foreneck. The feathers of the long tail are strongly graduated, but the central ones have continuous webs rather than racquet tips.

Habits and food. When foraging, motmots perch motionless until their keen eyes detect a beetle, caterpillar, spider, butterfly, cicada, small frog, lizard, or snake, on foliage, on the ground, or in the air. Then they dart swiftly, seize the victim, and carry it to a perch, against which, if large, they beat it before gulping it down. Small fruits, including those of palms, plucked while the bird hovers, enter conspicuously into the diets of some of the bigger motmots. These large species often forage with the mixed flocks that follow the army ants *Eciton*, catching small fugitive insects and other creatures rather than the ants themselves.

Voice. Although the utterances of motmots are all structurally simple, they vary immensely in tone from species to species. The Turquoise-browed Motmot voices a dull, wooden *cawaak cawaak*. The call of the widespread Blue-diademed Motmot *Motmotus momota* is a full, froglike, not unmelodious *coot coot*. At dawn, the rain-forest of southern Caribbean Central America is filled with the hollow hooting of the Rufous Motmot, a mysterious sound often difficult to trace to its source, for these motmots stay high in trees. The most melodious of the motmots is the Blue-throated, whose delightfully clear and mellow notes are heard chiefly at dawn, when the members of a pair often sing in unison just after they emerge from the burrow where they slept.

Behaviour. In courtship, two or more motmots call back and forth, often continuing for surprisingly long intervals. Sometimes, while so engaged, they hold pieces of green leaf or other fragments of vegetation in their bills—a puzzling habit, since such material is not carried into the nest burrow. The Blue-diademed, or Blue-crowned Motmot dust-bathes, sometimes on roadways in the evening twilight.

Breeding. Motmots nest chiefly in burrows, which are dug by both sexes of the species for which information is available. They loosen the earth with their bills and remove it by kicking backward with their feet each time they enter to resume digging. The female Turquoise-browed Motmot seems to do the greater share of the work, but her mate sometimes gives her an insect. Often the burrow is in the vertical bank of a watercourse or road; but the Blue-diademed Motmot may dig its tunnel in the side of a mammal's burrow or a narrow pit in level ground, which makes its nests very difficult to find. In this species, as in the Blue-throated Motmot, the burrow may be crooked, with one or several sharp turns; but that of the Turquoise-browed Motmot is often only slightly curved. Motmots' tunnels up to 4.3 m long have been recorded, but most are much shorter. Along the bottom of an occupied tunnel are two distinct parallel grooves, made by the birds' short legs as they shuffle in and out. In limestone regions, motmots sometimes nest in caverns or in niches in the sides of wells.

Two to 4, rarely more, broad, roundish, pure white eggs are laid on the bare floor of the enlarged chamber at the end of the burrow. They are incubated by both parents. One member of a pair of Blue-diademed or Broad-billed Motmots enters the burrow early in the morning and sits for 6–8 hours, rarely longer. At midday or later, the other replaces it and remains in the burrow until the following dawn. While incubating, motmots regurgitate many chitinous fragments from their insect food and an occasional seed, all of which are trampled into the floor of their chamber. The incubation period of the Blue-throated Motmot is 21–22 days; that of the Turquoise-browed Motmot, 15–19 days.

Nestling motmots, hatched blind and with no trace of down on their pink skins, are brooded and fed by both parents, who do not try to keep the nest clean. Young Blue-throated and Turquoise-browed Motmots leave the burrow at 28–31 days of age, and young Blue-diademed Motmots at 29–38 days, but those of the small Broad-billed Motmot fly when only 24–25 days old. They remain in the nest until they are well feathered, much in the pattern of the adults, and fly well. Their stubby tails, of course, still lack the racquet tips. Blue-diademed Motmots and Turquoise-browed Motmots are single-brooded.

Turqoise-browed Motmots start to dig their burrows as the spring or early summer breeding season approaches. Blue-diademed Motmots often begin in the autumn to dig burrows in which they will breed 4 or 5 months later. Blue-throated Motmots dig their burrows even earlier, in June or July, soon after their young are fledged. These tunnels are soon finished, and are then used as dormitories by the constantly mated pair throughout the winter months, when nights are cold and frosty. Even after eggs are laid in these old burrows in the following spring, both parents continue to sleep in them, as they do with the nestlings. After the latter emerge, they do not return to sleep in the burrow; but the parents sometimes continue to lodge in it until a new burrow is completed nearby. The motmots of the lowlands, however, appear not to use their burrows as dormitories, and only one parent sleeps with the eggs and young, until the latter are about 5 days old. A.F.S.

King Penguins *Aptenodytes patagonicus* (left) after and (right) during moult. (*Photo: N. Rankin*).

MOULT: or 'molt' in American usage, the periodic shedding and replacement of plumage, and, in some species, of certain accessory structures of epidermal origin, e.g., tarsal scales and horny sheaths of the bill (see FEATHER; PLUMAGE; BILL); the term is also applied to the period during which moulting occurs. The extent of moult and its timings during the year are adaptively integrated with the other main events of the ecophysiological cycle, namely reproduction and migration (if this occurs)—see BREEDING SEASON; MIGRATION.

Function. Periodic replacement of feathers is needed to maintain a high level of flight performance; to assist in regulation of body temperature by modifying the rate of heat loss from the skin; to maintain the waterproof nature of the plumage of some species; and to allow seasonal changes in appearance, often associated with reproduction (though such changes may occur through abrasion of feather edgings; see later).

Mechanism. Feathers grow from follicles in the skin. During the whole life of a bird, a series of feathers are produced from each follicle. At certain times, the dermal papilla at the base of the follicle is stimulated and in turn activates growth of the epidermis to produce a new feather. This pushes the old feather out of the follicle (Watson 1963). Stimulation of the papilla is usually under internal physiological control, but may occur in response to loss of a feather by plucking or by 'fright moult', the simultaneous shedding of large numbers of feathers from certain parts of the body, a phenomenon that sometimes occurs when birds are frightened by a potential predator.

Pattern. Within each pteryla or tract of feathers (see PTERYLOSIS), feather loss and replacement proceeds in a regular sequence. In general, within tracts of contour feathers, waves of moult pass outwards from the mid-line and downwards towards the tail. Moult of flight feathers begins from certain foci in each tract, often proceeding in both directions with sequential loss of adjacent feathers, but sometimes in only one direction, as in moult of the primary feathers of most passerine birds, in which the short innermost primary is shed first and moult proceeds steadily towards the longer outermost feathers.

Members of several other orders of birds, e.g. Procellariiformes, Accipitriformes, normally follow the pattern of 'descendent' moult of the primaries found in the passerines. However, in the Falconiformes, moult commences with loss of primary 4 (and in the parrots with primary 5) and then progresses sequentially both inwards and outwards from this focus. In the budgerigar *Melopsittacus undulatus*, for example, before the tenth primary has completed growth, primary 5 may have been shed again, at the start of the next moult, so that two 'waves' of moult are present briefly in the same bird. The presence of more than one cycle of moult within the same set of primaries has been termed 'Staffelmauser' (= stepwise moult) by E. Stresemann and occurs in some terrestrial non-passerines and in many seabirds, particularly the larger species in which the onset of breeding is delayed for several years. The pattern is established gradually during the first few years of life. One of the most complicated patterns of moult of the primaries discovered so far occurs in cuckoos, e.g. *Cuculus canorus* in which primaries 1–4 moult descendently but the remaining set of feathers moults ascendently and alternately, i.e. 9–7–5–10–8–6; the relative timing of the moult of these two sets of primaries is not fixed. The pattern of moult of secondary feathers of large terrestrial and large seabird species is also highly irregular.

The pattern of moult in all feather tracts should be considered as adaptive. Since the distribution of pterylae and apteria (areas of skin that are bare or covered only by semiplumes or downs; see FEATHER) is important in the control of body temperature (Clench 1970), growth of new body feathers starting from the centre of each tract ensures minimum loss of skin cover during moult. Similarly, replacement of primaries from the innermost outwards allows most passerines to fly during wing moult, even though several adjacent feathers may be growing at any one moment. By means of this sequence, the inner-growing primaries are also protected by the old outermost feathers. A similar protective function of old feathers is shown in the sequence of tail moult of woodpeckers, in which the long inner pair of feathers—used for support in climbing—are retained until the other pairs have been replaced. In most other families, tail feathers are shed sequentially from the innermost outwards, or vice versa.

Control. Many experiments have been undertaken on captive birds to establish the hormonal control mechanisms leading to the activation of feather follicles. Most of these have involved hormone injections, but changes in photoperiodic regime or nutrition, known or thought to affect hormone levels, have also been used. The results and relevance of these experiments need to be viewed against the known patterns of moult of different feather tracts. Few experimental treatments have led to sequential moult of feathers in a tract at rates corresponding to what happens in the wild.

It is clear from wild birds that the focus or foci at which moult begins in each tract are the same in successive (complete) moults. Miller (1941) suggested that the first feathers to be shed may be those with increased blood supply, but this has yet to be confirmed. Alternatively, or additionally, the follicles at the foci may have lower thresholds of response to hormonal or other stimuli than other feathers in each tract. Once moult has begun, the sequential shedding of feathers could arise by stimulation of growth in one follicle by the growth of an adjacent feather, perhaps by improvements in blood supply. Alternatively, follicles in a sequence could require progressively higher levels of hormones to elicit their growth responses; or each follicle could be time-programmed to begin growth slightly out-of-phase with its neighbour (Ashmole 1968). There is some support from experiments of the concept of local (spatial) variations in sensitivity of follicles to hormonal stimuli, but long-term time-programming of responsiveness of follicles may also be involved, since different levels and combinations of hormones can elicit moult in the domestic fowl according to the number of months since the previous (natural) moult.

In general, hormonal treatments of wild birds with androgens and oestrogens inhibit moult, but the species investigated so far include chiefly those whose schedules of breeding and moult do not overlap in the annual cycle. Although breeding, moult and migration are often mutually exclusive, many species are known in which overlap of these events occurs (see later). Levels of gonad-stimulating hormones show no seasonal variations that can be correlated exclusively with moult, rather than breeding, and any inhibitory actions of the hormones FSH and LH on moult that have been demonstrated are probably attributable to the results of increased production of androgens and oestrogens. Similarly, there are no clear-cut relationships between seasonal prolactin levels and the initiation of moult. The results of direct treatments with prolactin are equally diverse, any positive effects probably occurring indirectly through alteration of androgen and oestrogen levels. Almost all the experiments involving the hormones mentioned so far were carried out before any real appreciation existed of the circadian rhythms of release of hormones from the pituitary, of circadian rhythms of sensitivity of target sites, and of seasonal variations in these rhythms.

The involvement of the thyroid in the control of moult has been the subject of extensive research, much of it summarized by Voitkevich (1966). This work, and more recent studies, have been reviewed critically by Payne (1972) who concludes that it is uncertain whether thyroid activity is directly involved in the control of the start and patterns of moult in wild birds.

Of external stimuli that might alter hormone balances and so initiate moult, changes in photoperiod have been studied most extensively. Most experiments have involved species that breed in northern temperate latitudes. In these, exposure to artificially long photoperiods, after exposure to natural short winter daylengths, usually leads to development of reproductive condition, and, in those species that moult into a special plumage for the breeding season, to feather replacements. However, the timing of this moult, relative to the timing of fat deposition for migration (if any) and of gonadal enlargement, may not parallel exactly the situation in wild populations. Other experiments have sought to prolong reproductive condition by maintaining birds on artificially lengthened photoperiods after the end of the normal breeding season. Eventually gonadal regression occurs, and the normal complete moult after breeding is usually postponed in these experimental birds until this time. Taken together, all the photoperiodic experiments indicate an effect of gonadal hormones (usually inhibitory) on the time of the start of moult.

Day-length may not be important in controlling the timing of events in the annual cycle in equatorial regions, and its importance at higher latitudes may also have been overstressed. Many species show circannual rhythms of breeding, moult and preparation for migration if held in conditions of constant photoperiod, temperature and humidity for several years. In most species these rhythms persist for more than one year, and so are not simply an autonomous sequence of events triggered each spring by an external stimulus. The circannual period length (between successive events of the same type) may differ for moult and reproduction, indicating that there is no obligatory connection between the start of a moult and the stage of breeding (see, for example, Gwinner and Dorka 1976).

Energy and nutrient requirements. The additional energy required for feather production during moult by Chaffinches *Fringilla coelebs* has been measured as 140 kCal. spread over 70 days (Dolnik and Gavrilov 1979). This was required to produce 1.4 g of feathers, whose energy content (if burnt in oxygen) would be only about 7.7 kCal. Unlike this experiment, which was carried out at 26°C, within the thermoneutral zone, most measurements of additional energy requirements during moult have been carried out at lower temperatures and so include not only the energetic costs of feather production but also an element for the increased costs of maintenance of body temperature during the period of greater rates of heat loss, from surfaces with growing feathers. Measurements of the costs of feather production in House Sparrows *Passer domesticus* have been made for two geographical populations and are slightly higher than the 100 kCal/g estimated for Chaffinches—namely 185 kCal for 1.7 g and 218 kCal for 2.0 g of plumage in the USA and USSR respectively.

Measurements of increased energy requirements during moult in captive birds held at natural temperatures indicate an increase in metabolic rate of around 30% in many passerines. However, the duration of moult in captives has often been longer than in wild birds of the same species, so the increase in metabolic rate may have been over-estimated. It is also not known to what extent wild birds compensate for the added energy costs of moult by reducing their energy expenditure on activities such as flight and foraging. Quite possibly their daily food requirements during moult are not much higher than before moult begins.

Feather KERATIN contains higher proportions of sulphur amino-acids, particularly cystine, than those present in most animal and (particularly) plant proteins. It has often been suggested that the cystine content of birds' food during moult might be limiting, rather than the energy content. Dolnik and Gavrilov (1979) have concluded that during the first part of the complete moult of Chaffinches, the increase in food consumption by captive birds chiefly provides the required amounts of the sulphur amino-acids, and that heat production from the daily food intake exceeds that required for thermoregulation at this period.

Most species maintain feather growth by both day and night even though they feed only by day. This may result in the transfer of amino-acids from muscles to growing feathers either in the short-term (overnight, as in some passerines) or the longer term (several weeks, as in the Canada Goose *Branta canadensis*, in which the wing, but not the leg, muscles atrophy during the flightless period).

Moulting during breeding. Since moulting does require extra energy, and therefore extra food intake unless activity can be reduced, the separation of moulting and breeding could be adaptive on energetic grounds, particularly in species that feed their young in the nest and therefore cannot 'afford' to reduce energy expenditure on foraging. One might expect most overlap of breeding with moult in species in which feather replacement spans a long period of the year, so that the extra energetic demands are small at any one moment, and in those living in tropical areas where thermoregulatory energy requirements should not be increased by moult.

The first of these generalizations is broadly correct, but the second is not. Many tropical species show seasonal breeding, and moult is often delayed until the end of the reproductive period. In those species that utilize foods whose abundance does not vary seasonally, moult may be protracted and overlap with breeding. Other species may vary the timing of breeding from year to year, but show consistency in the timing of onset of moult. This leads in some years to separation but in others to overlap between breeding and moult, and occurs especially in arid-zone birds which breed whenever droughts are broken by irregular rainfalls. The multitude of different schedules and degrees of overlap of breeding and moult in different species are reviewed thoroughly by Payne (1972).

Duration of moult of flight feathers. Amongst European passerines, few species renew their primary feathers in less than 5 weeks. In closely related species, e.g., the finches, migratory species take less time to complete primary moult than do sedentary ones. This is true even within a species, e.g., the wagtail *Motacilla alba*, in which Finnish populations of the migratory *M. a. alba* complete moult in 45–50 days, whereas the sedentary British *M. a. yarrellii* take 76 days, on average, to grow new primaries. Wing-moult of the sedentary species often commences later in the year than that of related migratory species.

Suspended moult. Under certain circumstances, birds that have begun feather growth may interrupt their moult, growing feathers being completed but feathers next in sequence to be moulted being retained until a later date. This occurs in some species that breed irregularly; moult is interrupted during breeding. (Others, with protracted moults, may continue to moult during breeding, as detailed earlier.) Moult of flight feathers may commence before migration in some species, particularly those breeding in the arctic, but may be interrupted during migration itself. A few species may undertake short migrations with incompletely grown outer primaries.

Flightlessness. Some birds lose the power of flight during moult. This occurs for part of the moult period in certain arctic passerines that migrate south soon after breeding and compress moult of the flight feathers into a 5–6-week period. More than 5 adjacent primaries may be growing at any one time and all pairs of tail feathers may be shed simultaneously (Haukioja 1971). Individuals of the same species, e.g., Willow Warbler *Phylloscopus trochilus*, breeding at more temperate latitudes, spread their wing moult over a slightly longer period and do not lose completely the ability to fly. Nevertheless, most passerine species become less active and less conspicuous during moult, in part to avoid avian predators (Newton 1966) but presumably also to reduce daily existence energy requirements.

In 11 families of birds, many comprising fairly large-sized species, for example the ducks, geese and swans, divers and grebes, all flight feathers are shed simultaneously, and individuals are unable to fly for a period of a month or more. Because they are vulnerable to mammalian as well as avian predators at this period, some species spend the moult on large lakes, offshore islands or the open sea. This may require a 'moult-migration' from the breeding area to a relatively safe moulting site. Most northern European Shelduck *Tadorna tadorna* gather to moult in July and August on the sandbanks in the Heligoland Bight; many species of arctic-nesting geese undertake such migrations, those involving non-breeding individuals often leading them to still higher latitudes (Salomonsen 1968).

Eclipse plumage. In some groups the full adult plumage, in which the birds breed, is replaced at the end of the reproductive season by a dull 'eclipse' plumage that is worn for only a very few months before a fresh adult plumage is acquired; this is found among the ducks, cuckoo-shrikes, sunbirds, and weavers. It is particularly striking in the males of typical duck species, which lose their very distinctive plumage early in the breeding season and become more like the cryptically coloured females.

In these birds, the body plumage is lost before the wing feathers are replaced, and the second moult of the body plumage, into the colourful breeding plumage once again, may commence before the wing feathers are fully grown. Therefore, although the drakes are protectively coloured during most of their flightless period, it would appear that the advantage of reacquiring the colourful breeding plumage early, in terms of enhancing their chances of successful matings, outweighs the value of prolonging the period in which they are protectively coloured, even though this may increase each individual's chances of survival.

Frequency. All birds moult at least part of their plumage once a year, many species twice, and a few thrice. If breeding and moult do not overlap, the main function of the 'postnuptial' moult is the renewal of worn and faded plumage; it is therefore general and almost always complete. In some groups, such as birds-of-prey and swallows, the moult of the remiges and rectrices may be delayed until mid-winter. This adaptation seems to be correlated with migration, during which birds of the two named groups are often in close association.

The 'prenuptial' moult, when present, is usually partial. It intensifies the secondary sexual characters by brighter colours or by adding plumes or other adornments (e.g., the facial warty excrescences in the Ruff *Philomachus pugnax*). This moult tends to be more evident in males than in females; exceptions include the phalaropes. Part of the colour change apparent at this season is in some species due to abrasion of the edges of feathers. Miller (1961) found that the Andean Sparrow *Zonotrichia capensis* has two complete moults annually, each of two months' duration.

In the Ptarmigan *Lagopus mutus* there is a partial moult during the late summer and autumn, when an admixture of the grey breeding dress and the brownish autumn plumage is observable before the birds pass into the white plumage of winter. Assumption of this winter plumage has been shown to depend on a fall in temperature; this, by responsively increasing metabolism and acting through the endocrine system, suppresses melanin production (Salomonsen). The prenuptial moult in spring, later in males than in females, brings the birds into breeding dress (see also COLORATION, ADAPTIVE).

The moult can be a purely local and normal condition, as in the case of defeathering of the incubation patch area which is initiated by the hormone prolactin, prior to the increased vascularity, epithelial hypertrophy, and oedema in preparation for incubation (Bayley 1952).

Terminology. From the beginning of the 20th century, the terminology used to describe moults and plumages was based on temperate-zone passerine birds, in which breeding and moult are usually separated in time. This led to use of terms such as 'pre-' and 'post-nuptial' moult, which are difficult to apply to many tropical birds and to others in which there is total overlap or no constant relationship between the timings of moult and reproduction. Humphrey and Parkes (1959) reviewed the then-existing descriptive systems and proposed one of their own which is now widely used. They recognized that new 'aspects' (plumages) arise from new feather generations in at least some of the feather tracts, and that since new feathers push out old (except in fright moult or defeathering of the incubation patch), moults should therefore be named with reference to the incoming generation. These generations are named in a way that avoids seasonal, reproductive or age criteria. The first covering of true feathers is named the juvenal feather generation, and this plumage never recurs after later moults.

At some later stage, the incoming feather generation in a particular tract is identical in appearance with one that has developed at an earlier time in that same tract. The interval between these moults is known as a cycle, and is normally of 12-months' duration. If only one feather generation is produced within a cycle, it is termed basic; if two, the second is termed alternate; in those rare cases in which three generations are produced in a single feather tract during one cycle, the third is termed supplemental. The moults are described as pre-basic, pre-alternate, etc. The appearance of a bird can be deduced from knowledge of the feather generations (basic, alternate, juvenal, etc.) present in each feather tract at the time in question.

Moult of accessory structures. These cases can be divided into three classes. First, there are those that come under the heading of secondary sexual characters accompanying and supplementing the prenuptial moult, being developed expressly for the breeding season and being discarded at its end. Typical examples are found in the auks, the Puffin *Fratercula arctica* providing a familiar instance; in this species the highly coloured parts of the bill, the two small supraorbicular excrescences, and the puffy 'rosettes' at the angles of the gape are shed. Also, the Hornbill Auk *Cerorhinca* ('*Ceratirhina*') *monocerata* moults the internaral protuberance. A further example is the 'bill-horn' of the males of the American White Pelican *Pelecanus erythrorhynchus*, the horn falling off at the end of the breeding season.

Secondly to be mentioned is the moulting of the claws in ptarmigan *Lagopus* spp. It is very probable that the tarsal scutellae are also moulted regularly; evidence in support of this is provided by the case of a Song Thrush *Turdus philomelos* with abnormal cutaneous horns on its head and on one leg, these being cast each time the bird moulted. Probably this applies to all pathological structures arising from tissues of epidermal origin, including those of the uropygeal OIL GLAND (which in certain circumstances can produce a 'horn' that is moulted regularly).

The third category consists of structures that serve a temporary function only. In the Hoatzin *Opisthocomus hoazin* the young have functional claws on the 1st and 2nd digits of the manus for the first week of life only; these are shed and during after life the claws are represented by minute callosities. A further instance of structure of this nature is afforded by the 'heel' pads of woodpeckers and wrynecks, toucans, and scansorial barbets, this structure falling off when the birds leave the nest.

MOULT MIGRATION: a regular movement by certain birds to and from an area where they moult (see MIGRATION; MOULT).

MOUND-BIRDS; MOUND-BUILDER: see MEGAPODE.

MOUNTAINEER: *Oreonympha nobilis* (for family see HUMMINGBIRD).

MOUNTAIN-GEM: substantive name of *Lampornis* spp. (for family see HUMMINGBIRD).

MOUPINIA: substantive name of the 2 species of *Moupinia* of south-east Asia (for family see BABBLER).

MOURNER: substantive name of species of *Laniocera* and *Rhytipterna* (for family see FLYCATCHER (2)).

MOUSE-BABBLER: substantive name of the 3 species of *Crateroscelis* of New Guinea (for family see RAIL-BABBLER).

MOUSEBIRD: substantive name, alternatively 'coly', of the species of Coliidae (sole family of the Coliiformes); in the plural ('mousebirds,' 'colies'), general term for the family.

The family contains 6 species, all very similar to each other and so specialized in character that the family is generally placed in an order of its own—the only order endemic to Africa.

Characteristics. All are small-bodied, weighing 38–68 g, two-thirds of the length of 30–36 cm contributed by the characteristically long graduated tail. The plumage is drab grey or brown relieved in most species by a patch of red, blue or white on the head, neck or rump or by barring or speckling. The body feathers are soft and hair-like with remarkably long aftershafts, and are poorly waterproof. The wings are short and rounded, with 10 primaries and 10 secondaries. All species have a pronounced crest which is normally carried erect. The sexes are alike. The bill is short, slightly downcurved, and strong. The 4 toes are normally all directed forward, but the outer toe on each side can also point backwards. The usual perching attitude is with the feet and shoulders at about the same level, the belly hanging down exposed between the legs, but mousebirds occasionally perch normally too. On the ground they can hop, run or walk surprisingly fast. The flight normally consists of alternate bursts of flapping and gliding but can be fast and direct; often a flock will fly straight into the centre of a bush. They are highly gregarious, and probably as similar to each other in behaviour and ecology as in structure.

Blue-naped Mousebird *Colius macrourus*. (*N.A.*).

Habitat. Most of the wooded and bushy environments of Africa south of the Sahara, avoiding open plains and forest interiors.

Distribution. Throughout the Afrotropical region. The 4 species of the *Colius striatus* group include the widely distributed *C. striatus*, the allopatric *C. castanotus*, the partly sympatric *C. colius* and the almost completely sympatric *C. leucocephalus*; none of these species extends west of the River Niger. The members of the *C. macrourus* superspecies replace each other geographically, *C. macrourus* in the north and north-west to the Atlantic coast and in the east, *C. indicus* south of about 8°S; some authors put these 2 species in the genus *Urocolius* (e.g. Schifter 1972).

Populations. Mousebirds are often extremely numerous, especially around small-scale cultivations; although several species are widely sympatric, normally one is noticeably commoner than the others in any particular locality.

Movements. Mousebirds are highly sedentary; movements are probably confined to feeding and roosting flights.

Food. Mousebirds are almost exclusively vegetarian; nearly half the diet in some populations is leaves, the rest fruit, seeds and nectar with little if any animal matter. In gardens and on small fruit and vegetable farms they may be serious pests locally, but they do not adapt well to large-scale monocultures and so are of little importance agriculturally except to small-scale farming. Their diet is notable for the high proportion of plant species containing toxins or irritants. Mousebirds drink pigeon-fashion, sucking water up with the head lowered.

Behaviour. Mousebirds are gregarious at all times of year, moving in parties of normally up to 30 birds, roosting in tight huddles, sunbathing and dustbathing together, and often nesting in close proximity. Allopreening is common. Roosting birds cluster tightly together in trees and bushes, sleeping with the head upright but withdrawn into the shoulders; suggestions that they are incompletely homoiothermic are unfounded, but heavy rain can impair their insulation to the extent that they die of cold. Courtship behaviour is poorly known, but *C. indicus* and *C. macrourus* have a perch-jumping display in which one or both birds bounce up and down, sometimes with one wing held up.

Voice. They are highly vocal birds, whistling and chattering almost incessantly. Flight and alarm calls are hard or buzzing; *C. macrourus* has a clear whistle on the wing.

Breeding. Nests may be solitary or loosely clumped, shallow cups or open platforms in bushes; some are built on top of old nests of the same or other species, and most are ornamented with fresh green leaves. Eggs are dull creamy white, immaculate in some species, speckled and blotched in others. Clutch size is normally 3 but ranges from 1 to 8, the larger clutches often caused by more than one female laying in the same nest. Eggs weigh 2.7–2.9 g. Both sexes incubate, for 11–14 days. Chicks are fed by regurgitation, by both sexes, and fledge after 15–20 days. Adults incubate and brood very tightly.

Moult. Birds may begin moulting as early as 2 months after fledging. Moult is protracted; it is normally serially descendent but ascendent and stepwise moults have also been recorded. A.W.D.

MOUSTACHIAL: applied to a streak, in some plumage patterns, running back from the base of the bill.

MOUTH: see BILL; TONGUE; also ALIMENTARY SYSTEM; RESPIRATORY SYSTEM.

MUD-HEN: popular name for the American Coot *Fulica americana* (see RAIL).

MUDLARK: see MAGPIE-LARK.

MUDNEST-BUILDERS: see MAGPIE-LARK.

MULE: aviculturist's term for a hybrid between a Canary and another species of finch.

MULGA: name for a type of bush country in Australia, characterized by *Acacia aneura*.

MÜLLERIAN MIMICRY: see MIMICRY.

MULTI-BROODED: see CLUTCH-SIZE.

MUNIA: substantive name in Asia of various species of Estrildidae; in the plural, sometimes used as a general term for the group (see ESTRILDID FINCH).

MURRE: alternative substantive name (preferred in American usage) of guillemots of the genus *Uria* (Alcidae)—see AUK.

MURRELET: substantive name of species of *Brachyramphus* and *Synthliboramphus* (see AUK).

MUSCICAPIDAE: a family of PASSERIFORMES, suborder Oscines, forming part of a group of 12 families of Primitive Insect Eaters, the main body of which consists of the so-called Muscicapid assemblage. This embraces an exceptionally large number and wide variety of largely insectivorous, mainly Old World, ten-primaried song-birds in which bright coloration and conspicuous patterns and structures are scarce. Hence, the group is treated in Peters *Check-list of Birds of the World* on reasonable grounds as one family, Muscicapidae, comprising the subfamilies Turdinae, Timaliinae, Cinclosomatinae, Paradoxornithinae, Polioptilinae, Sylviinae, Malurinae, Muscicapinae, and Pachycephalinae. Most of these had been treated as families by most authors. Though the differences seem trivial in some cases, particularly in many species of the Old World tropics, the lumping of these groups obscures such differences as do exist and results in a family which (at least in bird systematics) is very large and unwieldy. In the classificatory system used here the Muscicapid assemblage includes the families Turdidae (THRUSH), Sylviidae (WARBLER (1)), Muscicapidae (FLYCATCHER (1), Rhipiduridae (FANTAIL), Monarchidae (MONARCH FLYCATCHER), Pachycephalidae (THICKHEAD), Timaliidae (BABBLER), and Aegithalidae (TIT, LONG-TAILED). The general opinion is that the members of these families are closely related and probably more so to each other than to the remaining families of the group of Primitive Insect Eaters with the exception of the Mimidae (MOCKING-THRUSH) which on recent evidence may be very close to the Turdidae.

MUSCLE: see MUSCULATURE.

MUSCULAR CONTRACTION: see ENERGETICS.

MUSCULATURE: the system of muscles, which are the specialized organs for effecting movement. Collectively these form the 'flesh', which in an average bird constitutes almost half the total body weight.

Characters of muscular tissue. The essential feature of muscular tissue is its specialization for contraction, in the course of which force is developed. Muscle tissue in birds and other vertebrates occurs in three principal forms. Unstriated ('smooth' or 'involuntary') muscle consists of quite short fusiform cells in which longitudinal filaments may be discerned with appropriate techniques, but little else. Striated or voluntary muscle consists of very much longer multinucleate fibres, which show a characteristic pattern of crossbanding. Cardiac muscle, found only in the heart (see HEART), consists of a network of fibres showing some distantly spaced crossbars. Unstriated muscles occur mainly in such situations as the gut, viscera, glandular ducts or feather bases; they are innervated by autonomic nerves (see NERVOUS SYSTEM) and are not normally under the control of the will. Striated muscles occur principally in association with the skeleton (see SKULL; SKELETON, POST-CRANIAL), hence their alternative name of skeletal muscles. They are innervated by cranial and spinal nerves and are under the control of the will. It is with these that the remainder of this article is concerned. For a fuller review of the structure and properties of avian skeletal muscles, the reader is referred to Bock (1974).

Contraction. A muscle exerts force only when contracting, and has no intrinsic means of lengthening; stretching of a muscle can only be brought about by an external force, usually that of another muscle. Muscle contraction can take place without shortening if the force it develops is equalled by an opposing external force; 'isotonic contraction' refers to contraction involving change in length, and 'isometric contraction' to the situation when the muscle produces force without changing in length. Many muscles function primarily through isometric contraction, providing holding or stabilizing forces, e.g., in the maintenance of body posture. However, all muscles play some part in this, exhibiting a low level of contraction ('muscle tone') even when apparently at rest.

Fibre types. Striated muscle fibres show important variations in structure and histochemical properties which are correlated with physiological differences, though the details of the relationship are very imperfectly understood at present. Two main sets of types of fibre are recognized in avian muscles: red and white muscle fibres, distinguished by myoglobin content, and twitch and tonus fibres, distinguished by innervation and structural details.

Red and white fibres may eventually prove to be simply the extremes of a continuum, but the dichotomy is a familiar one, since muscles consisting largely of white fibres (e.g., the breast muscles of a chicken) are very obviously different from those composed mainly of red (e.g., the same muscles in a pigeon). No bird possesses muscles composed entirely of white fibres, though the pectoral muscles of hummingbirds appear to consist entirely of red. Apparently red fibres fatigue more slowly, but white fibres can produce a higher rate of work over a short period.

Twitch and tonus fibres also show some differences in rate of fatigue, but should not be equated with white and red; there appears to be no simple correlation between the two types. Twitch fibres respond to a stimulus with a rapid contraction which ends almost immediately the stimulus ceases. Tonus fibres respond to stimuli with a contraction which builds up more gradually, and falls off very slowly after stimulation stops. Most bird muscles that have been studied consist of a mixture of the two types, but in varying proportions. Probably a high proportion of tonus fibres indicates a postural function, while a high proportion of twitch fibres suggests a more active role.

Muscle architecture. In describing the gross structure of a muscle it is usual to refer to the attachments of its two ends as 'origin' and 'insertion'. The origin is strictly the end attached to a stationary bone, while the insertion is the attachment on a bone which is moved by the muscle's contraction. In practice, very often both bones are moved by the muscle, but the terms are still employed, if arbitrarily, for convenience.

The arrangement of fibres within the muscle—its architecture—is of great importance in understanding its action and adaptations.

Two basic arrangements are generally recognized. In parallel-fibred muscles, the fibres are oriented along the line of action of the muscle, and run from origin to insertion; hyoid muscles such as M. stylohyoideus or M. cleidohyoideus furnish good examples. Pinnate muscles are those in which fibres are attached, at least at one end, to a tendon—a structure composed largely of collagen, which functions to transmit the force of the fibres to a bone. The simplest type of pinnate arrangement (unipinnate) is with fibres attached at one end to one surface of a tendon or aponeurosis (tendinous sheet), and at the other to a bone. Bipinnate muscles have fibres attached to either surface of an aponeurosis, and multipinnate muscles have several internal aponeuroses ('raphes'), usually arising alternately from origin and insertion, and interdigitating.

The functional properties of parallel-fibred and pinnate muscles differ in important ways, stemming basically from the length and number of fibres in the muscle. Fibre length affects only the speed and range of shortening of a muscle, while the force that it can develop depends fundamentally on fibre number. In general, parallel-fibred muscles can have much longer fibres, but the number that can be accommodated is much less than that possible with pinnate architecture. Pinnate muscles are generally to be found in situations requiring the development of large forces, but relatively little shortening ('excursion'). Extremes of pinnate development, with several raphes and large angles of pinnation commonly occur in muscles sited very close to an articulation, such as the jaw muscle M. adductor mandibulae externus caudalis, or other situations involving little or no excursion, such as with the Mm. intertransversarii linking adjacent cervical vertebrae.

One- and two-joint muscles. An important distinction should be made in regard to the siting of muscles. One-joint muscles are those which arise on one bone and insert on the next in succession, spanning a single articulation. Two-joint muscles arise on one bone, miss the next and attach on the third in the series, thus spanning two articulations. (Three or more joint muscles also exist but, with the exceptions of some neck muscles, their forces are usually redirected via tendons traversing pulley or sling devices—a feature of avian limb systems which enables the weight of major muscle masses to be concentrated closer to the bird's centre of gravity.) Two-joint muscles minimize energy expenditure for many actions and, due to their length, can shorten faster than one-joint muscles. Disadvantages are that they cannot individually control the forces about each articulation, and lack the stability for holding the system under static conditions. Thus, in most major systems such as limbs or jaws, two-joint muscles provide a large part of the force, with just sufficient one-joint muscles for precise control of movement at each joint, and for stability.

Nomenclature. Muscles may be named after site, shape or action, or on the basis of presumed homologies (see HOMOLOGY). Complications have been caused by attempts to homologize bird muscles with those of mammals, producing conflicting terminologies. The Nomina Anatomica Avium (Baumel *et al* 1979) should resolve this confusion, and its nomenclature is followed here. For a detailed survey of bird muscles see George and Berger (1966).

Subcutaneous muscles. These are thin sheets or bands of muscle lying under the skin, and often adhering to it. The presence or absence of M. biceps brachii, pars propatagialis, is of significance in the diagnoses of several major groups. Subcutaneous muscles are striated, with the exception of M. expansor secundariorum, the only non-striated muscle specifically mentioned in this account (see Muscles of the wing).

Cranial muscles

1. Ocular muscles. These are the small muscles concerned with moving the eyeball, and differ little from those in other vertebrates. Included here also is the levator muscle of the upper eyelid and the muscles (M. pyramidalis and M. quadratus) responsible for the movements of the nictitating membrane (see VISION).

2. Jaw muscles. Although only 8 in number, these muscles have attracted the attention of many investigators, since they show extensive variation among birds, correlated at least in part with differences in food and feeding techniques. Present terminology is based on the detailed study by Lakjer (1926).

The action of these muscles includes not only opening (depression) and closing (adduction) of the lower jaw as in mammals, but also extensive movements of the upper jaw. Muscles which raise the lower jaw fall into two groups. Those which originate on the skull (M. adductor mandibulae externus and M. pseudotemporalis superficialis) are two-joint muscles, frequently of multipinnate architecture; those which arise on the quadrate (M. pseudotemporalis profundus and M. adductor mandibulae caudalis) are one-joint muscles, which, with M. pterygoideus arising on the pterygoid, bring about retraction as well as adduction. M. pseudotemporalis profundus is absent in parrots, many kingfishers, and various other birds. M. pterygoideus is a muscle of considerable complexity. In many birds, especially passerines, it has a slip (M. retractor palatini) attached to the skull base, thus acting solely to retract the palate. M. pterygoideus has also given rise in parrots to a unique muscle, M. ethmomandibularis, which originates on the interorbital septum, and acts purely as an adductor of the lower jaw.

Protraction of the upper jaw is effected by M. protractor quadrati et pterygoidei, and depression of the lower by M. depressor mandibulae. Striking enlargement of one or both of these muscles is seen in birds whose feeding habits involve opening the bill against resistance, e.g., M. protractor in *Gallinago* or M. depressor in *Heteralocha* (Burton 1974a and b).

Muscles of the tongue and hyoid apparatus. Like the jaw muscles, these show much variation related to feeding adaptations, and are often also of taxonomic interest. Extremes of complexity are encountered in groups with highly modified tongues, notably parrots and woodpeckers. The tongue and hyoid muscles may be grouped into two categories: *Extrinsic* muscles have an attachment at one end to the lower jaw, and are responsible for large-scale movements of the entire tongue and hyoid apparatus. They include M. branchiomandibularis, with its insertion wrapped around the hyoid 'horn', which pulls the whole apparatus forward, and M. stylohyoideus which retracts it. *Intrinsic* tongue muscles have both origin and insertion within the hyoid apparatus, and permit finer control and more delicate movements; for example, M. ceratoglossus flexes the tongue downwards relative to the basihyal, while M. hypoglossus obliquus returns it to the resting position.

Muscles of the trachea, larynx and syrinx. Opening and closing of the laryngeal slit or glottis (e.g., when swallowing food) are brought about by two small intrinsic muscles (M. dilator and M. constrictor glottidis). An additional muscle (M. cricohyoideus) connects the larynx and hyoid apparatus. Tracheal muscles show much variation, but one present in most birds is M. tracheolateralis, which adheres closely to the side of the trachea, and inserts on the syrinx. In the highly developed vocal apparatus of passerines (especially oscines), however, a number of additional syringeal muscles are present (see SYRINX).

Neck muscles. The detailed comparative review by Boas (1929) has been the basis for most subsequent studies. Muscles of the vertebral column generally are grouped into an *epaxial* series, situated dorsally, and a *hypaxial*, providing lateral and ventral components. Six neck muscles, originating principally on the first neck segment, are inserted on the skull. Four are of epaxial origin, acting to raise or turn the head; and include M. complexus, which plays an important, if indirect, part in emergance from the egg. Two hypaxial muscles (M. rectus capitis lateralis and ventralis) act as head flexors.

The muscles of the neck proper include some of the most complex to be found in the avian body, spanning many articulations, with individual slips to several vertebrae. The principal epaxial system is that of M. longus colli dorsalis, including long multijoint components as well as shorter ones traversing only one or two vertebrae. Their principal actions are to straighten neck segments I and III, and to flex segment II upwards. Still more intricate is the hypaxial M. longus colli ventralis, the bulk of which consists of long slips arising posteriorly, but each one linked by individual short slips to the vertebrae it passes; its actions are the reverse of M. longus colli dorsalis. Hypaxial muscles also include lateral components, which contribute to lateral bending, as well as providing overall stability; they include both short muscles interconnecting successive vertebrae, notably Mm. intertransversarii and Mm. inclusi, and longer muscles linking 3 or more vertebrae, such as M. cervicalis ascendens.

Muscles of the trunk and tail. Within the body region, spinal mobility is much reduced, and consequently, fewer muscles that interconnect vertebrae are required. However, the axial skeleton of the trunk also provides origin for several muscles of the wing and body wall. The chief vertebral series comprises the epaxial muscles M. longus colli dorsalis, pars thoracicus, and M. iliocostalis et longissimus dorsi, the latter including M. thoracicus ascendens. Some of the slips of M. iliocostalis insert on the posterior surface of the bases of true ribs; upon their anterior faces are inserted the hypaxial series of Mm. levatores costarum. Anteriorly, M. scalenus inserts on the cervicodorsal ribs. From the hypaxial musculature are also derived lateral flank muscles and a rectus sheet enclosing the body wall ventrally. The lateral system is largely supported by the ribs, consisting principally of the internal and external intercostal muscles; in the abdominal region, where ribs are lacking, this system provides the external and internal oblique muscles, and M. transversus abdominis. Ventrally, M. rectus abdominis runs from the pubis to the rear edge of the sternum. Posteriorly, a specialized set of muscles of axial origin controls movements of tail and cloaca.

Muscles of the wing. The rigorous demands of flight impose rather narrow limits on the variability of the wing muscles. As a result, attempts to use these muscles for taxonomic purposes have generally been less fruitful than in the case of the hind limb.

The largest muscle of the wings, and indeed of the whole bird's body, is M. pectoralis, averaging some 15% of the total body weight. It forms the bulk of the fleshy mass on the breast, arising from the body and keel of the sternum and surrounding areas, and attaching by a stout tendon on the crista pectoralis of the humerus. A layered or modified bipinnate structure has been described in many birds. Deep to M. pectoralis is a smaller—but still large—muscle, M. supracoracoideus. It springs also from the keel and body of the sternum, with additional origin from the coraco–clavicular membrane. Its tendon passes through the foramen triosseum, and then over the shoulder-joint to insert on the head of the humerus. Its action is to elevate the humerus, while M. pectoralis depresses it, providing the powerful downstroke of the wing.

Overlying the shoulder prominence are M. deltoideus major and minor, the latter apparently absent in some hummingbirds and cuckoos. M. tensor propatagialis pars longa forms the support for the free margin of the propatagium; receiving slips from various other muscles, its tendon attaches in the carpal region. The muscle also includes a pars brevis, which inserts by various arrangements, often considered of taxonomic significance. Pars brevis is absent in several flightless birds.

On the dorsal side, M. latissimus dorsi, a broad triangular sheet, arises by aponeurosis from neural spines of posterior cervical or anterior dorsal vertebrae, and inserts on the upper side of the humerus. Deep to it lies M. rhomboideus, which originates in a similar way, but inserts on the scapula. The Mm. serrati, arising on anterior ribs, also insert on the scapula. Derivatives of M. latissimus and Mm. serrati act on the metapatagium.

The elbow joint is operated by flexor and extensor groups, the former including M. biceps brachii and M. branchialis, and the latter M. triceps brachii. The presence or absence of a 'biceps slip' (pars propatagialis) has been used in distinguishing major avian groups. Muscles controlling forearm movements include besides M. pronator superficialis and profundus ventrally whose combined action is to pronate the radius and thus depress the leading edge of the wing, and also the dorsal M. supinator which elevates it. In the upper arm region in addition is situated the interesting muscle M. expansor secundariorum, an unstriated muscle of dermal origin, which inserts fleshily on the bases of several proximal secondary quills. Typically it originates by a long tendon from the axillary region via a pulley device, and by a shorter tendon, absent in passerines and several other groups, from the vicinity of the elbow. This muscle has been frequently included in taxonomic diagnoses, but on present evidence is of doubtful value for such purposes.

The humerus also provides origin for some long two- or three-joint muscles acting on the carpus or carpometacarpus. Among these is M. flexor carpi ulnaris, whose long tendon passes through the humeroulnar pulley, a ligamentous loop at the elbow. Finally, muscles operating the digits are of great importance in controlling the movements of primaries and alula in flight; they were inadequately studied prior to Stegmann's (1978) detailed account, which has yielded valuable evidence on the relationships of several major groups.

Muscles of the hind limb. Leg muscles exhibit considerably greater variability than those of the wing, reflecting the wide range of adaptive modifications shown by the hind limb among birds. An excellent functional study is that by Cracraft (1971) on *Columba livia*—a species possessing all but one (M. iliofemoralis externus) of the 'formula' muscles (see below).

One-joint muscles arising on the pelvic girdle and axial skeleton include femoral protractors, such as M. iliofemoralis internus, retractors (such as M. flexor cruris lateralis) and rotators, such as M. ischiofemoralis and M. obturatorius. The two-part M. caud-ilio-femoralis probably functions mainly to produce lateral tail movements. Two-joint muscles with pelvic origin include extensors of the tibiotarsus (e.g., M. iliotibialis, M. ambiens) and flexors (e.g., M. biceps femoris). Muscles originating on the femur itself are predominantly two-joint or multi-joint. Of the former may be mentioned M. gastrocnemius, which acts partly as an extensor of the tarsometatarsus, and M. tibialis cranialis, a flexor. Multi-joint muscles arising from the distal end of the femur all act as flexors of the digits, and are considered in more detail below. The tibiotarsus provides origin for some single-joint muscles such as M. peroneus brevis, which flexes the tarsometatarsus, and M. peroneus longus which acts to extend it, as well as some additional multi-joint muscles acting on the digits. Finally, the tarsometatarsus itself provides origin mainly for a number of single-joint muscles which act as extensors of the digits, and in some cases provide lateral movement as well.

The foundation for taxonomic applications of hind limb myology was laid in the 19th century by Garrod. In the thigh region, he stressed the presence or absence of M. ambiens, and set up a formula in which the presence of components of M. caud-ilio-femoralis and M. flexor cruris lateralis was denoted using letters as symbols. Garrod's original formula, using the letters A, B, X and Y, has been expanded by later workers, and is now made up as shown below. Although most recent pelvic musculature studies use many additional characters, amenable to multivariate or other types of analysis, the formulae are still useful as a shorthand when compiling diagnoses of avian groups. In general, the presence of 'formula' muscles is regarded as a primitive state, and their loss as derived (see CLADISTICS); large complements occur among groups regarded as phylogenetically old (e.g., Galliformes, Gruiformes), while groups of more recent origin mostly show a reduced complement. ACEFMNXY is probably typical of most passerines, while drastic reduction occurs among the Apodiformes (e.g., AEN in *Chaetura pelagica*), related to that of their hind limbs in general.

The 'formula' muscles and their symbols are as follows:

A = M. caudofemoralis
B = M. iliofemoralis
C = M. iliotrochantericus medius
D = M. iliofemoralis externus
E = M. iliofemoralis internus
F = M. plantaris
G = M. popliteus
M = M. fibularis (peroneus) longus
N = M. fibularis (peroneus) brevis
X = M. flexor cruris lateralis, pars pelvica
Y = M. flexor cruris lateralis, pars accessoria
Am = M. ambiens
V = Vinculum between tendons of Mm. flexor perforatus digiti III and M. flexor perforans et perforatus digiti III.

Garrod also drew attention to the variable arrangements of the deep plantar tendons in birds, and these, too, have been much used in systematic studies. There are three principal sets of long flexors each of which may be represented by several muscles, the hallux having but one, digits II and III having three each, and digit IV two. Inserting tendons pass to the bases of 1st, 2nd, 3rd and terminal phalanges of the toes. Those inserting on the proximal phalanx are perforated, just prior to insertion, by tendons inserting on the 2nd and 3rd phalanges and these in turn are perforated by the tendons to the terminal phalanges, so that we speak of flexores perforati, flexores perforantes et perforati and flexor perforans, the latter being tendinous branches of M. flexor digitorum longus.

Mm. flexores perforati digitorum II, III and IV arise in various fashions, separately or partly fused, either from the intercondylar region of the femur or more distally from ligaments around the knee, or the upper part of the tibia and fibula, and from the tendon of M. ambiens. Mm. flexores perforantes et perforati digitorum II and III arise in similar fashion, except for the connection with M. ambiens. In many cases, the tendon to digit III receives a tendinous connection (vinculum) from that of M. flexor perforatus, denoted by 'V' in the muscle formula.

M. flexor digitorum longus ('perforans') is the deepest-lying stratum, with extensive origin on the back of the tibia and fibula. Its stout tendon passes deep to the preceding tendons over the intertarsal joint, and divides into three slips that proceed to the three anterior toes. The hallux has its own deep flexor, M. flexor hallucis longus, also arising distally on the femur; this bifurcates in the metatarsal region, one part forming a vinculum to the adjacent tendon of M. flexor digitorum longus, while the other goes on to insert on the terminal phalanx of the hallux. This vinculum (not to be confused with that between the flexors of digit III) ensures that flexion of the hind toe is automatically accompanied by flexion of the other toes, although these can, through their own deep flexors, contract without involving the hind toe. Where the hind toe is absent, the tendon of M. flexor hallucis longus fuses with that of M. flexor digitorum longus. (W.C.O.H.) P.J.K.B.

MUSEUM: an institution having nowadays the main function of preserving, for study and display, collections of specimens relating to particular subjects. Study collections of birds are usually to be found in museums or departments of natural history. The size of the museum largely determines its aims. In the largest, these may be to preserve as representative a sample as possible of the birds of the world, and to display every aspect of bird biology suited to display by exhibits; whereas in small museums the object may rather be to show mounted specimens of local species. Such local exhibits often fill in details for which there is no room in the more comprehensive displays.

Public interest is catered for by the education and recreational side of a museum's functions. The objects, captions and graphics of a traditional exhibit allow a visitor wide latitude in depth and speed of study, which is reduced when recorded talks are used. This tendency may be carried much further by reactive displays which put over effectively a limited number of concepts. The information constantly available may be supplemented by guided tours, lectures, demonstrations, classes and film programmes, while portable exhibits may be circulated to schools and other institutions.

While display and teaching are the chief concerns of most museums, the great natural history museums are primarily research institutions in which much more extensive specialized collections, supported by libraries and technical facilities, provide unique opportunities for research by their own staffs and visiting workers. Early collections were mainly received from individuals, since the first 'cabinets of curiosities' were founded by wealthy private collectors; but eggshells are now the only bird specimens subject to the collector's mania, and those who collect other material do so for the furtherance of knowledge. Most private collections have now found their way into museums, and collecting is increasingly purposive, whether as a technique of research or to fill gaps in the museum's own collections. Improving the retrieval of information through better arrangement of the specimens has been a powerful impetus to research into natural classifications (see CLASSIFICATION; SYSTEMATICS; TAXONOMY), which is one of the principal fields for study in natural history museums. Much staff time is spent in protecting the collections from physical and biological injury, which has resulted in the application of new techniques, and in refining their arrangement and documentation for the benefit of research workers.

Research specimens of birds used to consist almost entirely of study skins, simply stuffed in the field and presenting little more than the external appearance, but carrying essential field information on their labels. Though laborious to prepare, skins are easy to transport, store and examine. With their data, they have been of the greatest importance for studies on classification, variation, seasonal changes and distribution; and are still the principal material for investigating relationships at the species level. Other techniques, such as freeze-drying, for producing comparable specimens offer great advantages, but technical difficulties have so far prevented their widespread use in the field.

Since at the species level the classification of birds is uniquely well founded, the emphasis is now on higher classification for which anatomical specimens are more important. Collections of disarticulated study skeletons and of birds preserved in fixatives, though still small in comparison with skin collections, are now growing much more rapidly. New techniques of research (see DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA) can involve the formation of what are effectively new types of museum collection, like that of egg-whites at Yale. Archives of recorded bird calls, as at Cornell, are primary research material rather than libraries, and important for taxonomic as well as other studies. The promising new technique of electrophoresis using feather proteins enables the large skin collections to be used for biochemical taxonomy with little damage.

Other types of bird specimen are mainly important to aspects of biology other than taxonomy. Eggshells with their data show where and when a species has bred, and can provide material for the analysis of changing pollution. Nests encapsulate the movements used in building them. Preserved gut contents and gonads contribute to knowledge of diets and of breeding cycles. The maintenance of such a range of collections adds to the problems of curation, yet it may be desirable to maintain parallel collections even for a single type of specimen. For example, TYPE SPECIMENS may be segregated from the general skin collection because of their unique importance to nomenclature, as may the skins of extinct and endangered birds.

Much taxonomic research concerns variation, whether for its own interest or to establish norms. Birds of one population vary individually between age classes and sexes, and from season to season and may also be polymorphic. Populations of most species vary geographically, and sometimes with altitude. Clearly, to be able to provide a reasonable statistical sample of (say) adult males in fresh breeding plumage from each of many sample areas, over the whole range of one of the 9,000 bird species, requires very large total collections. The material in one museum is often insufficient for a particular study, and the natural history museums of the world are continuously engaged in lending specimens for research. Large collections have been made for special studies, but this method may be wasteful and better replaced by the recording of data from birds which are captured and released. Some museums accept extensive data for permanent preservation.

Though anatomical variation is potentially important, its study has scarcely begun because anatomical collections are still comparatively small. Besides their use for modern studies, skeleton collections are essential for the interpretation of older material. Fragments from archaeological sites and Quaternary deposits provide information on former distributions; but it is the rapidly increasing knowledge of bird fossils from the Tertiary which is resulting in fundamental reassessments of evolutionary history and higher classification.

Museums became important as more than mere cabinets of curiosities towards the end of the 18th century, when great national collections such as the Muséum National d'Histoire Naturelle in Paris and the Rijksmuseum van Natuurlijke Historie in Leiden were dominant. In Britain this was the era of the wealthy private collector, and the British Museum's natural history collections (separated as the British Museum (Natural History) about 1881) only gradually achieved pre-eminence as a result of amateur and official collecting throughout the Empire. Today the United States have the bulk of the specimens in the world, held in dozens of national, state, university and independent museums, whose ornithological staffs comprise the majority of all avian systematists. However, there are important collections and active research staffs throughout the developed world, while many developing countries are actively enlarging or founding their own. In numbers of specimens, the largest collections are those of the British Museum (Natural History) and American Museum of Natural History, since they each have about a million study skins, while the United States National Museum of Natural History is actively expanding exceptional anatomical collections.

Several British museums have important research collections of British birds, while for the birds of the world the most important after the BM(NH) are probably the Manchester Museum, Merseyside County Museum, National Museum of Wales, Royal Scottish Museum, and University Museum of Zoology, Cambridge. Some local museums have been designated as biological records centres under a national organization. While some of the functions of this organization are already carried out, for birds, by ornithological and natural history societies, the local centres should make a valuable contribution to planning and conservation. MUSIC, BIRDS IN: regarded here as an avian element in human culture. There are two other articles on this subject: Fisher (1966) and Scholes (1970). These between them list most of the references to birds in the musical repertoire to the end of the 19th century but few more recent ones. This article, therefore, while offering a necessarily selective survey of bird-inspired western music, treats later developments more fully.

Musical inspiration derives from: (1) songs and calls; (2) line and movement; (3) literary sources; and (4) fabulous and mechanical birds. Treatment may be direct sound-imitation; symbolic; impressionistic. In the last few decades, (5) 'concrete' bird music (recorded bird sounds in intact or modified form combined to create musical works) has evolved into a category of its own.

Of the three methods of treatment possible in vocal or instrumental music, direct sound imitation, though present in even the earliest works, has perhaps made the greatest progress and impact in recent years. When birds are used as symbols, there may be no obvious reference but an appropriate 'atmosphere' is generated. Impressionistic treatment, despite its lack of definition, is probably the best vehicle for inducing a felicitous response, especially in the ornithologist who may justifiably be irritated by the inadequacy of human voices and instruments when they attempt to imitate all but the simplest bird calls.

All these three musical approaches have, however, appealed to composers of all periods, whatever the source of their inspiration (apart from the line and movement of birds which can only be treated impressionistically). Indeed, they are often combined in the same work.

The four voices of the 13th century canon 'Sumer is icumen in', the earliest known English secular composition, imitate the Cuckoo's call and it has been musically echoed down the centuries. Janequin's 'Song of the birds' from the early 16th century combines a realistic Cuckoo together with trilled *rrr*'s and fast staccato notes which merely hint at their living sources. Orlando Gibbons, a century later, in his madrigal 'The Silver Swan' takes this mute bird, which dying 'unlocks her silent throat' in wise utterance, as a symbol and the gravely flowing vocal lines mirror the slow, dignified movement of a swan floating on placid water: the beginning of a long tradition of symbolic swan music. Impressionistic use of bird sounds and movement has been continuously represented in instrumental works from, say, Vivaldi's 'Four Seasons' in the early 17th century, to Vaughan Williams's 'The Lark Ascending' and the compositions of Edward Cowie and Trevor Hold in the 20th.

1. Songs and calls. An index of species shows a great variety, with several favourites. The Cuckoo, with its familiar diatonic intervals, is the obvious point of departure for a composer wishing to introduce a pastoral flavour; Beethoven, in his Sixth Symphony, the most notable among them. But the bird also stimulated a number of compositions exclusively devoted to it: Couperin, Pasquini, Vivaldi and Daquin in the 17th and early 18th centuries, for example.

The Nightingale, another favourite but more difficult to represent, had Janequin and Couperin among its early devotees and Rameau (1683–1764) included an 'Air du Rossignol' in his opera 'Hippolyte et Aricie' with both vocal and instrumental imitation. Handel (1685–1759) made the bold attempt to combine Cuckoo and Nightingale in an organ concerto, and these two species and others are thought to be represented in Haydn's (1732–1809) Op. 33, no. 3, nicknamed the 'Bird Quartet'. In the famous Toy Symphony, formerly attributed to Haydn, Quail, Cuckoo and Nightingale figure on the toy instruments. It is now known that this composition is part of a work by Leopold Mozart; the toy instruments added, possibly by Joseph's younger brother Michael Haydn. Later admirers of the Nightingale have included Glinka, Mendelssohn, Liszt, Balakirev, Grieg, Granados, Ravel and Milhaud.

Respighi (1879–1936) arranged some 17th and 18th century works in his orchestral suite 'The Birds' whose subjects are Cuckoo, dove, hen and Nightingale. Doves, specific or unspecified, are numerous (see below) but the domestic hen is less usual, though one of Haydn's symphonies is called 'La Poule'. Humperdinck (1854–1921) in 'Hansel and Gretel' has a cock which diverts us with *ki-ke-ri-ki* in the English translation; he also has a vociferous Cuckoo and a Skylark, but this is a bird of vocal whimsy. Larks, too, go through the centuries from Janequin to Messiaen.

Other passerine species less commonly represented include the Goldfinch (Vivaldi), Linnet (Couperin, Haydn, Rachmaninov), Robin (Lalo and Peter Warlock), Swallow (Dvorak, Pierné, Tschaikovsky), Wagtail (Britten) and, exotically, the Scarlet Tanager (Dvorak's American String Quartet). Remarkably, the Blackbird attracted little attention until the present century. An unpromising species, the Magpie, is the subject of a Mussorgsky song; and the side-drum roll in Rossini's 'La Gazza ladra' could be an imitation of Magpie chatter.

Among non-passerines, there are songs about 'A greedy hawk' and 'Compel the hawk to sit' by William Byrd (1543–1623); and Thomas Weelkes (*c.* 1575–1623) composed the madrigal 'A Sparrowhawk proud'. Haydn has a song about a Blackcock; Beethoven (Sixth Symphony) and Schubert (C major Quintet) have Quails, and Mussorgsky an escaped parrot in the fifth act of 'Boris Godunov'. Prokofiev, in 'Peter and the Wolf', asks an oboe to give a duck squawk. Numerous other non-passerine species used by composers are treated more fully below.

Finally, in this summary of species representation, Boccherini (1743–1805) has a collection in 'The Aviary'—the title of a string quartet.

From the late 19th century to the mid-20th, continental Europe produced several fine composers of large-scale works whose careers overlapped and all of whom to some extent mirrored in their music the countryside of their birth.

The great Austrian symphonist Anton Bruckner (1824–1896) was said to 'reflect . . . the voice of Nature itself' in his Fourth Symphony. The only overt imitation occurs in the first movement; this is a song (more likely two song-types strung together) of a Great Tit. Of all direct imitations of bird song this is one of the most authentic and appealing, yet it emerges as an integral part of the movement, never a mere decorative accessory. But it is true to say, as of others among these composers, that Bruckner's music is informed by natural sounds, including birds, rather than formed from them.

Mahler (1860–1911) made use of birds, although their singing so distracted him when composing that he was known to shoot them. Yet his musical ear appreciated the Chaffinch call *zink zink*, thus transcribed in his own poem for one of his 'Songs of a Wayfarer'. A Cuckoo, singing a perfect 4th rather than the ubiquitous major and minor 3rds, pervades much of his First Symphony along with some unspecified bird song. Another Cuckoo and a somewhat capricious Nightingale turn up in the Third Symphony. The slow section of 'The Drunkard in Spring' from 'Das Lied von der Erde' includes bird calls and chirrups to tell the Drunkard of the arrival of spring and the last movement, 'The Departure', contains music strongly evocative of the natural scene in which the two friends say farewell.

Although Sibelius (1865–1957) was particularly responsive to bird sounds, he made little explicit use of them in his music. Yet he describes the call of the Crane as 'The leitmotiv of my life' and noted on Villa-Lobos's music 'One can hear that he was brought up in a quite different bird world from me' (Levas 1972). His devotion to swans is evident in the enraptured poignancy of his 'Swan of Tuonela' whose long lament is played by the cor anglais.

Most swan music represents the Mute Swan *Cygnus olor*, a species not established in Finland until 1934. 'The Swan of Tuonela' was composed in 1893 and it was the migrating Whooper Swans *C. cygnus* that Sibelius used to greet each year when they were resting on a lake near his home. In the incidental music from Kuolema (where we also find the well-known Valse Triste) there is a 'Scene with Cranes' in which the birds' calls are imitated by two clarinets; and the concert suite from his music for Strindberg's 'Swanwhite' includes 'Peacock' and 'Listen, the Robin sings'.

The Danish composer Carl Nielsen (1865–1931) and Bela Bartók (1881–1945), deeply committed to his native Hungary (though his birthplace is now in Romania), were likewise musicians with an informed appreciation of bird sounds who mostly made implicit rather than explicit use of their carefully studied material. Nielsen chose an unusual avian model in his 'Song of the Siskin' for chorus. 'The First Lark' and 'Springtime on Fyn' are other choral works with bird associations and there is a hint of a Cuckoo in the 'Helios' overture. Basically, however, the loving perception he accords to birds, in his description of their special 'accents' on his native island of Fyn (in his essays 'Living Music'), is transmuted into orchestral colours and time-patterns, especially perhaps in his Wind Quintet.

Bartók produced his most overt nature music only after he had left Hungary for permanent exile in the United States. Biographers testify to his exact knowledge of all natural sounds and his unusually acute hearing. A buzzing, humming sound as of insects is often his way of suggesting a natural background. In 1943, already suffering from his terminal illness, he was sent to relax at Asheville, North Carolina, where he went for long walks and painstakingly noted down the songs of an avifauna that was new to him. When he came to write his last work, the

Third Piano Concerto, this material was transformed (particularly in the second movement) into the seemingly inexhaustible flow of motifs in this splendid work.

In contrast, Olivier Messiaen (b. 1908) brought precise bird vocalizations to the musical masses. A prolific composer and a good ornithologist, he has incorporated the songs or calls of 260 species from six faunal regions in at least 10 of his major works. It is notable, however, that when he contrasts his skilfully contrived overt imitations with impressionistic settings of the habitat—as in the 7-volume 'Catalogue d'Oiseaux' for solo piano—attention and imagination are stimulated. But in those works composed entirely of songs and calls, for example 'Reveille des Oiseaux' for piano and orchestra, attention is taxed to the point of confusion because of the polyphonic nature of the work, wherein as many as 21 species are presented simultaneously at the climax of the dawn chorus.

From such complexity, Messiaen turns to extreme simplicity in his 'Merle Noir' for solo flute with piano accompaniment. This does not aim at complete fidelity: the duration of the pauses between the phrases must be reduced to achieve continuity when there is no answering bird or background song; but it is a distillation of the species' song and a convincing work of art. Messiaen's other works devoted to, or incorporating bird sounds include Oiseaux Exotiques, La Fauvette des Jardins, Chronochromie, Couleurs de la Cité Céleste, Et Expecto Resurrectionem Mortuorum, La Transfiguration and Méditations sur la mystère de la Sainte Trinité. In 1974 Messiaen completed 'Des Canyons aux Etoiles', a 96-minute work which incorporates the songs of 60 species from Utah and the Hawaiian Islands.

There is a long tradition of bird song representation in French music and Messiaen's immediate predecessor and, maybe, his inspirational springboard, Maurice Ravel (1875–1937), has received little credit for his imaginatively unique contribution to it. In the scene 'Lever de Jour' from the ballet 'Daphnis and Chloë', three solo violins, piccolo and flute evoke the unspecified birds who greet the rising sun. They are followed by two shepherds playing pipes (piccolo and E flat clarinet). In no other musical work are we so delicately reminded of the tenuous borderline between avian and human music.

'L'enfant et les Sortilèges', a brief, bewitching opera, ends with a garden scene at night with only a child and the animal denizens taking part. Ravel, master of orchestration, requires a slide flute for his Tawny Owl. He abandons most of the conventional but inaccurate trills dealt out to Nightingales and gives his bird (piccolo) repeated notes and tremolo effects. When a soprano voice sings another Nightingale part there is little attempt at imitation and the bird has a lyrical descant above the other animal voices. In 'Ma Mère l'Oye', a suite of piano duets subsequently extended and orchestrated for a ballet, some unorthodox little birds cheep (complex violin harmonics) as they peck up the trail of crumbs laid by Tom Thumb, and a very orthodox Cuckoo calls in the same piece.

Ravel's most serious essay in bird vocalization is his impressionistic 'Oiseaux Tristes' for piano—an evocation of 'birds lost in the torpor of a forest during the most torrid hours of summer'. No other composer has achieved such a convincing representation of the sounds of birds in conditions where they tend to be vocally quiescent. The only firm evidence about species comes from the report of a friend which tells how Ravel went to the forest to listen to a Blackbird. In this work it sings precisely as Blackbirds do in such circumstances—sporadically and tending to repeat a single phrase. All else is implied, but the pairs of slowly repeated single notes can only be a Turtle Dove: a sudden explosion of alarm calls suggests a Chaffinch, followed closely by a single abbreviated Wren song as elicited by disturbance. Repeated drooping major and minor thirds suggest a slow and indeed a 'sad' Cuckoo. A three-line cadenza near the end of the work hints at subsong from several species and merges finally into the continued murmuring of the Turtle Dove.

Four birds appear in Ravel's song cycle 'Histoires Naturelles'. The noble, if vain, demeanour is depicted in 'The Peacock'; contrary motion black key glissandi represent the spreading tail; and the harsh cry is sung *Léon, Léon* with a properly dissonant accompaniment. 'The Swan' looks back to Saint-Saens' (and Pavlova's) famous bird, but with sophistication and irony. Twenty-three bars of pianissimo writing express the awe and delight of a fisherman whose rod is graced by 'The Kingfisher'. And in conclusion and contrast 'The Guinea-fowl' is conjured up, irascible and raucous, scratching in the soil and bathing in the dust.

Yorkshire-born Frederick Delius (1862–1934) lived not far from Ravel at Grez-sur-Loing. He remarked to Elgar that the song of the birds was the greatest music of all, an explanation, perhaps, for his uniquely tender treatment of the subject of 'On Hearing the First Cuckoo in Spring'. Even greater was his love and sympathy for the pair of Mockingbirds and all that they symbolize in Walt Whitman's 'Sea Drift'. This setting for baritone, chorus and orchestra must be the most extended (24 minutes) eulogy for a living, singing bird and threnody for a dead bird—the singer's mate—ever conceived.

Much bird music has come from the pen of Benjamin Britten (1913–1976). In the children's opera 'The Little Sweep' their voices give vivid renderings of Chaffinch call notes, the Heron, Tawny Owl and Turtle Dove. The Turtle Dove appears again (flutter tonguing on recorder) when Noah launches it from the ark in 'Noyes' Fludde', and yet again in one of Polly's airs in his realization of 'The Beggar's Opera'. In another air the flight of the Swallow is cleverly suggested by the flute. 'The Spring Symphony' has a merry Cuckoo and a quire of birds; piccolos represent the flight of the Skylark in 'A Midsummer Night's Dream'; and the fluttering of an unspecified wagtail comes in 'Winter Words': a cycle of Hardy poems which also includes 'Proud Songsters'. There is music for wild geese in the operetta 'Paul Bunyan' and an evocative reiterated Curlew motif in 'Curlew River'. 'Our Hunting Fathers' contains an angry 'Dance of Death' for Ravenscroft's 'Hawking for the Partridge'.

Amongst British composers, Trevor Hold (b. 1939) has published a study of bird vocalizations and their notation (Hold 1970) and has also used songs and calls, both explicitly and implicitly, in his works. Those in the first category include 'The Unreturning Spring', a song cycle for two voices and small orchestra wherein the Interlude before the final song has a 'mobile' of Song Thrush (flute), Corn Bunting (oboe), Reed Bunting (clarinet), Nightjar (bassoon) and Tawny Owl. Implicit (unspecified) song abounds in his instrumental and orchestral works, notably 'The Blue Firedrake', 'Calendar', 'Time Passes', 'Belfry Music' and 'Clare's Ghost'. In Hold's 'Signs of Winter', based on John Clare's poem, a solo horn represents ducks flying up from a pond.

Edward Cowie (b. 1943) has found inspiration in the environment of north-west Lancashire for several works composed in the 1970s. 'Gesangbuch' (Song book), in two versions, a series of four tableaux for voices and instruments is, in Cowie's words, a response to 'particular aural and visual signals' of these open, often marshy expanses. In one of them, 'Hest Bank' (1974), fragments of bird names and landscape features occur in his own text for the voice parts.

Of contemporary music derived from bird vocalizations obtainable only on disc or tape, outstanding is 'Calling Down the Flevo Spirit' by Kees Hazevoet and Aan Bennink (Snipe Records, 7678, Amsterdam). There is no score because the performers improvise brilliantly and imitate six species with some startling verisimilitude; the titles are Stone Chattin', The Woodcock, King of Saxony, The Roller, Snipe Drumming and Mot-mot.

Beyond Europe, Radio New Zealand leads with a disc (and cassette) of distinction: 'Children of Tane'. Tane is the Maori God of Nature and the birds are his children. Music, words and performance are all by Sydney (Hirimi) Melbourne, a member of the Tuhoe tribes (the people of the mist). Fourteen songs emerge from recordings of the birds' own voices and epitomize native mythology and imitation in the Maori tongue—ideal for the purpose with its many vowel sounds and soft delivery.

2. Line and movement. Sources of inspiration in the shapes and forms of birds at rest, hovering or in flight, and the visual satisfaction they offer, are more difficult to identify than aural sources. Perhaps Vivaldi, in his Flute Concerto 'Il Gardellino', was not as much stimulated by the Goldfinch's twittering, musical song, as by its rapid movements. Certainly Vaughan Williams in 'The Lark Ascending' was particularly sensitive to flight. In some 19th century ballet music, composers (notably Tchaikovsky) were concerned not only to represent birds in movement but to support the dancers when the choreography required emulation of flight. Few can remain unmoved by the artistry achieved by Tchaikovsky and Petipa in the 4-act 'Swan Lake'. But slighter bird works arising from the same composer–choreographer collaboration may arouse even stronger associative feelings on account of their light, delicate texture and the formal scaling down to size and rapidity of movement more compatible with our apperception of birds in general.

In 1964 a one-act ballet was based upon courtship display. Entitled simply 'The Display' its subject is the Lyrebird with music by the Australian Malcolm Williamson (b. 1931), Master of the Queen's

Musick, and choreography by Robert Helpmann. Another recent ballet 'Eagle's Nest' (music by Kamen and choreography by Falco) had its première at La Scala, Milan. The eagle portrayed therein is reminiscent of the magnificent Golden Eagle interpretation by the Indian dancer, Ram Gopal, in the 1940s. These are but a few examples from a field worthy of greater consideration; others will be found in section 4.

Much 'descriptive music', when birds are used as symbols or to create the atmosphere of a woodland, a particular season or time of day, is evidently inspired by visual as well as aural impressions of birds. Most 'swan' music, for instance, derives from the bird's literary and legendary appearances and the solemn atmosphere created by composers as diverse as Orlando Gibbons, Wagner, Ravel, Sibelius and Prokofiev seems to pay homage to the visible majesty of this great bird. Prokofiev's 'White Swan', composed in 1910 but not given its first performance until 1980 in a version edited by Rozhdestvensky, is a setting for female voices, horn and strings of a poem by Konstantin Bal'mont. In a few minutes of grave, gentle music, it presents the swan as 'a serene symbol of feminine beauty'.

Richard Strauss (1864–1949), in his 'Four Last Songs', incidentally illustrates the impossibility of strict categorization of bird-inspired music. In these settings of poems by Hesse and von Eichendorff, two Skylarks rise, hover and ultimately bring 'Im Abendrot' (In the Evening Glow) to a close with their tremulous music and flight. The words of Frühling (Springtime) refer merely to 'bird song'—at which point the vocal line soars above the orchestra in a long melisma.

3. Literary sources. These include all vocal settings of poetry as well as folk tales, legends and stories in which actual (as opposed to fabulous) bird species figure: many works of literary inspiration have been discussed in section 1. Whether poem or legend was the first source of inspiration or whether the composer was attracted to it by an interest in birds is open to argument, or biographical evidence, in individual cases.

After the Bible, the earliest inspirational text is probably 'The Birds' of Aristophanes (455–375 BC), treated by at least seven composers. Many legends have contributed to opera plots or tone poems, and forest or pastoral episodes in an even wider range of operas and ballets demand impressionistic treatment of bird sounds and movement as part of the orchestral scene-setting.

Neatly spanning the main period of European musical development 'The Suffolk Owle', originally a madrigal by Nicholas Vauter (born *c.* 1590), has a modern setting in the cantata 'Voices of Night' by Franz Reizenstein (1911–1968). Cock crows dramatically break into the sombre Passion music in the oratorios of Schütz and Bach and biblical inspiration also evoked bird music in Haydn's 'The Creation'. Handel, in 'Acis and Galatea' and in many pastoral themes in his operas and masques, shows his awareness of bird song, and is said to have 'imported live birds into his operas'. (A 20th century Ashton ballet to music by Messager also brings real birds on stage to supplement the dancers of 'The Two Pigeons'.)

German lieder, so many of them settings of 'open air' poetry, are less productive. Only an occasional hint of bird song, perhaps a grace note in the accompaniment, is used by Schubert and Brahms. Wagner (1813–1883), drawing on medieval legends for his opera plots, gives us the swan symbolism of 'Parsifal' and 'Lohengrin' but it is 'The Ring' cycle and the Siegfried Idyll that bear the strongest testimony to the enrichment of his music by recreated experience of bird sounds.

Liszt (1811–1886) also turned to legend in his pianistic tribute to St. Francis of Assisi preaching to the birds. Trills and arpeggio passages punctuated by brief, often staccato motifs represent the birds which are temporarily silenced by a gentle tenor recitative suggesting the voice of the Saint; this appears in the bass at a climactic point, then a long diminuendo leads back to bird song which drifts into near silence at the close. The impression of song and flight may owe inspiration to the Larks (or in one source the Swallows) which are said to have comprised much of the flock at St. Francis' sermon (see Armstrong 1973).

Dvorak (1841–1904) was constantly and openly inspired by bird song (using it thematically, for example, in two quartets and the 8th Symphony). He was a pigeon fancier but the species of his symphonic poem 'The Wild Dove' (Czech *Holoubek*) must be the Stock Dove, whose persistent cooing above her husband's grave drives an erring young widow to suicide. The complex orchestration—flutes, oboe, high repeated notes on harp and some muffled drumstick strokes on a cymbal—is peculiarly apt, as is Alec Robertson's description of the dove as 'self-righteous'! (Robertson 1964). The Skylark, Cuckoo, Swallow and House Sparrow are subjects of some of Dvorak's songs.

Schoenberg (1874–1951) was also inspired by dove song. The species of his 'Song of the Wood Dove' from the great choral–orchestral work 'Gurrelieder' seems to be the Woodpigeon if judged by the time patterning of fragments in the introduction and coda. But the mezzo-soprano's line is suffused with dove-like conjunct intervals as she declaims the death of Tove, tragic figure of Danish legend. (It appears to be fortuitous that the German *gurren* means to coo.) Schoenberg is again sensitive to birds in his setting of Petrarch's 'When little birds weep'.

Leoš Janáček (1854–1928), from Moravia, was steeped in the music of animal sounds which he notated as meticulously as he did the lines of human speech. Hence it is not surprising that in his captivating nature opera 'The Cunning Little Vixen' birds are prominent: there are a Cuckoo, Raven, woodpecker (xylophone), a Barn Owl, a Jay and a flock of Starlings. A domestic cock presides over his harem which clucks conventionally while their leader astonishes us and, no doubt, her sister hens with egg-inspiring trills and embellishments! 'Katya Kabanova' has bird music which evokes song, flight and the beating of clipped wings. In his last opera 'The House of the Dead' (set in a Siberian prison camp and based on Dostoyevsky's novel) Janáček introduces, ironically, a Cuckoo and, symbolically, an eagle: the Czar of the forest. The captive, wounded bird, its early attempts to fly and ultimate flight to freedom, symbolize the plight and hopes of the prisoners. Among his small choral works are 'The Dove' (Holubička) and 'The Wild Duck'. 'The Screech (Barn) Owl' and 'They Chatter like Swallows' are included in the piano suite 'The Overgrown Path'.

Rimsky-Korsakov (1844–1908), like Janáček, carefully notated bird vocalizations and was so scrupulous as to explain that the song of his pet Bullfinch had to be transposed down a tone 'for the convenience of the violin harmonics'. This bird's song and other bird voices can be heard in his operas 'The Snow Maiden' and 'Mlada'.

Further 20th century illustrations of literary inspiration (apart from the Britten works referred to in section 1) include Carl Orff's 'Carmina Burana', drawing on medieval sources, in which a Swan (again! but this time dead and roasted) finds tenor voice to lament its fate; and, in strong contrast, Peter Warlock's setting of Yeats' poem 'The Curlew' has an evocative flute line as part of the accompaniment.

4. Fabulous and mechanical birds. These are sparse in the musical repertoire wherein Schumann's (1810–1856) 'Prophet Bird' is probably the best known. Oddly, the Phoenix attracted little early attention, though there is an unaccompanied concerto for 4 bassoons by Michel Corrette (1709–1795). In the last 20 years, the bird has given its name to several works, including 'The Phoenix and the Turtle', an opera by Thea Musgrave (b. 1928). A near approach to the Phoenix is Stravinsky's (1881–1971) 'Firebird', composed for Diaghilev's Russian Ballet and choreographed by Fokine. The same composer based his opera 'Le Rossignol' on Hans Andersen's 'The Emperor and the Nightingale'. Subsequently, Diaghilev had it adapted as a ballet 'Le Chant du Rossignol' in which the 'real' Nightingale takes fright at the crude humming of the mechanical bird but ultimately returns to revive the dying emperor with its song.

Rimsky-Korsakov's 'Golden Cockerel', yet another creation for Diaghilev's Russian Ballet, approaches the fabulous (as does Wagner's Forest Bird), in its superavian abilities, although its crowing sounds real enough. Maeterlinck's (1862–1949) play 'The Blue Bird' also inspired works by Humperdinck and Norman O'Neill. In Ravel's opera 'L'Heure Espagnole' there is a fabulous bird 'L'Oiseau des Îles' (played by the piccolo) and a mechanical one: a little toy cock whose diminutive but shrill crowing is reproduced by the reed alone when removed from a sarrusophone. This work, set in a clockmaker's shop in Toledo and concerned with the amorous escapades of the wife of the absent owner, also gave Ravel double-edged scope for Cuckoos, both vocal and instrumental!

In the very different tradition of Brazilian folk music and legend, Deitor Villa-Lobos (1887–1959) composed his early symphonic poem 'Uirapurú': an enchanted and enchanting bird, worshipped as the King of Love. The story, of his own compiling from several legends, tells how the mellifluous nightly song of the bird lures people into the forest in search of it. An arrow-shot through the heart from a beautiful maiden transforms the bird into a handsome young man. But he, shot once again by an ancient Indian nose-flute player, turns back into a bird and flies away, singing, into the forest depths. The rich orchestration, which includes Latin American percussion instruments and violinophone (a violin with a horn attached) exploits fully the dramatic episodes of the story and the peaceful, rippling phrases of Uirapurú's song. In the Paul Schwartz recording this elusive bird has an exquisite and varied song such as Villa-Lobos could not have heard.

5. **Concrete music.** This most recent development, only possible since the advent of the tape recorder, demands a brief separate section because bird voices not only fire the composer's imagination but are the music itself. However, contemporary composers had a predecessor in Respighi who, in his tone poem 'The Pines of Rome', presented an early gramophone record of a real Nightingale song. His treatment is so subtle as to debase neither the music nor the song of the bird.

In America, James Fassett created his 'Symphony of Birds' entirely from recorded vocalizations (Stillwell Recordings, Ficker, USA). Less ambitious is 'Symphony of the Birds' by Johan Dalgas Frisch (MGM Records, New York) which comprises recordings of Brazilian birds, with background music which may or may not please the listener. But predictably Swedish Radio, and the composer Karl-Birger Blomdahl (1916–1968), take precedence with 'Altisonans'. Blomdahl's ideas originated from an observation by the physicist Ludvik Liszka that certain satellite signals exactly resemble the song of the Redwing. The composer then blended unmodified bird voice recordings with 'space' sounds: satellite signals and magnetic storms re-recorded at various playback speeds. The result is impressive and appropriately unearthly. Coincidentally, 'Children of Tane' (see Section 1), otherwise so different in conception, incorporates thunder storms.

Finally, and to solace the mind which may recoil from some contemporary bird music, there is a slender vignette by Percy Buck (1871–1947): 'The Blackbird's Song', a three-part setting for female voices of Henry Kingsley's poem. Only its unashamed romanticism in an age of rampant eclecticism can explain its neglect for, within melodic and harmonic enchantment graced with delicate traces of its song, the bird pleads for the forgiveness of man's sins and in so doing sings itself to sleep. Scholes, P. 1970. Oxford Companion to Music. London.

MUSKEG: an environment, consisting of grassy bog, characteristic of much of northern Canada.

MUSOPHAGAE: MUSOPHAGIDAE: suborder and family of CUCULIFORMES (see TURACO).

MUTATION: see GENETICS.

MUTTON-BIRD: local name for various species of petrel (Procellariidae); applied in New Zealand to the Sooty Shearwater *Puffinus griseus*, and on the southern coasts and islands of Australia to the Short-tailed Shearwater *P. tenuirostris* (see PETREL). The young of both species are in these areas collected commercially in large numbers for human consumption. The latter species is known as the Whale-bird in Alaska, which it visits during the northern summer.

MYCTERIINI: see STORK.

MYIASIS, WOUND: the presence of maggots in a wound on a living bird.

MYNAH: substantive name of various Asian species of *Acridotheres*, *Gracula*, and *Sturnus* (see STARLING).

MYOCARDIUM: see HEART.

MYOLOGY: the scientific study of muscles (see MUSCULATURE).

MYTHICAL BIRDS: see FABULOUS BIRDS.

MYZA: substantive name of the 2 species of *Myza* of Celebes (Sulawezi) (for family see HONEYEATER).

MYZOMELA: substantive name of some species of Myzomela, a large genus of Australasian and Pacific island HONEYEATERS.

MYZORNIS: substantive name of *Myzornis pyrrhoura* of south-east Asia (see BABBLER).

N

NAIL: a horny plate-like structure, shaped like a shield, found at the tip of the upper mandible of all species of wildfowl.

NALOSPI: the distance between the forward edge of a bird's nostril and the tip of the bill; term derived from the German NAsenLOch-SPItze.

NAME, COLLECTIVE: see ASSEMBLY, NOUN OF.

NAME, COMMON: sometimes used as an equivalent of 'vernacular name' or 'popular name' (see NAME, VERNACULAR). 'Common name' is subject to the slight ambiguity that it is also the translation of the *nomen triviale* of Linnaeus, which had the meaning of 'specific name' (see NOMENCLATURE).

NAME, ENGLISH: the name ('vernacular name', 'popular name') of a species or category of birds in the English language. English names, especially those of familiar birds, are part of the living language; as with other words, they are thus governed by usage, and this may change with time or differ between one English-speaking country and another. Unlike scientific names, which are based on international agreement among zoologists to accept certain conventions (see NOMENCLATURE), English names can be subject to no fixed rules, and their application may cut across taxonomic boundaries; also, they are usually not of international significance apart from the English-speaking world.

Nevertheless, it is expedient that there should be some approach to uniformity—by consensus of opinion—in the practice of ornithologists with regard to English names, at least during one period of time and in the same country. Clearly, a standard should be sought along the lines of determining the best current usage and of encouraging general adherence to it on the part of ornithologists. Some of these may have strong minority views that it would be improper to stigmatise as necessarily incorrect; but it seems probable that most of the diversity of practice is accidental rather than deliberate. Admittedly, there are in many cases alternative names to those given greatest acceptance by ornithologists—names that have also had substantial currency, and may even have been preferred at earlier dates, or that may be found in poetry or literary prose. There are also dialect names, locally or widely used, that have a place in the popular speech of the countryside and in writings embodying that.

Some ornithologists and others actively seek to influence usage by reviving older names or by introducing new ones because these are considered to be more pleasing or more appropriate. One may think that such attempts to change English names, widely used outside the realm of ornithology, may lead to confusion. On the other hand, it would be unreasonable to deny some latitude in the use of alternative names for which a case can be made (e.g. 'Dunnock').

There are certain tendencies in common usage that may well be encouraged by ornithologists. There is, notably, a welcome trend in the direction of shortening cumbersome compound names, such as the 'Golden-crested Wren' (a misnomer at that) of a few decades ago, now 'Goldcrest'. The prefix 'Common' likewise now tends to be omitted in many instances where it is really unnecessary, and the redundant second term to be dropped in 'Fulmar Petrel', 'Eider Duck', and others. Similarly, ornithologists may help to mould general usage by showing preference for the more appropriate of alternative names both in common use, e.g. 'Willow Warbler' rather than 'Willow Wren'.

In the case of birds familiar on both sides of the Atlantic, it is impracticable in the face of differing common usage to secure complete uniformity in English names as between the British Isles and North America, two areas with many birds in common (see below). Similar considerations apply to names used by English-speaking people in various other parts of the world. On the other hand, many English names have been invented by British ornithologists for birds that are not ordinarily found in their country and that are therefore nameless in common speech. Such names, if unsatisfactory, are more susceptible of deliberate change. In particular, it seems to be good practice to displace such a name in favour of one that is widely current in some part of the world where the bird is well-known; thus what was once the 'Buff-backed Heron' *Bubulcus ibis* of earlier British bird books was known to English-speaking people in Africa and Asia (more appropriately) as 'Cattle Egret' and this has become common usage. Again, in the British Isles, the English names used in North America may well be preferred for species that are merely stragglers from that continent.

Names for species and subspecies. English names are primarily the names of species. This follows naturally from the fact that subspecific forms are usually indistinguishable in the field, except in some cases by skilled observers; they can therefore have no names in common speech. Where it is desired to refer to a subspecies (or race) by an English name, this should consist of the name of the species prefaced by a qualifying adjective or adjectival phrase. Such compounded names for races are nearly all of comparatively recent origin; and indeed the desirable occasions for using them seem to be much fewer than some current practice would suggest. Subspecies can be referred to either by their scientific names, as befits a technical concept, or by such expressions as 'Northern race' in relation with the English name of the species.

There are a few inevitable exceptions, where subspecies are so distinct in appearance that they have acquired separate English names in common speech. If such names are firmly embedded in the language, as where 2 races of *Motacilla alba* are known respectively as 'Pied Wagtail' and 'White Wagtail', it seems impossible to do otherwise than accept the situation. Unfortunately, this means that there is no English name covering the species as a whole; and this in turn involves the invention of additional English names for any forms of it other than the 2 in question.

Initial capitals. Whether or not to use capitals for the initial letters of the English names of species is a controversial point. Ordinary literary usage would prefer small letters, and some ornithological publications follow this. More commonly it is felt that, for scientific purposes, there are advantages in the use of capital letters. For one thing, references to particular species can be more easily picked out on a page. For another, certain ambiguities are avoided; thus, 'a Little Gull' can refer only to *Larus minutus*, whereas 'a little gull' might mean a gull of any small species.

When initial capital letters are preferred, they are used for each main term of the name but not for the second element of a hyphenated compound. Capital letters are in any event not given to English names when these are used in a general rather than a specific sense, e.g. 'gulls'.

Hyphenation. It has in the past been a frequent practice in ornithological publications to hyphenate two elements of a name where this consists of a noun preceded by a noun used as an adjective; but not to insert a hyphen between a true adjective and a following noun. This is a tiresome convention, because it involves e.g., for various tits *Parus* spp., writing 'Marsh-Tit' on the one hand and 'Blue Tit' on the other. Moreover, an exception tends to be made when the adjectival noun is the proper name of a place, as in 'Sandwich Tern', and this further complicates the procedure.

There seems to be nothing in ordinary English usage of the present day to demand such a rule as that mentioned above. 'The hyphen is not an ornament; it should never be placed between two words that do not require uniting and can do their work equally well separate' (Fowler). The present tendency happily seems to favour the suppression of all unnecessary hyphens, including especially those that have been inserted merely because the word before it, used adjectivally, happens to be a noun. A hyphen is unnecessary between any two words of which the second would naturally be used for indexing.

On the other hand, some hyphens are made necessary by the sense, unless the two elements can be written as a single word; 'Oyster-catcher' is a case in point, as 'catcher' here means nothing by itself. Other necessary hyphens are those between elements of a compound adjective, e.g. 'Black-headed'. It seems desirable, however, to encourage a tendency to go further and to make single words out of properly hyphenated pairs when the sense allows. 'The conversion of a hyphenated word into an unhyphenated single one is desirable as soon as the novelty of the combination has worn off, if there are no obstacles in the way of awkward spelling, obscurity or the like' (Fowler). We already have many compound names such as 'Redpoll', 'Bullfinch', and 'Blackbird' that are always spelt as single words; and others that usually or sometimes are, such as 'Oystercatcher', 'Yellowhammer', and 'Hedge-sparrow'. There also seems to be no reason against adjectives such as 'Blackheaded' being written as single words; but there are instances where the result would be aesthetically disagreeable or not immediately intelligible.

A few hyphens are inescapable on account of awkward spelling, notably 'Bee-eater'—to write 'Bee Eater' (indexing as 'Eater, Bee'!) would be wrong; to write 'Beeeater' would be absurd.

Fabricated Names. Where common usage does not operate, ornithologists are free to invent English names (if these are considered necessary in the circumstances); Eisenmann and Poor (1946) have suggested certain principles, as follows. There should be an appropriate name for every species, applicable to the whole species and forming the latter part of the name of each included subspecies. A name should give no false impression of taxonomic relationship. The name of a species should not be formed from a geographical name, or any name from a personal one. The adjectives 'common' (at best of only local relevance), 'least' (or 'little'), and 'great', should be used with extreme care. A name should not be given that is identical with one already well established elsewhere for another species.

American usage. The English names used in the United States and Canada, even without going beyond those currently recognized by the American Ornithologists' Union, show some unavoidable differences from British ornithological practice. The same name may be differently applied; or different names may be used for the same species or group. It may be convenient to draw attention here to the instances over which confusion is most likely to arise.

The following collective names are applied in the respective hemispheres to birds that have superficial features in common but belong to different taxonomic groups: 'vulture', 'quail', 'flycatcher', 'warbler', 'oriole', and 'sparrow'—see entries under the several names and others to be mentioned below. The names 'hawk' and 'bunting' have a wider application in the New World.

Among names for species, applied quite differently, the following are outstanding examples:

	British Application	American Application
Blackbird	*Turdus merula*	*Agelaius* spp.
Robin	*Erithacus rubecula*	*Turdus migratorius*
Redstart	*Phoenicurus* spp.	*Setophaga ruticilla*
Tree Sparrow	*Passer montanus*	*Spizella arborea*

The name 'Great White Heron' is given to *Ardea herodias occidentalis* in America but was until recently applied in British bird books to *Egretta alba*, now designated an 'egret' with varying adjectives. There are of course many instances in which the same name is applied to closely related birds, with or without distinguishing adjectives apt to be omitted in ordinary use. Among unofficial American names, there are such uses as 'buzzard' for vulture (New World family) and 'yellowhammer' for a species of woodpecker.

Special American names for groups include 'loon' instead of 'diver', 'jaeger' instead of 'skua' for *Stercorarius* spp. (not *Catharacta*), 'murre' instead of 'guillemot' for *Uria* spp. (not *Cepphus*), and 'goatsucker' instead of 'nightjar'.

The most important instances of different substantive names for the same species are:

British Usage	American Usage
Long-tailed Duck	Oldsquaw
Goosander	Common Merganser
Hen Harrier	Northern Harrier
Little Auk	Dovekie
Sand Martin	Bank Swallow
Lapland Bunting	Lapland Longspur

There are many other instances in which a different adjectival name is used although the birds are at most subspecifically distinct, e.g. 'Kentish Plover' becomes 'Snowy Plover' in America, 'Grey Phalarope' becomes 'Red Phalarope' (refers to breeding plumage), and 'Common Gull' becomes 'Mew Gull'. Some American names such as 'Duck Hawk' for 'Peregrine' and 'Pigeon Hawk' for 'Merlin' are no longer the official preferences.

Finally, there are many cases in which a species is known in Britain by its substantive name without qualification, but an adjective is added in America for distinction from related species there, e.g. 'Rock Ptarmigan', 'Barn Swallow', 'Winter Wren'.

Other Usages. In the more widely divergent avifaunas of Australia and New Zealand, differences arise chiefly from the use of names familiar in Britain for birds that are not even closely related, e.g. 'chough', 'magpie', 'robin', 'treecreeper', 'warbler', and 'wren'—again see entries under the several names. In other parts of the world, even where English is largely spoken, this tendency is less noticeable; on the other hand, many compound names are merely ornithological fabrications, without roots in common speech and often varying from author to author. Sometimes a name from an indigenous language is adopted and more or less anglicized; or a scientific generic name (currently used or obsolete) does duty as an English substantive name. A.L.T.

NAME, POPULAR: recognized equivalent of NAME, VERNACULAR.

NAME, SCIENTIFIC: Carl Linnaeus (1707–1778) named many animals in addition to plants. The Swedes have a saying: 'God made the plants and animals, Linnaeus named them'; some scientists and evolutionists may not agree with the first part of this saying, but nobody can disagree with the second part. He was certainly the author of the Binominal (sometimes Binomial) System as in use today, and he proposed there must be two names, in Latin or 'Latinized' Greek so that they could be used throughout the world (see NOMENCLATURE).

Of course many scientific names (popularly known as Latin names) have been given and recognized by zoologists since Linnaeus's time. In some cases the scientific name of an animal has the generic name repeated as the specific name, for example, the Red Kite *Milvus milvus*. This is known as a tautonym, for *tauton* (Gr) the same, and *onoma* (Gr) a name; and has come about because of a change in the generic name; the International Code states that the specific name may not be changed, even though it results in a tautonym. The ruling has been modified for botanical names and tautonyms are not used for plants.

The Wren was among the birds that Linnaeus himself named, and he called it *Motacilla troglodytes*. Under his genus *Motacilla* he included a number of small birds which ornithologists have now split up into several genera, reserving *Motacilla* for the wagtails. In naming the American wren-like birds in the first decade of the 19th century, Vieillot chose the Linnaean specific name *troglodytes* (troglodyte or cave-dweller, by reference to the form of the nest) as a generic name. Later it was found that the European Wren was so closely allied to these that it must go in Vieillot's genus, so it became '*Troglodytes troglodytes*' (Tweedie 1963).

The Code states that the name of the nominate subspecies (race) must have a subspecific name that is the same, i.e. it must repeat, the specific name; the result was that the nominate subspecies of the Wren had to be named *Troglodytes troglodytes troglodytes*, and this ridiculous and lengthy name for such a little bird became something of a joke. Veteran zoologists, who were classical scholars, thoroughly disliked this: there were heated interchanges of correspondence and they refused to use these 'monstrosities'; however they passed from the scene and the rules were finally accepted.

Although Linnaeus used the name *Motacilla* for the wren, he took the name from Marcus Varro, the Roman scholar and author, to whom this Latin word is accredited; Varro died in 27 BC and this name must have been in use since about that time. *Motacilla* does not really mean 'wag-tail', from *motator*, a mover, and *cilla*, a tail, because *cilla* does not mean a tail, and in fact there is no such word. *Motacilla* is a Latin word, using *-illa* a diminutive suffix, and means 'little mover'; when Varro explained this name he said: *Quod semper movet caudam* (which is always moving its tail), when he might have been expected to say: *Quod semper movet cillam*, but he did not; one cannot help thinking that Linnaeus was well aware of this when he used the name for the Wren.

This wrong interpretation must have started long ago, and still persists among some ornithologists; for example we are quite happy to interpret

Haliaeetus albicilla as the White-tailed Eagle; the specific name was supposed to mean 'white-tailed', but it does not.

Names taken from Greek mythology were often used by Linnaeus and later zoologists; the generic name *Halcyon* for a kingfisher is an interesting example. There were strange legends about the kingfishers; the ancient Greeks thought they mated (conceived) at sea and built floating nests, and so at this time the gods favoured them and kept the sea calm. The Greek word for kingfisher, *alkuōn*, is derived from *hals* the sea, and *kuō* I conceive, hence 'halcyon days', calm days, kingfisher days.

An example of an apparently foolish name is a subspecies of the Great Tit, *Parus major minor*. In 1848 Temminck and Schlegel named a new tit from Japan *Parus minor*. Later it was considered to be an eastern member of the 30 or so races of *P. major*, so the subspecific name had to be *P. major minor*. Sometimes in an effort to give a new species a generic name that almost certainly had not already been used, a zoologist resorted to an anagram, for example *Daption capensis*, the Cape Petrel; the generic is an anagram of Pintado, the Portuguese name for this petrel.

The scientific name of an animal might originate from the naturalist who first discovered it, or from a zoologist working in a laboratory, and studying its anatomy; the specific name is quite often given in honour of a well-known person, or the collector who found it. The kiwis have the generic name *Apteryx*, which is derived from the Greek *a-*, a prefix meaning not, or there is not, and *pterux* (Gr) a wing. The wings of a kiwi are rudimentary, hidden by the body feathers, and useless for flight; the Great Spotted Kiwi *Apteryx haasti* was named in honour of Sir Julius von Haast, the New Zealand explorer. Col. R. Meinertzhagen, evidently in a flippant mood, took advantage of the now forbidden hyphen to name a babbler subspecies after his friend William Payn: *Argya fulvus billypayni*.

Tweedie, M.W.F. 1963. Those Latin names. Animals 2(22): 593.

NAME, SUBSTANTIVE: term used throughout this work for a noun that is the chief element in the English name of a number of species distinguished from each other by qualifying adjectives (including nouns and participles used adjectivally). Either or both elements of the full name may be compound, and each of them, unless written as a single word, should preferably be hyphenated (being indissoluble); on the other hand, the adjectival and substantive names should not be joined by a hyphen. For a few species a single word serves as a complete name, e.g. Brambling, Dodo. In other cases the substantive name may ordinarily be used alone where there is no other species with the same substantive name in the area, but in a wider context an adjectival name must be added. Occasionally there may be two independent (not hyphenated) qualifying names, e.g. Great Crested Grebe, Lesser Spotted Woodpecker. There is a certain analogy between an English substantive name and a scientific generic name, but this must not be pressed; unrelated species may have the same substantive name, and closely related species may have different ones. See NAME, ENGLISH.

NAME, TRIVIAL: see NOMENCLATURE—but also sometimes used in the sense of NAME, VERNACULAR.

NAME, VERNACULAR: 'the name of a taxon in any language other than the language of zoological nomenclature' (International Code)—see NOMENCLATURE; 'popular name' is a recognized equivalent. 'Vernacular name', however, is sometimes used in the restricted sense of a name in a local dialect or in the native language of a country foreign to the writer or speaker; this ambiguity can be avoided by using an adjective denoting the particular language. The vernacular names given in this work are, unless otherwise indicated, 'English names' (see NAME, ENGLISH). For names in other European languages see the works cited below.

NANDU: alternative name for species of Rheidae (see RHEA).

NAPE: see TOPOGRAPHY.

NARIS: usually in the plural ('nares'), for the paired openings of the nasal cavities in the SKULL. The anterior or external nares (nostrils) pierce the rhamphotheca of the upper mandible at varying distances from its base (uniquely at the tip in kiwis *Apteryx* spp.)—see BILL; the passages continue through apertures in the bones (premaxillae) into the nasal cavities. The posterior or internal nares (also called 'choanae') lead from the nasal cavities into the buccal cavity. For the nasal cavities and their functions see RESPIRATORY SYSTEM and SMELL; for the nasal glands see EXCRETION, EXTRARENAL.

The external nares are of various shapes, from round to linear; sometimes there is a central tubercle in each naris. Usually they are exposed (gymnorhinal); but in some birds they are concealed by frontal feathers, e.g. in crows and grouse. Sometimes each naris is protected by a flap (operculum), which in tapaculos is movable. In the Procellariiformes (Tubinares) the nostrils are carried in a double horny tube on top of the bill. The internasal septum, separating the right and left passages, is imperforate in most birds but perforate in a few. Although the nostrils remain open (pervious) in most birds, they are or become secondarily closed (impervious) in some Pelecaniformes; in such cases, entry to the nasal cavities is only from the mouth through the choanae, which may be quite large, and respiration is through 'secondary external' nares at the angle of the mouth.

The shape of the *bony* aperture of the nostril has been used as a taxonomic character. It is 'holorhinal' when the posterior margin is rounded, 'schizorhinal' when it forms a slit; 'pseudoschizorhinal' is a term applied to a modification of the holorhinal type; and 'amphirhinal' signifies that there are two bony apertures (one behind the other) on each side. In Sulidae (see above) even the bony aperture is blocked.

NARROW FRONT MIGRATION: see MIGRATION under Flight performance.

NASAL: a paired bone of the SKULL.

NASAL CAVITY: see NARIS; RESPIRATORY SYSTEM; SKULL; SMELL; and EXCRETION, EXTRARENAL.

NATIVE COMPANION: alternative name for the Australian Crane *Grus rubicunda* (see CRANE).

NATIVE HEN: substantive name, in Australia, of *Tribonyx* spp. including the flightless Tasmanian Native Hen *T. mortieri* (for family see RAIL).

NATURALIZED BIRDS: species that have been introduced by human agency, direct or indirect, into areas where they either had not yet spread by natural means or had become extinct, and that have successfully established themselves and are now breeding regularly as wild birds. Mere acclimatization in captivity, or even the casual escape of captive individuals, is excluded from the definition.

Extensive man-made changes have taken place in the world distribution of certain bird species within the past hundred years or so. The House Sparrow *Passer domesticus*, for instance, was a native of Europe and parts of Asia and North Africa but has been spread to the remaining continents by human agency. It now occupies almost the whole of North America, large parts of South Africa, as well as New Zealand, Cuba, Hawaii, New Caledonia, the Falklands, and many other islands. It has been estimated that within the past century largely man-made extensions have doubled the natural world range of the House Sparrow, which was over 15,000,000 km^2, so that it now occupies one-quarter of the earth's surface. The Starling *Sturnus vulgaris* has been artificially spread almost as widely, as will be further mentioned.

Introductions may be either deliberate or more or less accidental. Deliberate introductions have been made for three main reasons. In western Europe and in North America excessive shooting of game stocks has led to widespread and prolonged introductions of game-birds; this has sometimes, as with the Grey Partridge *Perdix perdix* from Hungary to Britain, been to supplement stocks of native species, but more often, as with the Pheasant *Phasianus colchicus* in both Europe and North America, to diversify the native game stocks with completely alien birds. Nostalgia for the sights and sounds of the home country led to large-scale and often highly successful introductions of western European song-birds into North America, South Africa, Australia, and New Zealand. In the

British Isles especially, the desire to increase the amenities of country estates led to the importation of large numbers of ornamental waterfowl, the progeny of which have sometimes been neither pinioned nor wing-clipped and have thus escaped to found feral populations. Some more or less domesticated birds have also been able to escape from captivity and establish themselves in the wild. In the British Isles, despite attempts to introduce upwards of 100 bird species (mostly during the past hundred years), only 4 completely alien birds have become thoroughly naturalized over a wide area; the Pheasant from various parts of Asia, the Red-legged Partridge *Alectoris rufa* from southern Europe, the Little Owl *Athene noctua* from western Europe, and the Canada Goose *Branta canadensis* from North America. In addition, the Mandarin Duck *Aix galericulata* and the Golden and Lady Amherst's Pheasants *Chrysolophus pictus* and *C. amherstiae*, all 3 from China, and the Ruddy Duck *Oxyura jamaicensis* from North America are naturalized in limited areas; the Capercaillie *Tetrao urogallus*, after becoming extinct in the Scottish Highlands about 1785, was successfully reintroduced there from Sweden in 1837–39; the Gadwall *Anas strepera* became naturalized in two small areas in south-eastern England at the same time as an apparently natural colonization from the Continent took place in Scotland; and the widespread present-day populations of both the Mute Swan *Cygnus olor* and the feral domestic pigeon *Columba livia* var. represent escapes from more or less domesticated stocks. Of these 12 species, 5 were introduced to supplement game stocks, 4 were ornamental waterfowl, 2 were formerly kept for food, and the Little Owl was introduced as an aesthetic whim of a handful of bird-loving 19th century landowners. The Ring-necked Parakeet *Psittacula krameri*, an escaped cage bird, appears to be established in one or two British localities, as it is in parts of the Middle East and Lower Egypt.

In France, on the other hand, the numerous introductions of birds over the past hundred years have resulted in only one additional species becoming established—Reeves's Pheasant *Syrmaticus reevesii* joining the already naturalized *Phasianus colchicus*. This is no doubt largely due to the fact that a continental area tends to have fewer vacant ecological niches than an island.

In North America the 2 most successful and widespread naturalized birds have been the House Sparrow and the Starling from Europe. The House Sparrow has now occupied the whole of the cultivated area of the United States and Canada. The Starling has spread, since 1891, over the whole continent north to the Gulf of St Lawrence and west to the Rocky Mountains; it also occurs in Jamaica as a result of a separate introduction in 1903. Small local populations of naturalized Grey Partridges, Pheasants, Goldfinches *Carduelis carduelis*, and Tree Sparrows *Passer montanus* from Europe have also been added to the avifauna of North America. More recently the Monk Parakeet *Myiopsitta monachus* from southern South America and the Mexican House-finch *Carpodacus mexicanus* have become widely naturalized and a number of escaped cage-birds, especially parrots and doves, have become locally naturalized around Los Angeles, California, and Miami, Florida. Honolulu, Hawaii, has its own special constellation of introduced species. The Greater Bird-of-paradise *Paradisaea apoda*, of the Aru Islands and New Guinea, was successfully introduced into Little Tobago, West Indies, in 1909.

Of the numerous European song-birds introduced into Australia and New Zealand by homesick emigrants, mainly in the 1860s, 8 are now naturalized in Australia and 13 in New Zealand. The Skylark *Alauda arvensis*, Song Thrush *Turdus philomelos*, Blackbird *T. merula*, Greenfinch *Carduelis chloris*, Goldfinch, House Sparrow, and Starling are found in both countries today. In New Zealand an interesting by-product has been the interbreeding of subspecies of the Redpoll *Carduelis flammea* from different parts of Europe, and perhaps also of the Yellowhammer *Emberiza citrinella*.

Asian birds naturalized in Australia include the Indian Spotted Dove *Streptopelia chinensis suratensis*, the Common Myna *Acridotheres tristis* (also naturalized in Hawaii and New Zealand), and the Red-whiskered Bulbul *Pycnonotus jocosus*. All the birds of the last-named species now at large in New South Wales and Victoria are said to derive from some that either escaped or were liberated from an aviary in Sydney, a city where they are now plentiful in the parks and threaten to become a pest to fruit-growers. From Africa, the Ostrich *Struthio camelus* was introduced into South Australia under domestication and has become feral in one or two areas. Non-European birds naturalized in New Zealand, in addition to the Common Myna, include the California Quail *Callipepla californica*, the Canada Goose, which is now locally abundant, the Black Swan *Cygnus atratus* from Australia, and the White-backed Magpie *Gymnorhina hypoleuca* (Cracticidae) also from Australia.

Success in deliberate attempts at naturalization is quite haphazard, as the British record shows. Animal species are well adapted to their native environment but, if they are to establish themselves firmly in a completely different part of the world, a whole complex of factors, such as climate, food supply, and cover for both nesting and roosting, must be suited to them; nor must pressure from predators be too great. A.C. Twomey has pointed out that imported European birds became naturalized in the United States only in regions with temperature and rainfall corresponding to those in their native breeding places. In New Zealand the introduced European species have completely supplanted native birds over most of the cultivated area, being for the most part pre-adapted to the habitat created by the destruction of the native vegetation and the substitution of imported crop plants. No doubt the native New Zealand birds would in time have adapted themselves to the areas cultivated by man, but the presence of the European birds has deprived them of the chance.

Several other island archipelagos also have their inhabited and cultivated areas dominated by introduced species, notably the Seychelles in the Indian Ocean, where the 3 commonest land birds are the Common Myna, the Peaceful Dove *Geopelia striata*, and the Cardinal or Madagascar Fody *Foudia madagascariensis*. The dove, called also Barred Crown Dove and Zebra Dove, has a very involved history. A native of South-east Asia and Australia, it was first introduced to Mauritius (where it is still common) by Indian traders, and thence to the Seychelles. Some 30 introduced species of birds are also at least locally established in the Hawaiian archipelago, out of well over 100 that have been liberated at one time or another.

Theoretically, its own fecundity is the only limit to the increase of an introduced bird population in a suitable new habitat, until it comes up against the natural ceiling that the environment imposes on it. The expansion of the Starling and House Sparrow populations in North America bears this out well; so does the increase, from 2 cocks and 6 hens to 1,898 birds in 5 years, of a population of Pheasants on a small island off the western coast of North America.

When populations build up to their natural ceiling on an island, the surplus may attempt to spread oversea, as is suggested by the fact that, as Williams (1953) has shown, many of the small birds naturalized in Australia and New Zealand began to appear by the end of the century on the small islands that lie mostly 320–880 km to the southward of the two main landmasses. There can be little doubt that most of them were blown there by the wind. Campbell Island, for instance, 700 km south of Dunedin, now has breeding Blackbirds, Song Thrushes, Starlings, Redpolls, Chaffinches *Fringilla coelebs*, and Dunnocks *Prunella modularis*, all almost certainly self-introduced—but from stocks naturalized in a secondary area.

No highly migratory species have succeeded in keeping their migratory habit while becoming naturalized in a new country. Most of the European birds that have been so successful in other parts of the world are at most partial migrants in Europe. The Canada Goose in Britain, however, provides an instance of a migratory bird population that has lost its urge to migrate during a period of captivity and has become wholly sedentary in its secondary home, apart from a moult migration between some English breeding populations and the Beauly Firth in Scotland. The Pheasant, on the other hand, is normally a wholly sedentary bird but has shown some signs of acquiring a migratory habit in the harsher climate of Sweden, while Swedish Canada Geese winter in Germany and the Netherlands.

Bird introductions have on the whole proved less disastrous than introductions of mammals and insects, but the examples of the Starling in North America and perhaps of the Red-whiskered Bulbul in Australia are there to point the dangers of irresponsible introductions. R.S.R.F.

NATURAL SELECTION: all those factors that lead to systematic differences between various genetic forms in a population in their rates of survival or reproduction. Such differences lead to differences in fitness—the relative contribution each genotype makes to the next generation. Natural selection is the main factor bringing about evolution, as first suggested by Darwin and Wallace and confirmed by subsequent studies, particularly in genetics and ecology, and by the development of the mathematical theory of population genetics.

Genetical variation within populations is the pre-requisite of natural selection. Such variation is abundant. Although about two-thirds of the genetic material carried by each individual is identical in most members of the majority of animal and plant populations, the remaining one-third varies from individual to individual—i.e. the alleles at each locus are not the same in all members of the population (see GENETICS). This variation may be manifest in various ways in the characters of the organism. A characteristic may vary continuously from one extreme to another, with no division into distinct classes (e.g. body-weight) or with such division being imposed merely by the integral nature of the characteristic (e.g. CLUTCH-SIZE). Alternatively, variation may be discontinuous, with sharply distinct classes (e.g. the bridled and unbridled forms of the Guillemot *Uria aalge*. See POLYMORPHISM). Variation is found in all types of characters (morphological, physiological, biochemical, behavioural) and all types may be subject to natural selection.

Natural selection in birds was first clearly demonstrated by H.C. Bumpus in 1898. He studied 136 House Sparrows *Passer domesticus* found exhausted after a severe snowstorm: 72 survived and 64 died. The mean total length of the survivors was 158.7 mm, while that of those that died was 160.5 mm. Thus there was strong and significant selection against longer birds.

Studies of predation by birds on the peppered moth *Biston betularia* provide an illustrative example of natural selection. This species is typically pale in colour with darker markings that render it highly cryptic on the lichen-covered tree-trunks on which it rests by day. There is a melanic variety of the species that is conspicuous in such locations. Direct observations of moths on tree-trunks show that birds tend to find the melanic variety much more readily that the typical form. As a result, the survival rate of melanics is much less than that of the typicals. Converse results have been obtained in areas affected by atmospheric pollution. There the tree-trunks present a dark background, having few epiphytes, and the melanic moths appear less conspicuous than the typicals. As expected, birds find the typicals more easily than the melanics in such places and the resultant mortality rate of the typicals is higher than that of the melanics.

Natural selection often results in the maintenance of the *status quo* with regard to the genetical constitution of populations. Thus most *Biston betularia* of rural areas are of the typical form. Melanics occur, as a result of mutation (see GENETICS) or of immigration from polluted regions, but their frequency is kept extremely low because the birds find them more easily than they find the typical ones. Another example of stabilizing selection is found in Bumpus's study of House Sparrows. Humerus lengths were significantly more variable among the dead birds than among the survivors, though the mean lengths were the same: this means that birds with extreme humerus lengths, whether long or short, survived less well than birds with humeri of average length. Such elimination of the extremes is commonly found in studies of selection acting on continuously varying characters. In general, stabilizing selection is likely to occur whenever a population has been living in a fairly constant environment for some time.

When environmental conditions change, the relative fitnesses of the genotypes in the population may change. A form which previously survived relatively well may survive relatively poorly in the changed conditions. The result of this will be that its frequency in the population will decline. The resultant gradual change in the genetic composition of the population is the basis of evolution. Thus prior to the industrial revolution most areas that now suffer atmospheric pollution did not do so and the trees growing in them supported abundant epiphytic lichens. At that time, melanic *B. betularia* were universally rare. The pollution consequent upon industrialization killed the lichens and so changed the direction of selection, the melanics subsequently surviving better than the typical moths. As a result, the frequency of the melanics rose from about 0% to over 90% in 50 years in many industrial centres in Britain.

At first sight one might expect that selection would tend to eliminate all genotypes except the one with the highest fitness and thus give rise to genetic uniformity. That this is not always true is demonstrated by the large amount of genetic variation to be found within natural populations. This variation originates by mutation and by the continual production of new combinations of genes that results from sexual reproduction (see GENETICS). It is maintained in populations by various forms of natural selection. One such form is selection in which rarer genotypes have relatively high fitnesses by virtue of their rarity. Such selection may arise in various ways. For example, experiments with various birds and other animals have shown that when they are feeding on food of more than one type, they tend to overlook the rarer forms of food, so that they not only take an absolutely larger number of the commoner forms but also a disproportionately larger number. In nature, if the different forms of food are the different genotypes of a single species then, because each genotype is selectively advantageous when rare but disadvantageous when common, a variety of genotypes is preserved in the population. FREQUENCY-DEPENDENT SELECTION of this form may be of great importance in the maintenance of genetic variation.

Selection may vary with frequency in ways that do not conserve genetic variation. If the fitness of each genotype is greater when that genotype is commoner, then rare genotypes are rapidly eliminated and eventually only a single type remains. This occurs when some birds feed on prey which are packed closely together, such as Goshawks *Accipiter gentilis* feeding on flocks of Domestic Pigeons *Columba livia*: they take more light birds from flocks that are mainly dark and vice versa.

Selection is measured as fitness, which may be most precisely defined by example. Suppose that one has a population in which there are simply two genotypes, A and B. Consider the newly-fertilized eggs of one generation and the birds developing from them: some will not survive long enough to reproduce themselves; of those that do survive, some may have only a few offspring while others may have many. Suppose that the average number of newly-fertilized eggs of the next generation to which an egg of this generation contributes is a if the egg is of genotype A and b if it is of genotype B. Suppose that A is the fitter genotype, i.e. a is greater than b. Then, by convention, the fitness of genotype A is 1 and the fitness of genotype B is b/a. Thus the fitness of a genotype is the average contribution made by an individual of that genotype to the next generation, measured relative to the fitness of that genotype which contributes most (which has a fitness of 1 by convention), with the point of measurement in each generation being the newly-fertilized egg stage.

The definition of fitness in terms of average contributions of genotypes clarifies an important point. To say that natural selection, in the form of predation by birds, favours melanic *Biston betularia* over typicals in industrial areas means not that the birds eat none of the melanics and all of the typicals but that they eat a higher proportion of the typicals. Nor is the fact that many of the deaths are 'accidental', i.e. unrelated to the genotype of the individual, important: so long as there is some systematic difference in average rates of survival and reproduction, natural selection is occurring.

Since fitness is a relative measure, based on comparisons within a single population, one cannot validly speak of the fitness of a whole population. The mean fitness of a population is a mathematical abstraction, quite unrelated to the potential growth-rate, size, or competitive ability of the populations. It cannot, therefore, be used for comparing the probability of survival of different populations.

A source of confusion is that 'fitness' is a technical term with a precise meaning but is also a word in general use with other meanings. An Olympic athlete may be fit in the evolutionary sense, but not necessarily: 'physical fitness' is only one factor in genetic fitness. In evolutionary biology, the latter is of prime importance, so 'fitness' should only be used in its technical sense in evolutionary discussions.

The fitness of the individual is an insufficient explanation for the phenomenon of parental care, manifest more in birds than in any other class of animals. A genotype that produced large numbers of eggs but which failed to care for them, so that none survived, would rapidly disappear from a population. Genotypes that produced fewer eggs but which cared for them, so that some survived to adulthood, would prevail in evolutionary time. Thus it is not just the fitness of the individual that must be taken into account but the fitness of its offspring. However, because of the biparental nature of sexual reproduction, only half of the genetic material in an offspring is received from each of its parents. Thus, for the potential genetic contribution to future generations, the fitness of an individual's offspring is only half as important as the fitness of the individual itself. To take an extreme and simplified example, a genotype that lays down its own life to ensure the survival of more than two offspring to reproductive age will tend to prevail in evolution whereas a genotype that lays down its life to ensure the survival of less than two offspring to reproductive age will not.

Individuals share part of their genetic endowment not only with their offspring but also with all their relatives: brothers and sisters have half their genetic endowment in common, full first-cousins have one-eighth in common, half-brothers have one-quarter, etc. Thus genotypes that have characteristics benefitting their relatives will prevail in evolution, so long as the characteristics do not cause too great a loss of fitness to the individual. The DISTRACTION BEHAVIOUR of ground-nesting birds provides an example of this: it increases the probability of survival of the eggs or chicks without involving a great risk to the parent. W.D. Hamilton has analysed the theory underlying this idea and has shown that the important factor, in terms of evolution, is the 'inclusive fitness' of an individual—i.e. its own fitness (defined as above) plus the fitnesses of all its relatives, weighted according to their degree of relatedness.

In mobile species in which individuals have no great tendency to live near their relatives, the characteristics of an individual will be largely irrelevant to the fitness of its relatives. Thus only offspring need to be considered in calculating inclusive fitness. But in species where individuals tend to associate with their relatives, inclusive fitness in a broad sense is important and selection must be considered in terms of the relatives of the individual as well as the individual itself—KIN SELECTION. The Tasmanian Native Hen *Tribonyx mortierii* provides an example. The sex-ratio is biased, with an excess of males. Some birds breed in pairs but others form trios of two males and a female, each male obtaining about half the copulations and probably fathering about half the offspring. Such an arrangement is extremely rare: in most species two males display or fight until one gains sole possession of the female. The wife-sharing in *T. mortierii* is facilitated by the two males usually being brothers. Thus although each male only fathers half the offspring, he is uncle to the other half. This reduces the selective pressure on males to fight for sole possession of the female.

Competition between members of one sex for access to members of the other gives rise to a particular type of natural selection known as SEXUAL SELECTION.

As a result of natural selection, organisms have characters which aid their survival in their particular ecological niches—they are adapted to their environments. The study of adaptations is a key area of evolutionary biology. In studying the evolutionary forces that have resulted in a particular character, one is in a sense studying the function of the character (without implying that the evolution that produced it was orientated to the goal of producing it). The study of adaptation has, therefore, been named teleonomy by analogy with, and to distinguish it from, Aristotelian teleology. The particular form of any teleonomic study depends on the character being studied but the aim is always to identify, and if possible measure, the selection pressures responsible for the evolution and maintenance of the character.

The evolutionary forces responsible for the origin of a character may be considered the 'ultimate causes' of that character, in contrast to the processes occurring during the individual's development that result in the character being formed, the 'proximate causes'. Thus the ultimate cause of flipper-like wings in penguins is that penguins use their wings for submarine locomotion; the proximate cause is that the developmental pathway of the penguin's wing is deflected somewhat from that found in typical birds. The existence of two levels of causative explanation, as a result of evolution by natural selection, is one of the unique features of biology. (A.J.C.) J.J.D.G.

NAVIGATION: here used in the sense that a bird may be considered to have navigational ability if it is able to orientate its flight path in the absence of landmarks previously known to it. The orientation may be simply in a fixed compass direction, or towards a particular area (homing), from any direction.

Many birds appear simply to shuttle back and forth between summer and winter quarters. To reach the latter the only requirement for the young, naive bird, when not accompanied by experienced adults, is for it to be innately programmed to fly for a certain distance in a given direction, distance-and-bearing navigation in sailors' parlance.

If young migrants are held captive in an unchanging, artificial environment when they would normally be migrating, they show periodic bouts of fluttering and hopping, migration-restlessness. It is found that long-distance migrants continue to show this activity for much longer than closely related species migrating only short distances. Since the time spent in flying (if they were free) would determine the distance covered, one element of the migration programme is thus established. See MIGRATION.

The restlessness of caged migrants also has a directional component which can be automatically registered on a circle of pressure-sensitive perches. The scatter this produces about a mean direction is generally wide, but if the mean of each day (or night) is calculated and the means over, say, a month are examined, they are found to cluster in the general direction of the seasonal migration. Anomalous directions may also be taken up and these 'nonsense orientations', unrelated to migration or home direction, have been studied especially in Mallard *Anas platyrhynchos*, using free-flying birds and examining the cluster of bearings on which individually released birds vanish from sight when observed through powerful binoculars.

The sun is the primary basis for compass-orientation, with an element of time-compensation to allow for its apparent movement round the sky. Caged birds change orientation as the sun position is deflected by mirrors, change their angle to a fixed, artificial sun throughout the day and switch through 90° if their internal 'clocks' are shifted by 6 hours by being kept in an artificial day out of phase with the normal (see RHYTHMS AND TIME MEASUREMENT). A 12-hour shift produces a 180° switch when the artificial and normal days overlap. If the birds are released by day when their shifted clocks register night-time, various directions are taken up. These have been interpreted as showing that the mechanism changing their flight angle to the sun by 15°/h during the day goes into reverse during the night.

There are indications that the position of sunset is an important clue to birds migrating later in the night. But Mallard, released long after the sunset glow has gone, orientate well if the moon is the only visual clue (the stars being obscured by cloud). Time-shifting modifies this orientation, but it is not clear if the same 'clock' is involved as for sun-compass orientation.

If the stars alone are visible, compass orientation is shown which is not influenced by imposed time-shifts. This leads to the interpretation that it is the shape of the constellations and their relation to the fixed point (north) marked by *Polaris* that are the clues used. This concept has been explored in detail using caged passerines under the domes of planetaria. The naive young bird learns firstly the point of least rotation in the night sky and the relation constellation patterns (which need not be ones occurring in nature) bear to this. Subsequently the constellations themselves are used to find the north, much as we do ourselves. The circumpolar constellations which are above the horizon at night throughout the year are the important ones. The constellations farther from the pole can be blotted out without loss of orientation. Seasonal changes, in which different non-polar constellations become visible at night, do not determine the migratory direction taken up. This depends on the bird's physiological condition, governed primarily by photoperiod.

Migration predominately occurs under clear or partly-clouded skies. However, field evidence, particularly from radar observations, has shown that well-orientated flights occur when astronomical clues are not available, even when birds are flying between cloud layers. This has re-awakened interest in orientation with reference to the earth's magnetic field. Marginal orientations in the appropriate migratory directions have been shown by caged migrants confined in closed rooms. These orientations have been switched by artificially moving the magnetic pole. Moreover birds appear to determine the direction of the magnetic field through its tilt from the horizontal, the downward pole being taken as north. Some evidence suggests that the magnetic compass is actually used to calibrate the sun-compass and the constellation compass, i.e. it is the 'primitive' compass. The mechanism whereby the magnetic field could be detected is baffling, though crystals of magnetite, found in the heads of birds, may be the intermediary. Great difficulty has been experienced in demonstrating a direct sensitivity to magnetism, one exception being a training experiment in which pigeons had to make their choices while actually in flight.

When migrants have been displaced laterally, by wind drift or by experiment, the young birds on their first migration tend to proceed in the programmed direction. Older birds, with experience of at least one migration, tend to correct for the displacement and 'home' to the normal winter-quarters. This implies a much more advanced form of navigation than a simple distance-and-bearing procedure.

Most homing experiments have been carried out on breeding birds, since their urge to return is strong and only a small area round the nest need be kept under observation. Those breeding in colonies offer obvious advantages in this respect. Many migratory species have homed from remarkable distances. The longest flights on record are those of a Manx Shearwater *Puffinus puffinus* which homed 4,910 km in 12½ days, and of Laysan Albatrosses *Diomedea immutabilis* which covered 5,150 km in 10 days and 6,630 km in 32 days. These, and many shorter journeys, are done in times indicative of more or less straight line flight rather than of random wandering in search of known landmarks. Homeward orientation has also been demonstrated while the birds are still in sight of the observer. Indeed the bulk of experimental work has concentrated on the scatter of vanishing points of individually released birds. The distance to which birds may be followed has been increased, in some researches, by the attachment of minute radio-beacons on their backs. Overwhelmingly the domestic pigeon *Columba livia* has been the preferred species, because of the ease with which large numbers can be reared and kept under precisely known conditions. Although originating from non-migratory stock, pigeons have been selected over many generations to the point that many will home rapidly from hundreds of kilometres away. It is argued that if pigeons can undertake some navigational task, long-distance migrants could surely do better.

Homeward orientation within a few kilometres of the home site may reasonably be ascribed to visual recognition of previously known landmarks, though there is some argument about this. Farther away from home, several workers have found a zone of disorientation and it is not until about 80 km that consistent homeward orientation reappears, possibly improving with distance thereafter. This apparent requirement for a minimal displacement has led to the concept of a navigational 'grid' (or, as some would have it, 'map'). This visualizes at least two physical features varying more or less regularly in a quantitative way across the earth's surface, but with their gradients crossing each other. The values of these factors at the release point (if sufficiently far away) will be detectably different from those at home and so indicate their relative positions on the 'grid', and thus the direction in which the bird must fly to regain home. The bird will also need to know how the 'grid' relates to local topography—the grid may indicate home is to the north but it must know which direction is north. The compass mechanisms discussed earlier would suffice for this; the real problem is what are the bases for the 'grid'.

The common observation that homeward orientation, and homing, were much better in conditions of broken cloud, led to the examination of possible astronomical bases. Homeward orientation has not been demonstrated in free-flying birds under a night sky and some supposedly positive evidence from caged migrants is now treated with caution. A vast amount of experimentation has been undertaken to test whether a sophisticated interpretation of the sun's position in the sky is open to a bird, much as it is for human navigators. The simplest method would be to observe the sun at its highest point (local noon) enabling a time comparison to give the change in longitude. The sun's angle of elevation at that time, and comparison with the home value, would give the change in latitude. However, birds can orientate towards home at various times of day, not only at noon. They would therefore have to detect the movement of the sun and, in effect, compare with the remembered condition at home at that time. Alternatively the bird might extrapolate the observed portion of the sun arc to guesstimate the highest elevation and make comparison at that point. This would require much less of its memory.

Most field experiments have indicated that the sun's only role in the homing process is as a compass, though there are some exceptions. The most positive support has come from experiments with pigeons held rigidly and exposed to variations in the position of an artificial sun or to the real sun being apparently shifted by the use of prisms. The birds' responses indicated that they could detect movement slower than that of the normal sun, remember its position to within half a diameter for 24 hours, and react to changes in its elevation as if they were due to changes in latitude. The evidence for time-comparison ability is much more nebulous. However, biological clocks with very precise periods (±2 min in 24 h) have been demonstrated. Mostly these have periods slightly more than or less than 24 hours and so slide out of phase if not subject to regular checks against sunrise/sunset. But for a really constant 'chronometer', natural selection has only to favour a 24.0 hour clock-period.

Where pigeons experience prolonged overcast conditions and are only flown in such conditions, homeward orientation is demonstrated in the absence of astronomical clues. Homeward orientation has also been found in pigeons where eyesight has been severely restricted by cloudy contact lenses. These results have led to the search for other possible components of the navigational grid, especially those concerned with the earth's magnetism. Homeward orientation of pigeons flying below overcast is disrupted by attached magnets and can be turned about by changing the tilt of the field imposed by electrical coils mounted on the birds' heads. But this evidence does not suggest that more than a magnetic compass is involved. Some disruptions of orientation by magnetic anomalies or storms are slightly more indicative of a magnetic grid.

A long range of experiments, mostly in Italy, suggests that olfaction may play a part in homing. This was affected by surgical or other interference with the nerve tracts and olfactory organs, or by diverting the direction of the winds impinging on the birds at home. The theory is that the pigeon builds up an olfactory map around home, associating one smell with one direction, another with the opposite, and so forth. There is conflicting evidence, and at best such a system could not be effective any great distance from home.

Inertial navigation, whereby every change of direction and acceleration during the outward journey is recorded and integrated to give the overall angular displacement from home, has often been proposed. But imposition of highly complicated, irregular accelerations, in a revolving drum, had no effect on homing ability. Nor did surgical interference with the inner ear mechanism, most likely site of such a mechanism. Experimenters should remember that the whole bird is the flying machine and that it is capable of flying skills that would defeat a human aviator.

In summary then, there are two main forms of navigation shown by birds; a simple distance-and-bearing type programmed innately in inexperienced birds, and a more complex displacement-correcting mechanism in older, experienced birds. The compass element in the former can be based on clues from sun, moon, stars and the earth's magnetism. The 'grid' needed in the latter may involve the sun's position (at least its elevation), magnetic information or even olfactory clues, but the evidence is still far from clear. G.V.T.M.

NEARCTIC REGION: the usual designation in zoogeography for North America north of the tropics (see DISTRIBUTION, GEOGRAPHICAL). The borders are the Arctic Ocean in the north, the Bering Strait and the Pacific Ocean in the west, and the Atlantic Ocean in the east. A border in the south is more difficult to draw; it is usually placed through Mexico, along the northern edge of the tropical rain-forest (see NEOTROPICAL REGION). Thus defined, the Nearctic Region extends from about 83°N to about 20°N.

Physiography. In this vast area almost the entire range of possible climates is encountered. The major geographical features of North America, in contrast to Europe, extend longitudinally. The west consists of parallel mountains, the Rocky Mountains and related chains, extending from Alaska southward into Mexico and Central America and continuing into the Andes of South America. The interior of North America is occupied by plains extending from the Gulf of Mexico northward into Canada, where they comprise the vast Canadian Shield. In the east a minor chain of mountains, the Appalachians, extends from Georgia and Alabama into Pennsylvania and continues in several more or less isolated mountain ranges in New York, Vermont, New Hampshire, Maine, and the Maritime Provinces of Canada. This essentially longitudinal arrangement of the major geographical features is, to a large extent, responsible for some of the otherwise puzzling features of the North American bird-life.

Many attempts have been made to subdivide the Nearctic Region into local provinces, from the life zones of Merriam to the biotic provinces of recent authors. Since all these zones intergrade insensibly, none of the attempts can be considered fully successful. On the whole, bird-life and landscape change latitudinally, with the climatic and vegetational belts becoming increasingly better defined northward. A circumpolar tundra belt north of the tree-line is well defined. A 'Canadian' coniferous belt with its characteristic avifauna is fairly well defined. Both extend southwards along the mountains. Farther south there is a less well defined series of belts of deciduous forest, limited to areas of higher rainfall. Between the Mississippi Valley and the Rocky Mountains lie extensive plains ('prairies'); and in northern Mexico and the south-western states are extensive arid areas, some of them true deserts. The bird-life of each of these vegetational areas differs more or less drastically from that of other areas.

History of the avifauna. The composition of the North American bird fauna is best understood in the light of its history. The North American continent was connected with Europe (via Greenland) in the early Tertiary when the Atlantic Ocean was much narrower; it has had intermittent connections with Asia across the Bering Strait bridge; and it was separated from South America, at least from the early Eocene to the late Pliocene, by a series of Central American water-gaps cutting through what are now Nicaragua, Panama, and north-western Colombia. This history of the North American landmass explains the composition of its avifauna. After the late Eocene separation from Europe the fauna evolved in isolation from both Eurasia and South America, but there has been opportunity for a limited amount of faunal exchange across the Bering Strait bridge and the 'stepping-stones' in the Panamanian gap.

During the first half of the Tertiary the southern half of North America was humid and tropical as far north as latitudes 38°–40°, as shown by the palaeo-botanical record. This permitted the evolution of a tropical North American fauna rather distinct from the tropical fauna of South America. The two tropical faunas intermingled when the Panamanian land-bridge was established near the end of the Tertiary (late Pliocene). In the meantime there had been a steady process of cooling and reduction of rainfall in North America, in part caused by the rising of the mountain ranges in the western parts. This resulted in the development of deserts, subsequently populated by colonists from the adjacent, more humid habitats.

In addition to sea birds and world-wide taxa, the North American avifauna consists essentially of four elements: (1) an old indigenous one that developed during the Tertiary isolation; (2) a less old Holarctic element dating back to the Eocene trans-Atlantic connection with Europe; (3) more recent Holarctic immigrants from Asia; and (4) immigrants from South America. The fauna as a whole is thus somewhat intermediate between that of South America and that of Eurasia. Even though there is some ambiguity in any faunal analysis, it is fairly easy to determine to which of the four stated faunas most genera and families of North American birds belong.

Indigenous elements. Five families of songbirds can be considered indigenous North American elements. The wrens (Troglodytidae) have more genera north of the Tertiary gap through Central America than they have in South America, but more species south. The large number of endemic species and genera in the arid, subtropical zone of Mexico and the south-western United States is further proof of Nearctic origin. A single species, the well-known Winter Wren *Troglodytes troglodytes*, has crossed into Eurasia. Other well-known North and Central American species are the House Wren *Troglodytes aedon*, the Carolina Wren *Thryothorus ludovicianus*, the Marsh Wren *Cistothorus palustris*, and the Rock Wren *Salpinctes obsoletus*. Wrens are found in nearly every habitat from the most desolate desert to marshes and the tropical rain-forest.

The mocking-thrush family (Mimidae) contains many well-known North American birds of gardens, woodlands, and open country, such as the Gray Catbird *Dumetella carolinensis*, the Brown Thrasher *Toxostoma rufum*, and the Mockingbird *Mimus polyglottos*; the family is restricted essentially to the areas south of the coniferous forest belt. The vireos (Vireonidae), a family of small, mostly greenish, insect-eating birds of the leafy canopy of trees and bushes, are particularly well represented in the southern United States, Central America, and the West Indies, but there are also many South American species; the Red-eyed Vireo *Vireo olivaceus* is perhaps the most common North American woodland bird, the polytypic species extending as far south as southern South America. The American wood-warblers (Parulidae) are a group of colourful but structurally little diversified warbler-like birds well represented also in the northern coniferous belt, and 2 species have indeed crossed over into eastern Siberia; the northern species are highly migratory, and their passing through the United States in spring and fall, in enormous numbers, is one of the most spectacular aspects of bird-life in North America. Although the general pattern of distribution, as well as the number of endemic genera, indicates that tertiary North America was the home of these 4 families, all of them have crossed over into South America rather early, and have there produced a secondary radiation of species.

The fifth family consists of the buntings or American sparrows (Emberizidae). This family is highly diversified in the New World, so much so that it is difficult to delimit it against the tanagers (Thraupinae) and other finch-like birds. Well-known North American species are the Song Sparrow *Melospiza melodia* with over 30 subspecies extending from the Aleutians and Alaska south to Mexico, the Field Sparrow *Spizella pusilla*, the White-throated Sparrow *Zonotrichia albicollis*, and the Rufous-sided Towhee *Pipilo erythrophthalmus*. These buntings, like their Eurasian counterparts, are largely birds of the open country, from deserts to prairies and marshes; but many other species are typical of the undergrowth of the forest, particularly in the tropics.

Some small families or subfamilies that are presumably indigenous North American elements are the dippers (Cinclidae), the gnatcatchers (Polioptilinae), the waxwings (Bombycillinae), the silky flycatchers (Ptilogonatinae), the mostly tropical motmots (Momotidae), the West Indian todies (Todidae) (known from North America as fossils), and the Palmchat (Dulidae). Several families of non-passerine birds are perhaps indigenous North American elements, such as the New World vultures (Cathartidae) represented by the Turkey Vulture *Cathartes aura*, Black Vulture *Coragyps atratus*, and California Condor *Gymnogyps californianus*. The American quails (Odontophorinae) are derived from the pheasants and partridges (Phasianinae) of the Old World. Two species of turkey (*Meleagris*) are the most spectacular gallinaceous birds of the New World.

Old World element. Since North America and Europe were a single continent up to the Eocene, permitting considerable faunal interchange across the transatlantic connection, it is impossible to determine the exact area of origin of the older Holarctic element, such as cranes (Gruidae), pigeons (Columbidae), cuckoos (Cuculidae), certain owls and nightjars, kingfishers (Alcedinidae), the bluejay group (Corvidae pt.), Cardueline finches, and certain thrushes (Turdidae). The grouse subfamily (Tetraoninae), with numerous woodland species but also birds of the open country such as the extinct Heath Hen (an eastern subspecies of the surviving Greater Prairie Chicken *Tympanuchus cupido*) and the spectacular Sage Grouse *Centrocercus urophasianus*, apparently originated in the Old World, but had a rapid radiation in North America in the late Tertiary. A more recent Palearctic element evidently came across the Bering Strait bridge. This includes larks (*Eremophila*), creepers (*Certhia*), pipits (*Anthus*), nuthatches (*Sitta*), wrentit (*Chamaea*), some Corvidae (*Perisoreus*, *Pica*, *Corvus*, *Nucifraga*), Paridae (*Parus*, *Auriparus*, *Psaltriparus*), kinglets (*Regulus*), Barn Owl *Tyto alba*, and some Hirundinidae (*Riparia*, *Hirundo*, *Petrochelidon*). NECK: see TOPOGRAPHY.

NECTAR-FEEDERS: birds that feed on the sugary liquid in the calyces of some flowers. The habit has been evolved in several unrelated families in different parts, mainly tropical, of the world. The principal groups are the hummingbirds and honeycreepers of the New World, the sunbirds of Africa and southern Asia, the honeyeaters and flowerpeckers found chiefly in Australasia, and the Hawaiian honeycreepers (Drepanididae).

NECTARINIIDAE: a family of the PASSERIFORMES, suborder Oscines, SUNBIRD.

NEDDICKY: name, in South Africa, of *Cisticola fulvicapilla* (for family see WARBLER (1)).

NEGRITO: substantive name of *Lessonia rufa*, a South American tyrant-flycatcher (see FLYCATCHER (2)).

NEGRO-FINCH: substantive name of *Nigrita* spp. (see ESTRILDID FINCH).

NEMATODE: see ENDOPARASITE.

NE-NE: Hawaiian vernacular name, widely adopted, for the Hawaiian Goose *Branta sandvicensis* (see under DUCK).

NEOGAEA: see under ARCTOGAEA; DISTRIBUTION, GEOGRAPHICAL.

NEOGNATHAE: a superorder (see under CLASS).

NEOGNATHOUS: see PALATE; SKULL.

NEOMORPHINAE: see CUCKOO.

NEONATE: a newly hatched bird.

NEONTOLOGY: the study of geologically recent forms of life (contrasted with PALAEONTOLOGY).

NEORNITHES: a subclass (see under CLASS).

NEOSITTIDAE: a family of PASSERIFORMES, suborder Oscines, SITTELLA.

NEOSSOPTILE: term applied to the natal down plumage (where present), as contrasted with 'teleoptile' (see PLUMAGE).

NEOTENY: persistence of embryonic characters into adult life.

NEOTROPICAL REGION: usual designation in zoogeography for tropical America and the non-tropical parts of South America, together with the West Indies and other islands near South America (see DISTRIBUTION, GEOGRAPHICAL). South America is the real home of the Neotropical fauna, while Central America and the West Indies occupy a special position discussed below. The Neotropical Region extends from the northern edge of the tropical rain-forest in Mexico, about 20°N (see NEARCTIC REGION), south to Cape Horn, in about 57°S.

Physiography. South America is characterized by numerous geographical superlatives. The Andes, forming the western edge of the continent throughout its length, are the longest mountain range in the world, extending through 80° of latitude. The Amazon is the world's greatest river. The region is dominated by tropics and subtropics, and the southern third of the continent is so narrow that it leaves only little space for a temperate zone fauna. There are two areas of mountains east of the Andes—the isolated Guiana-Venezuela highlands (with Mt Roraima and Mt Duida), and the eastern Brazilian mountains. There are some extensive savannas ('llanos') north of the River Amazon, particularly in the upper Orinoco basin of Venezuela and north-eastern Colombia, and more extensive ones from the Matto Grosso south into Patagonia. Very arid country, some of it true desert, extends from the Pacific coast of southern Ecuador south through coastal Peru and Chile to about Valparaiso, southwards extending increasingly far into the mountains and encroaching in northern Argentina beyond the foot of the eastern Andes. As Wallace said, the Neotropical Region 'is distinguished from all the other great zoological divisions of the globe by the small proportion of its surface occupied by deserts, by the large proportion of its lowlands, and by the altogether unequalled extent and luxuriance of its tropical forests'.

History of the avifauna. The avifauna of South America not only is the richest in the world but is also remarkably uniform throughout the continent. There are no latitudinal barriers anywhere east of the Andes, and the Andes themselves have served as a distributional pathway, permitting the colonization of the lower latitudes by many temperate zone elements. The south temperate avifauna is characterized more by the paucity of its elements than by its distinctiveness. There are, however, a number of endemic genera, some of them, such as the seedsnipe (Thinocoridae), forming an endemic family. The Rhinocryptidae are of largely temperate zone distribution.

Although South America is now in land connection with North America across the isthmus of Panama, the two continents were isolated for most of the Tertiary Period and perhaps for much longer. Three major water-gaps ('portals') are known to have existed during this period; one across Nicaragua, one across Panama, and the third across north-western Colombia. These water-gaps were bridged by insular 'stepping-stones' for those faunal elements capable of island-hopping. The last of the portals (between Panama and Colombia) did not close until the Pliocene, presumably about 3 million years ago. There is no ornithological evidence for any connection with Africa. Prior to the break-up of the Gondwana plate South America was connected (directly or by stepping-stones) with Antarctica-Australia. The ratites are the only element in Australia clearly a remnant of this former connection. South America has acquired several species from Africa by recent transoceanic colonization such as that demonstrated by the Cattle Egret *Bubulcus ibis*, the Green-backed Heron *Butorides striatus*, 2 whistling ducks *Dendrocygna* spp., and a pochard *Netta erythrophthalma*.

Indigenous element. The old indigenous South American element includes a number of small families (the number of included species is indicated in parentheses), such as the rheas (Rheidae) (2), screamers (Anhimidae) (3), hoatzin (Opisthocomidae) (1), trumpeters (Psophiidae) (3), sunbittern (Eurypygidae) (1), seed-snipe (Thinocoridae) (4), potoos (Nyctibiidae) (5), and oilbird (Steatornithidae) (1). Fossil rheas are known as far back as the Eocene, while for the 8 other families the assumption of a South American origin is based on inference (absence from all other continents, either living or as fossils). Five other non-passerine families are much richer in species in South America than anywhere else, and for them a South American origin is hardly in doubt: tinamous (Tinamidae) (47), hummingbirds (Trochilidae) (300), puffbirds (Bucconidae) (33), jacamars (Galbulidae) (14), and toucans (Ramphastidae) (37). They include some of the most characteristic elements of the South American avifauna.

South America is characterized, even better than by these non-passerines, as the home of the Clamatores (= suborder Tyranni) the true mesomyodian passerines. All the families of this suborder are Neotropical (except for a few Old World genera with simplified syringeal musculature, which may well have acquired this similarity by convergence). The South American Clamatores are divisible into two main branches, the Tracheophonae (= Superfamily Furnarioidea) and the Haploophonae (= Superfamily Tyrannoidea). The Tracheophonae, in which the syrinx is entirely tracheal, consist of the tapaculos (Rhinocryptidae) (26), gnateaters (Conopophagidae) (10), antbirds (Formicariidae) (221), ovenbirds (Furnariidae) (212), and woodcreepers (Dendrocolaptidae) (47). This group, including more than 500 species, forms a dominant element in the South American avifauna. The antbirds are particularly characteristic of the undergrowth in the tropical rain-forest, while some of the genera of ovenbirds contribute conspicuous species to the temperate zone fauna of the continent, both in the southern latitudes and at the higher altitudes of the Andes.

In the haploophone Clamatores, the syrinx muscles are tracheobronchial, but are attached only at one end of the bronchial rings. This includes the tyrant-flycatchers (Tyrannidae) (366), the manakins (Pipridae) (51), cotingas (Cotingidae) (61), and the plantcutters (Phytotomidae) (3). This group thus comprises nearly 500 species. Indeed, the 2 groups of Clamatores combined contain nearly one-eighth of all the known species of birds of the world.

Most of the indigenous South American bird families, like their mammalian counterparts, have been poor colonizers. Only the hummingbirds and the tyrant-flycatchers, among the truly South American elements, seem to have colonized North America across the Central American stepping-stones to develop subtropical and temperate zone representatives in the North American fauna. The other families crossed into Central America late in the Tertiary, most of them apparently only after a complete land connection had been established.

Nearctic element. The stepping-stones between North and South America were used much more actively by North American elements to carry on a steady colonization. The earliest of these immigrants—the tanagers and honeycreepers (Thraupinae), cardinals (Cardinalinae), and troupials (Icteridae)—settled there such a long time ago that, except for their evident relationships with North American elements, they have acquired all the characteristics of South American families. The Emberizidae should perhaps be included in this group. Much of the adaptive radiation of these families took place in South America.

Other immigrants radiating secondarily in South America were contributed by such pantropical groups as the parrots, the trogons, the barbets, and one or two smaller groups. Other somewhat later arrivals from North America include the guans (Cracidae), the American quail (Odontophorinae), pigeons (Columbidae), jays (Corvidae), and thrushes (Turdidae). Typically North American families, such as the wrens (Troglodytidae), vireos (Vireonidae), wood warblers (Parulidae), and motmots (Momotidae), invaded South America presumably prior to the closing of the water-gap, because certain genera speciated there quite actively, having now more species in South America than in North America. The Andean chain, through Central America in almost continuous mountainous connection with the North American Rocky Mountains, has permitted the immigration of some typically Holarctic elements into South America, such as pipits *Anthus* spp., the Horned (or Shore) Lark *Eremophila alpestris*, and the Short-eared Owl *Asio flammeus*.

Needless to say, the South American continent has a rich fauna of fresh-water birds, consisting essentially of cosmopolitan families but with many endemic genera and species. Among the more characteristic of these the following may be mentioned: torrent ducks *Merganetta* spp., the Coscoroba Swan *Coscoroba coscoroba*, the South American sheld-geese *Chloephaga* spp. and the steamer ducks *Tachyeres* spp. (mostly salt water).

Subdivisions and Islands. Attempts to subdivide the Neotropical Region into subregions have been unsuccessful as far as the area south of Panama is concerned. The 'Guianan' and 'Brazilian' districts are occupied by some different species and genera, but the total character of the local faunas depends more on climate and vegetation than on historical features.

Central America, 'tropical North America' as Wallace quite rightly called it, contains a strongly mixed fauna—an old indigenous element and numerous post-Pliocene invaders from South America. The West Indies have an unbalanced and impoverished avifauna, indicating that they received their fauna by transoceanic dispersal; this is confirmed by studies of mammals, reptiles, fishes, and insects. Most of the avian immigrants came from tropical Central America, for a long period before and after the closing of the Panamanian gap. Typical for the West Indies are certain thrushes, mocking-thrushes (Mimidae), vireos, wood warblers, tanagers, finches (Fringillidae), icterids, and the peculiar Palmchat *Dulus dominicus* (related to *Bombycilla*), some tyrant flycatchers, the endemic family Todidae, some trogons, some hummingbirds (including the smallest bird in the world), some parrots, pigeons, and some hawks, to mention the more important. Other islands, such as the Galapagos, the Falklands, and the Juan Fernandez group, received most of their fauna from the adjacent parts of South America. E.M.

NEOTYPE: see TYPE SPECIMEN.

NEPHRON: an excretory unit of the kidney (see EXCRETORY SYSTEM).

NERVOUS SYSTEM: in birds, built on the same plan as in vertebrates generally; it resembles that of reptiles, especially the Crocodilia and certain lizards, very closely. The difference from reptiles is chiefly one of relative size; in a bird the brain is 10 or more times larger than the brain of a reptile of similar body weight. See also DEVELOPMENT, EMBRYONIC; GROWTH.

Central and peripheral systems. The nervous system consists of a central nervous system (C.N.S., the brain and spinal cord) and a peripheral nervous system (the cranial and spinal nerves, and the visceral or autonomic nerves and ganglia). The peripheral nerves are made up of nerve fibres that can be divided into two main categories; those that conduct impulses from the special sense organs such as eyes or from the skin and deeper tissues to the C.N.S. (afferent or sensory fibres); and others that conduct impulses from the C.N.S. to the muscles, causing them to contract and produce movements (efferent or motor fibres)—see also MUSCULATURE. Viscera such as the heart, blood-vessels, glands, and the alimentary canal are supplied by efferent nerve fibres that are classed as autonomic or visceral and are further subdivided into sympathetic and parasympathetic. Viscera usually have a double nerve supply, sympathetic and parasympathetic; these are in general functionally antagonistic—for example, parasympathetic stimulation slows the rate of the heart beat, whereas sympathetic causes acceleration. Viscera are also supplied by many afferent fibres.

Functions. It is the general function of the C.N.S. to integrate the information reaching it in the form of afferent or sensory impulses from all parts of the body and from the outside world, into patterns significant in the life of the animal. It must also be capable of storing this information selectively, so that it can form the basis of memory and learning; but the physical form in which information is stored in the C.N.S. is not known. The C.N.S. must also have motor functions; on the basis of the information reaching it at any particular time, combined with what has been stored from previous experiences, it must integrate or co-ordinate outgoing efferent impulses to the muscles and viscera so that useful movements and patterns of behaviour result.

To a large extent the particular kind of behaviour that can be integrated by the nervous system depends on its intrinsic structure, its 'built-in' characteristics (which are inherited). Such behaviour is activated automatically in response to appropriate sensory stimuli and is called reflex or instinctive. The extent to which it can be modified or added to as a result of experience varies in different vertebrates (see LEARNING). In birds it is limited, and much avian behaviour consists of complex but relatively stereotyped patterns, as is well seen in the reproductive cycle (mating, nest building, and so on). Patterns of behaviour depending on inherited structure are not so conspicuous in mammals, where the nervous system is less rigidly organized and shows greater plasticity in its functions: behaviour in consequence depends to a larger extent on learning and the storage of information. However, the learning ability of birds is certainly superior to that of many mammals: pigeons, for example, in some circumstances perform rather better than domestic cats. These differences between birds and mammals are reflected in fundamental differences in the structure of the nervous system, particularly in the part called the fore-brain (see below).

The functions of the nervous system in co-ordinating and activating patterns of behaviour can also be strongly influenced by chemical substances, hormones, circulating in the blood. These are produced by the endocrine glands (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM), some of which (the pituitary and the suprarenal glands) are closely associated anatomically with the nervous system. The effect is well illustrated in sexual behaviour. When, as in the male animal, male sex hormones are predominant, the behaviour integrated by the nervous system will be that appropriate for the male; experimentally the same nervous system can be shown to be capable of integrating female sexual behaviour under the influence of female sex hormones. Although such effects can be demonstrated in mammals, they are particularly characteristic of birds, where 'built-in' mechanisms form a more important part of the nervous system.

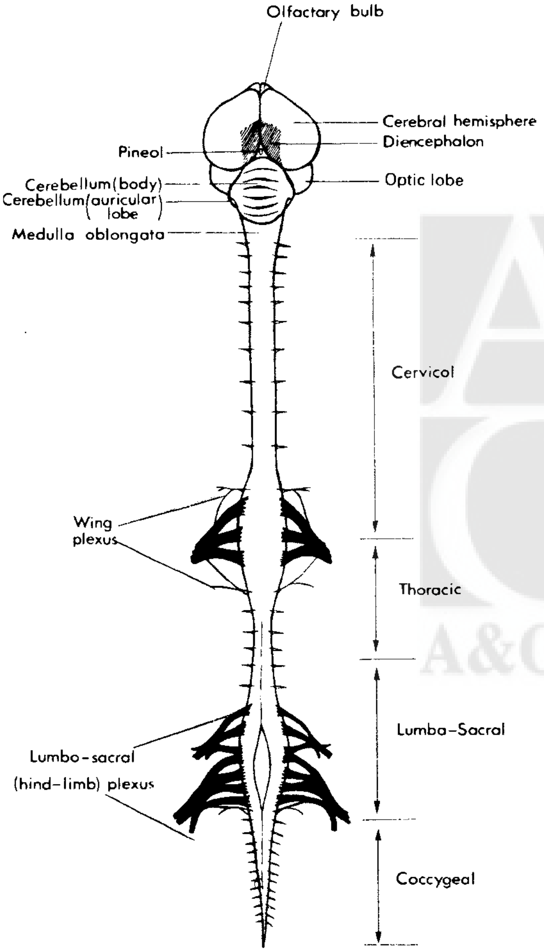

Fig. 1. Diagram of the nervous system of a bird (*Columba*). (Modified from Kappers, Huber & Crosby 1936).

Spinal cord. The spinal cord (Fig. 1) is co-extensive with the vertebral column, as in most other vertebrates except mammals, and contains a narrow channel throughout its length known as the 'central canal'. The cervical and lumbo-sacral regions are long, the thoracic and coccygeal relatively short; there are well marked cervico-thoracic and lumbo-sacral enlargements where the nerves to the wings and legs arise. A feature peculiar to birds is the 'rhomboid sinus'; this is a mass of gelatinous tissue, rich in lipids and glycogen, which separates the dorsal parts of the lumbo-sacral region of the spinal cord (Fig. 2); its significance is unknown. In the same region collections of nerve cells situated superficially on the lateral aspects of the cord form the 'nuclei of Hoffmann'. Somewhat similar but less conspicuous marginal nuclei are present in reptiles. The spinal cord is connected by well developed ascending and descending tracts with the medulla oblongata (see below) and the cerebellum; the latter is largely concerned with the maintenance of equilibrium, a particularly important function during flight. Other connections with the brain are much less well developed, and the spinal cord possesses considerable autonomy. It is able to co-ordinate the movements of the wings in flight, or the legs in running, with little assistance from the brain; it is well known that movements of this kind are often carried out actively for a short time after decapitation.

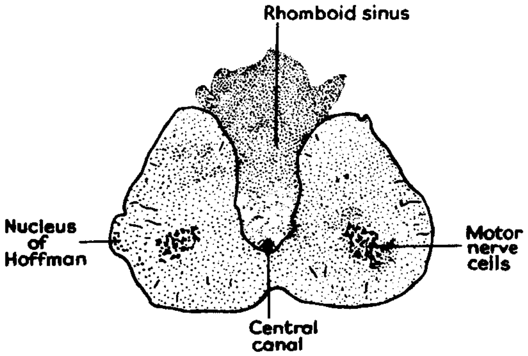

Fig. 2. Transverse section through lumbo-sacral region of the spinal cord of a pigeon *Columba* to show the rhomboid sinus. (Modified from Kappers, Huber & Crosby 1936).

Brain stem. As the spinal cord enters the skull it enlarges to form the medulla oblongata, from which most of the cranial nerves arise (Figs. 1, 3, and 4). In the same region the central canal enlarges to form a cavity called the 4th ventricle. The parts of the brain stem surrounding this ventricle belong to a subdivision of the vertebrate nervous system known as the hind-brain; it includes the pons in mammals (small in birds) and the cerebellum (see below) as well as the medulla oblongata. Except in detail the medulla oblongata of birds does not differ markedly from the usual vertebrate pattern. Its expanded cranial end is continuous with the next part of the brain stem, the mid-brain, which is characteristically specialized. It possesses two more or less spherical swellings, the optic lobes, which develop on its dorsal aspect and remain in that situation in all other vertebrates; in birds they are displaced laterally and ventrally by the backward enlargement of the cerebral hemispheres (Figs. 1, 3, and 4).

Cerebellum. The cerebellum (Figs. 1 and 3) is large, and situated on the dorsal aspect of the hindbrain. The main part, the corpus or body, is somewhat compressed from side to side and elongated cranio-caudally; it corresponds with the vermis in mammals and there is only rudimentary representation of the lateral extensions that form the mammalian cerebellar hemispheres. The body is divided by transverse furrows into anterior, middle, and posterior lobes, corresponding closely with the same subdivisions in mammals. These lobes are further divided by secondary furrows into folia; the most caudal of these is the nodule, and, strictly speaking, should not be included in the body of the cerebellum. On each side the nodule gives rise to a lateral extension which varies in size in different birds. This is the auricular lobe (Fig. 3), corresponding to the

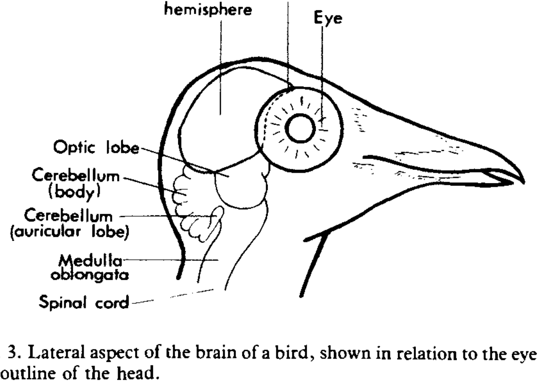

Fig. 3. Lateral aspect of the brain of a bird, shown in relation to the eye and the outline of the head.

flocculus of mammals. The whole complex (the nodule with its lateral extension) is called the auriculo-nodular lobe, corresponding to the mammalian flocculo-nodular lobe, and is a primitive part of the cerebellum that receives many connections from the vestibular division of the 8th cranial nerve.

Functionally the cerebellum is essential for the maintenance of posture and equilibrium and for regulating the range and force of movements. It may be thought of as acting like an 'automatic pilot', maintaining stability and direction during flight, and it is noteworthy that the tracts connecting it with the centres in the spinal cord through which bodily movements are controlled are well developed in birds. The absence of cerebellar hemispheres is also understandable; they are a characteristic feature of the mammalian brain, where they are concerned in the regulation of learnt skilled movements, particularly of the limbs, and movements of this kind play little part in the behaviour of birds.

Fore-brain. The cranial end of the brain stem, the mid-brain, is continuous with a complex mass of nervous tissue, the fore-brain. This consists of a median part, the diencephalon, directly continuous with the mid-brain, and bilateral expansions forming the cerebral hemispheres (Fig. 1). The whole forebrain is hollow, the median cavity of the diencephalon being called the 3rd ventricle. It is continuous caudally through the mid-brain and the 4th ventricle of the hind-brain with the central canal of the spinal cord. On each side the cavity of the 3rd ventricle extends into the cerebral hemisphere to form small lateral ventricles (Fig. 4).

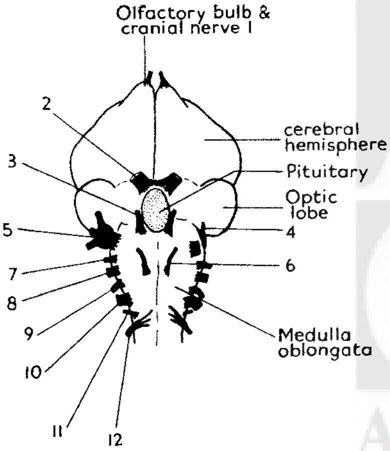

Fig. 4. Ventral aspect of the brain of a pigeon, to show the roots of the cranial nerves.

The median diencephalic part of the fore-brain is concealed from view by the cerebral hemispheres (Fig. 1). On each side it contains complex masses of nerve cells, the thalami, which are similar in their organization to the same parts in reptiles. Ventral to the thalami and forming the floor of the 3rd ventricle is the hypothalamus, another complex of nuclei, connected by a thin stalk to the pituitary gland (Fig. 4). On the dorsal aspect of the diencephalon the pineal apparatus is found; it is vestigial, and no parietal eye is present as in some reptiles.

The cerebral hemispheres are rounded and smooth, lacking the convolutions characteristic of the mammalian brain. The olfactory bulbs (Figs. 1 and 4) attached to the anterior poles of the hemispheres are generally small and sometimes fused together. The olfactory sense is correspondingly poorly developed, so that most birds are classed as microsmatic; most vertebrates have a well developed sense of smell and are classed as macrosmatic. In a number of avian species, however, e.g. ducks, the domestic fowl, and most markedly the kiwis *Apteryx* spp., the bulbs are quite well developed; but, with the possible exception of the kiwis, it is doubtful if any birds could be described as macrosmatic (see SMELL).

In all vertebrates the cerebral hemispheres are divided into dorsal and ventral parts forming the roof and floor respectively of the lateral ventricles. In the dorsal part the extensive superficial cortex so characteristic of mammals is formed; the ventral part forms the basal ganglia of the hemisphere.

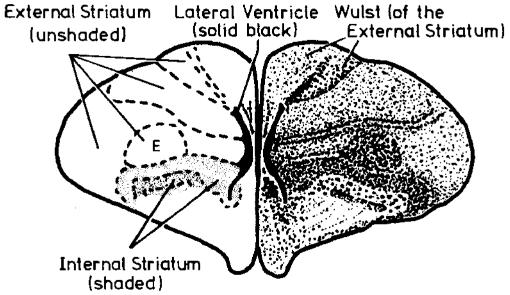

Fig. 5. A section through the cerebral hemispheres of a pigeon. On the left, the subdivision of the basal ganglia into internal and external striatal segments is indicated. On both sides, the complicated subdivision of the external striatum is easily seen. 'E' is the ectostriatum.

In birds the most immediately striking features are the small and rudimentary character of the cortex proper, and the relatively enormous development and complex differentiation of the basal ganglia (Fig. 5). This appearance is, however, deceptive. The 'basal ganglia' of birds can in fact be divided into two parts, the internal striatum and the external striatum. The smaller of these, the internal striatum, corresponds to the corpus striatum of mammals and is concerned with the control of movement. The larger external striatum is more sensibly grouped with the rudimentary cortex, since, like the cerebral cortex of mammals, it receives sensory information (especially from the eyes, the ears and, to a lesser degree, that related to the sense of touch) relayed, just as in mammals, through the thalamus of the diencephalon. A part of the external striatum may correspond to the mammalian 'motor cortex', in as far as it sends nerve fibres directly to the spinal cord. It seems that during evolution birds, like reptiles, failed to find the mechanism for expanding these forebrain masses into a sheet-like cortex. This evolutionary failure perhaps accounts for the lesser evolutionary success of birds in the production of types capable of the very flexible and adaptable behaviour patterns characteristic of higher mammals. In one respect though, birds outdo mammals in this all-important area of plasticity: in song birds there are collections of neurons in the external striatum which control the production and pattern of song. These neurons are remarkable in that they change their structure with the seasons and circumstances, corresponding to the natural seasonal variation of song pattern in these species. There is no doubt that the large basal ganglia are functionally concerned with the integration of the instinctive behaviour of birds, and it is probable that the hyperstriatum is of particular importance in relation to the activities of the breeding cycle. These neural mechanisms are very sensitive to facilitation or inhibition by hormones.

The hypothalamus of the diencephalon is closely associated with the pituary gland. It is mainly concerned in the integration of visceral and metabolic activities and has been described as the head ganglion of the autonomic nervous system. In mammals its functions are not purely neural, and it can secrete hormones that pass down the stalk to the pituitary, so that it is very closely associated with the endocrine system; it probably has similar functions in birds. Centres for the regulation of the excretion or retention of water, for temperature regulation, for a general inhibition resulting in sleep, and a number of other functions have been identified in the hypothalamus, which is a very important part of all vertebrate brains.

Cranial nerves. The 12 pairs of cranial nerves (Fig. 4) characteristic of higher vertebrates are all present in birds. The 1st (olfactory) are slender (see above). The 2nd (optic) are particularly large and decussate completely in a chiasma or crossing. They discharge to the optic lobes of the mid-brain, which contain what is probably the most highly differentiated neural tissue in the avian nervous system. The size of the nerves and the complexity of the optic lobes is associated with the great importance and high degree of development of the visual sense in birds (see VISION).

The visual system is organized in the same way as that of all vertebrates: the optic nerves discharge directly to both the optic lobes of the midbrain and to the thalami of the fore-brain. The optic lobes also send information to the thalami, and from this structure all the visual information passes to the cerebrum. In mammals, the connection from the eyes to the midbrain is relatively smaller than that made directly with the thalami: the ultimate target for the information is the cerebral cortex.

In birds, although the main visual centres are undoubtedly in the midbrain (the optic lobes send fibres to the brain stem and so are able to control many motor responses to visual information in a reflex way), optic nerve fibres certainly do run directly to the thalami. There is evidence that the appreciation of the nature of seen objects requires the cooperation of those parts of the avian external striatum (the Wulst or hyperstriatum, and the ectostriatum—E in Fig. 5) which are the destination of visual informmation from the thalami. The 3rd (oculomotor), 4th (trochlear), and 6th (abducens) nerves are all purely efferent and supply the ocular muscles as in vertebrates generally. The 12th (hypoglossal) is also efferent and supplies the tongue muscles; it gives a branch to the muscles of the syrinx, which are therefore not comparable with laryngeal muscles (supplied by the vagus)—see SYRINX. The 5th (trigeminal), 7th (facial), 9th (glossopharyngeal), 10th (vagus), and 11th (accessory) form the usual series of branchial or visceral arch nerves. They contain, of course, no component from lateral line organs as in aquatic vertebrates, and only a few special avian features need be mentioned. The 5th nerve is well developed and supplies complex sensory corpuscles, such as those of Grandry and Herbst, which are often associated with the bill; while usually considered to be tactile, their function is not fully understood (see TOUCH). Fibres serving the sensation of taste are present in the 7th and possibly in the 9th nerves, but are very few in number on account of the poor development of this particular sense in birds (see TASTE). The 11th nerve (accessory) is small and constitutes one of the caudal roots of the vagus; there is no spinal component as in mammals. There remains only the 8th nerve, which has both auditory and vestibular divisions with connections in the brain stem resembling those of mammals rather closely. The auditory division (from the lagena) is comparatively small, but the vestibular is well developed, as would be expected in animals where the maintenance of equilibrium is a particularly important function (see HEARING AND BALANCE).

Spinal and autonomic (sympathetic and parasympathetic) nerves. These are arranged on the same general plan as in mammals and reptiles, but there are many detailed differences related to the different proportions of the parts and organs of the body.

The roots of the spinal nerves are shown attached in series to the spinal cord in Fig. 1. They are enlarged opposite the wing and the hind limb, where they form the brachial (wing) plexus and the lumbo-sacral plexus respectively, as in all tetrapoda. Autonomic nerves are not shown: they arise from ganglia (collections of nerve cells), outside the C.N.S., that are classified in two categories, sympathetic and parasympathetic (see above). The former are arranged in two regular chains, approximately one pair of ganglia for each segment of the body, on each side of the vertebral column; the latter are more irregularly scattered, usually close to the viscera they supply. Both sympathetic and parasympathetic ganglia are connected to the C.N.S. through spinal or cranial nerves, so that their activity is centrally regulated and integrated.

Differences among Birds. There are great variations among birds in the size of the brain and in the proportions between its parts. In general the gallinaceous birds show primitive characteristics, with relatively small cerebral hemispheres and well developed olfactory bulbs, and the same may be said of pigeons and plovers. Crows, owls, and parrots are at the opposite extreme, with particularly large cerebral hemispheres. (In all birds the cerebral hemispheres comprise a relatively larger part of the brain than in reptiles. Indeed, in this feature birds vie with many mammals.) The 'ratite' birds tend to have relatively large olfactory bulbs, and among them the kiwis have already been mentioned as possibly macrosmatic; these birds also have the large cerebellum typical of birds generally, suggesting that they are descended from ancestors able to fly (see EARLY EVOLUTION OF BIRDS). In the fossil *Archaeopteryx*, the earliest known bird, the endocranial cast indicates that the brain was essentially reptilian in form; the cerebral hemispheres were elongated, possibly with long olfactory peduncles as in a typical lacertilian brain, and there is no evidence of enlargement of the cerebellum or of ventral displacement of the optic lobes (see ARCHAEOPTERYX). The evidence from endocranial casts of fossil forms is always to be accepted with caution, since it cannot be known with certainty how completely the cranial cavity was filled by the brain. In modern birds (unlike reptiles) the cranium does in fact fit closely around the brain, so that a cast gives an accurate representation of its form and proportions. It is of interest that in the fossil flying reptiles (Pterosauria) there seems to have been a similar close relationship between the cranium and the brain, which is shown by endocranial casts to resemble that of modern birds closely, perhaps more closely than is the case with *Archaeopteryx*.

Some small birds, notably the hummingbirds, have a particularly large brain/body weight ratio. In spite of this, the cerebral hemispheres are very primitive and reptile-like, so that their claim to be neurologically advanced depends chiefly on the cerebellum and mid-brain. Most of the differences between the brains of different birds can be related to differences in their mode of life; they do not seem to have much systematic relationship to taxonomic subdivisions, since quite large differences may be found between birds not widely separated in taxonomy. NEST: popularly the word 'nest' implies a structure, made by a bird, in which eggs are laid and incubated; it is perhaps usually thought of as shaped like an open bowl; to ornithologists this meaning is inadequate. Many birds make no nest; others excavate or use holes without nest material; still others make structures but do not incubate the eggs. Further, though eggs are normally incubated in one spot till they hatch, the Black Vulture *Coragyps atratus* of the New World may move its eggs for appreciable distances during incubation, as may some nightjars. Thus, a comprehensive definition of 'nest' would be: a structure built or excavated by a bird or already in existence, or a spot or area, in which eggs are laid and remain till they hatch (after incubation by the species concerned or by some other means). The only exceptions are brood-parasites, such as Old World cuckoos (Cuculidae), cowbirds (Icteridae) of the New World and some others that make no nests of their own (see BROOD-PARASITISM), and some penguins, e.g. Emperor *Aptenodytes forsteri* and King *A. patagonicus*, that incubate the single egg between belly and tarsi or feet and may move about with it thus held, so having nothing that can be called a nest. (See also NEST BUILDING; NEST FUNCTION; NESTING ASSOCIATIONS.)

Nests are often specifically distinct in materials or site or both. For instance, the tyrant-flycatcher *Tachuris rubrigastra* of Argentina makes a beautifully felted cup of yellow plant-down attached to a single reed; the Paradise Riflebird *Ptiloris paradiseus* of Australia often decorates its nest with a discarded snake-skin; and the Crested Bellbird *Oreoica gutturalis*, also of Australia, customarily puts hairy caterpillars on the rim of, or inside, its nest. Moreover, closely related species tend to make similar nests and place them in similar sites, so that the nest has some practical value for taxonomy; thus woodpeckers excavate holes in trees and make no nest inside, the anis *Crotophaga* spp. line their untidy nests with fresh green leaves and buzzards *Buteo* spp. and other raptors decorate theirs throughout occupation with some fresh material. However, though auks mostly nest on ledges or in crevices on cliffs near the sea, the Marbled Murrelet *Brachyramphus marmoratus* has recently been found to nest high in branches of tall conifers and Kittlitz's Murrelet *B. brevirostris* lays its egg on bare ground above the tree-line and far from the sea. Similar remarkable exceptions occur among parrots, which can be said to nest generally in holes of one sort or another; several pairs of Monk Parakeets *Myiopsitta monachus* build their nests of thorny twigs together at the ends of branches, finally forming large structures made up of separate nests, and the Australian Ground Parrots *Pezoporus wallicus* and Night Parrots *Geopsittacus occidentalis* construct nests of grasses in or under tussocks.

The greatest complexity and variation of construction occur among passerine birds. Non-passerines mostly build simple structures of sticks, reeds, etc., place their eggs on the ground or make holes for themselves, without adding material. In contrast, passerines that nest on the ground or in holes make more or less substantial nests. The earliest birds probably had the simplest nest-making habits, placing their eggs on the ground or in cavities without any material; later birds came to build simple structures or excavate holes. Presumably ground- and hole-nesting passerines adopted these habits secondarily.

Non-passerine birds. Though non-passerines mostly have rather crude nests, there are interesting contrasts and exceptions. Some hummingbirds build the smallest known nests, 2 cm across and 2–3 cm tall, whereas a long-established nest of the Osprey *Pandion haliaetus* or White-bellied Sea-Eagle *Haliaeetus leucogaster* may be a metre or more across and 2m tall. Also, the perfectly felted cups of plant-down and cobweb made by hummingbirds contrast extremely with the imperfect platforms of sticks made by some pigeons, though the frail nests of some doves (*Columbina* spp.) become consolidated and built up by the excreta of the young to form substantial structures.

Incubation mounds. The Australasian MEGAPODES have the remarkable habit of 'artificial' incubation. They make big mounds of sand, earth and leaves, in which the eggs are hatched by the heat of decaying vegetable matter, or lay the eggs in sand and crevices where they are incubated by the heat from the sun or from volcanic emanations. The Malleefowl *Leipoa ocellata*, and perhaps other species, carefully control the temperature in the mound during incubation.

Use of saliva. Swifts are interesting because many species use saliva for building and stick their nests in the shape of half cups on the sides of caves, in hollow trees or elsewhere. The Palm Swift *Cypsiurus parvus* of Africa sticks its nest to the underside of palm leaves. In the Far East species of *Aerodramus* nest in huge numbers in caves and provide edible nests, being the only birds of economic importance in this respect (see EDIBLE NESTS). The Cayenne Swift *Panyptila cayennensis* makes a remarkable cylinder, about 70 cm long, open at the bottom, of plant material and feathers felted together with saliva, the outside being left rough and plastering being done only from inside; about half-way up inside, a small shelf is made, where the eggs are laid; thus, like most other swifts, the bird nests in a hole, but it constructs its own hole.

Though swifts are well-known users of saliva in building, they are probably not the only group of birds to do so. The Australian scrub-birds *Atrichornis* spp. line their nests with masticated wet plant material, which dries out into a cardboard-like substance and in which saliva may play a part. Some cuckoo-shrikes (Campephagidae) probably use saliva to bind together plant material for nests or to make the nests adhere better to airy forks of branches where they are placed but this needs confirmation.

Aquatic nests. Grebes make pads of vegetation floating on water but attached to a plant; jacanas often make nests of rushes on the floating leaves of water-lilies or lotus; some rails and *Chlidonias* terns make simple nests of reeds and water-plants over water but usually in less open situations and not truly floating.

Ground-nesting. Other non-passerines may be roughly divided into ground-nesters, hole-nesters and builders of simple nests in trees. Simple ground-nesting without any material is characteristic of the Ostrich *Struthio camelus* (though other ratites may assemble some material in their nests), sand-plovers *Charadrius* spp., thickknees, sandgrouse and nightjars. Interestingly, the Egyptian Plover *Pluvianus aegyptius* (Glareolidae), the Kentish Plover *Charadrius alexandrinus* and at least some other species of *Charadrius* in Australasia bury their eggs in sand, though it is not entirely certain whether all do so by design rather than by accident, and cover them with sand when leaving the nest. Apart from auks (see above), most other Charadriiformes make some nest of plant material on the ground, often substantial as in the Black-winged Stilt *Himantopus himantopus*, and many gulls; yet the Green Sandpiper *Tringa ochropus* habitually uses the old nests of other species in trees. Albatrosses (Diomedeidae) build big mounds of soil and vegetation, and flamingos, mounds of mud. Other ground-nesters are some penguins (e.g. Adélie *Pygoscelis adeliae* and Chinstrap *P. antarctica*), making a scrape lined with pebbles; most ducks and geese (Anatidae), which are unique in using their own down as lining (though it is curious that lyrebirds *Menura* spp. add their own body-feathers to the lining of their nests during incubation); pheasants and their allies (Galliformes), which usually line their scrapes with leaves and grass; buttonquail, which make a partly domed nest of grasses; and cranes and rails (Gruiformes), which make substantial structures of plant material.

Hole-nesting. Non-passerines nesting in holes in the ground include shearwaters (Procellariidae), storm-petrels (Hydrobatidae), some kingfishers, motmots and bee-eaters, the last 3 making their own holes (often of considerable length) in banks or on flat ground, whereas the others are less liable to dig their own burrows. Groups that generally use existing holes in cliffs, trees or buildings are parrots, owls, trogons, rollers and hoopoes. Hornbills also do so, with the interesting modification that the entrance is usually restricted with plaster of some sort, the female helping to immure herself. Woodpeckers and barbers mostly make their own holes in trees but some do so in ants' or termites' nests and one woodpecker lays on the ground.

Simple structures. Pelecaniformes (cormorants, pelicans, frigatebirds), Ciconiiformes (herons, storks), birds of prey, Cuculiformes (cuckoos, turacos) and pigeons mostly make simple, if large, nests in trees but many, especially among birds of prey, use the old nests of other species, or nest on ledges or even on the ground. Among the Ciconiiformes, the Hamerkop *Scopus umbretta* of Africa is remarkable for making a big dome of sticks cemented with mud about a metre high and with the entrance at the side.

Passeriformes. In spite of great variety of form and building skill, most passerines make simple cup-shaped nests. The range of size and materials may be represented by crows *Corvus* spp. with big nests of sticks lined with finer plant material and wool, and by many small birds (e.g. fantails Rhipiduridae) with small neat cups of the finest plant material and cobweb. Nevertheless, small birds may make huge nests, the Firewood Gatherer *Anumbius annumbi* (Furnariidae) of Argentina being the classic example; it makes a nest about 70 cm deep and 30 cm across of big sticks with the entrance at the top and a crooked passage leading down to the nest cavity. On the other hand, some species make such flimsy nests that the contents are visible from below, e.g. the Ecuadorian Finch *Sporophila peruviana*, the Rufous Whistler *Pachycephala rufiventris* of Australia and even some honeyeaters (Meliphagidae). Most simple nests are supported in forks or on branches but open cups may be slung by the rims from supporting twigs, often at the inaccessible ends of branches; this habit seems more prevalent in the tropics and Australasia than in the Northern Hemisphere and is characteristic of some antbirds (Formicariidae), vireos (Vireonidae), crombecs (*Sylvietta* spp.) of Africa, orioles (Oriolidae) and many honeyeaters. Reed warblers *Acrocephalus* spp. customarily bind their nests to two or three upright supports.

Enclosed nests. Spherical nests of various sorts are common. Domed nests built of interlaced plant material with a large side entrance are characteristic of such low-nesting birds as warblers of the genus *Phylloscopus* (Sylviinae), pittas, lyrebirds, acanthizids of the genus *Sericornis*, fairy-wrens (Maluridae) and even some icterids, e.g. the Long-tailed Meadowlark *Sturnella loyca*. Others are neater, more felted structures of fine plant material and moss with small entrances at the side, as in some wrens (Troglodytidae), tyrant-flycatchers (*Camptostoma* spp.), becards (Tyrannidae), though these typically make flat tops to their nests, and acanthizids of the genera *Acanthiza* and *Gerygone*. The Yellow-rumped Thornbill *Acanthiza chrysorrhoa* has the extraordinary and unexplained habit of building an ordinary cup-shaped structure on top of, or near, its rather bulky and untidy domed nest, the entrance of which may be hard to find. Some warblers of the genus *Cisticola* achieve a similar result by binding in growing grass as a partial dome. Perfect ovoid nests with a small side entrance towards the top are built of moss and lichen by the Long-tailed Tit *Aegithalos caudatus* and even more perfect nests, felted out of fine plant down to the texture of surgical lint, are made by penduline tits *Anthoscopus* spp. of Africa and the Mistletoebird *Dicaeum hirundinaceum* of Australia. Untidy pendent structures, up to a metre or more long and often with a beard of material hanging down from the bottom and a projecting porch over the entrance, are made by some sunbirds. The African broadbills *Smithornis* spp. also make nests with a beard and the Common Tody-flycatcher *Todirostrum cinereum* constructs a long streamer of hanging material, in the centre of which it later works an aperture for the nest cavity. Ovoid, retort-shaped or bottle-shaped nests, occasionally on the ground, are made by estrildid finches of interlaced grasses, and individuals of some species (*Estrilda melpoda*, *E. troglodytes*, *E. atricapilla*) attach a semi-covered upper story or extension, apparently used for roosting. More striking are the large retort-shaped nests of spinetails *Synallaxis* spp. (Furnariidae), which make big spheres of thorny twigs measuring about 45 by 30 cm, enclosing a large nest chamber, with a long winding narrow tunnel as an entrance. Tailorbirds (*Orthotomus* spp., Sylviinae) in Asia and allied forms in Africa bind leaves together with cobweb or other material and build a nest in the pocket so formed.

Woven nests. Weavers (Ploceidae) of the Old World make various sorts of woven nests, from the globular structure of Village Weavers *Ploceus cucullatus*, which weave it rather carelessly out of strips of palm leaves, making an entrance near the top covered with a small porch, to the inverted sock of some species of *Malimbus*, neatly made from the fibres of palms with a tubular hanging entrance as much as 70 cm long and 10 cm wide. The culmination of this habit is shown by the Social Weaver *Philetairus socius* (Ploceipasserinae) of South-West Africa, which first constructs a roof of coarse straws in a large tree or on a telephone pole and then makes many nest chambers below, the whole forming a single huge mass. In contrast, the Icteridae (oropendolas, caciques and New World orioles) weave pendent bags with an entrance through a slit at or near the top. These bags may be a metre or so long in larger species and, because the birds usually nest colonially, a nesting tree may seem to be laden with monstrous fruit; however, some icterids (e.g. *Icterus mesomelas* and *I. graceannae*) make small, more conventional woven cups, pendent from their rims.

Mud nests. Perhaps the most remarkable mud-nest among passerine birds is that of the ovenbird *Furnarius leucopus* of South America, which makes a thick-walled domed structure on branches with an entrance at the side leading by a corridor into the nest chamber. The rock-fowl *Picathartes* spp. of West Africa make mud structures plastered on rockfaces. Simple, though large and heavy, mud cups are made by the White-winged Chough *Corcorax melanorhamphos* and Apostle-bird *Struthidea cinerea* (Corcoracidae) and magpie-larks (Grallinidae) of Australasia. Some thrushes (e.g. Song Thrush *Turdus philomelos* and Blackbird *T. merula*) and some corvids (e.g. Magpie *Pica pica*) use mud as a lining or foundation in more conventional nests as do phoebes *Sayornis*. Many swallows also use mud either for simple half-cups plastered to some support or for more complex flask-shaped nests.

Hole- and ground-nesting. The passerines with these nesting habits need no special mention, because the peculiarities of their nests are more often those of site rather than structure. However, it is interesting that pardalotes (Dicaeidae) make domed nests within the cavities where they nest. Also nuthatches *Sitta* spp. tend to restrict the entrance to their nests with mud. The Sand Martin (or Bank Swallow) *Riparia riparia* is notable for burrowing tunnels up to a metre in length. S.M.

NESTBOX: see NEST SITES, MAN-MADE.

NEST BUILDING: behaviour concerned with the excavation or construction of nests. Most species of birds lay their eggs in a previously constructed nest, which may be anything from a mere scrape in the ground to a highly elaborate structure, the building of which involves complex patterns of behaviour and the use of many different materials (see NEST). Construction is usually by the female, but the male often helps and in some polygamous species he may do nearly all the work (see POLYGYNY).

Nest building may involve the selection of a site (see NEST SITE SELECTION), its preparation, the collection of material, the carrying of that material to the site, and the actual construction of the nest. Preparation of the site is usually unnecessary in species which build open cup-nests, but in hole-nesters it may involve excavation or the cleaning out of a pre-existing cavity. Many ground-nesting birds first make a depression in the earth or sand.

In most simple nests, and in some complex ones, only one type of material is employed; but usually there are a number, some being used for the outside and some for the lining. Thus the Long-tailed Tit *Aegithalos caudatus* uses mainly moss, spiders' silk, lichen, and feathers. If more than one type of material is used, which type is brought to the nest may be dictated either by the internal state of the female or by stimuli from the partially completed nest. In domesticated Canaries *Serinus canaria* the change-over from collecting grass for the cup to feathers for the lining depends in part on stimuli from the partially constructed nest, and in part on an internal, possibly hormonal, change in the female (Hinde 1958). A variety of relatively stereotyped patterns of behaviour may be used in collecting the material and preparing it for use. Thus weavers (Ploceidae) tear up grass leaves longitudinally (Crook 1960) and Canaries sometimes mandibulate material in water. Nest building by the Wren *Troglodytes troglodytes* is stimulated by rain, the function of this apparently lying in the increased flexibility of the material (Armstrong 1955).

The material is usually carried in the bill; in some cases special movements make it more easily transportable (e.g. *Parus* spp.). Some love-birds *Agapornis* spp. carry material in the rump feathers (Moreau 1948).

Nest construction involves the integration of a number of stereotyped movements characteristic of the species. Closely similar movements are often characteristic of a wide range of related species. Amongst passerines, common movements are 'pulling and weaving', in which loose strands projecting from the rim arc pulled towards the breast and pushed down into the cup; 'scrabbling', in which the female presses down into the cup and pushes back hard with each leg alternately; and 'turning', in which she turns round while sitting in the nest and thus shapes the cup. Sometimes quite complex movement patterns appear; thus some weavers knot strands round twigs with half-hitches.

Redpoll *Carduelis flammea* collecting thistledown as nest material. (*Photo: K.J. Carlson*).

The appearance of each activity involved in nest building depends both on a certain internal state and on external stimuli. Thus all the nest-building activities of Canaries are increased by injections of oestrogen: the behavioural effectiveness of oestrogen is augmented by longer daylengths and by male song (Hinde and Steel 1966, 1978). In addition each nest-building activity is elicited by a particular stimulus situation (e.g. collecting by stimuli from the material, scrabbling by stimuli from the nest cup).

For the construction of a nest, these various patterns of behaviour may be integrated into functional sequences. The principal processes involved are:

(i) The various behaviour patterns of nest building share common causal factors, e.g. certain hormonal states.

(ii) Nevertheless, the various activities may appear at different threshold levels of these factors: thus as a female passerine comes into reproductive condition, she first shows gathering, then carrying, and then the stereotyped movements of nest construction.

(iii) Often each activity brings the bird into the stimulus situation where the next one is evoked; thus, gathering leads to carrying, carrying to placing material in the nest, and so on.

(iv) The performance of each activity is associated with a decreased tendency to continue or repeat that activity; thus the change-over from gathering to carrying, or from sitting building in the nest-cup to gathering again, depends not only on the stimuli presented as a consequence of the first activity, but also on a decreased internal tendency to continue it.

(v) Stimuli from the partially constructed nest may influence subsequent behaviour; thus a decrease in the size of the nest-cup may cause Canaries to bring a high proportion of lining material, and to bring material less often. In this way stimuli from the near-completed nest are instrumental in causing building to cease.

(vi) Although, in all species so far studied, the various constituent activities appear in individuals reared away from their parents and even away from the species-characteristic nest, learning may play an important role in nest construction. Thus the location of suitable sources of material must be learnt: Canaries kept without material learn to pull out their own feathers.

(vii) W.H. Thorpe has suggested that learning plays an essential role in the fine integration of the activities of nest building. Thus he suggests that, while building, the bird is responsive to stimuli similar to those

Crombec *Sylvietta brachyura* building nest. (*Photo: K. Carlson*).

which would be provided by a perfect nest; actions which make the existing structure approximate more closely to a finished nest are reinforced and thus repeated.

Existing evidence shows (*a*) that the performance of the constituent activities of nest building has some reinforcing value (e.g. the Canaries deprived of material, cited above, whose abnormal behaviour involved the movements of nest building but never led to the construction of a nest); (*b*) since the abnormal patterns seen in Canaries deprived of material do not appear in undeprived birds, it seems that the construction of the species-characteristic nest is learnt in preference to the mere performance of constituent activities which do not lead to a completed nest; (*c*) stimuli characteristic of the finished nest produce a decrease in building behaviour. All these points are in harmony with Thorpe's view, but experimental evidence in support of it is still lacking.

The hormonal basis of nest building probably differs between species. Oestrogens are primarily responsible in Canaries, but in some species androgens may be important (Noble and Wurm 1940). The behavioural effectiveness of a given hormone level may vary with external factors (Hinde and Steel). In many species there is a close link between nest building and courtship, and the peaks of nest building and copulation may coincide.

The nest is of obvious functional significance: the differences even between the nests of closely related species may be adaptive. Thus the nest form amongst West African weavers is more closely related to habitat than to systematic relationships, and each nest type has special protective functions in its environment (Crook). Some species decorate their nests; thus tits place fragments of torn leaves round the nest cup, and Starlings *Sturnus vulgaris* gather flowers; the significance of this is not understood.

Little is known of the evolution of nest building. It has been suggested that some of the shaping movements are derived from copulatory movements, and the collection of material from aggressive movements redirected on to grass stems, but there is no evidence to support these views. See also BEHAVIOUR, DEVELOPMENT OF. See photo ECTOPARASITE.

NEST, COCK: term sometimes applied (also 'cock's nest') to extra nests or nest-like structures, not used for laying eggs, although the birds may roost in them. The male Wren *Troglodytes troglodytes* is well known to build as many as 8 of these unlined but otherwise substantial nests in a season. The female may choose one or more for lining and laying eggs in, sometimes in a subsequent year.

NEST FUNCTION: the common statement that a bird's nest is built to hold eggs does less than justice to its other functions. Among the thousands of species of birds there are many different types of nest: Collias (1964) and Goodfellow (1977) give good descriptive accounts of the range of nests built by birds. In the following discussion the word 'function' has been given a broader meaning than that adopted by some authorities, who would allow no functions for a bird's nest other than those of holding the eggs and chicks.

Protecting the eggs. Nests act to protect birds' eggs, both from environmental conditions and from predators. The temperature inside the nest of the Sociable Weaver *Philetairus socius* (see SPARROW-WEAVER AND SCALY-WEAVER) is as much as 23°C above the external temperature in winter in the Kalahari. Village Weavers *Ploceus cucullatus* spend less time incubating the eggs at high ambient temperatures than at low ones. Furthermore, the attentive periods of Village Weavers incubating in well-insulated nests are shorter than those of the same species incubating in less well-insulated nests. The Malleefowl *Leipoa ocellata* (see MEGAPODE) builds a nest that is also an incubator, a mound that not only passively protects the eggs from fluctuations in ambient temperatures, but one that is modified by the birds' behaviour to ensure that the two fluctuating heat sources, rotting vegetation and solar radiation, do not overheat the mound and that the heat lost to the environment does not cool it too much. The bird works daily to achieve a balance between these heating and cooling factors so that the temperature of that part of the mound where the eggs lie remains between 32° and 35°C throughout the 6 months when the eggs are in the nest.

Collias documents studies which indicate that some aspects of nesting behaviour and of the construction of birds' nests function to protect the nests, eggs and chicks from predation.

Stimulating the female. Experimental work has indicated an important stimulatory consequence of birds' nests, in addition to other, better documented, functions. Hinde (1967) and Hinde and Steel (1978) showed that, as the time of egg-laying approached in the domestic Canary *Serinus canaria*, the female's abdomen became increasingly sensitive to tactile stimuli (see NEST BUILDING). Further, they were able to show that ovulation could be induced by providing the birds with a nest of such shape that it fitted the female's body neatly and therefore stimulated her increasingly sensitive abdomen as much as possible. They concluded that the nest acted as an integrator of reproductive behaviour, especially as egg-laying approached, and that its structure was important in providing stimulation to the female which led to the secretion of secondary reproductive hormones, the development of the oviduct and ovulation itself.

Working in America with another species, the Ring (or Barbary) Dove *Streptopelia risoria*, Lehrman *et al* (1961) were able to show that egg-laying occurred faster in females given mates and nesting material than in those given mates but no nesting material. The significance of these experimental results may provide the key to understanding the bewildering variety of types of nests and at the same time offer an explanation of the frequency with which false nests are built before egg-laying, the considerable time spent by females of some species sitting in nests for some days before an egg is laid, the very small size of some nests compared with the size of the brood they eventually need to protect, and the structural differences between nests built before laying and those built or reconstructed at laying.

Hinde and Steel reported that male Canaries were less likely to sing when the female was engaged in nest-building than when she was not. Davies (1974) in a study of the Ring Dove concluded that much of the male's display and calling led to seating the female in a nest or potential nest site, and that once she was sitting on the nest, calling and display ceased. Unless it was crucial for the male to draw the female to the nest, it seems puzzling to risk directing the attention of predators to the nest even before the lengthy incubation period started. Davies suggested that the male had made a major contribution to the success of the breeding attempt if he got the female to sit in a nest, and thereby to receive tactile stimulation on her abdomen that would lead to rapid ovulation.

Skutch (1961) has reviewed the use made by birds of nests as roosting sites. He lists 79 species in which he found evidence of this behaviour, and it is now possible to add many more.

In Skutch's study of roosting, the nests of some species were specially built to serve as roosts and in others the birds used old breeding nests, but in some species the birds used the nest for roosting only during the period shortly before the eggs were laid in it, and then, especially those in which only the female roosted, the nest may have been acting to stimulate her to ovulate as well as acting as a roosting site.

Although this interpretation ought not to be generalized uncritically to apply to all species, nests have been reported to be regularly used as the focus of courtship by 43 species from 26 families, indicating that their nests may have an important function in the pre-egg-laying phase of the breeding cycle as well as in the protection of eggs and young. In a number of species one of the ritual displays given before egg-laying directs the attention of the female to a nest or potential nest site, and it is interesting to note that males of 349 species from 66 families have been observed to assist with nest-building, even if they take little other part in the parental care of their offspring.

The use of the nest in courtship and the male's assistance with nest-building are more conspicuous in some avian families than in others. In the Anhingidae, Ardeidae, Ciconiidae, Columbidae, Diomedeidae, Fregatidae, Pelecanidae, Procellariidae, Scolopacidae, Spheniscidae, Sulidae and Threskiornithidae the use of the nest as a focus of courtship is probably widespread, although it has been documented in only one or two species of each.

In most of these families, as well as the Accipitridae, Gaviidae and Picidae, the male is the principal nest-builder, especially in the early part of the breeding cycle. The use of the nest in courtship is probably less common in the passerines but is widespread in the Paridae, Ploceidae and Tyrannidae. On the other hand in 156 species from 24 families of passerines the male has been recorded assisting the nest-building, sometimes taking a major role, as in the Corvidae, Emberizidae, Icteridae, Parulidae, Troglodytidae and Tyrannidae, so that his interest in the nest during the courtship period is manifest. The involvement of the male in nest-building among the passerines has recently been reviewed by Verner and Wilson (1969) who conclude that males of most North American species assist with nest-building.

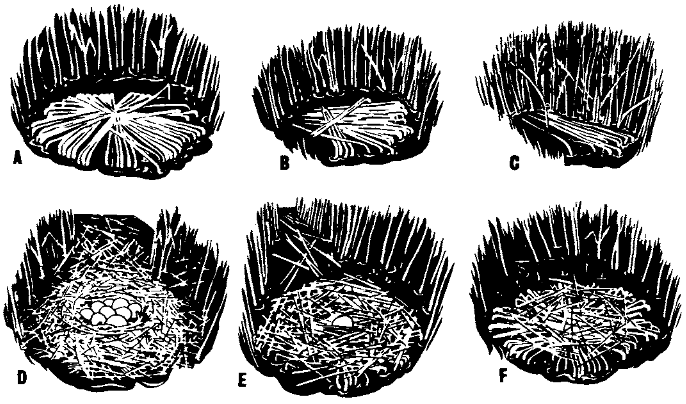

Fig. 1. Various nests of Magpie Geese *Anseranas semipalmata*, showing **A–C** roosting and courting forms, and **D–F** after egg laying.

Magpie Geese *Anseranas semipalmata* (see DUCK) illustrate the multiple role of birds' nests well. They build many, increasingly complex nests before egg-laying (Fig. 1) (Davies 1962). The convex types are used for roosting and courting. When the first egg is laid on one of these, uprooted vegetation is dragged onto it and it is converted into a concave cup which contains the eggs securely. Males undertake twice as much of the nest-building as the females in this species.

Many species are known to build and sit on false nests before egg-laying occurs, but the behaviour is well documented in the Magpie Goose. Brockway (1969) has described the behaviour of captive Budgerigars *Melopsittacus undulatus* in detail. She has shown that females enter the nestbox in response to a male giving the soft warble call and interprets this to mean that the call itself stimulates the female to ovulate. But if the sojourn of the female in the nestbox stimulates her to ovulate, the sequence of behaviour is then analogous to that of the male and female Barbary Dove described above.

Bowerbirds. If the nest is such an important part of the male's contribution to the breeding success, then the BOWERBIRDS present a particularly interesting case. The males build and attend a bower, a nest (in the widest sense of the word) which is never used as an egg nest at all. The bower can be viewed as a supranormal nest built by the male to stimulate the female to ovulate and accept copulation. The bower itself, of the avenue builders at least, is nest-like in structure, and careful study of the nests of the Satin *Ptilonorhynchus violaceus* and Spotted *Chlamydera maculata* Bowerbirds shows them to have flimsy bower-like walls. Many of the objects collected by the birds to decorate the bowers match the colours of the species' eggs and may therefore add to the effect of the bower as a supranormal nest.

Summary. The nests of birds hold the eggs and shelter them from some environmental hazards; they protect eggs, young and parents from predators; they serve as roosts and they act to co-ordinate the behaviour and physiology of the birds before egg-laying. The structure which is the characteristic nest of each species will represent a compromise that best serves each of these functions without damaging its usefulness in fulfilling the others. NESTING ASSOCIATIONS: the term includes all instances of one bird species often or habitually placing its nests singly or in colonies near those of other species or near habitations or structures of other living organisms. In many cases, these associations may be regarded as true symbioses. Excluded here are instances of organisms, usually insect larvae, which often are found in birds' nests.

The following types of associations have been described.

With other birds. A. Monospecific aggregations, or mixed species colonies of two or more often related species, e.g. gulls and terns, herons, icterids (see ORIOLE (2)), weaverbirds (Ploceidae).

B. One species nesting, singly or in scattered pairs, among pure or mixed colonies of other birds, e.g. Long-tailed Duck or Oldsquaw *Clangula hyemalis* and Sabine's Gull *Xema sabini* in colonies of the aggressive Arctic Tern *Sterna paradisaea*; the Turnstone *Arenaria interpres* among gulls and terns, and the Black-necked Grebe *Podiceps nigricollis* moving its nests with the yearly movements of Black-headed Gulls *Larus ridibundus*.

C. Groups of non-aggressive species near nest site of an aggressive, usually raptorial species, e.g. Starlings *Sturnus vulgaris* and House Sparrows *Passer domesticus* breeding on the fringes of the nest of an Imperial Eagle, *Aquila heliaca*, many African weavers building near a Black Kite *Milvus migrans* or a Marabou Stork *Leptoptilus crumeniferus* nest; species of tundra-breeding birds like geese (Anatidae) and waders (Scolopacidae) nesting with Snowy Owls *Nyctea scandiaca* and auks with Peregrines *Falco peregrinus*.

D. Single pairs of different species, e.g. Redshanks *Tringa totanus* near the alarm-giving Lapwing *Vanellus vanellus*; Yellow Warbler *Dendroica petechia* near aggressive Red-winged Blackbirds *Agelaius phoeniceus* or the Grey Catbird *Dumetella carolinensis*, both of which repel the brood-parasite, the Brown-headed Cowbird *Molothrus ater*.

E. Two bird species in the same nest, as in BROOD-PARASITISM, which is normally considered disadvantageous to the host species; but at least one species association, that of the Giant Cowbird *Scaphidura oryzivora*, a parasitic icterid and its icterid hosts, results under certain conditions in a peculiar symbiosis in which nests having one host chick and one cowbird have better host fledging success than nests having one or two host chicks but no cowbirds.

Only 13% of all birds are colonial nesters, but 93% of all marine birds nest in colonies, often mixed. Monospecific coloniality usually, but not always, evolves when a species exploits a food resource which is not defensible. This permits the evolution of nest aggregations. But the apparent converse does not always follow, i.e. even if food is defensible within a nest territory, coloniality may on occasion evolve, as in the marsh-dwelling blackbirds (Icteridae) of the New World.

The selective forces producing multispecies associations appear to be (1) nest site availability, (2) food availability and exploitation, and (3) predator pressure. In most associations, all three are involved to varying degrees. Aside from the aggressivity of the species involved, large numbers of birds simply nesting together can result in a swamping effect on predators. The earlier idea that some species are innately sociable is no longer tenable.

With insects. A. Nest cavity in structure made by insects, particularly both ground and arboreal termitaria. The habit is widespread, particularly in the tropics in trogons, puffbirds, kingfishers, jacamars; apparently habitual in the Buff-spotted Woodpecker *Campethera nivosa* of Africa and in the parrot genera *Aratinga* and *Brotogeris* in South America. In the cases involving some trogons, puffbirds, and parrots, the birds co-habit with the termites. The Neotropical White-tailed Trogon *Trogon viridis* habitually nests inside large nests of polybiine wasps. The wasps usually, but not always, desert their invaded nest. The woodpecker *Micropternus brachyurus* regularly nests in the spherical papier-maché-like nests of certain ants (*Crematogaster*) in South America.

B. Nesting near structures of stinging or biting social hymenoptera (wasps, bees, and ants), is widespread, particularly in the tropics in many passerine families e.g. Tyrannidae, Troglodytidae, Nectariniidae, Icteridae, Ploceidae, Fringillidae. Some raptors and storks also place their nests near aggressive ants or wasps.

With vertebrates. Birds have not formed strongly developed associations with many vertebrates other than that with man; some exceptions are:

A. The Water Thickknee *Burhinus vermiculatus* is said to place its nest near crocodile nests which are usually guarded by the female reptile, presumably against predators. Other associations consist of the use either by the bird or its associates of one or the other's burrows in the earth, e.g. the Tuatara lizard *Sphenodon punctatus* in the burrows of the New Zealand shearwaters, *Puffinus carneipes* and *P. bulleri*, the furnariid *Geositta cunicularia* nesting in the burrows of the Chinchillid rodent *Lagostomus maximus* in the Argentine pampas, and the Blue-and-White Swallow *Notiochelidon cyanoleuca* which in turn uses the abandoned nestholes of *Geositta*.

B. With man, commensalism is marked in several groups such as swallows (Hirundinidae) which use buildings as nest sites, storks (Ciconiidae), pigeons *Columba livia*, Jackdaws *Corvus monedula*, Rooks *Corvus frugilegus*, and various sparrows and weavers, especially *Passer* and *Ploceus*.

That one or more of the partners in most mixed associations is aggressive or offers efficient predator alarm argues that the antipredator function is a very strong selective component. That these associations are not more widespread also suggests that there are disadvantages as well. This has been documented in certain oropendolas and caciques (colonial-nesting Neotropical icterids), some species of which almost always nest in association with stinging wasps (*Protopolybia*, *Stelepolybia*, etc.) or stingless but biting bees (*Trigona*). Some species have colonies which traditionally associate with such insects and colonies which do not. A chief source of death in their chicks results from ectoparasitism by botflies (*Philornis* spp.). But colonies associated with wasps or bees suffer significantly less from botflies than do those without. The hymenoptera repel the flies in a manner which is not yet clear. Removal of the wasps and bees results in an almost immediate high incidence of botfly attacks. Similarly, colonies with wasps or bees suffer less from predation by opossums, toucans, and snakes (*Spilotes*, *Pseustes*) than do colonies which lack the hymenoptera. But because of apparent seasonal vicissitudes affecting the insects, colonies associating with wasps or bees have a short breeding season and but one chance per year to reproduce while those not associating have a relatively longer breeding period and may have two or three chances per year. An additional disadvantage is that branch breakage is common because of the weight of the bird nests surrounding the insect's nest. Oropendola and cacique nests in colonies lacking bees or wasps have a high incidence of brood-parasitism by the Giant Cowbird, with its advantages and disadvantages. The cowbird chick is fed by the host female and in turn eats ectoparasitic botfly larvae from the host's chick which results in lower mortality of the host chicks (see above). The oropendola chicks do not reciprocate. The advantage conferred by a single cowbird to its host sib is apparently lost in nests having 2 or more cowbird chicks because food competition between cowbird siblings is then involved. While the evolutionary advantages to this association may be clear, the proximate mechanisms are not. Oropendolas and caciques, or any bird that habitually associates with bees, ants, or wasps, are attacked, especially at the initiation of the association, but the Hymenoptera quickly habituate to them. Both visual and olfactory components may be involved. Many birds which habitually associate with stinging or biting Hymenoptera have a rather strong musty body odour, apparently lacking in close relatives which do not form such associations. The nature of this odour is unknown; naked chicks lack it and feathered adults possess it even after death. It is apparently not the same odour in different species—it is significant that almost all species in such associations build covered nests, presumably to cover the chicks from wasp or bee attacks. A current hypothesis is that the odour is not a repellent, but is rather a recognition signal promoting habituation in the aggressive insects. It must be emphasized that it is the birds which join the aggressive insects, not the reverse. However, docile wasps and bees often join the association after its initiation for much the same reasons as did birds. Lack of knowledge of the chronology and behaviour of these subsequent joiners has confused the issue of the evolutionary significance of the association. This is not to say that the aggressive insects do not receive an advantage. The birds often vigorously defend their colony site against anteaters (*Tamandua* spp.) which are enemies of stingless bees and against the caracaras *Daptrius ater* and *D. americanus* (Falconidae) which are enemies of both wasps and bees. The nesting associations here described do not confer equal advantages to all the partners nor complete protection to any. But that they do so more often than not, on the average, is the reason for their existence. (S.M.) N.G.S.

NEST RECORDING: the central collection of avian breeding information by voluntary contributors using standardized recording cards. The accumulation of sufficient cards allows the analysis of particular aspects of breeding in different years, habitats and geographical regions.

History. The idea of a central collection of cards containing breeding data came from Sir Julian Huxley after his analysis of the detailed nest histories of the birds using nestboxes erected at Whipsnade Zoological Park, Bedfordshire, England in 1936. With J. Fisher, Huxley designed recording cards for the Hatching and Fledging Inquiry, as it was then called, and these were distributed to members of the British Trust for Ornithology in 1939. Observers were asked to concentrate on certain common species and the principal object of the Inquiry was to collect data on incubation and fledging periods, as well as clutch sizes of British birds.

In the first year some 600 cards were returned and this total doubled in 1948 when the present name Nest Records Scheme was adopted and a new recording card design used. During the 10 years 1970–1980 the annual intake rose to between 22,000 and 30,000 cards. The first full time organizer of the BTO Nest Records Scheme was appointed in March 1960 following the award of a grant from the Nature Conservancy.

A number of countries have started nest record schemes based on the original BTO format. Among the earliest were the USA and Canada, Germany, Switzerland and Finland by 1948, South Africa by 1951 and New Zealand by 1959. Many European countries now have schemes operating, including Belgium, Czechoslovakia, Denmark, Hungary, Iceland, the Netherlands, Italy, Spain and Sweden, while further afield schemes have been started in Australia, Zambia and Zimbabwe.

Objects. The objects of nest recording are to collect as complete a picture of the nesting cycle of the bird as possible by utilizing the often incomplete nest histories recorded by amateur birdwatchers, so amassing breeding information impossible to collect in any other way except at immense cost. Each card on its own tells very little but when several thousand are available for analysis the sample containing useful information becomes meaningful.

The card is designed so that one half contains boxes which give information on the species, observer, year, geographical locality, altitude, habitat, nest site and height of nest above ground. The other half of the card enables the observer to complete one line for each visit made to the nest, giving the date, time, number of eggs and/or young and a brief note on the observation if necessary: for example, whether eggs are warm or cold, female or male sitting and age of young. There is also a space for evidence of the success or failure of the nest. In the case of colonial species, special colony sheets may be provided.

The value of nest record cards is that they provide, in the case of common species, large annual samples coming from a wide geographical area and selection of habitats. Many birdwatchers are naturally interested in looking for nests and a lot of potentially useful information would be lost in individual notebooks if no standardized recording scheme existed.

The most important information which the observers record is the date on which the first egg was laid, clutch size, number of eggs hatched and number of young reaching an advanced stage such that there is a good likelihood of their leaving the nest successfully. To record these it is unnecessary and undesirable to visit the nest every day and observers are encouraged to plan their visits to collect the maximum amount of information with the minimum of disturbance.

Uses of the data. The nest record cards provide data on the basic breeding biology of each species. The main parameters that can be extracted are those for laying dates, clutch size and breeding success. If sufficient records are available, the effects of weather, habitat, latitude and altitude can be determined. Some nest record schemes now use computer facilities for the input of annual samples of cards for selected species so that any marked effect on breeding performance caused by environmental changes, such as the introduction of new agricultural chemicals, can be detected.

Certain types of bias are inherent in the nest record data and the analyst needs to be aware of them. Observers tend to search more vigorously early in the breeding season (in Britain) when the vegetation cover is least dense and nests are easier to find. The recording of nesting success has two main types of bias. Firstly, it is much easier to record a failure than a success and, secondly, nests found at later stages of the nesting cycle are biased towards success. Therefore various methods of analysing the data have been devised to eliminate as much of these biases as possible. R.A.M.

NEST SANITATION: see PARENTAL CARE.

NEST SCRAPE: a small hollow excavated by a bird in soil, sand or shingle and which it may line with pieces of grass or similar material.

NEST SITE SELECTION: an aspect of behaviour the study of which involves such considerations as the season when birds select their nest sites, the interval between nest site selection and the start of building, the share of the sexes, and the factors that may influence birds in selecting nest sites. For the variety of sites used see NEST. In some species the availability of nest sites may be a critical factor in habitat selection (see HABITAT and TERRITORY).

The selection procedure

Time. Although the nest site is generally selected shortly before breeding, birds may also show interest in such sites in the preceeding autumn (as some birds of prey) or even several years before breeding (as the Fulmar *Fulmarus glacialis*). Mild spells in late winter can initiate song, courtship, and even nest site selection, in species that will not begin to build until several weeks later. There is thus often an appreciable interval between selection and building, from several weeks or months down to a day or less. A bird that has lost an early nest, or is proceeding to a second brood, may condense its nest site selection and building time in the urgency to breed. The pre-laying period is also short at high latitudes where the spring and summer seasons are short. In Norway the spring arrival time of the Brambling *Fringilla montifringilla* is about 3 weeks after the Chaffinch *F. coelebs*, but the onset of nest building is only separated by a few days in areas in which the two species breed sympatrically. Perhaps species with a more southern distribution, like the Chaffinch, have a long pre-building period in order to obtain an optimal territory in the more crowded southern areas, and also in order to locate suitable and well-hidden nest sites. Nest predation is more severe at low latitudes.

Shares of sexes. A survey of some 170 representative British breeding species (C. and D. Nethersole-Thompson 1943, 1944) included none in which the male and about 30 in which the female normally takes sole charge in nest site selection; in the remaining species both sexes participate, with males taking the initiative rather less often than females. This pattern is repeated in most orders of birds, although in the Anatidae and Galliformes the males evidently take little or no active part.

In some species (as in the *Sylvia* warblers) the male arrives before the female and builds several uncompleted nests, so that the female later on can choose which of them she prefers. The male Pied Flycatcher *Ficedula hypoleuca* also arrives before the female and defends a nest hole which the

Galahs *Cacatua roseicapilla* looking out of nest hole. (*Photo: J. Warham*).

female, in turn, may accept. The suggestion, based on observations at other stages in the breeding cycle, that in species in which the males take the initiative they are more brightly plumaged than the females, seems not to hold for males taking an active part in nest site selection, e.g. it holds for the Pied Flycatcher but not for the *Sylvia* warblers.

Titmice. In general, the bird's routine tends to be elaborate in species with special requirements, as in tits. They mostly nest in holes and may frequently be seen inspecting the holes from September to April, most actively just before nest building in spring, but also exhibiting a lesser peak of activity in October and November. Since tits also roost in holes in winter, their activity in autumn could equally be roost site selection; but as winter roosts are often used later for breeding, this distinction may be unimportant (see ROOSTING). In spring, hole inspection is most frequent in the morning and tails off markedly in mid-afternoon. Tits commonly deposit nest material in several holes before eventually lining and laying in one of them. In a typical hole inspection by the Great Tit *Parus major*, the male flies to the hole, leaving the female near by, and peers inside, turning his head sideways to display the white cheeks; he may also tap at the entrance. If the female responds by approaching the hole, she shivers her wings, increasingly the nearer she comes, and then normally enters the hole, sometimes preceded by the male; she may remain inside for a few minutes. If the female does not respond, the male usually returns to her and repeats the performance at the same or another hole. Thus he suggests a number of sites to the female, one of which she is likely to accept.

Fairy Tern *Gygis alba* egg in site on branch. (*Photo: N. van Swelm*).

Gulls and waders. Contrasting with the elaborate routine of many hole-nesting species is the nest site selection of gulls and waders (Charadrii). The male and female Herring Gull *Larus argentatus* indulge in frequent preliminaries to nest building, moving from one possible site to another. The final selection and beginning of an actual nest at one or other of the sites seems quite haphazard. In the Red-necked Phalarope *Phalaropus lobatus* both sexes together spend several days making scrapes in the soil more or less at random. Then, about an hour before laying, the female revisits many of the scrapes and apparently lays in whichever scrape she happens to be at when the egg appears. There are exceptions, of course, to this seemingly casual pattern, such as in the Greenshank *Tringa nebularia*, which prefers to nest close to some small landmark such as a log or large stone in the otherwise rather featureless landscape (C. and D. Nethersole-Thompson).

Nuthatch *Sitta europaea* at nest hole, reduced by mud plaster. (*Photo: E.J. Hosking*).

Open-nesting song-birds. Nest site selection by the majority of these comes somewhere between the elaborate procedure of the hole-nesters and the casual choice of most gulls and waders. In Scottish Crossbills *Loxia scotica*, for example, the nest site is usually chosen in a distinctive tour by both sexes, during which the female broods in various crotches; this is accompanied by frequent snatches of such irrelevant behaviour as bill-wiping, 'false feeding', and preening (see DISPLACEMENT ACTIVITY). The final choice of site is the female's.

Survival value.

Nest predation. Birds prefer to nest in sites which are not easily accessible to predators, e.g. holes, on cliffs, and on small islands. Certain tropical birds nest in close association with wasps' nests; and Bramblings often nest in colonies of Fieldfares *Turdus pilaris*, which are especially active in defence of their nesting area, and Tufted Ducks *Aythya fuligula* in mixed colonies of terns and gulls (see NESTING ASSOCIATION). The Redwing *Turdus iliacus* builds its nest higher up in trees and bushes early in the season before the vegetation develops than later on, probably in order to reduce nest predation.

Cover. Birds select sites which provide shelter against rain, wind, and sunshine. The White-crowned Sparrow *Zonotrichia leucophrys* builds its nest above the ground in those years when there is a lot of snow.

Competition. Competition for nest sites is generally keenest among birds with specialized requirements; in the Swift *Apus apus*, for example, exceptionally prolonged struggles for the possession of nestboxes have been described. Competition between members of the same species may be, to some extent, avoided by the territorial systems of some birds. Competition for nesting space is especially marked in densely colonial species, e.g. among seabirds, each species demanding a special type of ledge or other support for its nest, the presence of which may govern the birds' local distribution in the breeding season.

Building effort. Purple Martins *Progne subis* prefer apartments which have not been cleaned out after a previous occupancy. In open-nesting species the same nest may sometimes be used for subsequent nestings, within the same season (as in the Blackbird *Turdus merula*) and in successive years (as in the Fieldfare). This habit is rather unusual among song-birds, but is the rule among many birds-of-prey. Eyries of the Golden Eagle *Aquila chrysaetos* may be occupied (by succeeding generations) for centuries, although the birds often ring the changes on two or more alternative sites. By using an old nest as a basis, less energy is needed in building. An old nest may also be an indication of a safe site: the nest is not likely to fall down. For such species the breeding population size may occasionally be increased by providing artificial nest sites (as for the Osprey *Pandion haliaetus*). The Green Sandpiper *Tringa ochropus* is remarkable among waders for laying in old nests, mostly of the Song Thrush *Turdus philomelos*. Some birds appropriate freshly completed or occupied nests of other species; thus the House Sparrow *Passer domesticus* habitually evicts the House Martin *Delichon urbica*; and a pair of the American Parasitic Flycatcher *Legatus leucophalus* sometimes causes the rightful owners of several occupied nests to desert before settling on one of them. Nest appropriation has evolved independently in a number of different groups of birds throughout the world; it has perhaps reached its most refined form in wholly parasitic species such as the Cuckoo *Cuculus canorus* (see BROOD-PARASITISM).

Food. Nests are placed at convenient sites according to the food resources. For example, Great Tits collect food closer to the ground than Blue Tits *Parus caeruleus*, and also prefer lower nest sites. Species which defend a feeding range often build the nest at the centre of the territory.

NEST SITES, MAN-MADE: a wide range of types of artificial structures designed to attract and provide safe nesting places for birds. Most are nest 'boxes' suitable for species normally breeding in holes and cavities; others include ledges, excavated holes, artificial islands, floating platforms and the rearrangement of natural vegetation. The nestbox derives originally from the clay flasks first recorded in the late Middle Ages in Holland—they can be seen in F. van Valkenborch's Kirchmessfest (1597)—and from wooden cistulae (flasks) used in Silesia. Both were utilitarian: the first broods of sparrows *Passer* spp. and Starlings *Sturnus vulgaris* hatched in them were taken for food; so were the eggs of the Goldeneye *Bucephala clangula* 'farmed' in Lapland, at first by means of improved natural sites and later in boxes. (In recent years colonization of Scotland by this species has been largely effected by the provision of nestboxes.) In 1782 Gilbert White recorded that his brother had nailed up several large scallop shells under the eaves of his house in South Lambeth, London, and that they were immediately occupied by House Martins *Delichon urbica*, but Charles Waterton, the early 19th century Yorkshire squire, is believed to have been the first naturalist to put up numbers of boxes simply to encourage birds, and their use for this purpose developed during the century; by 1897 J.R.B. Masefield knew of 20 species that had occupied boxes or artificial platforms in Britain. Nestboxes were first applied on a large scale to attract and increase the numbers of 'beneficial' insectivorous birds in forests by Baron von Berlepsch in Germany; by about 1905 all the 300 boxes in his park, and 90% of some 2,000 boxes in his woods, were occupied by birds of 14 different species. Soon afterwards it was realized that whole populations of certain species could be induced to use nestboxes if enough were provided, and could thus be studied in many aspects of their population structure. Pioneer studies were those of S.P. Baldwin and W.W. Bowen on the House Wren *Troglodytes aedon* in the USA, begun in 1915, and of K. Wolda and his associates on the Great Tit *Parus major* in Holland, begun in 1920. But the species most suited to nestbox studies is probably the Pied Flycatcher *Ficedula hypoleuca*; since L. von Haartman began work on it in Finland in 1941, populations have been 'emboxed' in all the European countries where it breeds commonly, and tens of thousands of birds have been ringed.

The 19th century nestbox was made of wood, with a round entrance hole and a fixed lid, and was designed primarily to attract tits, Nuthatches *Sitta europaea*, redstarts *Phoenicurus* spp. and Pied Flycatchers. Von Berlepsch favoured a hollowed-out section of log, resembling as closely as possible the nest-hole of the Great Spotted Woodpecker *Dendrocopos major* which these small birds were accustomed to use under natural conditions. It has since been found, however, that the shape and external appearance of the box matter very little and that those made of planed boards are quite as effective as 'rustic' boxes with bark-covered sides. Certain rules nevertheless govern the correct construction and maintenance of safe and durable nestboxes and these have been described in a field guide published by the British Trust for Ornithology. For example, the entrance hole should be sufficiently high up the side or front panels of the box to make it hard for larger predators to reach the contents of the nest; the roof or lid should overlap the sides to keep off raindrops; and there should be no perches or ledges on which predators can get a grip.

Towards the middle of the 20th century nestboxes in materials other than wood were developed; plastics, cement and sawdust, cement bricks, hardboard, and tin all found advocates. Their advantage over wood lies in superior resistance to weather and to attacks by squirrels and Great Spotted Woodpeckers which became increasingly a nuisance in Britain in the 1950s. Their disadvantages include expense, brittleness, liability to overheating in exposed sites, excessive condensation, and in some instances weight. The Russians have experimented with bottle gourds as the cheapest form of artificial nest cavity; but it is apparently not possible to inspect the contents.

Nestboxes should normally be sited on the side of a tree or wall away from the hottest sun. H.N. Kluijver pointed out that on trees in western Europe this makes them vulnerable to the maximum flow of water after a rainstorm, but some compromise position can usually be found. In woods the main consideration is to site boxes away from twigs and branches which can be used by predators; an open approach for the nesting bird is also important. Provided that they are securely attached to a trunk or branch, nestboxes need not be rigid; in closed canopy woodland they can be fixed to branch snags by a wire loop and lifted down by the loop for inspection. In Britain, the Nature Conservancy Council conducted an experiment to find out the height preferred by small birds using nestboxes, but the results after 5 years were inconclusive; it seems probable that most species have little or no preference. However, boxes in most localities have to be sited at least 3 m above the ground to avoid human damage.

Ideally, a nestbox should have a fixed roof and open at the front for inspection; but where it is desired to catch the parent birds in the box for ringing and examination, a movable lid is preferable. Various devices have been developed for retaining adult birds in the box, from small external spring nets to internal treadles that release a shutter. In Britain, J.A. Gibb adapted the automatic swinging door used by racing pigeon owners in their lofts. This was followed by non-automatic shutters remotely operated by means of a fishing line passing under the lid and over the side of the box; J.H. Jenkins and P.A. Banks were responsible for ingenious variations of this idea. After capture in the box, the birds are most easily removed through a detachable version of the sleeve used in the catching boxes of Heligoland and other large traps (see TRAPPING).

The traditional design of nestbox has been adapted to attract various species: there have been boxes with narrow entrances and with entrances at the back, both intended for treecreepers *Certhia* spp.; multiple boxes for the Purple Martin *Progne subis*; boxes filled with wood chippings, sawdust, balsa wood or polystyrene blocks for birds like Chickadees *Parus atricapillus*, Willow Tit *P. montanus* and Great Spotted Woodpecker to excavate. D. Lack evolved elongated boxes with holes opening downward to embox a colony of Swifts *Apus apus*; others have taken this idea further to counterfeit the burrows of Sand Martins *Riparia riparia*, Wheatear *Oenanthe oenanthe* and Madeiran Petrels *Oceanodroma castro*; while artificial nests for Swallows *Hirundo rustica* and House Martin *Delichon urbica* have been successful in Switzerland and Britain. Removal of half the front panel converts the traditional nestbox into a covered tray or ledge suitable for Spotted Flycatchers *Muscicapa striata*, Robins *Erithacus rubecula*, and many other species. By increasing the size, owls, Kestrels *Falco tinnunculus*, Jackdaws *Corvus monedula*, Stock Doves *Columba oenas*, and ducks can be attracted. For the Tawny Owl *Strix aluco* a quite distinct chimney design was used most successfully by H.N. Southern, who slung it by wire bands under an upward sloping bough; an inspection mirror was fastened to the mouth of the chimney and a perforated floor allowed drainage. Similar but narrower boxes slung from horizontal boughs are attractive to Little Owls *Athene noctua*.

As well as nestboxes and their obvious derivatives, many other artificial means have been used to encourage nesting; the cart-wheels or platforms put up on houses in Holland and elsewhere for the White Stork *Ciconia ciconia* are one of the oldest devices and have been copied in the USA to attract Ospreys *Pandion haliaetus*. Woven baskets for Mallards *Anas platyrhynchos* are another Dutch idea, while in Iceland stone 'houses' are built for Eiders *Somateria mollissima*. Egg collectors used to 'farm' Greenshanks *Tringa nebularia* in Scotland by providing ideal nest sites for them, and other ground-nesting birds have been catered for in the same way. Von Berlepsch suggested tying twigs together to make better than natural forks for bush-nesting birds, 'nesting substrates' have been used by several species in America, and man-made stick nests taken by Long-eared Owls *Asio otus* in woods devoid of the old nest platforms of other large birds. The creation of bare ground patches or tunnels in dense ground vegetation have provided suitable nest sites for Nightjar *Caprimulgus europaeus* and Shelduck *Tadorna tadorna* respectively. More elaborately, artificial banks have been built up, in which Kingfishers *Alcedo atthis* were attracted to burrow.

The main development of the nestbox up to the middle of the 20th century took place in Europe and North America, although it was still not proved that large numbers of boxes did more than concentrate the birds using them. For example, in the Forest of Dean (Gloucestershire, England) as many as 189 out of 200 nestboxes spread over 24 ha were occupied in 1949; but no control data are available for the area before boxes were first put up there in 1942. In Russia, large-scale attempts to attract birds to forests involved over 10,000 nestboxes in 9 areas in 1953; they were occupied by nearly 4,000 pairs of 18 species. Partially successful attempts were also made to transfer both adults and nestlings to newly afforested areas. Foresters in India began putting up boxes in the 1950s, but the great variety of tropical species nesting in holes and cavities offer further opportunities for nestbox techniques. Water bodies such as reservoirs and gravel-pits which lack natural nesting places like graded banks, spits and small islands can be improved through the creation of rafts and raised islands providing nesting places for grebes, ducks and geese, waders, gulls, terns, rails, even passerines like the Reed Bunting *Emberiza schoeniclus*.

NETTING: see TRAPPING.

NEUTRAL CATEGORIES: in taxonomy, categories that can be used as terms without commitment to a view of the status of the subject matter, e.g. FORM; GROUP; COMPLEX.

NEW GUINEA SUBREGION: see AUSTRALASIAN REGION.

NEWTONIA: substantive name of the 4 species of *Newtonia*, a genus of flycatchers endemic to Madagascar (for family see FLYCATCHER (1)).

NEW ZEALAND SUBREGION: a division of the Australasian Region, but by some zoogeographers regarded as a separate minor region (see AUSTRALASIAN REGION; DISTRIBUTION, GEOGRAPHICAL).

NICATOR: substantive name of the 2 species of *Nicator*, an African genus formerly placed in the shrike family but now considered to be closer to the BULBULS.

NICHE: a term, often used loosely, referring to the ecological role that a species plays within a community; or, more rigorously, to the full range of environmental conditions within which it can survive. See ECOLOGY.

NICHE EXPANSION: an increase in the places where a population will breed or feed, or an increase in the kinds of food members of the population will eat. Niche expansion is most often discussed in the context of a change in the feeding ecology of a population of one species in the absence of one or more species with which it normally competes. The population may then be able to exploit a food resource or a feeding site previously used by the competitor. DENSITY COMPENSATION is a likely consequence of niche expansion.

Niche expansion may also happen in the absence of any change in the competitive environment, when a population learns to exploit a new food resource or nesting site.

NICTITATING MEMBRANE: a transparent fold of skin, present in birds, which can be drawn across the eye to form a third eyelid (see VISION).

NIDICOLOUS: young birds that remain in the nest after hatching. See YOUNG BIRD.

NIDIFUGOUS: young birds that leave the nest immediately or soon after hatching. See YOUNG BIRD.

NIGHTHAWK: substantive name of various New World species of Caprimulgidae; in the plural, general term for the subfamily Chordeilinae (see NIGHTJAR).

NIGHTINGALE: substantive name of some *Luscinia* spp.; used without qualification, in Britain, for *L. megarhynchos* (see under THRUSH). See photo VOCALIZATION.

NIGHTJAR: substantive name of the Old World species of Caprimulgidae (Caprimulgiformes, suborder Caprimulgi); in the plural, a general term for the family, but American usage prefers 'goatsuckers and nighthawks'; some species have special names derived from the calls.

About 70 species are known, generally grouped in 18 genera. On the basis of anatomical differences the family can be divided into 2 subfamilies, the Chordeilinae (nighthawks) and the Caprimulginae (goatsuckers).

Characterstics. Nightjars are mainly 16–41 cm long, up to 78 cm in a few species with greatly elongated tail feathers. The plumage is soft and is buffish, rufous, greyish, or nearly black. The upper parts are in general strongly mottled and vermiculated; the under parts are mostly barred or spotted and often with white patches on chin and throat, on the wings and on the tips of the tail feathers. In some species both a grey and a more rufous phase occur (see POLYMORPHISM). The sexes are normally somewhat different in colour. The tail is rather long; the wings are long and pointed; and the flight is silent and easy. The skull is flattened, with the bill short and weak. The gape, which is extremely wide, and in most species provided with strong bristles, enables the bird to catch insects (the main food) during flight. The eyes are large. The feet are commonly very short, with a feathered tarsus in some species; the toes are small, the middle toe possessing a pectinated claw.

Most species are crepuscular or nocturnal in habit. During the day the birds lie up closely and are difficult to detect owing to their cryptic coloration. Normally the birds perch on the ground or lengthwise on a branch.

Habitat. Some species frequent desert areas, others are inhabitants of open spaces in wooded districts, and some of forests.

Distribution and movements. This homogeneous family has a nearly world-wide distribution, but it is not represented in the most northern parts of America and Eurasia, in southern South America, or in New Zealand and many oceanic islands. The North Temperate Zone species migrate southwards for the winter.

Food. Insects are the main food of all nightjars.

Breeding. Generally no nest is made, the eggs being laid on the bare ground. These number 1 or 2, rarely 3. They are white to pinkish buff, beautifully marbled or blotched with black, brown or violet. Both parents incubate and care for the young, which are nidicolous and covered with protective (buff or greyish) down.

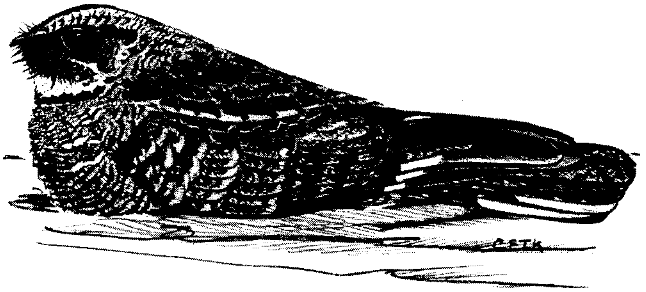
Chordeilinae. The nighthawks are restricted to the New World; the species lack rictal bristles. In North America the Common Nighthawk *Chordeiles minor* and the very similar Lesser Nighthawk *C. acutipennis* are well-known representatives. The first frequents open country or forest borders and is also found in the Greater Antilles; the latter, which is somewhat smaller and darker, ranges also over the greater part of tropical South America and is an inhabitant of desert areas or open sandy savannas. In both species the males are slightly larger than the females, and they have a white wing-patch and a subterminal tail-bar that are absent or smaller in the other sex. Both species are known to breed sometimes on the flat roofs of houses. The Lesser Nighthawk prefers to roost on the horizontal branches of low bushes.

Other species are the white-bellied Sand-coloured Nighthawk *C. rupestris* and the small Least Nighthawk *C. pusillus*. Both are distributed in the northern part of South America. The remaining 3 genera, which are monotypic, are likewise found in South America. The Nacunda Nighthawk *Podager nacunda* has a white belly and throat-patch, rather long unfeathered tarsi, and a melancholy voice; it is an inhabitant of the savannas and is known to migrate northwards.

Caprimulginae. More than half of the known species in the whole family belong to the typical genus *Caprimulgus*, of which many species are rather alike in plumage. The European Nightjar *Caprimulgus europaeus* is found from Great Britain and northern Africa far into Asia, and in winter migrants reach South Africa; the 'churring' or jarring note is the origin of the name. In eastern Asia the related Jungle Nightjar *C. indicus* occurs, and it is also distributed over India, in winter reaching the Greater Sunda Islands; the males differ from the European Nightjar in having subterminal white spots on the outer 4 pairs of tail feathers instead of on the outer 3 only. In the same area, from India and southern China through Indonesia to northern Australia, the Large-tailed Nightjar *C. macrurus* is widely distributed; it is distinguished from *C. europaeus* by the fact that the 4, instead of the 3 outer primaries show a white spot. In southern Europe and the western parts of North Africa, the Red-necked Nightjar *C. ruficollis*, with a yellow-rufous collar, is found. The paler and sandier coloured Egyptian Nightjar *C. aegyptius* inhabits the desert areas of south-western Asia and northern Africa. Different species occur in Africa, but the habits of many are not yet very well known, although mostly these seem not to differ greatly from those of the other members of the family. Some perform regular intertropical migrations (see MIGRATION). Some species, such as the Fiery-necked Nightjar *C. fervidus*, inhabiting the southern part of Africa, hunt from a fixed perch during the night instead of hawking over longer distances as do most of the other species. Different types of churring sounds are made by various species, while others have whistling calls.

North American representatives include the Whip-poor-will *Caprimulgus vociferus*, ranging from northern North America to well into Middle America; the closely related *C. noctitherus* from Puerto Rico had long been regarded as extinct, but has recently been rediscovered. Another species named from the call is the Chuck-will's-widow *C. carolinensis*; it is a somewhat larger species frequenting wooded marshes and rocky hills in the western parts of the United States and wintering in the West Indies and Middle America. Other species inhabit South America, such as the beautiful Cayenne Nightjar *C. cayennensis* with throat white, and sides of face and abdomen and the lateral tail feathers mainly white; another is the Dark Nightjar *C. nigrescens*, also found in northern South America.

The species of the genus *Eurostopodus* are distributed from south-eastern Asia through the Philippine and Indonesian archipelagoes to Australia. They lack the rictal bristles and have ear-tufts. Most species are rather large and dark, showing much black and dark brown but with a white throat-patch.



Large-tailed Nightjar *Caprimulgus macrurus*. (*C.E.T.K.*).

The White-necked Nighthawk *Nyctidromus albicollis* is an inhabitant of Middle and South America; it breeds under the cover of bushes, and the eggs are deposited on a thick layer of dead leaves. The Common Poorwill *Phalaenoptilus nuttallii* is a rather small species with a relatively short tail, occurring in North America. In winter birds of this species hibernate in rock niches and may return to the same hole every winter. During this winter dormancy the birds remain in a state of torpidity with an exceedingly low body temperature, 18°–19°C (64°–66°F) as against 40°–41°C (104°–106°F) normally (see TORPIDITY).

In some species the males show a remarkable elongation of certain feathers of wings or tail. In middle Africa the Standard-winged Nightjar *Macrodipteryx longipennis* is found; it is a rather dark species, in which the males have, during the breeding season, the shaft of the second primary (numbered from inside) greatly elongated, with the terminal portion vaned. In courtship the male flies very slowly, with wings stiffly bowed and vibrating, low over or around the female, with its standards held straight up above the wing and the shaft and terminal vane vibrating with the wing. In the southern part of Africa occurs the rather large Pennant-winged Nightjar *Semeiophorus vexillarius*; its second primaries are extraordinarily prolonged and ribbon-like. In the small Long-tailed Nightjar *Scotornis climacurus*, inhabiting middle Africa, the central tail feathers are greatly elongated. The males of the South American genera *Uropsalis* and *Macropsalis* are distinguished by a forked tail with much elongated lateral feathers. In *Hydropsalis*, from South America, the outermost as well as the central tail feathers are prolonged.

G.C.A.J. (J.M.)

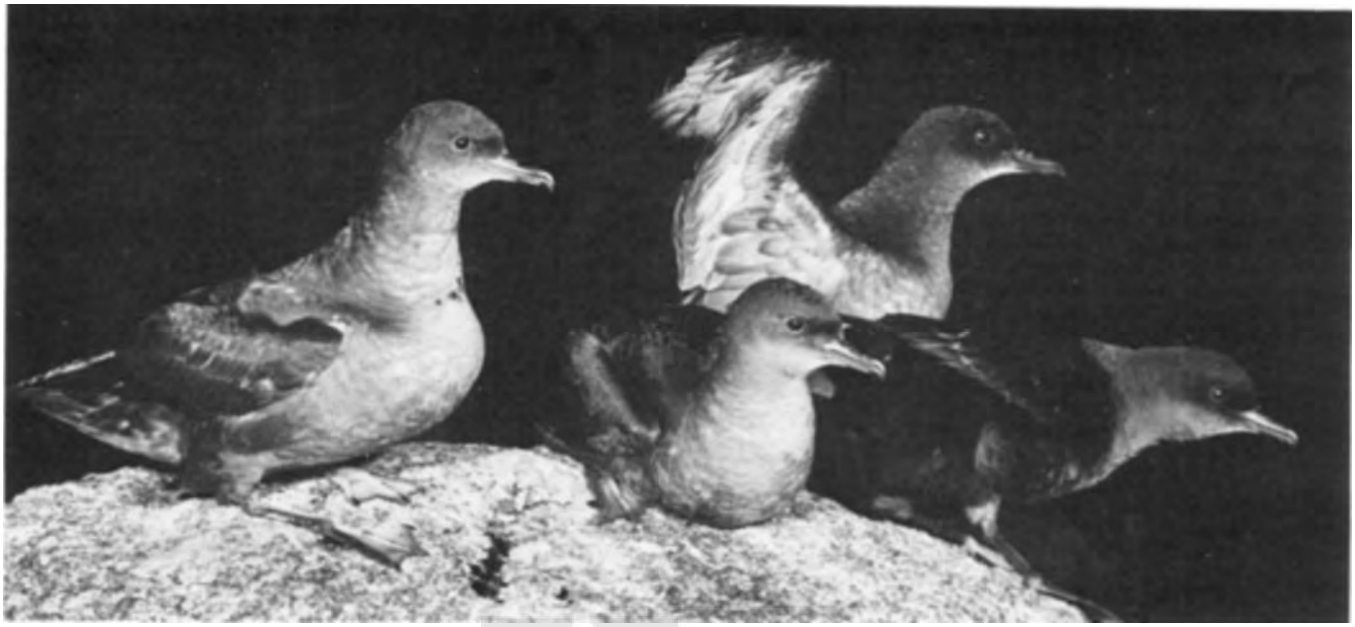
NIGHTJAR, OWLET: see OWLET-FROGMOUTH.

NIGHTJAR, TREE: see POTOO.

NILTAVA: substantive name of species of *Niltava*, a large mainly south-eastern Asian genus of flycatchers (for family see FLYCATCHER (1)).

NITROGEN METABOLISM: see EXCRETORY SYSTEM; METABOLISM.

NOCTURNAL HABITS: characteristic of a minority of bird species, the great majority being entirely diurnal. Outstanding examples of special adaptations to activity in minimal light intensities are found in the Strigiformes, Steatornithidae, and the Apterygidae (see, respectively, OWL; OILBIRD; KIWI); but some of the owls—although all show the main adaptations to nocturnal habits—are in fact diurnal, or largely so. Other birds, notably the Caprimulgidae (see NIGHTJAR), are crepuscular in habits, being active in the dim light of dusk and dawn rather than in full night or day; the Bat-hawk *Machaerhamphus alcinus* is a special case (see HAWK). Others again are nocturnal in their nesting activities but to a large extent diurnal in their search for food; examples are many of the petrels (Procellariiformes), e.g. Manx Shearwater *Puffinus puffinus*, and a few penguins (Spheniscidae), e.g. Little Penguin *Eudyptula minor* (see PETREL; PENGUIN). Further, many aquatic and wading birds (e.g. Anatidae and Charadrii), in particular, are partly nocturnal as well as mainly diurnal, showing considerable activity on nights that are not too dark on the water or open ground. Even among birds that are as a rule strictly diurnal, many migrate by night, e.g. numerous small species of the Passeriformes (see MIGRATION). This may be largely or wholly an adaptation to the need for using the day for feeding.



Short-tailed Shearwaters *Puffinus tenuirostris* waiting to take off from a vantage point, ascended before dawn. (*Photo: J. Warham*).

As the counterpart of nocturnal activity, quiescence during the day calls for concealment. This may be achieved in dense foliage or ground vegetation, or by virtue of cryptic coloration in more open situations. In many instances, however, the birds spend the day in holes or burrows used for nesting, and sometimes also for roosting outside the breeding season. This is true of various owls. Petrels that nest in burrows tend to have their comings and goings during the hours of darkness, and in the daytime are either underground or out at sea. The Little Penguin, mentioned above, is similarly nocturnal to a large extent when ashore at its breeding places. The Oilbird *Steatornis caripensis* nests, and has its daytime roosts, in the utter darkness far inside great caves, where it finds its way by echolocation; similar nesting and navigational habits are found in certain SWIFTLETS, but these birds are otherwise diurnal.

Nocturnal habits constitute a form of concealment, and like other forms may be either defensive or aggressive. The flightless kiwis feed at night; and the oceanic petrels safeguard their unavoidable visits to land, for breeding, by resort there to nocturnal habits. On the other hand, owls use darkness—and their silent flight—for hunting; at the same time they exploit a particular source of food in animals that are themselves nocturnal. Likewise, the crepuscular nightjars feed on insects that fly in the twilight; and the case of the Bat-hawk is self-explanatory. In contrast, the Oilbird is frugivorous—the only nocturnal bird that is. The activities of shore birds are often governed more by the state of the tide than by the alternation of night and day.

Tawny Frogmouth *Podargus strigoides* at night. Note the large eyes, placed for binocular vision, as in owls. (*Photo: J. Warham*).

Swallow-tailed Gull *Creagrus furcatus*; the large eyes indicate the habits of the only nocturnal gull. (*Photo: E.J. Hosking*).

For sensory adaptations to nocturnal activity see ECHOLOCATION; VISION.

A.L.T.

NODDY: substantive name (plural 'noddies') of *Anous* spp. (see TERN).

NOMADISM: term used to describe movements of species that do not normally revisit either breeding site or non-breeding areas (see MIGRATION).

NOMEN: with adjectives conservandum, dubium, novum, nudum, oblitum, and triviale (see below).

NOMENCLATURE: the scientific naming of species and subspecies, and of the genera, families, and other categories in which species may be classified (see TAXON). Scientific names are necessary because there must be names that are internationally understood, and also because vernacular names, where such indeed exist in common speech, are governed by popular usage and are thus liable to be inexact in their application or to change in meaning with the passage of time (see NAME, various entries). In practice, scientific nomenclature has fallen short of the ideal, for reasons partly inevitable and partly arising from human wilfulness and negligence. The only hope of uniformity lies in the subordination of individual views or prejudices to the generally accepted code and authority; to regard nomenclature as more than a means to an end is pedantry, and to take a minority course in a matter of convention is merely a nuisance.

International code. So far as the Animal Kingdom is concerned, the practice of scientific naming is governed by the International Code of Zoological Nomenclature, and no other code has validity in any branch of zoology. The International Code is a system of rules and recommendations originally authorized by the International Congresses of Zoology. The current (third) edition of the Code (formerly 'Rules') is that provisionally approved by the Division of Zoology of IUBS (the International Union of Biological Sciences) at Helsinki (1979) and published in 1984. 'The object of the Code is to promote stability and universality in the scientific names of animals, and to ensure that the name of each taxon is unique and distinct. All its provisions and recommendations are subservient to these ends, and none restricts the freedom of taxonomic thought or action.'

Two points in the earlier history of international rules are of particular ornithological interest. The first set of rules to be generally accepted was that adopted by the V International Congress of Zoology in 1901; the British representative on the small drafting committee was an ornithologist, P.L. Sclater. Among earlier codes was that prepared, with special reference to birds, by the American Ornithologists' Union in 1885. Notable predecessors were the Strickland Code adopted by the British Association for the Advancement of Science in 1842, and the Dall Code published by an American zoologist in 1877.

Binominal system. The Code embodies in legislative form the methods used by Linnaeus (Linné) and first consistently applied in the Tenth Edition of his *Systema Naturae.* These constitute the Binominal System (sometimes 'binomial' or 'binary'); and this has as its temporal starting point 1 January 1758, the year in which the edition was published. The essence is that every species is placed in a genus, and that the name of a species is a binominal combination, or 'binomen' (plural, 'binomina'), consisting of the name of the genus and a second word denoting the particular member of it; the first term of the binomen is the 'generic name', the second the 'specific name' (formerly 'specific trivial name'—the nomen triviale of Linnaeus himself). The name of a genus is used alone to designate that taxon as such. The specific name of a species has no meaning in isolation.

Trinominal system. This is a more recent extension (Schlegel 1844) of the Binominal System and is covered by the same rules. Where a species is divisible into subspecies (sometimes called 'races'), the binomen constituting the name of the species is for each of them extended by a third term, the 'subspecific name'; the 'trinomen' thus formed is the name of the subspecies. The species as a whole is nevertheless still referred to by its binomen. The subspecies that contains the name-bearing type of its species is the 'nominotypical subspecies', and the third term of its name is a repetition of the second.

The International Code expressly does not provide for the nomenclature of infrasubspecific forms, e.g. 'varieties'; nor does it extend to the naming of HYBRIDS. Further, when a number of geographical populations described as separate subspecies are found to intergrade, more or less continuously, the CLINE (although of great importance in reality) is not itself a nomenclatural entity.

Groups of taxa. The Code in its most recent form recognizes three basic taxa—the species, the genus, and the family. On these it founds what it calls (for purely nomenclatural purposes) the 'species group' of taxa, comprising species and subspecies; the 'genus group' of taxa, comprising genus and subgenus; and the 'family group' of taxa, comprising superfamily, family, subfamily, tribe, 'and any supplementary categories required'. The names used for taxa within each group are 'co-ordinate', and are subject to the same particular rules (additional to the general rules applicable to all names). The names of taxa in the genus group and family group are single words. (For the other meaning of the term see SPECIES GROUP (1)).

The Code expressly excludes provision for the nomenclature of taxa above the rank of superfamily. This is 'because the practice of zoologists in regard to them is not sufficiently uniform to permit the formulation of rules covering them at this time'. The taxa most commonly used at this level are class, subclass, superorder, order, and suborder; of these, class and order may be regarded as basic (see TAXON).

Availability of names. The first requirement of a name is that it should be made 'available' for the purposes of nomenclature. This is done by proposing it, for a particular use, in a publication. The form of the name, the information about its proposed use, the circumstances of proposal, and the method of publication must be in accordance with the conditions laid down in the Code. These conditions have been made progressively more stringent in respect of names proposed after certain dates—1930, 1950, 1960; the conditions applied to names proposed earlier (from 1758 onwards) are necessarily in more general terms. A name once duly made available, even if it is or becomes invalid for reasons mentioned later, retains a permanent status in nomenclature; generally speaking, it can be used (at the same group level) only for its original purpose—except that the availability of a specific or subspecific name in one genus does not affect the use of an identical name in another. A name proposed in a manner or circumstances that do not make it 'available' acquires no such status and is not thereby barred for the future; such a name is called a nomen nudum or (if it failed in respect of uncertain application) nomen dubium.

Priority; validity of names. 'Priority is the basic principle of zoological nomenclature. Its application may be moderated however, under conditions specified in the Code, to preserve a long-accepted name in its accustomed meaning.' Accordingly, the valid name of a taxon is the oldest available name applied to it, provided (i) that it is not invalidated by any provision of the International Code, e.g. those relating to homonymy (next section); (ii) that it has not been suppressed by the International Commission (mentioned later); (iii) that it has not become a forgotten name (defined below); and (iv) that it has not been superseded by the Commission's express grant of precedence to some other name (which thereby becomes what is sometimes called a nomen conservandum). The exceptional use of what are known as 'plenary powers' by the Commission, in the suppression and validation of names, is no new thing. Such a 'forgotten name' is one that 'has remained unused as a senior synonym of a name in general current use for more than 50 years', and it cannot be brought into use except by direction of the Commission. This provision should discourage the kind of antiquarian research that has too often led to instability of nomenclature by reviving names of overlooked priority discovered in old works, sometimes of indifferent merit.

Preoccupation; Homonyms. A name that has been made available is automatically invalidated if found to be preoccupied by an earlier use, either in the identical form (for species-group names) or in some very close approximation to it (as defined in the Code). The rule is that a name of supraspecific rank must be unique in the Animal Kingdom; a name of specific or subspecific rank must be unique in the particular genus. Identical names for different taxa are 'homonyms' of each other; a difference of a single letter, except where dependent on a variable spelling of the original word, is sufficient distinction (i.e. '*Apus*' and '*Apis*' are not homonyms). The name in its oldest use is the 'senior homonym', in any other use a 'junior homonym'. The 'law of priority' operates here also; the 'senior homonym' is valid, if other conditions are satisfied, while junior homonyms are invalid. They must be replaced, by a junior synonym, if one exists, or by a 'new replacement name' (nomen novum) if there is none—the term does not apply to a name for a new species.

'Primary homonyms' are those that were in fact homonymous from the outset, although possibly not detected as such until later. 'Secondary homonyms' are those that have become so as the result of taxonomic change—identical specific names may properly exist in related genera, but if these genera are later merged the two specific names become homonyms and one is invalidated; similarly, the splitting of a genus may validate a name that had hitherto been a junior homonym.

Synonyms. Whereas 'homonyms' are identical names proposed for different purposes, 'synonyms' are different names proposed for the same purpose. The operation of the 'law of priority' in respect of synonyms has already been noted, but some points of terminology remain to be mentioned. The oldest of a set of synonyms is the 'senior synonym', and is the valid name if other conditions are satisfied; the remainder are 'junior synonyms' and are invalid, except that the next in order of priority will be promoted if for any reason the existing senior synonym is invalidated (e.g. through being or becoming a junior homonym).

Synonyms are 'objective' (sometimes 'absolute' or 'nomenclatural') when they expressly refer to the same 'type' (see later), so that there can be no doubt about the identity of their meaning; they are 'subjective' (sometimes 'conditional' or 'zoological') when the identity of meaning is a matter of opinion and could thus be disputed. Loosely, 'synonym' without qualification is often applied to any junior synonym, as distinct from the valid name. A list of the names given by various authors to a particular taxon is known as the latter's 'synonymy'; this includes authors' names and publication dates, sometimes with full bibliographical references. The term may also be used for the relationship between different names for the same taxon.

The type concept. It has become a fundamental principle of nomenclature that a name is firmly attached to a 'type'. However the subjective limits of a nominal taxon may be altered, the name stays with the objective type, i.e. with the part of the original taxon that includes it. 'The name-bearing type provides the objective standard of reference by which the application of the name it bears is determined, no matter how the boundaries of the taxon may change.'

The type of a species-group taxon is a 'type specimen', originating from a 'type locality' (see TYPE SPECIMEN; and TYPE LOCALITY). The type of a genus-group taxon is a 'type species'. The type of a family-group taxon is a 'type genus'. Within a group the type of any taxon is also the type of its nominotypical subordinate taxon, if any.

A type species must nowadays be expressly designated by the author of the name of a genus-group taxon; for older nominal taxa there are various methods of selecting a type for a genus if no designation was originally made (see TYPE SPECIES). A type genus is that on which the name of a family-group taxon is based—the names of such taxa are purely derivative, not invented ad hoc. The type genus is not necessarily the one with the oldest name; and there are provisions to obviate changes in the names of the family-group taxa with changes in generic names.

Form of names. Scientific names must be either Latin or so formed that they can be deemed to be Latin; they are often derived from classical Greek, or formed from modern personal and geographical names or the like—and may even be arbitrary fabrications (thus, e.g. '*Dacelo*' is an anagram of '*Alcedo*' (see NAME, SCIENTIFIC)). They must be single words—two single words in a binomen, three in a trinomen; if a compound word is used, the parts must be united without a hyphen (subject to one rare exception probably not occurring in ornithology). Names must be written entirely in Latin or neo-Latin letters; and no figure, diacritic mark, apostrophe, or diaeresis may be used. The printing of linked vowels as diphthongs is now deprecated.

Pre-existing names that do not conform with the requirements are to be treated as incorrect original spellings and (like inadvertent errors) corrected; the corrected form keeps the date and authorship of the original. If the name consisted of two parts, these are to be united and any hyphen or apostrophe eliminated; if one part was in contracted form, the implication is that this should be written in full to make union possible. Diacritic marks are simply omitted, except that when the German umlaut sign is deleted the letter 'e' is to be inserted after the vowel that was modified. To give examples: *novae hollandiae, clot-bey, l'herminieri, st. thomae*, and *rüppellii* respectively become *novaehollandiae, clotbey, lherminieri, sanctithomae*, and *rueppellii*; to some extent usage had been tending in this direction before the 1961 Code made the changes mandatory. Certain recommendations concerning the formation of new names are appended to the Code.

Species-group names. A specific or subspecific name ('species-group' name in this sense—see SPECIES GROUP (1)) must be an adjective in the nominative singular agreeing in gender with the generic name, and changing in this respect if necessary; or a noun in the nominative singular standing in apposition to the generic name; or a noun (or, in some circumstances, an adjective used as a noun) in the genitive case. The genders and proper declension of non-classical names may often be difficult to determine, but the Code gives detailed guidance. A specific or subspecific name is always spelt with a small (lower case) initial letter.

Genus-group names. A generic or subgeneric name must be a noun in the nominative singular or be treated as such. It is always spelt with a capital initial letter. A subgeneric name does not form part of the binomen or trinomen, and except in taxonomic works it need not usually be shown at all; when required, however, the subgeneric name is given in parenthesis between the generic name and the specific name. (This practice must not be confused with that of showing a familiar but discarded generic name in parenthesis or brackets after the generic name actually used; such a name should be distinguished, within its parenthesis, by some such expression as '. . . formerly known as *X-us*'.)

Use of italics. Generic, subgeneric, specific, and subspecific names are preferably printed in a typeface different from that of the text, usually in italics. This does not apply to the names of higher taxa.

Family-group names. The names of family-group taxa are nouns in the nominative plural, and are always spelt with initial capital letters. They are formed from the name of the type genus, with the termination '-idae' (the 'i' is short) in the case of families and '-inae' in the case of subfamilies; the terminations '-oidea' and '-ini' are recommended in the case of superfamilies and tribes respectively.

Names of higher taxa. As already mentioned, the names of taxa above the level of superfamilies are not governed by the International Code, and even within the ornithological field there is variation of practice. One convention (followed in the present work) is to derive the name of an order or suborder from that of an included family, adding the termination '-iformes' in an ordinal name, and using a normal Latin plural for a subordinal name; when this is not done, there may be confusing identity between an ordinal name of one author and a subordinal name of another (see ORDER). In a different convention, ordinal names may be independent fabrications, e.g. 'Tubinares'. The type concept does not, in any event, apply at these higher levels.

Emendations. A scientific name, once established, cannot be rejected or altered simply because it is found to be inappropriate or even misleading. The stability of the conventional labels of which the system consists is more important than the accuracy of the meanings that prompted their adoption, e.g. than whether *maximus* is indeed the largest, or *sinensis* is characteristically Chinese. Further, a specific name cannot be rejected because it is a tautonym of the generic name, at one time thought by some to be objectionable.

It is, however, permissible to correct a lapsus calami or a copyist's or printer's error in a name as originally proposed (and mandatory to remedy defects in form such as the intrusion of a hyphen or apostrophe). Otherwise, the original spelling must be retained even if it is demonstrably erroneous in some respect. Subsequent misspellings of an original name—as distinct from deliberate 'emendations' within the permitted limits—have no nomenclatural significance.

Authorship. When the name of a genus (or subgenus) is mentioned by itself, the name of the author who first proposed it may be added; it is not usual to do this in respect of names of higher taxa. When the binomen constituting the name of a species is given, the name of the author who first proposed the specific name may be added; if he originally named the species in a different nominal genus, his own name is placed within parentheses to denote that he did not use the present combination in its entirety. A similar convention applies to the names of the authors of subspecific names, shown after trinominal combinations. The year of publication, or even the complete reference, may follow the author's name if the nature of the subject calls for this. Unless there is special reason to fear ambiguity in the use of a scientific name, however, authors' names are seldom necessary except in systematic publications.

International Commission. The International Commission on Zoological Nomenclature is a permanent body that originally derived its powers from the International Congresses of Zoology (now succeeded by IUBS). It makes recommendations to successive 'Congresses' for the clarification or modification of the Code. Between 'Congresses' it makes provisional amendments to the Code in the form of 'Declarations', and it gives 'Opinions' and 'Directions' on nomenclatural matters not involving changes in the Code. It exercises 'plenary powers' to suspend the application of provisions of the Code in particular cases where stability or universality seems likely to be disturbed; among other things, it can annul or conserve any name. On the basis of the Opinions rendered, it compiles 'Official Lists' of accepted, and 'Official Indices' of rejected, names and works. The International Trust for Zoological Nomenclature is an administrative body acting for the Commission in matters of property and publication. The Standing Committee on Ornithological Nomenclature, appointed by the International Ornithological Congresses, has no powers of decision but makes recommendations to the International Commission with regard to names in the Class Aves.

NOMINAL TAXON: the taxon, as objectively defined by its type, to which a given name applies (see NOMENCLATURE). A nominal taxon persists as a nomenclatural entity even if it has ceased to correspond with any taxon currently recognized for other purposes.

NOMINATE: obsolete equivalent of NOMINOTYPICAL.

NOMINOTYPICAL: adjective applied to a subordinate taxon, denoting that it contains the type of a subdivided higher taxon and bears the same name as that taxon (amended in suffix in family-group names, according to rank). Thus, every subdivided species has a nominotypical subspecies, in the trinomen of which the second and third terms are identical; every genus subdivided into subgenera has a subgenus with the same name as itself; and (for example) every family divided into subfamilies has a subfamily with the same name as itself (apart from ending in '-inae' instead of '-idae'). On the other hand, the definition (by its reference to types) excludes a species of which the specific name *happens* to be a tautonym of the generic name, and a genus with a name providing the stem of family-group names. It should be noted that the concept is purely nomenclatural; a nominotypical subspecies has no inherent pre-eminence over its fellows, and the term 'typical subspecies' is ambiguous as an equivalent. See NOMENCLATURE; TAUTONYMY; TYPE.

NON-BREEDER: an individual which does not nest in a particular breeding season.

NONPAREIL: cage-bird dealers' name for the Painted Bunting *Passerina ciris* (see BUNTING).

NONSENSE ORIENTATION: see NAVIGATION.

NON-VOCAL SOUNDS: see MECHANICAL SOUNDS.

NOSTRIL: see NARIS.

NOTOGAEA: see under ARCTOGAEA; DISTRIBUTION, GEOGRAPHICAL.

NUCHAL: pertaining to the nape (see TOPOGRAPHY).

NUCLEUS: see CELL.

NUKTA: name used in India for the Comb Duck *Sarkidiornis melanotos* (see DUCK).

NUKUPUU: *Hemignathus lucidus* (for family see HAWAIIAN HONEYCREEPER).

NULL HYPOTHESIS: see BIOSTATISTICS.

NUMBERS: the number of different kinds of birds in the world, and their distribution by zoogeographical regions; the numbers of individuals of any one kind in some stated area; the total of birds of all kinds in a given area; the grand total (so far as even an intelligent guess is practicable) of birds of all kinds in the whole world; also the number of individual birds constituting spectacular assemblies or taking part in great migratory movements. See also CENSUS; CLUTCH-SIZE; COUNT; DISTRIBUTION GEOGRAPHICAL; ECOLOGY; QUELEA CONTROL.

Number of species. Mayr (1963) estimated the number of living bird species at about 8,600. More recently a somewhat larger number is generally accepted, as there has been a tendency for some widespread polytypic forms to be subdivided and a number of new species have been discovered; a recent authoritative list (Morony *et al* 1975) recognizes 9,016 species. The new species discovered in successive recent decades are listed and discussed in a series of papers by Mayr and others (most recently, Mayr and Vuilleumier 1983). The number of new species found in the Peruvian Andes, including some very distinct birds of uncertain taxonomic affinities, has been especially striking.

Geographical incidence. No uniformly comparable estimates are available of the numbers of species in different zoogeographical regions. Obviously there is considerable overlap from region to region, and there is also the question of reckoning the sea birds, more readily grouped by ocean than by landmass. With such reservations in mind, general indications can be given: the number of breeding species in the Palearctic Region is about 950, in the Nearctic Region about 750. The Afrotropical Region may have over 1,500 species, Australasia (including New Guinea) about 1,100, seasonal migrants apart. The richest avifauna of all is found in the Neotropical Region—South America has been called the 'bird continent'—which is credited with some 2,500 breeding species.

Size of species populations. Accurate estimates of population size are usually extremely difficult to obtain. Large, spectacular birds which are easily identifiable and have a very limited range (like the California Condor *Gymnogyps californianus*) are relatively easy, as are those species restricted to just one or two islands; next come colonial seabirds with a limited number of colonies and a definite breeding season, so that expeditions may count occupied nests at each colony; thereafter the problems, and the errors in estimates, inevitably increase. A further hazard is that bird populations are dynamic in time, space and numbers: distributions may change and numbers may increase or diminish startlingly (in human terms) as part of a natural series of fluctuations. Nevertheless, such estimates as are available are of interest.

Small populations. Fisher (1960) listed nearly 100 species in danger of extinction or with populations of less than 2,000 birds. The IUCN *Red Data Book* documents many of these which must be on the verge of extinction. There were just 12 Japanese Crested Ibis *Nipponia nippon* in 1965, 22 in 1984; and the California Condor population, estimated at below 50 birds in 1975, had fallen to about 20 in 1983. The case of the Hawaiian Goose or Nene *Branta sandvicensis* is hearteningly different. Fisher listed only 50 birds remaining in 1946, but an intensive and skilfully managed rearing programme centred on the Wildfowl Trust at Slimbridge, Gloucestershire, and later in collections elsewhere, has raised this number sufficiently for several hundreds of captive-reared young to be liberated on a reserve specially purchased for them on the Hawaiian island of Maui. The Whooping Crane *Grus americana* had a world population of 33 in 1959, 50 in 1968; by 1980, partly as a result of cross-fostering, the eggs being incubated and the chicks reared by other crane species, this had risen to 120. The wild population in 1984 was about 100.

Some larger populations. In 1939, Fisher and Vevers surveyed 19 out of 22 known Gannet *Sula bassana* colonies, and believed that there were then about 165,600 Gannets breeding in the world. Since then, such large increases have occurred that the 1939 world population was almost doubled by the 1969 British and Irish 'Operation Seafarer' census of 138,000 pairs (Cramp *et al* 1974). The most recent estimate, in 1976, puts the world Gannet population at about 213,000 site-holding pairs, plus about 70,000 non-breeding birds (Nelson 1978). On a more parochial scale, the Great Crested Grebe *Podiceps cristatus* can be taken as an example of the handful of species in Britain for which regular census figures are available. From less than 100 birds in the latter half of the 19th century, the 1931 census showed about 2,800 adult birds. A repeat in 1965 showed an increase to about 4,500, and a further repeat in 1975 showed the increase to have continued, with between 6,000 and 7,000 adult birds counted. Possibly this increase arises in part from bird protection legislation, but more likely it is based on the tremendous boom in sand and gravel extraction for building purposes and the consequent creation of new stretches of suitable water. Even so, the grebes have had to contend with increasing chemical pollution of the water and disturbance from various recreational activities.

Whilst the threat of extinction may be an effective stimulus to count scarce species, the financial threat posed by some birds to agricultural crops has provoked censuses of potentially damaging species. Thus the US Fish and Wildlife Service was able to document the results of state wide Red-winged Blackbird *Agelaius phoeniceus* roost surveys during the winter 1976/77 in Tennessee and Kentucky, which showed 25 roosts containing in excess of one million birds each and a total of 47 million birds for the two states.

Also in North America, maximum annual wildfowl bags are established each year on the basis of population estimates. Regular counts of the Greater Snow Goose *Anser caerulescens* have shown a dramatic change in status from rarity to pest during this century. In 1900, the autumn population lay between 2,000 and 3,000; in 1921 between 5,000 and 6,000; in 1941 at about 20,000 and in 1966 about 80,000. Then the real expansion began, following a series of summers with good weather and successful breeding. A peak of almost 230,000 was reached in 1975, and numbers have since fluctuated about 200,000.

The commonest bird in the world. Darwin suggested that the Fulmar *Fulmarus glacialis* was the commonest bird, pehaps basing his view on his encounters with Fulmars at sea in the North Atlantic. Fisher disagreed and proposed that another predominantly Arctic-breeding bird, the Little Auk *Alle alle*, might exceed the Fulmar in numbers. Difficult though such numbers are to estimate, or indeed comprehend in Britain where only a handful have been seen, there may be more than 100 million of the Antarctic-breeding Wilson's Petrel *Oceanites oceanicus*.

It is possible also to guess at the most numerous land-bird. It could be either the House Sparrow *Passer domesticus* or the Starling *Sturnus vulgaris*, both now world-wide in scope, partly because of introductions. One of the weaver birds, the Red-billed Dioch or Quelea *Quelea quelea*, widespread in tropical Africa, in which single flocks may be over 1,000,000 strong, is an even more powerful contender. *Quelea* causes serious damage to cereal crops, and it is recorded (Crook and Ward 1968) that in the Republic of South Africa devastation of crops continued even after the slaughter by aerial spraying of over 100 million *Quelea* in one year. Considering that this estimate is only of the proportion of dead birds from only a proportion of *Quelea*'s vast range, this is likely to be the world's most numerous bird.

Some local populations. At least three attempts have been made to estimate the summer land-bird breeding population of Britain. The first was by E.M. Nicholson, who in 1932 arrived at a figure of about 80 millions. J. Fisher calculated about 100 millions in 1939, revising this to about 120 millions in 1946. These estimates were based on randomly taken sample counts from various habitats at various times, but since 1961 most census work has been carried out by members of the British Trust for Ornithology, on a greatly expanded and properly organized basis in the Common Birds Census (CBC). Using figures available from the annual census returns, and Ministry of Agriculture land-usage statistics, Fisher and Flegg (1974) arrived at a figure of about 134 millions for 1972.

Bird population density varies widely with habitat: rough figures derived by Fisher and Flegg from the CBC indicate that with 17 birds/hectare, scrub is the richest habitat, closely followed by suburban and woodland areas, with a considerable gap to farmland at 6 birds/hectare, water areas 2.5 and most barren, moorland and hill grassland with about 1 bird/hectare.

Obviously, the numbers of the various species differ greatly. Of about 500 species on the British list, only about 100 contribute significantly in numbers, and the great bulk—about 75%—is made up by less than 50 species. Fisher (1940) calculated that the most numerous birds in England and Wales were the Chaffinch *Fringilla coelebs* and the Blackbird *Turdus merula* with about 10 million each, followed by the Starling and the Robin *Erithacus rubecula* with 7 million each and the House Sparrow with 3 millions. Fisher and Flegg (1974) produced new estimates, with the Blackbird at 15 million, a newcomer, the Wren *Troglodytes troglodytes* in second place at 10.5 million, the Robin at 10 million, Chaffinch and Dunnock *Prunella modularis* at 8 million, and the Willow Warbler *Phylloscopus trochilus*, the most numerous summer migrant, with 6 million. An interesting contrast comes from Merikallio (1958), who carried out a comprehensive study of the birds of Finland. Most numerous was the Willow Warbler, with about 11.4 million, followed by Chaffinch (10.6), Tree Pipit *Anthus trivialis* (3.3), Willow Tit *Parus montanus* (2.8) and Spotted Flycatcher *Muscicapa striata* (1.9).

Assemblies and movements. Some of the most spectacular manifestations of bird-life are to be seen at the breeding places of colonial nesters. Even the enormous gannetries of Grassholm, Bass Rock and St Kilda in Britain are dwarfed by the Antarctic rookeries of the Adélie Penguin *Pygoscelis adeliae* with over one million pairs or Sooty Tern *Sterna fuscata* colonies on oceanic islands estimated at 1–10 million pairs. Perhaps the most spectacular feeding concentration of all must be the million or more Lesser Flamingos *Phoeniconaias minor* gathering on Lake Nakuru in Kenya. Roosts, too, hold large numbers. City centres like Trafalgar Square in London attract huge Starling flocks, but reed-bed roosts of millions of Sand Martins *Riparia riparia* and in the USA of the Red-winged Blackbird *Agelaius phoeniceus* may contain birds at a density exceeding 2.5 million birds/hectare.

Birds on migration often travel in vast flocks, though as so many are night migrants, these tend to be more often observed by radar. Perhaps the most spectacular sights are at the short sea-crossings beloved by soaring birds, at the Bosphorus and the Straits of Gibraltar, where countless thousands of raptors and storks cross to Africa in spirals vanishing from sight into the sky. Looked at on a wider scale, the figures are even more impressive. Moreau (1961) gave his reasons for supposing that about 600 million European birds perform the Mediterranean-Saharan transmigration each autumn. This means that 150,000 birds per km of longitude enter North Africa, an average of 2,500 per km daily over 2 months. (A.L.T.) J.J.M.F.

NUMBER SENSE: see COUNTING.

NUMERICAL TAXONOMY: see CLASSIFICATION.

NUMIDINAE: see GUINEAFOWL.

NUN: substantive name of some mannikins *Lonchura* spp. (see ESTRILDID FINCH).

NUNBIRD: substantive name of *Monasa* spp. (see PUFFBIRD).

NUNLET: substantive name of *Nonnula* spp. (see PUFFBIRD).

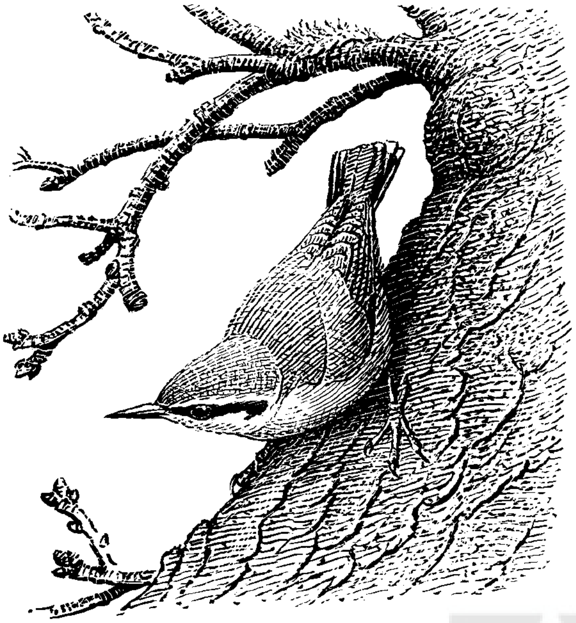
NUPTIAL: pertaining to the breeding season, a term applied especially to plumage and display.

NUTCRACKER: substantive name of the 2 species of *Nucifraga*; used without qualification, in Britain, for *N. caryocatactes* (see CROW (1)).
See photo FOOD STORING.

NUTHATCH: substantive name of the more typical species of Sittidae (Passeriformes, suborder Oscines); used in Britain without qualification for the common European species; in the plural, general term for the family. The family is widely distributed.

Characteristics. Nuthatches are small birds, mostly *c.* 14 cm long, but some up to 20 cm. They are all similar in form; a compact body with a short tail, very long sturdy toes and claws, and a long symmetrically tapered bill. In many species a black stripe runs through the eye, and some have a black cap. The upper parts are blue-grey in most of the typical species, blue-green in 3 found in southern Asia. The under parts are white, grey, reddish brown, or chestnut. Sexual dimorphism is already evident in the juvenile plumage of some species.

All members of the family are climbing birds that seek their food on trees, or in a few cases on rocks. Instead of using the tail for support when clinging to a tree trunk, like woodpeckers or treecreepers, they climb obliquely, with one foot high to hang from, and the other low for support. They can climb down a tree, head foremost, by the same method.



Nuthatch *Sitta europaea*. (*D.W.*).

Habitat. The great majority of the true nuthatches *Sitta* inhabit broadleaved, coniferous or mixed woodland, either lowland or montane, though the rock nuthatches *S. neumayer* and *S. tephronota* are found typically on rock faces or on buildings, as is the European *S. europaea* occasionally.

Distribution. The family is predominantly Holarctic, with 4 species in North America and the rest in Asia and Europe. The family is not represented in South America, Australia or New Zealand. So far as is known nuthatches are non-migratory, except for individuals of the Red-breasted Nuthatch *Sitta canadensis*. The most widely distributed species is *S. europaea*, of which the many races range through the whole of Europe and northern Asia to the limit of tree growth, with a small population in Africa across from Gibraltar. The recently discovered *S. ledanti* is restricted to one mountain in Algeria. *S. europaea* is particularly adaptable, not specialized but capable of utilizing most kinds of trees and of seeds, making caches of the latter in autumn. The Chestnut-bellied Nuthatch *S. castanea* of southern Asia is similar, but differs in voice and in showing marked sexual dimorphism. The Eastern Rock Nuthatch *S. tephronota*, specialized as regards habitat, is found in the warmer parts of Asia; in Persia it occurs along with Neumayer's Rock Nuthatch *S. neumayer*, which reaches its western limit at the Adriatic. The Giant Nuthatch *S. magna* is restricted to the mountains of central Burma, northern Thailand, and Yunnan; it is as large as a Great Spotted Woodpecker *Dendrocopos major* and flies like a member of that family (Picidae). Other species in eastern Asia are the White-tailed Nuthatch *S. himalayensis*, the Yunnan Nuthatch, *S. yunnanensis*, and the Chinese Nuthatch *S. villosa*. Very similar is the Corsican Nuthatch *S. whiteheadi*, once thought to be conspecific with the Red-breasted Nuthatch of North America. In the Near East is found the rather unusually coloured Krüper's Nuthatch *S. krueperi*. In the southern part of North America are found 2 closely related forms, the Pygmy Nuthatch *S. pygmaea* and the Brown-headed Nuthatch *S. pusilla*. In the mountain ranges of Afghanistan and Kashmir dwells the White-cheeked Nuthatch *S. leucopsis*; very similar but somewhat larger is the White-breasted Nuthatch *S. carolinensis* of North America. In southern Asia there are 3 brightly coloured species: the Velvet-fronted Nuthatch *S. frontalis* (coral-red bill in some races), the Azure Nuthatch *S. azurea* (confined to Indonesia) and the Beautiful Nuthatch *S. formosa* (Sikkim to eastern Assam).

Food. Insects, spiders, and other small invertebrate animals are eaten. The birds inhabiting northern or mountainous areas feed largely on seeds in winter, and some small species are specialized for eating the seeds of conifers. Seeds and all larger prey species are hammered into cracks and are there either broken into small pieces or opened up by strong pecks. The European species is able to open even hazel-nuts, hence the name 'nuthatch' (nut hack). Many species store food, especially seeds, by hiding them singly in cracks or under bark, if possible hiding them so that they are not visible.

Behaviour. Nuthatches are strongly territorial, and some defend a territory even in winter, when, however, some are social and form flocks.

Voice. There are various calls, but the song mostly consists of repeated single notes that often sound like a trill. The songs of several species can be imitated by whistling.

Breeding. Members of the genus *Sitta* mostly nest in natural hollows in trees, but some small species make holes for themselves in dead wood; 2 species nest in crevices in rocks. Several species reduce the size of the entrance with mud and fill up all cracks; one fills up cracks only. Two rock nuthatches wall up a semi-enclosed hollow and constructs an entrance tube.

The 6–10 eggs are white with reddish spots. Incubation takes 14–15 days. The young usually remain in the nest for 22–24 days and when fledged are fully capable of flying and climbing; in a further 8–12 days they are independent.

NUTRITION: the qualitative and quantitative aspects of diet. An adequate diet must supply a bird with (1) sufficient energy for activity and thermoregulation and (2) specific nutrients, such as amino acids, vitamins and minerals that are essential for body growth and maintenance. Energy requirements have been extensively studied in many domestic and wild species under a variety of environmental conditions (see ENERGETICS) but the detailed requirements for specific nutrients of most birds are still poorly known.

Energy. Energy-yielding compounds are usually required in daily amounts of several grams per kilogram body weight. For many bird species the major energy-rich component of the diet is carbohydrate in the form of starch and sugars derived from vegetable foods such as seeds, fruit and foliage, though some seeds and fruit are also rich in fats. Cellulose and lignin are not digested by most birds, though those with large gut caeca, e.g. the subfamily Tetraoninae, may do so (see ALIMENTARY SYSTEM). Animal prey provides fats and some carbohydrates as a direct energy source. Usually, however, the large proportion of protein in animal food must also provide energy by the deamination (removal of the nitrogen group) of its constituent amino acids. The resulting organic acids can then be metabolized in the same way as the breakdown products of fats and carbohydrates (see METABOLISM).

In the long term the energy expenditure of a bird is balanced by an equal intake of energy as food. If food intake is temporarily insufficient the remaining energy requirement is supplied by the consumption of body reserves, primarily fat, e.g. during overnight fasting, during incubation, or to sustain long-distance migration. If food intake exceeds the immediate energy requirement the surplus may be stored as fat, irrespective of the nature of the food.

Water. Water comprises about 70% of non-fat body tissue. Small birds lose water more rapidly than large ones so that the daily rate of water intake is inversely related to body size. However, the minimum water requirement to avoid dehydration is considerably less than the *ad lib* consumption. Some desert birds may not need to drink at all, maintaining their water balance by concentrating their urine and by efficient conservation of the free water in their food (even dry seed contains some free water), together with water produced chemically by oxidation of the food.

Specific nutrients. While an adequate energy balance may be maintained by the breakdown of a wide variety of fats, carbohydrates and proteins, other essential metabolic processes demand the inclusion in the diet of minimum quantities of specific nutrients.

Protein and amino acids. The maintenance of life requires a basal rate of nitrogen metabolism adequate for the continual renewal of body tissues. Additional nitrogen is required for processes such as growth, moult and reproduction. In the chicken on a nitrogen-free diet the basal rate of nitrogen excretion is about 2 mg per calorie basal energy expenditure but is double this amount when dietary nitrogen is freely available. In chickens and in the American Tree Sparrow *Spizella arborea* the latter rate of nitrogen excretion is obtained on a diet containing about 7% protein.

The form in which dietary protein is ingested is of great importance. The amino acids from which new protein is constructed cannot all be synthesized in the body from other nitrogen sources. Certain essential amino acids (arginine, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan and valine) must therefore be present in the food, usually in daily amounts of about 0.1 g per kg of body weight or less. Not all are essential at all stages of the life cycle, e.g. histidine is not required for maintenance yet is essential during growth and reproduction, whereas glycine is necessary during growth only. The synthesis of large amounts of feather keratin during moult requires an abundant supply of the non-essential sulphur-containing amino acid cystine, which is not required in such quantities by other body tissues. Most birds, whose moult is prolonged over many weeks, can nonetheless meet this extra demand from the diet or by synthesis from other amino acids (Newton 1968).

The seasonal dietary changes observed in wild birds will frequently indicate changes in requirement for protein, or for particular amino acids. For example, while the seed food of granivorous birds may provide an adequate balance and quantity of amino acids for moult, it may be inadequate for egg production and chick growth. In particular seeds are deficient in lysine, so that the diet during breeding, particularly of laying females and growing chicks, is supplemented by insects that are rich in lysine. An interesting temporary dietary specialization is shown by parent Great Tits *Parus major*, which feed their nestlings between 5–8 days old with large numbers of spiders (Royama 1970). Presumably spiders, which are otherwise unprofitable food, contain a nutrient essential at that stage of growth, which is scarce in other food.

Minerals. As well as the main structural elements (calcium and phosphorus) and elements essential for maintaining homeostasis in body fluids (sodium, potassium, chlorine), other trace elements are required in much smaller amounts (magnesium, manganese, zinc, iron, copper, selenium and iodine). Compared with the organic constituents of the diet, minerals show a much higher degree of recycling within the body. Iron (for haemoglobin synthesis), iodine (for thyroid hormone synthesis) and calcium are all recycled to some extent, so that the daily maintenance requirements may be difficult to determine. Calcium is particularly important during growth for bone formation and during laying for eggshell production. The maintenance requirement for calcium in hens is about 100 mg per day. Some of the calcium for eggshell formation is stored prior to use in medullary bone but many species supplement this to a large extent from dietary calcium, often collected specially in the form of snail shell, bone fragments or calcareous grit on the days when the eggs are receiving their shells in the oviduct. Calcium has been thought to limit reproduction in vultures, which feed only on the soft portions of carcasses. Various diseases of poultry are known to result from deficiencies of trace elements such as zinc, copper, manganese and selenium.

Vitamins. Vitamins are required daily in the diet in only microgram quantities per kg of body weight but their absence can cause severe deficiency diseases. The water-soluble vitamins (e.g. the B vitamins thiamine, biotin, riboflavin and folic acid; vitamin C) function as coenzymes in specific metabolic reactions that occur widely in the body. Deficiencies of several B vitamins result in various leg disorders, at least in poultry, where they may develop rapidly despite the synthesis of all the B vitamins in the gut by microbial action. Many birds synthesize vitamin C in the kidney or liver or both, while others require a dietary source, e.g. the Red-vented Bulbul *Pycnonotus cafer*.

The fat-soluble vitamins (A, D, E and K) act only at restricted locations in the body. Vitamin A is essential in the formation of visual pigments in the retina. It may be obtained directly in the diet or by the ingestion of β-carotene from plant food, which is converted to vitamin A in the intestinal wall. Carotenoids are also important in the diet as precursors of many feather pigments, e.g. the yellow of orioles *Oriolus* spp. and the reds of bush-shrikes *Laniarius* spp. and the Scarlet Ibis *Eudocimus ruber*. An adequate dietary supply of vitamin D_3 is important to laying hens since this has to be stored in the egg to ensure proper bone mineralization in the chick. Vitamin K stimulates the normal clotting of blood and deficiency, to which poultry are particularly susceptible, leads to haemorrhaging. P.J.J.

O

OBSERVATORY, BIRD: an establishment, usually on a coastal headland or off-shore island, maintained primarily for the study of bird migration by observation and ringing (see MARKING; TRAPPING). In Britain, the mainland observatories tend to operate throughout the year whilst most island observatories confine activities from early spring to late autumn. The opportunity of handling large numbers of birds caught for ringing is used for various associated studies. Some observatories have experienced full time wardens, whilst others rely entirely on voluntary manning. Visitors are accommodated at most observatories.

The prototype observatory was established on the North Sea Island of Heligoland in the mid-19th century when Heinrich Gätke commenced systematic recording of migrants. In addition to collecting specimens, which included many vagrants previously unknown in Western Europe, Gätke introduced a daily survey and estimation of numbers of migrant birds, which he continued until 1887. The daily census of birds present within a defined area is now standard practice at all British bird observatories and at many on the continent of Europe. The modern bird observatory at Heligoland was established by Weigold in 1909, when large scale trapping and ringing of migrants in specially designed wire-netting traps (still universally known as 'Heligoland traps') largely replaced the collection of specimens.

In the early years of the present century, pioneering work in the British Isles was carried out by W. Eagle Clarke who spent substantial periods at such vantage points as Fair Isle, St Kilda, the Kentish Knock Lightship and the Eddystone Lighthouse. The repeated visits by Misses E.V. Baxter and L.J. Rintoul to the Isle of May (Firth of Forth) and of C.J. Patten to various Irish lighthouses were in the same tradition. Regular observatories came later, and their development has been a marked feature of non-professional ornithological endeavour since 1945.

In Britain only two observatories were in operation before 1945: on the island of Skokholm (Dyfed) founded by R.M. Lockley, and on the Isle of May. Following the war disruption, both observatories reopened and others were started by local interests, often at locations where ornithologists of an earlier generation had found observation and collecting profitable. Observatories have always remained autonomous, but have enjoyed very close links with the British Trust for Ornithology which has co-ordinated their activities and regularly published their findings.

Most observatories have produced detailed annual or bi-annual reports, and considerable analyses have been carried out, using the voluminous logs containing daily counts. Published results have shown the timing and scale of visible migration and, in many cases, the different migratory patterns of birds originating from different geographical areas. Furthermore, the daily counts of migrants covering a period of past decades are being used as crude indicators of the fluctuations of bird populations.

The present English observatories are Dungeness and Sandwich Bay, both in Kent, Portland Bill in Dorset, Lundy Island off Devon, Walney Island in Cumbria, and on the east coast Holme in Norfolk, Gibraltar Point, Lincolnshire, and Spurn Point, Yorkshire. Bardsey Island, Gwynedd, is the main Welsh observatory following the termination of ringing at Skokholm in 1976. The Calf of Man is located just south of the Isle of Man.

In Scotland, Fair Isle, Shetland, is especially famous for rare vagrants and the Isle of May is situated in the Firth of Forth. Cape Clear in south-west Ireland is an outstanding observatory for recording seabird migration. An observatory is established on Copeland Island off the east coast of Northern Ireland.

Observatories elsewhere in Western Europe record visible migration and operate ringing stations, especially in the Baltic Countries. In 1903, ringing commenced at Rossitten—a location then German but now renamed Rybachi and still operating as an observatory under its Russian staff. In southern Sweden, vast migrations are continuously recorded at Ottenby and Falsterbo, the latter being a particularly famous location for the observation of Scandinavian raptor passage. Ringing stations, too numerous to name individually, are now operating observatory techniques in most Western European Countries.

In North America bird observatories are fewer than in Europe, but tend to be far larger establishments, each with permanent scientific staff. The Manomet Observatory in Plymouth, Massachusetts, and Point Reyes Observatory in California both research bird migration and are important ringing stations. These observatories are also concerned with wider ecological studies, especially on marine mammals.

In Canada, Long Point Observatory is located on the north shore of Lake Erie. The observatory provides accommodation for both amateur naturalists and professional biologists and additionally Long Point administers two local summer field stations where visitor accommodation is also available. OCCIPUT: the back of the head (adjective 'occipital')—see TOPOGRAPHY.

OCEANIC BIRDS: birds capable of supporting themselves by feeding at a distance from land. Species confined to inshore waters such as divers and ducks are not usually included among seabirds, and it seems logical to exclude from the oceanic category the diving petrels, cormorants, darters, pelicans, skimmers, and about two-thirds of the terns and gulls as well, which rarely or never feed as far as 20 km from land. Distributions of inshore feeders are based on the geography of the land, and oceans tend to be barriers to their spread, whereas the distributions of the most pelagic species (e.g. albatrosses Diomedeidae) are based on the geography of the oceans and correspond, e.g. with those of whales. This restriction leaves a total of about 175 oceanic species, belonging to 13 families in 4 orders: (1) Sphenisciformes—PENGUINS; (2) Procellariiformes—albatrosses, shearwaters, PETRELS, storm-petrels; (3) Pelecaniformes—boobies, GANNETS, FRIGATEBIRDS; (4) Charadriiformes—PHALAROPES, SKUAS, GULLS, TERNS and AUKS.

Feeding ecology. All sea-feeding birds have enlarged nasal glands, capable of excreting brine through the nostrils or mouth (see EXCRETION, EXTRARENAL) and thus ridding the body-fluids of excess salt. Oceanic birds have no need of fresh water; and none are dependent on plant foods. As on land, species frequenting the same feeding areas (habitats) tend to occupy different niches, separated by the nature of the foods they eat and/or their feeding methods (Ashmole 1971; Murphy 1936; and Fig. 1). Bird habitats at sea are defined by less familiar variables than those on land.

Primary production in the ocean depends on microscopic green plants which live within 50–100 m of the surface (the euphotic layer); at greater depths there is not enough light for photosynthesis. The limit to productivity is set by the amount of nutrients available (especially nitrates and phosphates) and the rate at which they circulate through the food chain. The plants are eaten by small herbivores, mostly crustacea, and these by one or more tiers of carnivores. The cycle is completed by microbes which decompose dead organic matter and return the nutrients to the water; but there is a tendency for some of it to fall out of the euphotic layer before decomposition is complete, and thus gradually remove the nutrients from the system.

Over the continental shelf productivity is generally high because, in comparatively shallow water, nutrients are fairly quickly restored to the surface by tidal and other water movements. This constitutes the *neritic province*, and in it living food of suitable size for birds is often abundant, not only at the surface but in midwater and on the bottom. One finds surface-feeders like gulls, and diving birds like cormorants, penguins, auks and ducks, some of which can go right to the bottom at 100 m or more. In high latitudes plant productivity falls low in winter when the days are short, and some parts of the sea are covered with pack-ice, but many of the animals (including fish) survive in undiminished numbers, in more or less quiescent states. Zooplankton is greatly reduced. Some of the birds migrate towards or even beyond the tropics, but many temperate neritic species are able to stay broadly in the same waters throughout the year.

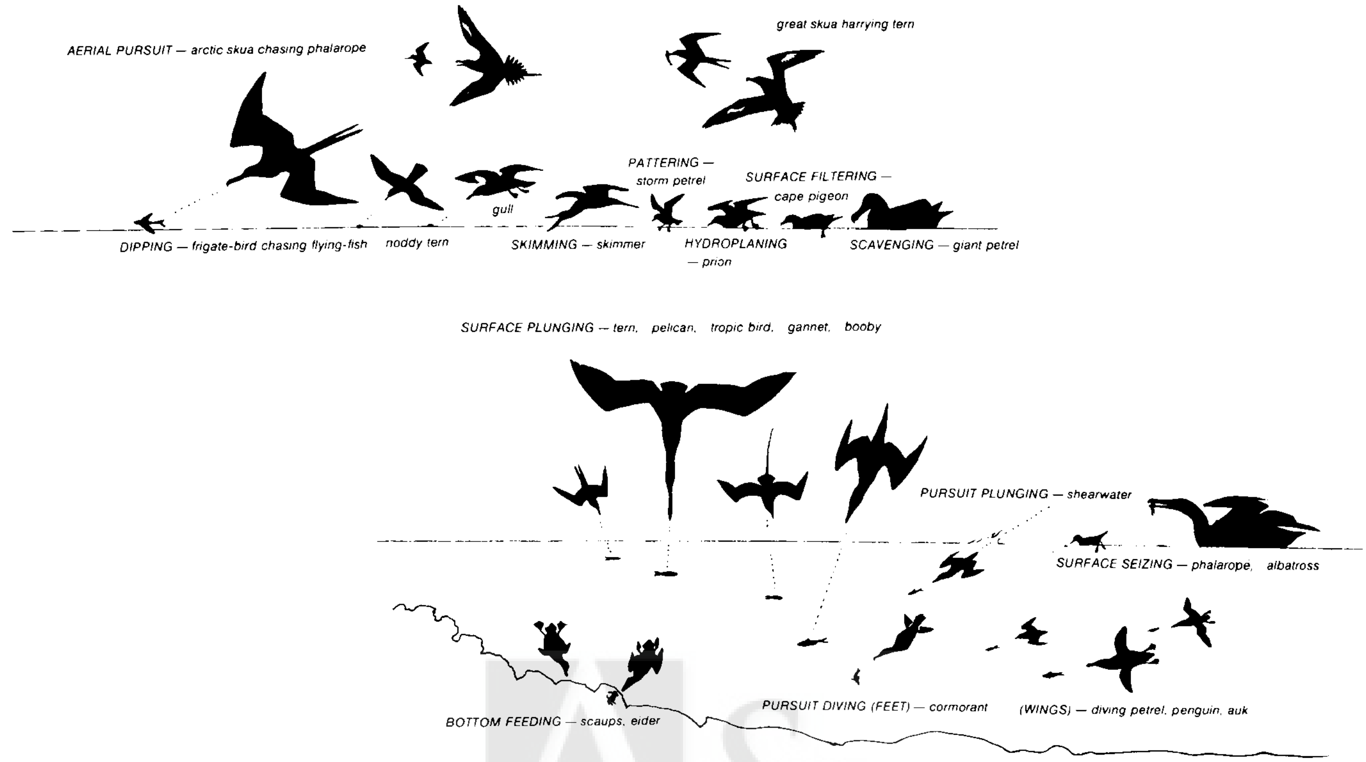

Fig. 1. Seabird feeding methods. (After Ashmole in Nelson 1978, The Gannet).

Outside the continental edge lies the deep-water *pelagic province*. At the higher latitudes the plankton is again seasonal, often with a major burst of plant cells in the spring. Much of the abundant dead matter falls straight into the depths below and its nutrients are lost, at least for the rest of the season; they are only restored to the surface mainly through water-mixing in winter storms. The annual productivity of bird foods—mainly fish, squids and shrimps—is only a half to a third what it is in neritic waters on the same parallel; but a dozen or so transequatorial migrants among the shearwaters and storm-petrels manage to enjoy summer feeding twice a year.

Seasonal changes are less marked in the subtropical and tropical waters. A very warm and therefore light and stable stratum, floating on top in the absence of strong winds, tends to prevent mixing. Productivity, although continuous, is therefore low, of the order of 1% of that in temperate neritic waters. The dearth of living organisms makes the water clear and blue, and deepens the euphotic layer; but what nutrient cycling there is, is efficient in the sense that little organic matter is lost into the abyss (Cushing 1975).

The squid and fish that support the birds are sparse and keep down out of reach by day. Nevertheless this is the habitat of many gadfly-petrels and storm-petrels, tropic- and frigate-birds, boobies and sooty terns, all remarkably adapted to search for scarce food. Most feed from the air by dipping or quick-plunging (swimming under water evidently does not pay; the water being so clear, taking prey by surprise may be impossible). Their opportunities come when they find and follow schools of dolphins or tunnies, which drive flying-fish and other prey to the surface; or in the dusk and darkness when the plankton migrates to the top; or in places where the productivity is higher.

High productivity in tropical waters is confined to local areas where nutrient-rich water has upwelled from below, as it does on a vast scale in the Canary and Benguela currents, and the California and Peru currents, which flow towards the Equator along the western coasts of Africa and the Americas. Trade-winds blowing offshore (and Coriolis force) roll the currents over to seaward, bringing up richer water on the landward side in which the plankton quickly starts to 'bloom'. Productivities can rise as high or higher than any found in temperate neritic seas, as off Peru with its once vast anchoveta fishery and its teeming guano birds. In some places the water drifts out to the westward in a tongue for hundreds of kilometres before the effect has completely waned, and so provides a large fertile enclave, isolated at a great distance from the nearest comparable habitat. As a result, while low-latitude pelagic birds tend to have wide if not pantropical ranges, the upwelling specialists typically include endemics. The Humboldt-Peru current has most, including the Peruvian Booby *Sula variegata*, but the Benguela quite closely resembles it in having an endemic penguin and two salt-water cormorants, all diving in the turbid waters.

Upwellings cause water to spread out on the surface, creating a 'divergence'. Winds can also drive two currents together, and force the denser water-mass to dive under the lighter, at a 'convergence'. The movements, though sometimes vast, are slow, so that anything carried on the surface stops when it reaches the sinking front and stays there. The front is soon marked by flotsam and a slick of oil (at least in part of biological origin) and immediately below the surface there is a similar pile-up of plankton buoyant or active enough to remain at the top and escape going under. This attracts fish and squids, and they attract birds sometimes in hundreds, hour after hour, at what may be the only place in a day's flight where they can feed to repletion and pick up a load for a far-away chick. Many such convergences (and divergences too) are local and transient, being produced by the swirls where currents meet. They occur in all seas, attracting terns, storm-petrels and phalaropes among other birds, but their importance diminishes in the higher latitudes where food is easier to find.

In the global patterns of ocean circulation, particular water masses tend to perpetuate their own special characteristics of temperature, salinity and productivity. Recent exploration, e.g. the International Indian Ocean Expedition in the 1960s, has served to emphasize how responsive oceanic birds can often be to small differences in these characteristics, and the extent to which the birds have exploited them to diversify the number of pelagic niches. Many pairs of related species can be listed which avoid the costs of interspecific competition by becoming specialized to live in subtly different ocean habitats and thus promoting their own mutual exclusion.

Wind drift. The wind must also play a part in differentiating habitats. Oceanic birds range from sparrow-sized storm-petrels to the great albatrosses weighing 7–12 kg. A wind strength of 100 km/h is enough to blow spume off the combers, and the smallest swimming birds risk hurtling with it, unable to hold on. Wrecks of Leach's Storm-petrels *Oceanodroma leucorhoa* are well known in Britain, when migrant individuals have been caught in autumn gales and driven exhausted ashore. Less commonly phalaropes are similarly overtaken, and also Dovekies or

Little Auks *Alle alle* although they, being able to dive, are less vulnerable. Normally the boreal storm-petrels and phalaropes complete their passage south before the gales, and they winter in calmer climes. Some terns make non-stop ocean flights but are not necessarily in danger when driven ashore.

The larger pelagic species can often use the wind to advantage, e.g. to increase their hunting range. Sooty Shearwaters *Puffinus griseus* breed in the southern hemisphere and winter in the temperate westerlies of the North Pacific and North Atlantic. The majority of them direct their northward flight to reach the windward side of either ocean, thereby providing for the maximum leeward travel before they eventually return south to breed, thus completing a wide loop. The Short-tailed Shearwater *P. tenuirostris* does the same, but only in the Pacific. Many ringing recoveries of young Giant Petrels *Macronectes giganteus* prove that the majority leave their birthplace downwind, and that some survivors are capable of circling the southern ocean in 12 months (J.W.H. Conroy); this may be a normal though perhaps not inevitable routine. Some Wandering Albatrosses *Diomedea exulans* evidently do the same (J.L. Mougin *et al*). A yearly circuit on the 50th parallel would require a mean leeward drift of 70 km/day, a trifling distance to these untiring travellers.

Oceanic birds show by their ability to get back, after long absences, to remote islands that are dots in the ocean, and to their nests, when experimentally removed and released at distances exceeding 1,000 km, that they have superb navigational powers. These resemble in their effectiveness those exercised by a mariner with his sextant, chronometer and almanac. They may also be the same in principle, because physics seems to offer no feasible alternative (see NAVIGATION).

Flight. Albatrosses and large shearwaters rival the vultures as economical fliers. They obtain free 'lift' from the combination of wind and waves. Waves tend to run with the wind but less fast, so that the overtaking air-stream flows up the back of each swell. Borne on its long stiff wings the bird alternately rises and falls, sweeping down into a wave-trough across the wind, turning steeply to windward to rise into the updraft above the on-coming wave, which carries it slanting up to a height of 10–15 m where the air-stream levels out. It then uses its height to glide off in the desired direction. The manoeuvre is endlessly repeated, 10–15 times a minute, the rate varying with the size of bird, wave and wind. P. Idrac found that albatrosses could glide indefinitely, given a surface wind of 18 km/h or more; a Fulmar needed at least 22–25 km/h. Calm weather tends to impose insupportable costs on an albatross and may force it to stay on the water. For this reason most species keep out of the tropical doldrums, though the Waved Albatross *D. irrorata* is endemic to Galapagos, which is on the Equator.

Most if not all oceanic birds habitually fly by night as well as day. More remarkably, frigatebirds are known to reach 1,000 km from land at times, and Sooty terns *Sterna fuscata* can turn up almost anywhere in the tropical oceans, without ever resting on the water at all. Neither of them have waterproof plumage. Sooty terns experimentally prevented from taking off became waterlogged in as little as 25 min and were unable to rise until they were dried. Frigatebirds take longer to soak but are equally averse to swimming; they are big birds but astonishingly light, patrolling from a height as they ride on thermals and eddies. The Sooties beat their buoyant wings like other terns, and are not known to alight except on land at their breeding places. Indisputable facts have finally eroded disbelief, and the conclusion first published by the pioneer behaviourist J.B. Watson in 1908, that they can remain airborne, feeding by dipping to the surface, for months at a time has finally won the day. It is not inconceivable that they could doze at times, holding their posture, altitude and course by subconscious perception and control.

Many oceanic birds will land unafraid on floating objects including bergs and sea-ice, though they will not alight on unfamiliar ground or, in the case of terns, on the water.

Population ecology. The southern hemisphere, with vaster oceans, supports far more species than the northern. The largest taxon, the Procellariiformes (see PETREL), comprises nearly 100 species of which well over half breed in the South Temperate and Antarctic zones, about a quarter in the tropics, and only the remaining sixth in the North Temperate and Arctic. Oceanic birds generally nest colonially. The pelagic foragers especially have frugal, protracted life-styles presumably evolved in response to low and irregular rates of food intake. Most lay only one egg or rear only one chick from c/2. Incubation and fledging periods are prolonged, the former for reasons unknown, the latter presumably because the requisite amount of food may often take long to provide, even for one chick. Although parents and chick are both inured to fasting, nestling losses are often high. Such slow reproduction must necessarily be matched by longevity; thus a Fulmar Petrel *Fulmarus glacialis* (the best attested example), if it survives to breed, will live on average to about 44 years of age, showing how remarkably the risks to survival can be avoided. Predators lurk in the water, not in the air, which may partly explain the value of perpetual flight, as an alternative to speed in the water.

Another common trait is long adolescence, often exceeding 5 and sometimes 10 years, which holds an unusually large segment of the population as non-breeders, permanently at sea or annually visiting the breeding colonies just to prospect. The reproductive rate is so low, even at best, that it needs only minor misfortune to put mortality ahead. The equilibrium would be unstable were it not for this great reserve of recruits, built up in good years, ready for the chance to fill gaps in the breeding establishment. Being colonial birds as well, the breeders must be prone to occasional wholesale destruction from local disasters. A standing reserve appears to be an essential stabilizing element in the long-life, slow-breeding strategy. An added benefit is that, except in emergencies, all new breeders will already have survived an arduous test of fitness (Wynne-Edwards 1962).

Efforts to study the oceanic distribution of seabirds and its seasonal changes, go back to about 1920. Bird densities are still measured and compared by counting the numbers seen per unit time, in strip-transects from moving ships or (rarely) from light aircraft. Because there are specific differences in bird size, conspicuousness, and behaviour towards ships, it is difficult to convert the data into absolute densities per unit area. A few estimates of biomass, food consumption and energy flow have, however, been attempted (see Sanger 1972 and Furness 1978 for further references). See photo AGE. V.C.W-E.

OCELLA: eye-like pattern on plumage, e.g. in the train of a Peacock *Pavo* sp.

OCREATE: same as 'holothecal' (see BOOTED).

ODONTOGLOSSAE: former ordinal name of the Phoenicopteri (see under CICONIIFORMES; FLAMINGO).

ODONTOGNATHAE: a superorder of extinct birds (see under CLASS).

ODONTOPHORINAE: see PHEASANT.

ODONTOPTERYGES: see under FOSSIL BIRDS.

ODOUR: not noticeable in most birds, but some species give off a characteristic smell. The latter is often, for widely unrelated species, described as 'musky', but in the absence of any systematic study it cannot be assumed that the realities so named are similar. The male Musk Duck *Biziura lobata* in the breeding season is said to be inedible because of its musky odour. The mature Muscovy Duck *Cairina moschata* smells musky and so does the adult Magpie Goose *Anseranas semipalmata*. Among other birds in which a characteristic odour is commonly remarked are the Hoatzin *Opisthocomus hoazin*, Bald or Waldrapp Ibis *Geronticus eremita*, Puffin *Fratercula arctica*, Hoopoe *Upupa epops*, several Hawaiian honeycreepers (Drepanididae) and most, if not all, of the Procellariiformes. The comparatively odourless state of the intact body of most birds, as contrasted with mammals, can be related to the scarcity of cutaneous glands. Glands in the ear secrete a wax and others around the vent of some birds produce a mucus, but when an odour is present it is usually ascribed to the fatty acids of the uropygial or oil gland (see OIL GLAND; SKIN). Such compounds may enable colonial procellariiform birds to identify by smell their own burrows, chicks and mates. Grubb (1979) found that breeding Leach's Storm Petrels *Oceanodroma leucorhoa* walked upwind to their burrows after dark, and that plugging the nares or olfactory nerve prevented return. The functions of any scents from the uropygial glands of other birds have not been examined.

One species where the oil gland does not seem to be implicated in a noticeable odour is the Crested Auklet *Aethia cristatella* where the bill plates have been described as smelling like tangerine oranges.

Offensive odours may be emitted by ejecta from either end of the alimentary canal, both vomiting and defaecation being common reactions to threat of danger. In certain species these seem to have a repellent role. The wax esters in the stomach oil of Procellariiformes (see PETREL) have been shown to be dietary in origin and not the result of proventricular secretion as was thought. Regurgitation is more frequent and appears to be under greater control in the chicks of surface-nesters than of hole-nesters, suggesting that the squirting of stomach oil is a defence mechanism in the former. Many female ducks produce offensive excreta while incubating, and are apt to defaecate over their eggs when suddenly flushed. In the Eider *Somateria mollissima*, the faecal matter is particularly foul-smelling. Its unusual nature is probably due to the absence of food in the gut (incubating females sit for 26 days without eating) and the activity there of many anaerobic bacteria. The presence of the excreta with its foul odour has been shown to give the eggs protection against egg-eating mammals such as rats, and against Crows *Corvus corone*. Faeces from non-breeding Eiders do not have the same deterrent effect.

The nesting and roosting places of some species become highly odorous through the accumulation of droppings and food refuse. The nests of many sea birds, raptors, and coraciiform species are cases in point.

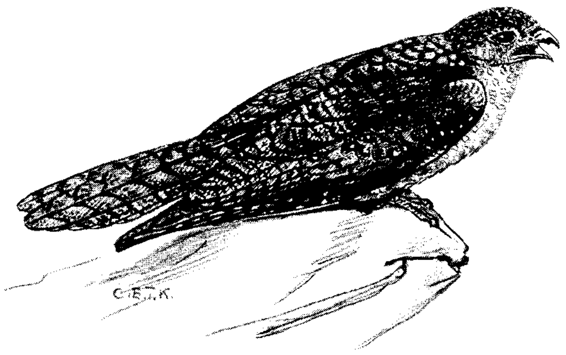
OFFSHORE HABITAT: see OCEANIC BIRDS.

OILBIRD: *Steatornis caripensis*, sole member of the Neotropical family Steatornithidae (Caprimulgiformes, suborder Steatornithes). It is known also as 'Guacharo' and, in Trinidad, 'Diablotin'. Although the Oilbird is generally placed in the order Caprimulgiformes, usually in a suborder of its own, its affinities are still not clear; in any event it occupies a very isolated position. Anatomically it is in general closest to the caprimulgiform birds, but in some characters it resembles the owls (Strigiformes) more closely. In its ecology and behaviour it differs strikingly from the other caprimulgiform birds, and indeed from all other birds. It is the only nocturnal fruit-eating bird.

The Oilbird (length *c.* 35 cm) is in appearance something between a large nightjar (Caprimulgidae sp.) and a hawk (Accipitridae sp.). It has a powerful hooked bill surrounded by long vibrissae, long wings with a span of just over 1 m, an ample tail, and short weak legs. The plumage is rich brown, barred with black and with a scattering of white spots that are especially conspicuous on the wing coverts. Oilbirds are gregarious, cave-living, nocturnal birds; they spend all the day crouched on ledges in the caves that they inhabit, flying out at night to feed on the fruit of various forest trees, chiefly palms and members of the Lauraceae. The fruit is plucked on the wing by means of the strong hooked bill; in intervals between feeding the birds have been reported to perch on bare branches, but so far very little is known about their behaviour outside the caves. Fruit is brought back whole to the caves, apparently in the stomach (as there is no crop), and digested there during the day. The seeds are regurgitated and fall on the lower ledges and floor of the caves, forming a deep rich humus in which etiolated seedlings sprout but soon wither through lack of light.



Oilbird *Steatornis caripensis*. (*C.E.T.K.*).

In addition to the clicking sounds which enable Oilbirds to navigate in pitch-dark caves (see ECHOLOCATION), they utter extremely loud screaming and snarling calls, which from a chorus of several hundred birds in a large cave become almost deafening. When flying at night outside the caves they utter occasional harsh cries, but not the echo-locating clicks. As their eyes are rather large and very sensitive to light, it seems probable that it is by sight that they orientate themselves outside the caves.

It is probable that scent plays an important part in the locating of food trees. Many of them are notably spicy or aromatic, and the Oilbird's olfactory apparatus is very well developed.

The nest is a bulky structure with a shallow saucer-shaped depression, placed on a ledge usually high up on the cave wall. It is made predominantly of regurgitated fruit of paste-like consistency applied directly from the side of the bill, but disgorged seeds and to a lesser extent the bird's own excreta also contribute to the structure. Nests are used year after year and grow in height as more material accumulates. The tempo of breeding is extremely slow. The eggs, usually 2–4 in a clutch, are laid at intervals of several days; incubation lasts about 33 days; and the young remain in the nest for up to 120 days. Both parents incubate the eggs. The young are hatched with a little sparse down, grow a second coat of down after about 3 weeks, and then the adult plumage. They become very fat, reaching a weight half as great again as the adult's by about the 70th day and then gradually losing the excess weight as the feathers grow. Because of the great amount of fat, which when boiled down yields an odourless and durable oil, young Oilbirds used to be, and to some extent still are, collected by the natives of the regions where they occur—hence their name. In Trinidad, eggs may be found at any time; but most clutches are laid in the early months of the year.

Oilbirds occur from western Guyana through Venezuela and Colombia, to Ecuador and Peru, and in Trinidad. They are everywhere very local, depending on the presence of suitable caves. Most of these are in mountainous country, but in Trinidad there are some colonies in sea-caves along the rocky north coast. D.W.S.(1)

Snow, D.W. 1961–62. The natural history of the Oilbird, *Steatornis caripensis*, in Trinidad, W.I. Zoologica (N.Y.) 46: 27–48; 47: 199–221.

OILED BIRDS: see OIL POLLUTION.

OIL GLAND (alternatively 'uropygial gland'): an externally secreting organ located at the rump in the dorsal caudal tract at the bottom of the tail feathers. The uropygial gland (other synonyms: preen gland, glans uropygialis) is a symmetrical bilobed organ, the halves of which are separated by an interlobular septum which ends in a muscular isthmus in the papilla. Each lobe possesses a large number of tubules in which fat cells are produced. The decay of these cells (holocrine type of secretion) forms the greasy gland secretion which then enters into a cavity whence it leaves the gland through two or more orifices. The exterior of the gland, although concealed by overlapping plumage, may be bare but surrounded by a circlet of small feathers or covered by down.

The gland may be more or less well developed in different groups of birds; swimming and diving species, however, generally possess large glands (e.g. penguins, grebes, petrels, gulls, ducks). It is also very large in the Osprey *Pandion haliaetus*. But even passeriform birds have comparatively large preen glands. The relatively heaviest glands (in percentage of body weight) were found in the Little Grebe *Tachybaptus ruficollis* (0.61%) and the Wren *Troglodytes troglodytes* (0.58%); the lightest (0.02%) in the fruit-doves (*Ducula, Ptilinopus*). Small or very small glands are found in pigeons, nightjars, parrots and herons. It seems that originally all birds possessed an uropygial gland, but some species lost it during evolution. Actually, a gland can be recognized in the embryonic stages of birds which lack a gland in the adult form (bustards, rheas, emus). Except for some small glands in the external ear passages, the uropygial gland is the only entirely developed skin gland in birds in contrast to the numerous sebaceous glands in mammals. Nevertheless, there exist numerous fat-producing loci in the integument of birds.

The uropygial gland secretion predominantly consists of monoester waxes composed of more or less highly branched fatty acids and alcohols. The qualitative patterns vary significantly at the ordinal, or in some cases even at the family level. Thus relationships among birds can be studied by comparing these patterns (Chemotaxonomy); e.g. penguins and petrels exhibit very similar patterns and the wax profiles are consistent within the Anseriformes.

Although early speculations on the function of the uropygial gland secretion agreed that it serves as a water repellent and preserves the bird against wetting, recent investigations make other functions more likely. Besides making the feathers flexible, the secretion seems to play an important role in plumage hygiene, since some of its constituents possess bacteriostatic and fungistatic properties; in the female Mallard *Anas platyrhynchos* fungistatic fatty acids are produced exclusively during the pre-incubation period and disappear thereafter.

Regarding the often strong smell of preen gland secretions (especially in petrels) which is supposed to originate from the free wax constituents after lipolysis (the waxes themselves are odourless), it has been claimed that they are involved in chemical communication (pheromonal activity). Recent findings support this at least for geese.

Experimental evidence has been presented that in some birds (e.g. the domestic chicken) the secretion applied to the plumage may have an antirachitic function enabling vitamin D to be synthesized under the influence of sunlight. These findings, however, could not be reconfirmed with pullets or pigeons, and it is thus very doubtful that the uropygial gland generally provides birds with vitamin D.

Gland-ectomizing experiments have been performed with various species. No adverse effects were observed after the removal of the gland in pigeons, sparrows and chicken. Experiments on ducks, however, mostly agree in the observation that the plumage condition degenerated after gland removal, feathers becoming rough, dry and disordered. (A.L.T.) J.J.

OILING: see COMFORT BEHAVIOUR; OIL GLAND.

OIL POLLUTION: the discharge of petroleum oils at sea became a serious problem when ships were converted from burning coal to oil during the second decade of the 20th century. Adverse publicity followed by legislation in the industrialized countries led to some improvement between the wars, but the problem recurred in a new form after the second world war when oil was no longer refined on the fields and tankers carrying it to users started to wash the waxy residues out of their tanks at sea afterwards. This has now been controlled to a large extent by the provision of reception facilities for waste oil at tanker ports, but they are still lacking in some ports used by cargo vessels while 'flag of convenience' fleets in particular are still notoriously careless. The great increase in size of tankers in recent years has also led to some spectacular wrecks, starting with the *Torrey Canyon* off Cornwall in March 1967, while during 1979 an oil-well began to leak off the east coast of Mexico.

Oil floats on water and presents a special hazard to social aquatic birds which are accustomed to react to hazards by diving rather than flying, such as penguins, auks, divers, grebes, cormorants and sea duck. It varies in composition and has a variety of actions. Initially it may contain toxic compounds which may be inhaled by birds or get on their exposed parts and be ingested while preening, and these may cause local inflammation, pneumonia, enteritis and systemic poisoning, notably damage to the liver and kidneys, though it is not clear to what extent this is also due to stress, exposure, hypothermia, dehydration and electrolyte disturbances. These toxic compounds may be lost from the oil by evaporation and solution and it then becomes inert and causes its worst damage through contamination of the plumage and destroying its buoyant and insulating properties. The birds are no longer able to fly or feed, exhaust themselves swimming and keeping warm and die of exposure. Quite a small amount of oil may be sufficient to kill them or contaminate eggs.

In recent years there has been a growing number of investigations of oil pollution. Light crude oils soon evaporate, while heavy ones are reduced to solid inert tar-balls, and the worst damage is caused by refined residual fuel oils which remain liquid longer and may contain toxic substances. The movement of the oil is most markedly influenced by the wind, and travels at about 3.3% of its speed; bird bodies drifting after the oil at about 2.2% of the wind's speed, so the extent to which spilt oil and bird bodies come ashore depends on the wind. The amount of damage caused to bird populations depends mainly on whether the oil happens to drift into areas such as feeding grounds, the waters off breeding colonies, or estuaries frequented by large concentrations of social swimming species. The damage tends to be very much worse in hard weather during the winter in high latitudes, probably because the oil remains fluid longer at low temperatures and large numbers of birds then tend to accumulate in vulnerable places. Investigations have shown that the mortality which is usually under one dead bird per km of beach surveyed may then reach tens or hundreds of birds per km.

Disasters involving thousands of birds are not infrequent and they may at times involve tens of thousands, but while mortalities running into hundreds of thousands have been claimed they have still to be proved. It is also still debatable whether oil pollution causes permanent harm to bird populations. It has been claimed that oil is responsible for a decline of auks along the southern periphery of their range all round the Northern Hemisphere, but in western Europe at least the decline began in the eastern English Channel before the onset of serious oil pollution. While massive oil pollution certainly caused a temporary decline of auks and especially Puffins *Fratercula arctica* on the most important French colony on the Sept Iles off Brittany, it remains to be seen whether the damage is permanent. Similarly, while it has been reported that oil pollution has caused a decline of sea-duck, especially Long-tailed Duck or Oldsquaws *Clangula hyemalis* wintering in the Baltic, the reliability of the figures is questionable.

While the permanence of the damage caused by oil to bird populations is questionable, there is no doubt whatsoever that oil pollution presents a humanitarian problem. Oiled birds are very conspicuous along the shore and attract vast public sympathy. Continual attempts are made to rescue them, often with little success. Recent research indicates that the main problems are that they often cannot be secured until they are moribund, and that people then have difficulty in feeding and cleaning them adequately. To achieve the best results the fittest birds must be selected and they then need to be fed and if necessary tube- or force-fed appropriate foods, usually small fresh fish (except for ducks), until they have at least regained their natural weight; they do better if they exceed it. When fit they need to be washed very thoroughly with a mild detergent or soap and rinsed continually until their plumage spontaneously regains its normal fluffy quality, after which they must be kept clean. The Royal Society for the Prevention of Cruelty to Animals is now obtaining a ⅓ success rate with auks in Britain, and the South African National Committee for the Care of Coastal Birds (SANCCOB) a ⅔ success rate with penguins. The procedure is hardly economic, but could be sufficient to save small threatened bird populations.

It is better to avoid pollution. Ornithologists were largely responsible for securing the first legislation by the United Kingdom in 1922 prohibiting the discharge of waste oil in territorial waters. Other countries took similar action, but it was soon recognized as an international problem. An international conference was held in Washington in 1926 when it was debated whether to prohibit discharges entirely, or restrict them to specified zones; a convention to observe zones was never ratified though some shipping companies observed it. An Advisory Committee on Oil Pollution of the Sea was set up on the initiative of the British Section of the International Council for Bird Preservation to bring together all the interests in the countries affected in 1952. This committee organized another international conference the following year; the UK convened an inter-governmental conference in 1954 which agreed on a new convention. Among other things it provided for extensive zones where pollution was prohibited, for the installation of separators to remove oil from discharged ballast-water, and for reception facilities for the oil in ports. After it had been accepted by 10 nations this Convention came into force for tankers in 1958 and dry-cargo ships in 1961, by which time 15 nations supported it. It was the precursor of many further measures.

In recent years the aim has been to prevent pollution entirely by increased care, enforced by severer sanctions and the development of a growing series of procedures for cleaning ship's tanks and then purifying any water that is discharged, and ultimately to keep ballast water in separate tanks away from contaminants. There has also been growing research into means of clearing up spilt oil, though these remain extremely inefficient and expensive. A growing number of nations is now also taking measures to regulate the condition and movements of shipping. It has become clear that the easiest way to control this persistent problem is through strict supervision of oil-handling procedures to prevent leaks, though regrettably it seems unlikely that they will ever be eliminated entirely. The results of individual incidents appear to be purely temporary, and despite a great deal of discussion and some research no remote consequences of pollution by the commoner petroleum compounds have yet been proved though persistently repeated pollution certainly leads to a local deterioration of the environment. OIL, STOMACH: see PETREL.

OLDSQUAW: American name (spelt as one word in AOU list) for the Long-tailed Duck *Clangula hyemalis* (see DUCK).

OLD WORLD WARBLER: see WARBLER (1).

OLFACTION: see SMELL.

OLFACTORY BULBS: parts of the forebrain (see NERVOUS SYSTEM; SMELL).

OLIGOTROPHIC: see EUTROPHIC.

OLIVE-BACK: alternative substantive name of some waxbills *Estrilda* spp. (see ESTRILDID FINCH).

OMAO: or Hawaiian Thrush *Phaeornis obscurus* (for subfamily see THRUSH).

OMENS, BIRDS AS: the use of birds in augury (ornithomancy) or, more loosely, as omens individually (see FOLKLORE, BIRDS IN). This can be traced back into many parts of the Ancient World, where, for instance, birds were among the sacrificial creatures in whose entrails portents were 'read'. Indeed, the very word 'augury' refers to divination by means of birds, the first syllable, *au-*, deriving from Latin *avis*; similarly *auspex*, whence our 'auspicious', denoted a man who watched birds (for divinatory purposes). In recent times organized omenist systems have survived in vigorous form only in south-eastern Asia, where in some places they constitute a full-scale 'animist pagan' system of ethics. This system is strongest among the inland peoples of Borneo, all of whom have versions of belief by which actions of a few selected species of mammals, reptiles and especially birds are taken to indicate metaphysical conditions favourable or otherwise to current or intended enterprises. Birds generally form between half and three-quarters of the animist code. Identification between birds and man is easy enough, in a pre-Darwinian context where man seldom feels superior and often regards other life around him, e.g. the munias (Estrildidae) which threaten his rice crops each year, as nearly co-equal.

The position of the bird in relation to the observer, and its movements or calls in flight, are the principal factors in interpreting the augury. A bird crossing one's path from left to right may be dangerous, from right to left very encouraging. Variants are innumerable, methods of propitiation numerous. In extreme conditions of persistent bad omens a group may even abandon their whole longhouse village; among the remote Sabans and Muruts of central north Borneo, to abandon a rice-field painfully cleaned from virgin jungle is not at all uncommon.

Elaborate bird usages have lately disappeared from all but the remotest areas. Bird beliefs remain deeply engrained, however, associated with the part omen and other birds play in folklore, notably as ancestral demigods and mighty warriors. Bird augury was based largely on fertility and associated beliefs linked to head-hunting and war, and augurs were deliberately consulted before any such operations could be undertaken. The cessation of head-hunting in this century invalidated some of the basic premises. Yet the greatest ceremony over a large part of Borneo today is still 'Gawai Burong', the Feast of the Birds, now in effect a peaceful secular continuation of a once blood-marked rite of rejuvenation and continuity, symbolized in the great birds.

A feature of bird augury is the variability of the birds selected. Thus the Sea Dayaks of south Borneo use one of the medium-sized woodpeckers and a tiny one *Sasia abnormis*, a rare jungle kingfisher *Lacedo pulchella*, the noisy Crested Jay *Platylophus galericulatus*, two rather uncommon and quiet trogons (Trogonidae), and a beautifully voiced shama *Copsychus* sp. The Land Dayak, Maloh, Kenyah, and Kayan peoples, however, put dominant emphasis on noisy, small, very common spider-hunters *Arachnothera* spp. and determine much of their daily and nightly lives thereby—whereas the Sea Dayaks ignore these.

The Sea Dayak omen birds are all regarded as interchangeable bird-man deputies for their ancestor hero, Sengalang Burong (Hornbill-Kite), and his brave sons-in-law. Related ideas were held in ancient Greece, northern India, and modern Africa; Sir James Frazer wrote in *The Golden Bough*: 'When the Nandi men are away on a foray, nobody at home may pronounce the names of the absent warriors; they must be referred to as birds'.

All the Borneo omen birds are resident species; but it does not follow that all were originally so in the lands whence these peoples came in protohistorical times. Certainly, there is another important sequence of thought—notably in China and Borneo—centred on migratory birds. It is not difficult to see how this could lead directly to an omenist system. In China such beliefs persist even under Communism. The 'Red Bird of the South' ('teng huang'), a frequent phoenix-like form in Chinese art for over 2,000 years, is a symbolic bisexual conglomerate of several birds—the quail, coming to north China from the south as a portent of summer all along the mighty Yellow River, the peafowl, pheasant, junglefowl, eagle, and flying dragon. At the other end of the scale, in the remotest hinterland of central Borneo, the Kelabits determine their crucial rice-planting cycle by the arrival of a series of migrating birds reaching the Equator from the far north, indicating to man the sequence of clearing and planting, bedding, weeding, protecting, and harvesting the vital rice padi. These birds, which give their names to the months, are an eastern race of the Yellow Wagtail *Motacilla flava*, Brown Shrike *Lanius cristatus*, Japanese Lesser Sparrowhawk *Accipiter gularis*, and Siberian Pale Thrush *Turdus pallidus*; all 'winter' above 900 m in the Bornean uplands and return north during March-April, after the rice crop has been gathered in. (T.H.) G.E.S.T.

OMNIVOROUS: having a varied and unspecialized diet.

ONTOGENY: the developmental history of the individual (see DEVELOPMENT, EMBRYONIC; GROWTH; also BEHAVIOUR, DEVELOPMENT OF). This is contrasted with the evolutionary history of the species (or other taxon)—see PHYLOGENY.

O-O: see HAWAIIAN HONEYCREEPER.

OOCYTE: a cell in the sequence leading to the formation of an ovum (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

OOLOGY: the scientific study of the eggs of birds, with particular reference to external characters such as shape and size, texture and coloration of shell, and number in clutch (see EGGS). Extension beyond this overlaps the more general field of reproductive physiology and behaviour (see, for example, BREEDING SEASON; CLUTCH-SIZE; IN-

CUBATION; LAYING; BROOD-PARASITISM). The study of the contents of the egg, and of the developing chick within it is covered by DEVELOPMENT, EMBRYONIC.

The main descriptive phase of oology as a form of systematic work has been completed for most parts of Europe and North America; but in some parts of the world there is still very much to be learnt, the eggs of many species being as yet either wholly unknown or the subject of only meagre information. Regrettably, scientific oology is obscured by controversy over egg-collecting, now illegal in many countries except under licence, but still rife in Britain. B.C.

OPENBILL: also 'Open-billed Stork' *Anastomus* spp. (see STORK).

OPEN SEASON: period when certain birds may legally be shot for sport.

OPERCULUM: a covering flap, as over the anterior nares or the external auditory meatus in some birds (see BILL; NARIS; OWL).

OPISTHOCOMI; OPISTHOCOMIDAE: see under GALLIFORMES; HOATZIN.

OPTIC LOBES: parts of the brain (see NERVOUS SYSTEM).

OPTIC NERVE: see VISION; NERVOUS SYSTEM.

OPTIMAL FORAGING THEORY: the application of OPTIMALITY THEORY to the study of how animals search for and exploit food. In this approach it is hypothesized that foraging behaviour can be described by mathematical models which assume that the animal is designed (by natural selection) to maximize some aspect of foraging success such as energy intake, protein intake or balance of nutrients. Such models can be tested, thus revealing whether the particular design criteria and constraints embodied in the model are correct.

OPTIMALITY THEORY: a body of mathematical theory concerned with the analysis of the 'best way' to allocate 'scarce resources' among various alternatives. Although originally developed in the context of engineering and economics, optimality models have been applied to biology in an attempt to understand how organisms have been designed by natural selection. For example, many features of living organisms, from the biochemical to the behavioural level of organization, can be accounted for by the hypothesis that the maximal energetic efficiency is a design criterion.

It is sometimes mistakenly thought that optimality models are used to test the idea that organisms are optimal. This is not so. They allow one to test whether the design criteria and constraints embodied within the models are realistic. Optimality models are used as an analytical tool because of the conviction that natural selection favours good design.

ORANGEQUIT: *Euneornis campestris*, a small Jamaican passerine bird of uncertain affinities, tentatively placed in the subfamily Thraupinae (see TANAGER). It has a sharply pointed, decurved bill and feeds largely on nectar.

ORANGETHROAT: *Luscinia pectardens* (for subfamily see THRUSH).

ORBIT: see SKULL.

ORBITAL: applied to a distinctive area, in some plumage patterns, round the eye.

ORBITOSPHENOID: a paired bone of the SKULL.

ORDER: a primary taxonomic category, a sub-division of a class, and a grouping of families; other categories may be interpolated between these primary ones to build up a more elaborate hierarchical system, especially subclass and superorder on the one hand, suborder and superfamily on the other (see CLASSIFICATION; TAXON). In accordance with the International Code of Zoological Nomenclature every ordinal name ends in '-iformes'; earlier use favoured '-morphae'.

Whereas the family is the most convenient group for most general purposes, the aim of ordinal grouping is to express a supposed phylogenetic relationship between families. At this level, however, the suppositions tend to become very uncertain and highly speculative; the content of orders has therefore not only changed greatly with advancing knowledge but is also the subject of differing views. Authorities who are sceptical about evidence of relationships naturally tend to preserve a greater number of separate orders of limited content; those who are bolder place more families together and thus reduce the number of orders. Authors who adhere to cladistic systematics must by necessity use either a relatively large number of orders or an almost infinite number of taxonomic subdivisions or do both.

Nevertheless, many orders are not in serious dispute. Some of these comprise only a single family, and the ordinal rank merely expresses the view that the family does not appear to have any known near relationships; others comprise a few families that are generally accepted as being more related to each other than to other families. The greatest difference of opinion concerns the large assemblages of families regarded by some as gruiform and coraciiform respectively. Even the Order Passeriformes, generally accepted as having ordinal characteristics clearly separating it from all the other groups, has been treated in a cladistic system as two orders of supposedly independent phylogenetic origin: Tyranniformes and Passeriformes *sensu stricto* (Feduccia 1975, 1977).

In listing orders it is customary to begin with those that are believed to be the most primitive and to proceed towards the most highly developed, the Passeriformes. The placing of the orders is obviously speculative in high degree; any list must be arbitrary in that no linear arrangement could adequately express four-dimensional relationships grown in space and in time. The classification of orders followed here is that proposed by Voous and represents in some way a combination of the well-known systems of Wetmore and Stresemann. It can be found in the Table of Classification in the preliminary pages.

Suborder. The suborder is a secondary taxonomic category, a subdivision of an order and a grouping of superfamilies (if any) and families. Not all orders are divided into suborders, the category being used only when required; its necessity depends on the philosophy of the classification system followed and is greatest in cladistic systematics. Other systems may tend to give independent ordinal rank to what are considered suborders elsewhere. Names of suborders end in ordinary Latin plural forms ('-i, '-ae', '-es'). As some authors end their ordinal names in the same way, these can be identical with the subordinal names of others. The International Code of Zoological Nomenclature does not apply at this level.

For superorder see under CLASS; for superfamily see under FAMILY.

ORIENTAL REGION: one of the main zoogeographical divisions of the Earth (see DISTRIBUTION, GEOGRAPHICAL); also known as the Indian Region, although that adjective is better retained for the subregion covering the greater part of continental and peninsular India, with Sri Lanka.

Boundaries. The Oriental Region lies mainly between 68° and 135°E and between 10°S and 32°N, therefore largely within the tropics. Its northern boundary, dividing it from the Palearctic Region, runs from the Hindu Kush Mountains in the west along the entire length of the Himalaya, and farther east to include Yunnan and Szechuan. It continues roughly south of the basin of the Yangtze Kiang to form an indeterminate frontier with the Manchurian Subregion of the Palearctic till it reaches the East China Sea in the neighbourhood of Ning-po in *c.* 30°N. From its western extremity the boundary trends south-west, excluding Afghanistan and Baluchistan, and may conveniently be taken as the valley of the

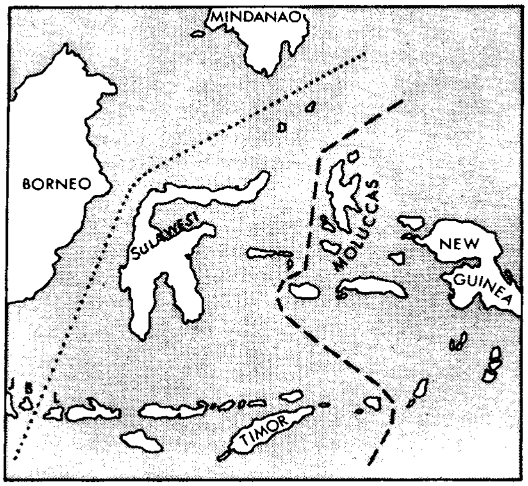

Fig. 1. Transitional zone at boundary with the Australasian Region. The classical Wallace's Line (dots) approximates to the western limit of this zone—J = Java (part), B = Bali, L = Lombok; Weber's Line (dashes) represents its median, where the two faunas are more nearly balanced. The islands between Wallace's Line and New Guinea are sometimes collectively termed 'Wallacea'.

Indus down to its mouth near Karachi in Pakistan.

South of the Asian mainland, the Oriental Region includes the continental islands of Taiwan and Hainan as well as the greater part of the Indonesian Archipelago, the Philippines, Borneo, Sulawesi, and the Greater and Lesser Sunda Islands east to Timor. There are curious clear-cut divisions as well as close intermingling between the characteristic Oriental and Australian faunas on many of the islands in this area, and the line of demarcation from the Australasian Region is not easy. In the last century, since Wallace first postulated the boundary between the islands with a mainly Indo-Malayan fauna and those with the Australo-Papuan type, a succession of investigators (including many ornithologists) have conducted intensive faunal studies on the islands to determine their correct biogeographical status. The demarcation originally proposed by Wallace—'Wallace's Line' as Huxley named it—on the basis of the presence or absence of certain typical bird and other animal groups of the Oriental and Australasian Regions at first enjoyed a wide measure of acceptance from zoologists on account of the truly remarkable examples of clear-cut divergence which it showed, e.g. as between the islands of Bali and Lombok, separated by a deep and narrow strait (only 25–30 km wide), and as between Borneo and Sulawesi. Many dominant Oriental bird groups, e.g. the barbets (Capitonidae), range as far east as Bali and then suddenly break off, being completely absent from Lombok and beyond. Woodpeckers (Picidae), abundant in the Oriental Region as far east as Borneo, Java, and Bali, are very poorly represented (by only 4 or 5 species) in Lombok, Sulawesi, and eastward up to the Moluccas, being absent over the rest of the Australasian Region. On the other hand, many typically Australian groups, e.g. honeyeaters (Meliphagidae) and cockatoos (Cacatuinae), reach westward as far as Lombok, but there end abruptly. The faunal differences on the opposite sides of the Strait of Macassar, between Borneo and Sulawesi, are superficially even more striking; they are not confined to birds but extend to mammals and other animal groups.

The line, as postulated by Wallace, passed between Bali and Lombok in a north-easterly direction, through the Macassar Strait separating Sulawesi from Borneo, and then on ENE between Mindanao and Sangi Islands, passing west of the Marianas or Ladrones group. Huxley's proposed modification, by drawing it north from the Macassar Strait to pass between Palawan and Mindoro Islands, excluded the Philippines from the Indo-Malayan Subregion.

On statistical analyses of the extensive data accumulated by investigators since Wallace's time, on a percentage basis of typically Oriental and typically Australasian faunal elements present or absent on the various islands, it was realized that a more rational boundary between the two regions would be one that showed a faunal balance, i.e. with the Oriental and Australasian elements in more or less equal proportions. A line of this nature can of course be only arbitrary, since the 50:50 balance does not hold good for all taxonomic groups. Such a line of faunal balance between the Oriental and Australasian faunas was first demonstrated by Weber, in 1902, to exist much farther east than Wallace's Line. As modified by subsequent investigations, Weber's Line runs roughly along the Molucca Passage between Sulawesi and the northern Moluccas, southward between Sula Islands in the west and Obi Islands in the east, swings west of Buru, and, leaving Timorlaut Islands on its east, curves WSW along the edge of the Sahul Shelf to include Timor in the Indo-Malayan Subregion. Thus, on consensus of current views, all the islands in the intermediate zone between Wallace's Line and its eastern counterpart—the 'Wallacea' of some zoologists—belong to the Indo-Malayan Subregion.

Characteristic groups. One bird family is peculiar to the Oriental Region, the leafbirds (Irenidae), and is in fact confined chiefly to the Indo-Chinese Subregion. The Oriental Region shares with the Afrotropical Region, either exclusively or overwhelmingly, the passerine families Eurylaimidae, Pycnonotidae, Nectariniidae, and Ploceidae. The typical Ethiopian family of the honeyguides (Indicatoridae) is represented here (but in no other region) by the common genus *Indicator*. Many genera, e.g. *Harpactes* (Trogonidae), *Nyctiornis* (Meropidae), *Psittacula* and *Loriculus* (Psittacidae), *Acridotheres* and *Gracula* (Sturnidae), and *Pericrocotus* (Campephagidae), are confined to it and do not occur at all outside its limits. The family Phasianidae is particularly well developed in the Oriental Region, the spectacular genera *Pavo, Gallus, Lophura, Pucrasia, Catreus, Argusianus, Polyplectron*, and *Rollulus* being peculiar to it.

Subregions. The region is readily divisible into the following three main subregions upon the general spectrum of their avifauna and other animal groups:

1. The Indo-Chinese Subregion (= 'Himalo-Chinese' of H.J. Elwes and H.F. Blanford)
2. The Indo-Malayan or Malaysian Subregion (= 'Malayan' of above authors)
3. The Indian Subregion

The first two are essentially very similar in regard to their physiography, being covered largely with tropical and subtropical vegetation, the result of heavy monsoon rainfall and high humidity. Nevertheless, they each exhibit marked peculiarities in many of their plant and animal manifestations, the first subregion showing an affinity with the Palearctic in its temperate zone forms, e.g. the Fringillidae, while the second possesses elements with distinctly Australo-Papuan affiliations.

The Indo-Chinese Subregion. This includes the southern aspect of the entire Himalayan Range (up to the tree-line—3,000 to 4,000 m elevation), particularly the section that lies east of the Arun-Kosi River in eastern Nepal. Beyond, its boundary extends into north-western and eastern China, marching with the Palearctic Region. Many typically eastern genera, e.g. *Paradoxornis*, terminate in Sikkim and Nepal, but the avifauna of the Himalaya westward of the division indicated retains its overall Indo-Chinese character in diminishing degree. This tendency is well illustrated by many other timaliine genera, e.g. *Garrulax*, abundantly represented in Yunnan and the eastern Himalaya, but sparsely in the western.

Besides the Himalaya, this subregion includes Assam, Burma, Thailand, and Indo-China (Vietnam), i.e. the entire portion of the Oriental Region lying on the Asian mainland east of the Ganges delta, with the exception of the Malay Peninsula. It also includes the islands of the Andamans group, as well as Taiwan and Hainan.

The Indo-Malayan or Malaysian Subregion. This lies for the most part within a tropical belt 10° on either side of the Equator and includes the Malay Peninsula south of the Isthmus of Kra, together with all the islands of the Archipelago west of Weber's Line. The Nicobar Islands, off the western tip of Sumatra, show closer avifaunal affinities with this subregion than with the Andamans, which are spatially nearer to Burma. This subregion is more exclusively tropical and forested than either of the others. Its avifauna lacks all traces of Ethiopian affinities, so noticeable in the Indian Subregion. It also lacks temperate zone forms of the Himalaya with Palearctic affiliations, such as the rose finches (Fringillidae).

The Indian Subregion. This stretches southward from the foot of the Himalaya to include the entire peninsula and Sri Lanka. Its western boundary is that of the Oriental Region—the Indus Valley—while on the east the deltas of the Ganges and Brahmaputra rivers demarcate it from the Indo-Chinese Subregion. Two clear-cut 'provinces' are recognizable which, for convenience, may be termed (*a*) The Peninsular Province, covering all India and Sri Lanka except the portions under (*b*);

(*b*) The South-western Province, the tropical humid, heavy-rainfall zone commencing at the northern extremity of the Western Ghats in Khandesh and the Surat Dangs, but more properly south from about Goa (c. 15° 30′ N) including western Karnataka, the Nilgiri and Palni Hills, and Kerala, together with its virtual extension in south-western Sri Lanka—the so-called 'Low-country Wet' and 'Central Hill' zones.

The avifaunal character of the Peninsular Province is largely Palearctic and Ethiopian. A typical example of the latter is the cursoriid genus *Rhinoptilus* (currently merged in *Cursorius*) with several species in Africa but only a single one, *C. bitorquatus*, in peninsular India. There is an almost complete absence of characteristic east-oriental genera of birds in this province, as there also is in the Afrotropical Region.

The South-western Province, although much smaller, is one of the most interesting areas, from the biogeographical point of view, by virtue of the very striking similarities and parallelisms its fauna and flora exhibit with those of the far-flung Indo-Chinese and Malaysian subregions. It constitutes the western terminal of what is known as the 'Indo-Malayan Arc' or 'Horseshoe' of animal distribution: Malaya–Burman-eastern Himalaya–Sri Lanka. Several typical sedentary birds inhabiting its two extremities (e.g. *Chrysocolaptes lucidus, Buceros bicornis*) are morphologically inseparable, even at subspecific level. These remarkable 'relict populations' of south-western India, now cut off from their nearest neighbours in the Himalaya by up to 2,500 km, have received special attention from zoologists in recent years. Much interest has been aroused by the very attractive 'Satpura hypothesis' of the Indian zoologist, S.L. Hora, which seeks to explain the history, route, and mechanics by which freshwater hill-stream fishes, and other specialized hygrophilous fauna of the Indo-Chinese Subregion, reached Kerala and Sri Lanka. This hypothesis postulates a once continuous mountain trend from the eastern Himalaya and Garo Hills, across peninsular India over the Rajmahal Hills and the Satpura Mountains, and then southward over the Sahyadris or Western Ghats to Kerala and Sri Lanka. Sri Lanka, which was alternately joined to and separated from peninsular India during various geological epochs, bears evidence of having received distributional faunal waves from the mainland. Under periods of prolonged isolation, many endemic races (or species, as some ornithologists consider them) have developed on the island.

The avifauna of the humid South-western Province contains one monotypical muscicapine genus, *Ochromela* (now *Muscicapa*), peculiar to its mainland section. Numerous examples can be cited of birds not occurring in the adjoining Peninsular Province, but having close affinity, or even identity, with forms living in the eastern Himalaya and in the Indo-Chinese and Indo-Malayan Subregions generally. Prominent among such are laughing thrushes *Garrulax* spp., Fairy-bluebird *Irena puella*, woodpeckers of the genera *Dinopium, Hemicircus, Dryocopus*, and *Picumnus*, Great Hornbill *Buceros bicornis*, spinetail swifts *Chaetura* spp., Broadbilled Roller *Eurystomus orientalis*, Malabar Trogon *Harpactes fasciatus*, Frogmouth *Batrachostomus moniliger*, and the falconid genus *Aviceda*. Some of these birds, e.g. *Dryocopus, Hemicircus, Picumnus, Buceros*, curiously enough, are not found in Sri Lanka: the complete absence of vultures *Gyps* spp., so common and abundant on the Indian mainland, is another anomaly not easily explained considering the powerful flight and far-ranging capabilities of these birds. ORIENTATION: see NAVIGATION.

ORIGIN OF BIRDS: see EARLY EVOLUTION OF BIRDS.

ORIOLE (1): substantive name of most species of Oriolidae (Passeriformes, suborder Oscines); in the plural, and in an Old World context, general term for the family Oriolidae. This is a homogeneous group of about 28 species placed in 2 genera, 24 species in *Oriolus* and the remainder in *Sphecotheres*. Tentatively classified with the orioles is the little known Kinkimavo *Tylas eduardi* of Madagascar, and it has recently been suggested that the 2 FAIRY-BLUEBIRDS, *Irena cyanogaster* and *I. puella* of the Oriental region may be aberrant orioles.

The family name is from the Old French *oriol*, which in turn was probably derived from the Latin *aureolus*, meaning golden or yellow, and applied originally to the Golden Oriole *Oriolus oriolus*.

Characteristics. The orioles differ from the New World orioles (Icteridae) by having 10 primary feathers (see ORIOLE (2)). Old World orioles are robust birds ranging in size from about 20–30 cm in length, and have decurved bills. The wings are long and pointed; the tail has 12 feathers.

Habitat, distribution and movements. The family Oriolidae occurs in forests and woodlands throughout Africa south of the Sahara, across Asia, the Philippines, Malaysia to New Guinea and Australia (though not in New Zealand) with one species, the well-known Golden Oriole *O. oriolus* ranging right across the southern Palearctic region as well as into India, but wintering exclusively south of the Sahara. Other non-forest inhabiting species are to some extent migratory. Speciation has been most active in the eastern quarter of the family's range, where there are so many islands. Most species of Oriolidae occur in the tropics or sub-tropics.

Distribution and characteristics. The Golden Oriole, 5 closely related African species, and some of the Oriental species have the male plumage patterned brilliant yellow and black, with black usually on the head, primary and secondary wing feathers and on the upper tail coverts. One species, *O. chlorocephalus*, limited to a few montane forests in eastern Africa, has the combination of clear yellow and rich olive-green. The 2 Australian species are much duller, greenish and streaky. Several Oriental species are predominantly black, with patches of rich crimson; e.g. the Maroon Oriole *O. traillii*; while the Black Oriole *O. hosii* is almost wholly black except for chestnut under tail coverts. As a rule, those orioles that have yellow pigment in the plumage have bills coloured a dull red or pink, while those with crimson in the plumage have the bills horn-coloured or bluish. The 4 species of figbird placed in the genus *Sphecotheres* occur in the forests and open woodlands of the Timor-New

Black-naped Oriole *Oriolus chinensis*. (*D.A.T.*).

Guinea-Australia area. They are distinguished by bare skin around the eye and an exceptionally short bill. Figbirds are duller in plumage than other orioles, and have dull yellow, green, brown, grey and white in their plumages. Bills are black and legs are red in males; females have both bills and legs reddish-brown. In at least one species, *S. vieilloti*, the red colour of the bare skin of the adult male apparently fades after the eggs have hatched. Throughout the family the females are, with very few exceptions, duller or more streaked—or both—than the males. Juveniles resemble females.

The orioles provide some typical examples of evolution on small islands. *O. crassirostris* of São Tomé in the Gulf of Guinea has lost most of the brilliant yellow so prominent in the African species from which it was probably derived, and it has an abnormally short and rounded wing. In the Moluccas, *O. bouroensis* and its relatives have lost both black and lipochrome to such an extent that they have become dull brownish birds (see MIMICRY).

Food. All the species are exclusively arboreal, feeding on insects and fruit. In the *Sphecotheres* spp., commonly known as figbirds, fruit is the major component of the diet. The African Blackheaded Oriole *O. larvatus* also takes nectar by probing into flowers.

Voice. Certain features of the voice are widespread in the family, namely the sweet, fluting and liquid songs and calls, and also a harsh growling or bleating note. The figbirds have a chattering call and appear to be more noisy than *Oriolus* spp., particularly when feeding.

Breeding. The typical nest of *Oriolus* spp. is a deep cup, closely woven of beard lichens or grass, and slung in a horizontal fork on a lateral branch high above ground. Nests of *Sphecotheres* spp. are not woven and are small untidy cups placed in horizontal forks in foliage and may be up to 20 m above ground. The eggs of *Oriolus* spp. have rich dark blotches or spots on a white, buff or pink ground. Eggs of the figbirds are greenish, from a pale apple-green to a dull olive-green, with dark markings. The nests and eggs of several species of Oriolidae remain to be described.

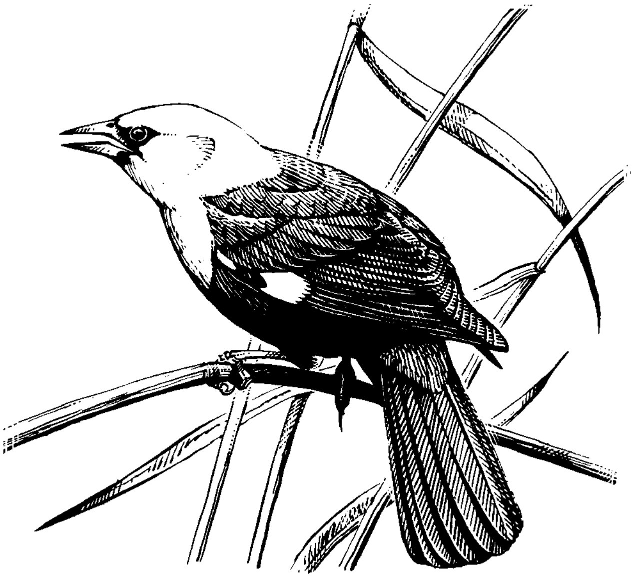
In the European Golden Oriole care of the eggs and young is shared by both adults of the pair (incubation and fledging periods each *c.* 14–15 days), but very few detailed studies of any of the other species have been made. (R.E.M.) W.R.J.D.

Greenway, J.C. Jr 1962. Family Oriolidae. *In* Mayr, E. & Greenway, J.C. Jr (eds.). Checklist of Birds of the World, vol. 15. Cambridge, Mass.

ORIOLE (2): substantive name of *Icterus* spp.; in the plural form 'American orioles', general term for the family Icteridae (Passeriformes, suborder Oscines). This strictly New World assemblage of 9-primaried song birds is derived from emberizine stock and forms a remarkably heterogeneous family of medium-sized birds that includes such diverse natural groups as the oropendolas, caciques, grackles, American blackbirds, American orioles or troupials, cowbirds and meadowlarks.

Characteristics. The approximately 90 species in this family range in size from 15–53 cm in length. All have unnotched conical bills that are usually pointed and not longer than the head; rictal bristles are lacking or obsolescent. In some of the larger species, especially oropendolas and caciques, the culmen is expanded or swollen basally, especially among males, to form a conspicuous frontal shield or casque. The predominant body colour in the family is black, but some species lack black entirely, and in most the basic colour is conspicuously patterned with red, orange, yellow or brown. Iridescent gloss is characteristic of the black of many species. Many species, particularly those with non-monogamous mating systems, are strongly sexually dimorphic in size and behaviour. Plumage dimorphism is also common, especially at high latitudes, but most of the tropical forest species are monochromatic. In many species with pronounced sexual dichromatism there is a first-year male plumage, typically intermediate between that of the female and the adult male, which may be highly variable. Streaked plumage is present in both sexes of grassland species such as meadowlarks (*Sturnella, Leistes*) and among females of many marsh (some *Agelaius*) and wet grassland (Bobolink *Dolichonyx oryzivorus*) species. In most species the non-breeding plumage is identical with the breeding plumage, but males of some black species acquire brown tips to their feathers during the post-breeding moult, the full black plumage being acquired gradually through wearing of the feather tips. The male Bobolink undergoes a striking change of plumage during the winter, acquiring the drab, streaked plumage of the female.

Distribution. American orioles are best represented in the lowland tropics, but there are common species at temperate latitudes and in tropical montane habitats. One species, the Rusty Blackbird *Euphagus carolinus*, breeds north of the Arctic Circle, while the Austral Blackbird *Curaeus curaeus* breeds to the southern limits of land in Tierra del Fuego. Icterids are found in virtually every type of vegetation in the New World except tundra. The largest number of species is found in tropical forests, especially disturbed areas, but these birds are among the dominant species in savannas, grasslands and marshes. In the western Amazon basin, up to 12 species can be found in a single habitat.



Yellow-headed Blackbird *Xanthocephalus xanthocephalus*. (*D.A.T.*).

Populations. Because many icterids are found in disturbed habitats, they have often benefited from human-induced environmental changes. Many species have readily adapted to croplands and grazed pastures. The Red-winged Blackbird *Agelaius phoeniceus* is one of the most abundant breeding birds in North America. The Brown-headed Cowbird *Molothrus ater* has undergone enormous expansion in both range and population size in North America during the past half century. Its southern counterpart, the Shiny Cowbird *M. bonariensis*, is also rapidly expanding its range northward through the West Indies. Some species, such as Red-winged Blackbirds, cowbirds and grackles *Quiscalus*, have become crop pests. None of the species, except for a few on the West Indian islands, appear to be declining in abundance or in danger of extinction.

Movements. Most tropical species of icterids are sedentary or undergo only limited seasonal movements in response to changing patterns in availability of fruit and insects or vegetation disturbance. There is one interhemispheric migrant, the Bobolink, which breeds in southern Canada and northern United States and winters primarily in the pampas of Argentina. Most of the North Temperate breeding species migrate south for the winter, but few penetrate farther than Central America, and many winter as far north as snow-free ground is usually available. In South America, where there is so little temperate land mass and climates are maritime, there is relatively little northward movement for the winter. Some species, such as the Yellow-headed Blackbird *Xanthocephalus xanthocephalus*, which depend on large populations of emerging aquatic insects for breeding, change breeding locations substantially between years, whereas others are highly sedentary and show great local variations in plumage and voice.

Food. The key to the evolution of the icterids lies in their ability to open their bills forceably against considerable pressure. Most species in the family use such gaping movements extensively during feeding and this behaviour reveals food not available to species that must find it on the surface. Gaping is used to extract food from epiphytes on trees, especially bromeliads (oropendolas, caciques, orioles and the endemic Jamaican blackbird *Nesopsar*), flowers (many genera), dead branches and crevices in bark (caciques), the bases of clumps of grasses (meadowlarks), pine needles (orioles), the ground (meadowlarks), under rocks and cowpats (many blackbirds, cowbirds) and fruit (orioles, caciques and oropendolas). Some, such as grackles, also have powerful muscles for closing the bill and are able to crush large seeds. The nestlings of most species are fed primarily on arthropods, but many species are partially frugivorous (tropical species) or granivorous (most temperate species) during the non-breeding season. Many icterids are highly adapted for foraging on the ground and progress by walking. Marsh-nesting species are able to forage efficiently in the dense vertical growth of those habitats, often by straddling between stems with their legs extending laterally from their bodies. Many are adept at holding prey in their feet while subduing and dissecting it with the bill. Ground-foraging species are also able to expose hidden food by scratching, usually using both feet in a rapid backward movement, one foot being moved slightly after the other. A common pattern of movement employed by flocking species feeding in open grassland and cropland is one in which birds at the rear of the flock fly over their flockmates to the front and feed in a fixed spot until they are at the rear, when they repeat the movement again. When viewed from a distance such a flock appears to 'roll' across the field.

Behaviour. Diversity of social organization is one of the most notable characteristics of the American orioles. Some species are monogamous and defend large, exclusive territories during the breeding season (meadowlarks, *Dives*, most orioles, some caciques), others are monogamous but colonial (*Quiscalus, Euphagus, Curaeus*), some are territorial but polygynous (some *Agelaius, Xanthocephalus, Dolichonyx*), some are colonial and polygynous (oropendolas, some caciques, some grackles, especially *Cassidix*). An unusual form of breeding is found in the cowbirds, most of which do not build their own nests but lay their eggs in the nests of other species. Only the Bay-winged Cowbird *Molothrus badius* of temperate South America incubates its own eggs and feeds its own young. Some of the cowbirds are highly host-specific, usually within the family Icteridae. For example the Screaming Cowbird *M. rufoaxillaris* apparently parasitizes only the Bay-winged Cowbird, while the Giant Cowbird *Scaphidura oryzivora* parasitizes only oropendolas and caciques. Even the more catholic species, such as Brown-headed and Shiny Cowbirds, heavily parasitize other members of the family. Occasional bigamous matings have been reported in normally monogamous species, presumably the result of local imbalances in sex ratios, but the well-developed non-monogamous mating systems are not due to sex ratio imbalances. Sex ratios of nestlings at the time of fledging are close to 1:1 in those few species that have been studied intensively. There are substantial populations of non-breeding males, usually younger birds, in the polygynous species. These non-breeders may obtain territories when numbers of older birds are low, and can be induced to take over territories by the removal of established adults.

Voice. Icterids produce a wide variety of notes ranging from harsh and guttural to very musical. In general the monogamous, territorial species are excellent songsters and some species, such as the Melodious Blackbird *Dives dives*, the Shiny Cowbird and the Chopi Blackbird *Gnorimopsar chopi*, are highly prized as cage birds in Latin America. Among tropical species that remain permanently paired on territories, it is common for both sexes to sing, probably because individuals of both sexes must seek replacement mates with approximately equal frequency. In a few species, most notably the Melodious Blackbird, this has been developed into a complex and precisely timed duetting in which each member of the pair sings a different part of the complex song. Song is restricted to males in most migratory monogamous species. Among monogamous species song rates drop strikingly as soon as pairing takes place, but song rates of polygynous males remain high through much of the breeding season. Males of many species sing regularly in autumn and winter flocks, often in loud choruses, but the function of that singing is obscure. In general, species with colonial breeding systems have more vocalizations than territorial species and, among polygynous species, males have many more vocalizations than females. In some polygynous species, females defend space within the territories of the males and may use specific vocalizations and displays to exclude other females.

Breeding. The nests of icterids are among the most varied of any avian family. Terrestrial species build well-concealed but simple (Bobolink) or domed (meadowlarks) nests on the ground. The marsh-breeding species build most of their nests in the emergent aquatic vegetation while savanna and scrubland nesting species build their nests in bushes and trees. Orioles suspend their woven, sack-like nests from the tips of the branches of trees where they are inaccessible to most mammalian and reptilian predators. The colonial oropendolas and caciques nest in large, usually isolated trees, and build their remarkable hanging nests, that may measure up to 1½ m in length, in large groups. In most species, nests are built entirely by the females, who also perform incubation unaided by their mates for 11–14 days. Clutches of 2–3 are characteristic of tropical species while 4–6 eggs are usual for the higher latitude species. Nestling periods range from about 10 days in the smallest to about 5 weeks in the largest species. In the monogamous species both sexes share in the feeding of the young, but in some polygynous ones only the female brings food. In these species the males continue to defend territories and attempt to attract additional females. The evolution of these differences appears to be related to the value to the males of differing patterns of investments. In the Yellow-headed Blackbird, for example, where breeding is highly synchronous, most males do feed nestlings, preferentially at the first nest to hatch on their territories. In the Red-winged Blackbird, however, where new females are attracted over a much longer period of time, most males do not feed nestlings, but many feed fledglings later in the season when the probability of attracting additional females is low. Many species are single-brooded, but double broods are raised by at least part of the population in a few species. In most species, renesting occurs if the first nest is destroyed. Helpers at the nest are known in several species (Bay-winged Cowbird, Austral Blackbird, Brown-and-yellow Marshbird *Pseudoleistes virescens*), but the genetic relationships between nest owners and helpers are unknown. However, helping does occur in species that do not remain as family units on territories during the non-breeding season. (E.R.B.) G.H.O.

ORIOLIDAE: a family of the PASSERIFORMES, suborder Oscines; ORIOLE (1).

ORNAMENTATION, BIRDS IN HUMAN: Gilbert's lines in *The Gondoliers*, 'I wonder whether she'd wear a feather—I rather think she should!' reflected the fashion of the age. They appeared in 1889, the very year that saw the foundation of the [Royal] Society for the Protection of Birds to combat the plumage trade. Appalling numbers of egret (e.g. *Egretta*) plumes (commercially misnamed 'ospreys'), as well as hummingbird (Trochilidae) and bird-of-paradise (Paradisaeidae) corpses, were being imported for the ornamentation of fashionable ladies, and it was not until the 1920s that legislation and the vagaries of *la mode* put a virtual end to the slaughter. Today in Britain some men's hats are still sold with a small gamebird feather in the band, but about 1950 hatters ceased to stock the sprays or 'mounts' of feathers that could be transferred from one hat to another. In the western world the wearing of feathers is nowadays restricted mainly to those who fulfil certain conditions. Ostrich *Struthio camelus* feathers adorn some official cocked hats, the bonnets of bagpipers, and until recently the coiffures of debutantes. Raptor plumes are thought proper to the bonnets of certain Highland chiefs, and the Black Watch wear the Red Hackle of feathers dyed to match the blood spilt by the regiment at Fontenoy. Here the aesthetic appeal of the feather is complemented by its function as a signal of rank, privilege, or group membership. The same is true in much of the 'primitive' world. To peoples without chemical dyes feathers offer a source of bright colour equalled only by flowers, and much less fragile; but some birds too have qualities that a man would wish to share, such as keen sight or skill in taking prey, and which he may acquire by donning their plumage. Dissociation of the purely decorative from the symbolic or the sacred in this field is difficult and will not be attempted here. For whatever motive, Man's use of feathers goes far back into prehistory and is, on varying levels of frequency, world-wide, attaining its most noteworthy development in the Americas and Oceania.

In North America eagle feathers were highly valued, especially the white, dark-tipped tails of the immature Golden Eagle *Aquila chrysaetos*. A few tribes kept caged eagles, but among some Plains Indians the birds were hand-caught by men concealed under carrion-baited screens of foliage and released minus tail. The feathers were hung from weapons, pipes and bridles, and especially worn in the hair of warriors to indicate, by a precise code of notches, painting and angle, the wearer's deeds. Originally only Plains men of outstanding valour might aspire to the now familiar eagle-plume 'war bonnet', which in its earlier forms was much less stylized both in shape and in the feathers employed. Various species contributed to the simpler crowns and circlets worn in the eastern and southern Woodlands, where the Wild Turkey *Meleagris gallopavo* was favoured. Among other uses, turkey feathers were tied into fibre netting to produce mantles both warm and decorative. Nineteenth century traders found an avid market for turkey feathers among the Upper Missouri tribes, outside the bird's normal range. The sedentary Pueblo Indians of Arizona and New Mexico used feathers mainly as altar decorations and aspergilla, and for *pahos*, the wooden pegs with a single pendant downy feather embodying a prayer and used somewhat in the manner of votive candles. Certain Pueblo ceremonies, however, called for topknots of scarlet parrot feathers, obtained from live birds traded north from Mexico.

The most imaginative North American featherwork developed in California, in the form of ceremonial kilts and elaborate head-dresses of brilliant passerine feathers, sometimes dominated by long black plumes from the Condor *Gymnogyps californianus*. The Pomo made exquisite coiled baskets studded with crests of quail (*Lophortyx* sp.), scalps of woodpeckers and flickers (Picidae), and hummingbird feathers. Red feathers from the Pileated Woodpecker *Dryocopus pileatus* served both for ornamentation and as currency. Birds were important to the Indians of the North Pacific Coast but their heraldic carvings of eagle, raven and hawk belong most properly to art. Feathers were little used here, but at the numerous formal feasts the bark head-rings of the participants must be filled with loose white down; and puffin beaks (*Fratercula corniculata* or *F. cirrhata*) were strung together for rattles and fringes. In the Subarctic (especially) bird quills were split and dyed for use in the ornamentation of moccasins and equipment, as a supplement to the more usual porcupine-quill embroidery. The Eskimo combined utility with decorative effect by piecing together the feathered skins of sea ducks and divers (Anatidae, Gaviidae) into garments, or turned them singly into pouches (as did the Swedish Lapps).

Native American featherwork reached its apogee in classical Mexico, the land of the Feathered Serpent. Little has survived, but one or two brilliant examples of feather mosaic may still be seen in museums, and precolumbian codices and sculpture show both Maya and Aztec nobles wearing stupendous headgear based on the plumage of the Quetzal *Pharomachrus mocinno* and the *Xiuhtótotl* (*Cotinga* sp.). The sacred quetzal plumes bulked large in the tribute exacted from subject tribes.

The textile-orientated civilizations of the Andes made no great use of feathers, although the reigning Inca wore above his brow, in life and in death, a pair of sacred plumes taken possibly from a fork-tailed nighthawk, *Uropsalis lyra* or *U. segmentata*. It is in the forest areas of tropical South America that naked or near-naked peoples wed fine craftsmanship to controlled aesthetic sense to produce a variety of resplendent chaplets and diadems. Important among the many species exploited are the toucans (Ramphastidae), parrots and macaws (Psittacidae), curassows (Cracidae), and the Harpy Eagle *Harpia harpyja*. Feathers are also worn on arms, legs and necks, and thrust through perforated ears, lips, cheeks and the nasal septum. In coastal Brazil the Scarlet Ibis *Eudocimus ruber* was semi-domesticated to supply feather mantles. Sixteenth century travellers in the same region saw prospective victims of cannibal rituals whose skin was coated with crushed blue eggshell; the same cosmetic is worn today by girls in the Xingu tribal refuge, without culinary connotations. More widespread is the adornment of the body, overall or in patterns, with down or chopped feathers glued on with resin or latex.

Amazonia is the home of a process, known to ethnologists as tapirage, for altering the pigment of living birds. Typically, green parrots are partially plucked and the bared skin rubbed with the venomous secretions of the Giant Toad *Bufo marinus* or frogs, *Dendrobates* spp., sometimes mixed with a vegetable dye (usually *Bixa orellana*). The next growth of feathers is yellow or red. The biochemistry of the method is unclear, and made more so by the variety of unguents used in marginal areas, including fish fat, or dye alone, but its effectiveness is unquestionable.

Feather ornaments of more sober hue were worn south of the tropics, right to the tip of Tierra del Fuego, where a scrap of birdskin served as a pubic covering for Yahgan women. Here too bird-bone beads were worn. On the pampa feathers of rheas, *Rhea americana* and *Pterocnemia pennata*, and of herons (Ardeidae) took precedence.

Tribal Africa is in general much less feather-conscious than America. Predictably the Ostrich holds pride of place, its plumes decking heads and shields in East and South Africa, most strikingly in the great face-encircling feather 'manes' of such warrior tribes as the Masai and Emberre (who mixed them with those of the guinea-fowl *Acryllium vulturinum*), and surviving most extravagantly in the attire of modern Kaffir rickshaw boys. Ceremonial feather fans from the West African emirates recall those of dynastic Egypt. The wearing of ostrich feathers may indeed have been continuous from the ancient world to the modern, radiating from the Mediterranean and supplied until recently from birds in the North African-Middle Eastern range. About 1870 the European vogue for feathers led to the large-scale farming of ostriches in South Africa, soon carried over into Australia and the USA; early in this century ostrich feathers ranked fourth in value among South African exports. Despite vicissitudes, ostrich farming continues, reinforced by a steady demand for skins, which are converted into fine leather goods. Beads of ostrich-egg shell, ground into button-like discs, are worn up and down Africa, and appear in Libyan graves dated at 700 BC.

The Peacock *Pavo cristatus* and other phasianids are high on the list of species whose plumage is used for dress accessories and the like in the Orient. Flexible peacock feather shafts, stripped of the rami, are stitched into Indian embroideries; forewings of eagles (*Haliaeetus leucocephalus* and *Aquila clanga*) make fans in Manchuria—as in North America (*A. chrysaetos*); and cheap metal jewellery set with bright feathers is popular in China. The Naga tribesmen in Assam greatly value rectrices of the Racket-tailed Drongo *Dicrurus paradiseus*, and it is here that we first meet a preoccupation with the hornbills (Bucerotidae) which recurs at intervals to the limits of Indonesia. The bold black and white tail feathers are worn in the hair and on the war-coats of Dayak headhunters in Borneo, and the solid casque of the Helmeted Hornbill *Rhinoplax vigil* is carved into ornaments which include ear-plugs denoting the taking of a head. Wooden representations of hornbills, variously conventionalized, are important in Bornean ceremonial life. (See also HORNBILL).

A more significant focus on bird exploitation is found in New Guinea, where both men and women delight in disguising themselves behind startling face-paint, pig tusks and shells, topped by enormous structures built up of hair, fur, leaves and feathers—of eagle (*Harpyopsis novaeguineae*), parrots and lorikeets (Psittacidae), cassowary *Casuarius bennetti*, and above all birds-of-paradise. Cassowary plumes are thrust into pierced nostrils as well as through the septum, and cassowary-bone spatulae through the ears. Live cassowaries are kept for their plumage, and change hands as bride-wealth. Across the Torres Strait the northern Aborigines make some use of the Australian species, *C. casuarius*, along with Emus *Dromaius novaehollandiae* and smaller species, but featherwork is not prominent. Bird down is worn at corroborees, affixed sometimes with the wearer's blood. Patriotic plumes for regimental slouch hats seem to be the emu's one tiny contribution to white Australian adornment.

In the western Pacific featherwork, tasteful generally, achieved a brilliant climax on Hawaii. Its most characteristic manifestation everywhere is the feather cloak. The New Zealand Maoris make them of Kiwi *Apteryx australis* feathers tied into a groundwork of native flax, and may trim them with those of the New Zealand Pigeon *Hemiphaga novaeseelandiae*, Kea *Nestor notabilis*, and others. Chiefs used to supplement the cloak with one or two tail feathers of the extinct Huia *Heteralocha acutirostris* in the hair.

The most precious sources of feathers in Polynesia however were the honeyeaters (Meliphagidae) and Hawaiian honeycreepers (Drepanididae). On Santa Cruz Island fibre belts over 6 m long, covered with the scarlet body feathers of the Cardinal Honeyeater *Myzomela cardinalis*, were currency. On the Hawaiian group half a dozen species contributed splendour to the high-born in the form of *leis*, plumed staves, helmets and, most notably, robes. Leis were feather garlands more durable than those of flowers which are draped over modern tourists. The official staves, *kahili*, were emblems of authority. The helmets, *mahiole*, were astonishingly like Graeco-Roman models in outline, with high, broad keels, but made of wicker and entirely covered with tiny feathers set almost as closely as on the bird itself. So too were the robes, *ahuula*, varying in size from shoulder capes to full-length cloaks. The basic colour was normally yellow, counterpointed by triangles or lozenges of red or black. The yellow came from the small axillary tufts of the mainly black O-o *Moho nobilis*, red from the Iiwi *Vestiaria coccinea* and Apapane *Himatione sanguinea*, and black and orange from the Mamo *Drepanis pacifica*; some other species were utilized to a lesser extent. To make a robe, tufts of up to 20 tiny feathers were tied in so thickly and evenly that the foundation of *Touchardia* fibre is quite invisible. A full-sized robe may have some 100,000 such tufts.

Examples of this work survive to dazzle the eye and the imagination, but no more can be made; O-o and Mamo, like the New Zealand Huia, have gone, killed off not by feather-hunters (the rarer birds were released to grow new feathers) but by the destruction of habitats. Elsewhere however conscience has prevailed over commerce in time to save the egrets and birds-of-paradise, and the taking of eagles for latterday Indian festival gear in the USA is forbidden by laws which the Indians brand as discriminatory.

This article is based mainly on a long acquaintance with museum collections. The subject is touched on in innumerable ethnographies but the 4 books listed below are particularly relevant. The present tense used herein may soon, or already, be rendered inappropriate in some contexts by the advance of Progress and denim; feather ornaments are worn often in inverse ratio to the amount of other covering, in the jungle just as in the cabaret. ORNIS: Greek word (plural 'ornithes') for bird, used scientifically (in the singular)—but seldom nowadays—in the sense of AVIFAUNA.

ORNITHIC: pertaining to birds.

ORNITHICHNITE: geological term for a bird's footprint preserved in stone.

ORNITHOGAEA: name for a zoogeographical region (not one of the classical divisions) considered to include New Zealand and Polynesia. Reasons are given elsewhere for treating New Zealand as a subregion of the Australasian Region, and for excluding oceanic islands from any such scheme (see AUSTRALASIAN REGION; DISTRIBUTION, GEOGRAPHICAL).

ORNITHOLITE: geological term for the fossilized remains of a bird (see FOSSIL BIRDS).

ORNITHOLOGICAL SOCIETIES: organized groups of ornithologists with a collective interest in watching, studying or enjoying birds; or in their protection and conservation (see BIRD-WATCHING; CONSERVATION; ORNITHOLOGY).

Probably more than in any other branch of zoology, progress in ornithology depends on wide participation. Trained scientists in universities, museums and similar foundations and research institutes play their part, especially in more complex fields such as physiology or behaviour, but many studies of distribution, biology, ecology and migration are founded on this general enthusiasm for collective participation by amateurs, pursuing ornithology as a hobby.

Typifying the potential scientific achievement of such collaborative effort is the *Atlas of Breeding Birds in Britain and Ireland*, published in 1976 (see ATLAS). The project to map the breeding season distribution, based on survey visits to the 10 km squares of the British National Grid, was initiated by the British Trust for Ornithology (BTO) and Irish Wildbird Conservancy (IWC) and ran for the 5 years 1968–1972. It has been estimated that up to 15,000 observers took part, contributing immeasurable hours of field-work to visit every one of 3,862 squares, resulting in an invaluable *Atlas* of a precision unthinkable by any other approach.

The senior ornithological body in Britain is the British Ornithologists' Union founded in 1858, a learned society publishing the journal *Ibis* and devoting some of its subscription income to supporting ornithological expeditions, research and publications in Britain and overseas.

Concerned with the practicalities of the study of all types of birds is the BTO (founded 1933; journals *Bird Study, BTO News, Ringing and Migration*), whose members are able to participate actively in a wide and ever-changing spectrum of censuses, surveys, biological studies and bird ringing. The extensive data collected from these co-operative ventures is analyzed either by an amateur enthusiast or by the Trust's professional headquarters staff. The Wildfowl Trust (journal *Wildfowl*), founded by Sir Peter Scott, has a network of reserves directed at waterfowl conservation but is better known internationally as a centre of waterfowl research, ranging from population estimation, movements and ecology to the captive breeding of the Ne-ne *Branta sandvicensis*.

In Scotland the Scottish Ornithologists' Club (SOC) with its journal *Scottish Birds*, and in Ireland the Irish Wildbird Conservancy (journal *Irish Birds*) fulfil national roles, often co-operating with the BTO and the Royal Society for the Protection of Birds (RSPB; magazine *Birds*) in research covering all Britain and Ireland. There is as well a remarkable regional and local network of societies. In 1982, excluding branches of the RSPB, there were 170 organizations devoted to birds against only 46 catering for all other aspects of zoology.

Most counties have their own society, providing meetings and excursions to inform and interest their members and maintaining records of the status of the county avifauna. Most countries in northern Europe have an infrastructure of regional and local societies and clubs broadly similar to, but rarely so extensive as the network in Britain.

There are 3 major scientific ornithological societies in North America: American Ornithologists' Union (journal *Auk*), Wilson Ornithological Society (journal *Wilson Bulletin*), and Cooper Ornithological Society (journal *Condor*). The National Audubon Society provides leadership in conversation issues. There are also many state and province societies. In Australia, the Royal Australasian Ornithologists' Union publishes *Emu*. In Europe, most countries now have a national society (for example, Société Ornithologique de France, journal *L'Oiseau*; Nederlandsche Ornithologische Vereenigung, journal *Ardea*; Deutsche Ornithologen Gesellschaft, *Journal für Ornithologie*). The oldest society in Asia, the Bombay Natural History Society, celebrated its centenary in 1983. (The journal *British Birds*, published monthly since 1907, is an exception in not being the organ of a particular society or institute.)

These periodical journals are the prime means of disseminating ornithological information and it is generally within their pages that additions to our knowledge of birds are published. Relatively little is found in more general journals connected with animal ecology, physiology or behaviour, a situation distinct from most other disciplines save perhaps entomology. Many of the specialist journals are now regularly abstracted by the various international biological data retrieval systems, and an annual guide to the past contents of the majority can be found in the *Zoological Record* published by the Zoological Society of London. Of the 36 most-cited journals devoted to birds, 13 are specifically named after birds. J.J.M.F.

ORNITHOLOGY: the scientific study of birds; that branch of Zoology concerned with the Class Aves. (See AVES; BIRD-WATCHING; CONGRESSES, INTERNATIONAL; ORNITHOLOGICAL SOCIETIES; and articles on general subjects.)

Birds are fascinating objects for scientific study: their feathers, respiratory and circulatory systems are unique and extremely effective in relation to their great mobility. Flight has opened up new horizons in the form of migration, but has also imposed some strictures. The forelimb is given over to flight, so the food-gathering 'hand' has been lost, but this in turn has led to the enormous adaptive radiation shown by birds' BILLS. Research on birds may be considered under main discipline headings, though, as in all branches of Natural Science, the boundaries between disciplines are not clearly defined: indeed one may often augment another.

Systematics. Deals with the identity and relationships of birds, both of the present time and those of the fossil record, and is based largely on anatomy but with an increasing input from elsewhere e.g. protein analysis. There is a natural connection to studies of evolution.

Anatomy and physiology. Birds as a Class are regarded by general zoologists as remarkably uniform compared with other animal groups. Thus the subtle distinctions between the different anatomical and physiological adaptations that fit each species or group to its way of life are particularly interesting.

Ecology and distribution. Studies which relate birds to their total environment, for example in terms of food or population dynamics, come under this heading. So too does MIGRATION, an ability widely and well developed in birds, and a fertile study area where several key questions remain unanswered.

Behaviour (or **ethology**) **and vocalization.** Deal with the habits, e.g. courtship and aggressive displays, of birds and their songs and calls, including their causation and biological function.

Applied ornithology. Deals with the interactions between birds and men. At one extreme fall the economic aspects of bird damage to crops and its prevention, and at the other lie studies of species threatened by habitat loss or pollution at man's hand. Between lies the role of bird populations as indicators of environmental change.

While ornithology has benefited widely from research in other branches of zoology—for example from studies of migrating fish—there are many cases where ornithological investigations have been the foundation stones of research throughout zoology. Charles Darwin's studies of the Galapagos finches (see DARWIN'S FINCHES) contributed to the formulation of his theories on the ways in which new species originate—views that were to revolutionize all subsequent biological thinking. P.L. Sclater's work on the geographical distribution of birds, propounded in 1858, opened this field of study to all zoologists, and Sclater's zoogeographical regions were largely adopted by Alfred Russel Wallace, 18 years later, for animals in general. More recently, V.C. Wynne-Edwards and David Lack have been pioneering theorists at the forefront of studies of the factors regulating animal populations. J.J.M.F.

ORNITHOMANCY: divination from observations of the flight of birds—the words 'augury' and 'auspice' both owe their origin to this superstitious practice, being derived from the Latin 'avis' (see OMENS, BIRD AS).

ORNITHOPHILOUS: botanical term applied to plants fertilized through the intermediacy of birds (see POLLINATORS).

ORNITHOSCOPY: same as ORNITHOMANCY.

ORNITHOSIS: term (plural 'ornithoses') applied to diseases identical with, or closely related to, psittacosis (occurring in birds not necessarily of psittacine species)—see PSITTACOSIS.

OROPENDOLA: substantive name of species in the tropical genus (*Psarocolius*) of Icteridae (see ORIOLE (2)).

ORPHANED BIRDS: see CARE OF SICK, INJURED AND ORPHANED BIRDS.

ORTHONYCHINAE: see RAIL-BABBLER.

ORTOLAN: name, alternatively 'Ortolan Bunting', of *Emberiza hortulana* (for subfamily see BUNTING); the gastronomic application of the name is wider than its specific one.

ORTSTREUE: fidelity to home area, used especially for the tendency of migrants to return to a previous breeding or wintering area. A German term that has been widely used in English publications. See DISPERSAL.

OSCINES: see under PASSERIFORMES.

OSPREY: *Pandion haliaetus*, in America often called 'Fish-hawk' (see HAWK). Also a plumage trade misnomer for egrets (Ardeidae).

OSSIFICATION: see AGE; SKELETON, POST-CRANIAL; SKULL.

OSSIFRAGE: archaic name for the Lämmergeier *Gypaetus barbatus* (see VULTURE (1); also BIBLE, BIRDS OF THE).

OSTRICH: the largest living bird, *Struthio camelus*, the only species of the Struthionidae (Struthioniformes), which are placed in the group of large flightless birds known as 'ratites'. Now confined to some of the more arid areas of Africa; 'American ostrich' is an outdated term for the RHEA.

Characteristics. Adult Ostriches stand about 2.5 m high and weigh up to 150 kg. The eyes are large, surrounded by conspicuous eyelashes, and give very acute vision. The neck is flesh-coloured and appears bare, being covered only with minute downy feathers. It and the bare thighs develop a bright red or blue colour (depending on the race) in breeding males. The feathers covering the body lack barbules, giving them a soft appearance. The adult male is jet black, with beautiful white primary plumes in the wings and tail, although the latter usually become stained dark, perhaps deliberately. The female is grey or grey-brown all over, and is slightly smaller than the male. The legs are long and powerful, ending uniquely in only two toes; they can carry the ostrich at a running speed of up to about 50 km/h.

Ostrich *Struthio camelus*. (*K.J.W.*).

Habitat. Ostriches inhabit a range of open habitats from desert to savanna; they do not occur in thick bush or forest. They occasionally reach densities of more than 1 per km^2, but in most places they are much less abundant.

Distribution. Only 4 races of Ostrich are now both recognized and still extant. The nominate race *S.c. camelus*, the North African ostrich, stretches along the southern side of the Sahara from Morocco to Ethiopia. The so-called Dwarf Ostrich *S.c. spatzi* from Mauritania was mistakenly classified on inadequate information. In the Horn of Africa lives the Somali Ostrich *S.c. molybdophanes*, the males of which have bright blue-grey skin on neck and thighs. There is very slight hybridizing and overlap in eastern Kenya with its southern neighbour, the Masai Ostrich *S.c. massaicus*, which has bright red skin during the breeding season. This race stretches south as far as the Katavi plain in south-west Tanzania.

The South African Ostrich *S.c. australis* is found south of the Zambesi river in suitable open arid country. The Arabian Ostrich *S.c. syriacus* once abundant, has become extinct since 1941 (or possibly 1966). Populations elsewhere are declining in range, but are generally not unduly persecuted or threatened.

At Oudtshoorn, in the Cape Province of South Africa, Ostriches have been farmed as domesticated birds since 1860, originally for the feathers only but now also for leather, meat and tourism. Hybridization with imported North African Ostriches at the end of the last century improved the quality of the feathers of the domestic stock; this mongrel variety has been released and become feral in parts of South Africa and Australia (see DOMESTICATION).

Movements. In the less arid regions of East Africa, ostriches are largely resident, the same individuals remaining in the same area throughout the year. In desert regions they are reported to migrate more, and probably cover considerable distances in search of food and water.

Food. Ostriches are clearly well adapted to feeding on scarce high-quality foods—they can stride effortlessly over a sparsely vegetated landscape, lowering the beak on the end of the long neck to pluck off selected food items. They are almost entirely herbivorous, choosing leaves, flowers and seeds of a wide variety of plants. There are only occasional reports of their eating insects and other animals in the wild, despite their well-deserved reputation in captivity for swallowing anything. When feeding, the food from many pecks is stored at the top of the neck and then all visibly passes as a single large bolus down the elastic neck.

Behaviour. The groupings of Ostriches vary with race, place and season. They are often seen singly, often in pairs, and often in small groups of up to 5 or 6 birds. In arid regions larger aggregations may occur at particular feeding or drinking places. The small groups typically seen in East Africa are loose and temporary, as individuals join and depart from others in an apparently casual way. Their exceedingly acute eyesight, and their conspicuousness, especially of the males, clearly helps them to locate other members of their species.

Within the loose groups, both or all the individuals tend to be engaged on roughly the same activity at the same time—feeding, standing alert, walking, preening, or dustbathing. Preening is a frequent activity, but apparently directed as much towards snapping at pestering flies as towards care of the feathers.

Motivation and dominance relations are expressed by different body postures and wing movements. During aggressive encounters, males draw themselves up to their full extent, erect the body feathers, raise the tail, and flap their wings up and down on each side alternately. Much time is spent on threats and chases between breeding adult males, but actual fights are rare. The feet are their only, but extremely effective, weapon; an ostrich can deliver a fearsome forward kick at its opponent's chest. Threat or mild aggression towards a group member is accompanied by raising both wings and opening the beak wide.

Voice. During the breeding season, male Ostriches utter a loud 3-note booming sound, which has been likened by Livingstone and others to the roar of a lion. It is used in proclaiming ownership of a territory and attracting females.

Breeding. In East Africa, Ostriches breed during the dry season, but in more arid regions elsewhere, at the onset of the rains. The males' necks acquire their bright coloration, and territorial defence begins. The males boom, chase out intruding males, and court any females which come through their large territory. The courtship display is spectacular. The male draws himself up high, raises and erects his tail, and approaches the female at a trot. Suddenly he drops to a squat and rocks from side to side, his black and white wings extended and waving in the air alternately. Meanwhile his neck, even brighter red (or blue, according to subspecies) than usual, writhes from side to side. He may wave his wings as many as 70 or more times in front of the female, who is usually in the submissive or soliciting posture with head and both wings lowered and quivering. The male stands, approaches the female, raises both his wings high above his back, and mounts the squatting female. The mating itself is accompanied by further wing waving.

The male prepares a number of shallow scrapes somewhere within his territory. One of these is accepted by a female (the 'major' hen) who lays the first egg in it and continues to lay there at regular 2-day intervals. Up to 5 other females (the 'minor' hens) lay in the same nest, also on alternate days. The male has usually mated with these minor females, and he leads them to the nest with a wing-lowered display like that of submissive females.

The eggs are almost round, usually between 1,300 and 1,900 g in weight. The shell is about 2 mm thick, pitted with small pores, and shiny creamy white in colour.

Nest destruction is frequent, caused by Egyptian Vultures *Neophron percnopterus* which throw stones at the eggs, and by jackals and hyaenas. After the first few days, an adult ostrich may attend the nest to protect it against both heat and nest predators.

The major female lays about 10 eggs in her nest before incubation begins, and the minor hens may between them have laid between 10 to as many as 30 or more eggs there. At the start of incubation, the major hen pushes out a number of surplus eggs into an outer ring 1–2 m away where they are not incubated and are doomed. She rarely pushes out any of her own eggs, but retains them among the 20 or so which she can cover and incubate in the centre of the nest.

Incubation takes about 42 days. It is done by the major female during the day and by the male at night. The minor females take no part in it. The chicks are nidifugous, and leave the nest with the adult pair soon after hatching. Over the next few weeks the brood often merges with the broods from other successful nests, resulting in large aggregations of chicks attended by only one set of adults. The chicks grow very fast and are almost full height within a year. They reach sexual maturity at 3–4 years old, and probably live for at least 40 years.

OTIDES; OTIDIDAE: see under GRUIFORMES; BUSTARD. (The spelling 'Otidae' is patently erroneous.)

OU: *Psittirostra psittacea* (for family see HAWAIIAN HONEYCREEPER).

OUTER TOE: see LEG.

OUZEL: substantive name, also spelt 'ousel', of the Ring Ouzel *Turdus torquatus*, but formerly applied to the Blackbird *T. merula* (cf. German 'Amsel')—see THRUSH. 'Water-ouzel' is a popular name in Britain for *Cinclus cinclus* (see DIPPER).

OVARY: female gonad, in birds usually developed only on the left side (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

OVENBIRD (1): substantive name of several species of Furnariidae (Passeriformes, infraorder Furnarii); in the plural, serves as a general term for the family but applies particularly to the nominate subfamily. The woodcreepers or woodhewers (Dendrocolaptidae) are often treated as a subfamily of the Furnariidae, but are here treated as a distinct family. The family is purely Neotropical and predominately South American; and it comprises about 221 species, in 58 genera, although many genera are considerably oversplit.

The Furnariidae are probably more diverse than any other avian family. Most systematists recognize subfamilies and these groupings may be usefully introduced here. The Furnariinae (confined to South America), besides true ovenbirds or horneros of the genus *Furnarius* (which build a mud nest like an old fashioned earth oven and thus give the family its name), include a variety of divergent genera such as the miners (*Geobates*, *Geositta*), the groundcreeper (*Clibanornis*), the earthcreepers (*Upucerthia*), the Tococo (*Chilia*), and shaketails or cinclodes (*Cinclodes*). Next and equally important are the Synallaxinae or spinetails, typified by the genera *Synallaxis*, *Cranioleuca* and *Asthenes*, which are rather less variable and tend to be characterized by peculiar tail structure and the building of relatively enormous enclosed nests, for this reason sometimes being called castle-builders. The genera of treerunners (*Margarornis*) and the Barbtail (*Premnoplex*) are often placed in a separate subfamily Margarornithinae, but are perhaps best included with Synallaxinae.

The third large and diverse subfamily, the Philydorinae, includes treerunners (*Pygarrhichas*), treehunters (*Thripadectes*), Hookbill (*Ancistrops*), Pointed-tail (*Berlepschia*), cachalotes (*Pseudoseisura*), xenops or recurved-bills (*Megaxenops* and *Xenops*), and the foliage-gleaners (*Philydor*, *Automolus*, etc.). The Philydorinae represent the ovenbird subfamily closest to the woodcreepers (Dendrocolaptidae) and may be considered with certainty to represent a transitional group to the woodcreepers. The affinities of the Sclerurinae, genera *Sclerurus* (leafscrapers) and *Lochmias* (Streamcreeper), are uncertain.

Characteristics. Most of the family consists of small brown birds which is as much as can be said by way of generalization. The largest members are about 25 cm in total length, e.g. cachalotes, species of *Pseudocolaptes*, and the large *Cinclodes*. The colour of nearly all members of the Furnariinae is dull, being shades of brown sometimes tending to rufous or chestnut or with rufous parts, usually paler or even white below, and often with a striking wing bar. The miners, earthcreepers, and shaketails, which are all grey-brown or dark brown birds, perhaps paler and somewhat mottled below or with a white wing bar (*Cinclodes*), reach the acme of drabness. The true Ovenbird *Furnarius leucopus* ('El Hornero' of the South Americans) differs in being essentially bright chestnut above and white below. The spinetails tend to be less drab and uniformly coloured, being mostly variegated on the upper parts with brown, chestnut, and almost black, and sometimes with dark streaking on the throat and breast (otherwise usually almost white). Some members even have some bright colour, e.g. the White-cheeked Spinetail *Schoeniophylax phryganophila* with a bright yellow chin, and *Asthenes* spp. with a touch of reddish chestnut on the throat. Species of *Margarornis* are rufous above and dark olive below, heavily marked with pear-shaped drops of light buff, somewhat resembling a woodcreeper. Similarly, the Sclerurinae are generally dark coloured and may be scalloped with white below. Many of the Philydorinae resemble woodcreepers, again, with their characteristic streaking on head and under parts, e.g. *Berlepschia rikeri* and *Pseudocolaptes* spp., while the genus *Philydor* has bright orange underparts.

The wing is as variable as other features of the family, from soft, short, and rounded, to long and somewhat pointed. The tail may be normal, or rather short as in *Furnarius* and *Geositta*, but is remarkably diverse among the spinetails. In that subfamily there is a tendency for it to be graduated or forked, long and attenuated, with the feather barbs breaking down and the webs becoming degenerate so that the naked quills project. For instance, *Leptasthenura* spp. have long tails with tapering rectrices, and *Synallaxis* spp. have graduated tails with the ends of the rectrices frayed and broken down so that the shafts project. Most remarkable of all is Des Murs' Spinetail *Sylviorthorhynchus desmursii*, with a tail 2 or 3 times as long as the rest of the bird, of very thin feathers with poorly developed webs. On the other hand, 'softtails'—*Metopothrix* and *Xenerpestes*—have normally developed rectrices, but with the shafts not at all strong, while the rectrices of *Berlepschia* are sharply tapered. Those forms which resemble dendrocolaptids (*Pseudocolaptes, Syndactyla, Anabacerthia*, and *Philydor, Xenops*, etc.) are distinguished from members of that family by not having the shafts of the rectrices stiffened.

A very few species are crested, such as the Plainrunner *Coryphistera alaudina* and the Brown Cachalote *Pseudoseisura lophotes*. The bill is mostly rather short, straight and pointed, and is normally wide; but many variations occur, the bill being long and decurved in *Upucerthia*, short and slightly curved in *Geositta*, moderate in both respects in *Furnarius*, long and straight in *Sclerurus*, laterally compressed in *Xenoctistes*, and short, wedge-shaped with upturned mandible in *Xenops*. The legs and feet are usually medium to short, but are strongly developed in terrestrial forms such as the true ovenbirds and cachalotes.

Habitat, ecology and behaviour. Most genera and species inhabit thickly wooded habitats or areas with plenty of good cover, and this applies particularly to those within the tropics (where the majority of the family live); but even so there are differences in habitat and behaviour. The foliage-gleaners (*Anabacerthia, Automolus*) are birds of the canopy and forest trees, where they hunt through the leaves like warblers (Sylviinae). *Heliobletus contaminatus* has the habits of a treecreeper (Certhiidae) or woodcreeper (Dendrocolaptidae), as have the treerunners. The leafscrapers inhabit the densest undergrowth, are great skulkers, and have the habit of rooting through leaves and tossing them in the air in their search for food. The Sharp-tailed Streamcreeper *Lochmias nematura* is equally unobtrusive, and it shows such a preference for sewage effluent that the Brazilians have aptly named it 'president of filth'. More widely distributed birds such as the true ovenbirds and many spinetails are inhabitants of less densely wooded areas; the former, being largely terrestrial, prefer fairly open country yet with plenty of trees, while spinetails characteristically skulk unobtrusively in thickets or low cover even in treeless lands.

In the southern part of its range, and to a limited extent in the Andean highlands as far north as Colombia, the family shows the greatest measure of adaptive radiation. In the open pampa of Argentina and the mountainous fjord areas of Chile, different genera and species have invaded every possible habitat. The miners and earthcreepers are entirely terrestrial and typical both of barren mountainous country and of the flat pampa. The Patagonian Earthcreeper *Upucerthia dumetaria* is even unwilling to fly, preferring to escape by running.

The Brown Cachalote is also largely terrestrial and tends to run off behind trees and other obstacles rather than fly when disturbed. Species of *Cinclodes* occupy the niche of dippers (Cinclidae) and are always found near water, from mountain torrents in the high Andes down to sea level; they are even known to feed off-shore on the floating masses of giant kelp. The White-throated Treerunner *Pygarrhichas albogularis* of Chile and Argentina fills the niche of a nuthatch (Sittidae). The Black-faced Spinetail is a bird of the marshes, as is the Curved-billed Reedrunner *Limnornis curvirostris*. *Aphrastura* and *Leptasthenura* are arboreal genera. For the most part, members of the family are active yet unobtrusive birds, even in open country, keeping well to cover, constantly creeping about in bushes, reeds, or thick grass, and even running off like mice rather than flying; and they show a great tendency to remain in pairs. The Greater Thorn-bird *Phacellodomus ruber* in Argentina is exceptional in being not at all restless and never making an effort to hide.

Distribution. The family, like the Formicariidae (see ANTBIRD), ranges from the montane and lowland forests of southern and central Mexico through Central to South America; likewise it reaches Trindad and Tobago, but is not found in the Antilles. In the south its range is greater than that of the antbirds, being over the whole of the continent to Cape Horn and Tierra del Fuego, as well as the Falkland Islands, with a tremendous Andean radiation. Many specialized forms have developed in the open, barren lands of the extreme south, and the monospecific genus *Chilia* is confined to Chile, where it inhabits semi-arid country. In Argentina a few species, such as the Black-faced Shaketail *Cinclodes fuscus* and perhaps the Patagonian Earthcreeper, are said to be migratory. As with the antbirds, no comprehensive account of the family has ever been written, and the majority of species are known only by their appearance.

Food. Most species are insectivorous, but *Cinclodes* spp. also take small crustacea and aquatic animals, as would be expected, while some miners and the Tococo feed on seeds and vegetable matter.

Voice. Like all other characters, the voice varies considerably. Generally, the spinetails and many other genera have short, harsh, rattling and jarring calls; but miners have clear ringing reiterated cries, likened to the laughing of a child; the Ovenbird *Furnarius leucopus* has a sequence of clear, resonant notes produced as a duet or harmonious singing; the Black-faced Spinetail *Phleocryptes melanops* gives wooden-sounding raps and creaks; Hudson's Spinetail *Asthenes hudsoni* has a plaintive four-note song audible for 900 m or more; and the cachalotes are especially noisy with jay-like screams (Brown Cachalote) or a piercing chorus (White-throated Cachalote *P. gutturalis*).

Breeding. The breeding habits are known mostly from species inhabiting the open lands of the southern parts of South America, but even within these limits the diversity is astonishingly great. The only constant feature is that all lay white eggs—except the Black-faced Spinetail, which lays bright blue eggs, and a few others which lay slightly bluish or off-white eggs. Clutch size is usually 3–5, but as many as 9 eggs are mentioned for the White-throated Spinetail *Synallaxis albescens*, and tropical species probably tend to have smaller average clutches. Terrestrial forms such as miners and earthcreepers nest in holes in the ground, either natural cavities or tunnels dug by the birds themselves or by mammals, e.g. the Common Miner *Geositta cunicularia* nesting in the burrows of the Vizcacha *Octomys mimax* on the Argentinian pampa. *Cinclodes* spp. nest in rock cavities or dig their own holes. Leafscrapers and the Streamcreeper also nest in holes or burrows in banks, and the leafscrapers have an odd habit of flying out of the hole and clinging to a tree-trunk when flushed from the nest. *Aphrastura* and *Leptasthenura* nest either in holes in trees, behind bark, or in the abandoned nests of such birds as *Asthenes* spp.

In contrast, the true ovenbirds build very substantial, domed mud-ovens on the branches of trees well above the ground. The spinetails in general build vast nests, remarkable for such small birds. The Firewood-gatherer *Anumbius annumbi* (a bird about 21 cm long) makes its big structures of large twigs, even in tall trees to which it may have difficulty in carrying up the material. The White-throated Cachalote perhaps makes the largest nest of the family, an enclosed structure with a cavity big enough for an eagle or vulture, and strong enough for a man to stand upon without damaging it; the Brown Cachalote also makes a nest the size of a barrel. The Black-faced Spinetail makes a perfectly roofed nest, domed and impervious to the wet, with entrance near the top, out of grasses and leaves daubed together with mud and probably saliva. Species of *Phacellodomus* place their castles at the ends of branches that are at first several m from the ground, but as the structure grows the boughs bend down and the nest may eventually rest on the ground. Hudson's Spinetail makes domed nests on the ground under the thickest cover, such as the giant cardoon thistles. On the other hand, the Striped-crowned Spinetail *Cranioleuca pyrrhophia* and the Wren-like Spinetail *Spartonoica maluroides* make open cup-shaped nests, which is quite exceptional for the Synallaxinae.

Owing to the impossibility of observing the nests of most species of Furnariinae and Synallaxinae without destruction or excessive disturbance (the nests of these 2 subfamilies are much better known than those of the rest of the family), breeding details are virtually unknown in spite of the fact that these huge nests are such a conspicuous feature of the countryside in the open parts of South America. The incubation and nestling periods are very superficially known, for only 6 species, being 15–20 days and 13–18 days respectively. The abandoned castles of the spinetails and the ovens of El Hornero are often used by other birds such as cowbirds (Icteridae), swallows (Hirundinidae), wrens (Troglodytidae), and parrots (Psittacidae); sometimes the owners are even expropriated after building their nest. OVENBIRD (2): *Seiurus aurocapillus* (see WARBLER (2)).

OVERFLOW ACTIVITY: a behaviour pattern appearing in the absence of the usual external triggering stimuli, e.g. Canaries in the appropriate physiological state will show nest building responses even in the absence of nest material. Overflow activities (also called vacuum activities) have been interpreted as evidence for spontaneous generation of behaviour patterns in the nervous system. (See BEHAVIOUR, HISTORY OF).

OVERSHOOTING: movement beyond the normal limits of a bird's area of distribution by continuance in the usual direction of migration beyond the proper destination.

OVERWINTERING: see MIGRATION.

OVIDUCT: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; LAYING.

OVIPARITY: the characteristic of laying eggs in which the embryos develop outside the maternal body; universal in birds. See also under DEVELOPMENT, EMBRYONIC; EGG; LAYING.

OVIPOSITION: see LAYING.

OVOTESTIS: in virtually all birds only the left ovary is functional. The right ovary remains minute but if the left one is removed, or destroyed by disease, it can develop. Depending upon when this occurs the right gonad may turn into an ovary or a testis, or on occasion into a structure combining the germ cells of both sexes: an ovotestis. In such situations seminiferous tubules are visible in one part of the organ whilst the other contains growing follicles. The potentially ambisexual nature of birds is not confined to one group but is most well known in chickens. Sex changes were described by Aristotle and up to this century were often thought to be associated with the supernatural.

OVULATION: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; also LAYING.

OVUM: the female germ-cell (plural 'ova')—see DEVELOPMENT, EMBRYONIC; EGG; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; GENETICS.

OWL: substantive name of all species of Strigiformes and in the plural, general term for the order. With very few exceptions owls look like nothing but owls, i.e. they are soft-plumaged, short-tailed, big-headed birds with large forward-facing eyes, surrounded by a broad facial disc. Owls probably have the most frontally situated eyes of all birds. This, together with their ability to blink with the upper eyelids, gives owls a semi-human appearance, in which lies much of their appeal to man.

Owls have often been regarded as nocturnal counterparts of the diurnal birds-of-prey (Accipitriformes and Falconiformes), but most likely the Caprimulgiformes (oilbirds, potoos, nightjars and nighthawks) are the owls' nearest living relatives, which have evolved from a common, nocturnal ancestor, perhaps not more than 100 million years ago.

Barn Owl *Tyto alba*. (*K.J.W.*).

General and systematic characteristics. Although the members of the Strigiformes may be easily distinguished from members of other orders, the familial, subfamilial and generic relationships within the order are much less certain. According to present knowledge there are about 134 species divided between 25 living genera and 2 families: the typical owls, the Strigidae, and the barn owls, the Tytonidae. The barn owls differ only in minor osteological details from typical owls. Barn owls have proportionately smaller eyes and are easily recognizable by the heart-shaped facial disc and the long slender legs. The family comprises 10 species: genus *Tyto* consisting of 8 species and genus *Phodilus* 2 species, one occurring in south-east Asia (Oriental Bay Owl *P. badius*) and the other in Africa (African Bay Owl *P. prigoginei*). The facial disc of the Strigidae is circular and the legs are usually rather strong and in most cases thickly feathered. This family contains about 124 species, distributed over about 23 genera, of variable size, coloration, and habits. However, owl taxonomy is currently in a state of flux, and anything approaching a final tally of species or genera must await revision now in progress.

Owls are mostly birds of medium size with some species fairly large or fairly small. The largest are some eagle owls *Bubo* spp., reaching 73 cm in length, and the smallest the Least Pygmy Owl *Glaucidium minutissimum*, 12–14 cm long. Like many birds of prey the female is often larger than the male (see SEXUAL DIMORPHISM).

Owls have dense, soft plumage which makes them look much bigger than they are and helps to keep them warm during long periods of inactivity between hunting forays. The colour of the plumage is often cryptic, which makes the bird less conspicuous when it is resting during the day. Woodland owls tend to be brown or grey in basic coloration; owls living in open habitats are typically paler and those inhabiting desert country are distinctly sandy-coloured (e.g. Hume's Desert Owl *Strix butleri*). In many species, markedly different colour phases occur, e.g. the most common British owl, Tawny Owl *Strix aluco*, is typically brown but also has a rarer grey phase (see POLYMORPHISM). Sexual colour dimorphism is usually absent but there are a few exceptions; for example, the female of the Snowy Owl *Nyctea scandiaca*, is barred, whereas the male is pure white. Differences between juvenile and adult plumage are normally slight, but many species tend to become paler or more whitish in old age (e.g. Short-eared Owl *Asio flammeus*). Most owls have relatively large, rounded wings, shorter in those species which hunt in cover and much longer in those which hunt in open country or are migratory. Owls are light in relation to their wing area (in aeronautical terms they have a low wing-loading) which explains why they can fly buoyantly and effortlessly, with relatively little wing-flapping (see FLIGHT).

Owls show a number of adaptations which enable them to operate with outstanding efficiency as nocturnal predators. First of all they have well-adapted eyes to hunt their prey in poor light; in absolute darkness they cannot see. The huge eyes are shaped like tapering cylinders to provide the largest possible expanse of retina, and a notably thickened cornea acts as an additional lens (see VISION). Forward-facing eyes give a considerable degree of binocular vision, but the eyes themselves are almost immobile. The owl must turn its whole head to look sideways, but it has an exceptional ability to rotate its head; the head of the Long-eared Owl *Asio otus* has been reported to be capable of turning through at least

Tawny Owl *Strix aluco*. (*K.J.W.*).

270°. The number of light-sensitive elements (mostly rods) in the retina is very high, particularly in definitely nocturnal species such as the Tawny Owl, and these species sometimes appear to be blinded by very strong sunlight. But many owls are able to hunt in daylight, and none is really helpless during the day. This is made possible by an exceptional range of aperture (pupil size) controlled by the iris. It is always difficult to prove whether an animal can perceive colour. As owls have some cones in their retina, it seems likely that they can do so when the light is good. Experiments on the crepuscular Little Owl *Athene noctua* have shown that it can perceive at least yellow, green and blue; red and the darkest grey were confused (see VISION).

The owl's sense of hearing is no less remarkable than its exceptional sight. The inner ear of owls is very large, and the auditory region of the brain is provided with many more nerve cells than in other birds of comparable size. Aural abilities are aided by a wide outer ear tube and in some species by the presence of large conchae, which, surrounded by the feathers of the facial disc, can be erected at will. In some species a striking asymmetry in the shape and relative position of the external part of the ear, including the bones surrounding the tympanic region and the operculum, has been described. Asymmetrical ear openings are thought to help the owls to locate the source of sound with precision. In laboratory experiments Barn Owls *Tyto alba* have been capable of locating and striking an unseen living prey in complete darkness, using only their acute sense of hearing (see HEARING AND BALANCE). The high frequency squeals of small prey and the rustle of dry leaves contain all the information the owl needs to locate its intended prey. Assertions that the owl is visually sensitive to infra-red radiation given out by the body of a prey animal have been proved incorrect. Also in the wild many owls rely only on their remarkable auditory powers, at least in hunting rodents and shrews during the winter when these mammals often move under the snow cover. The Great Grey Owl *Strix nebulosa* is able to localize from the air invisible small mammals and to catch them blindly on the right spot below the snow-surface. Those owl species not having the ears so highly developed can always combine their acute visual and aural abilities, because there is never total darkness in a place where an owl is likely to hunt. The 'ear tufts' which many species possess have nothing to do with the auditory organ; they express mood and act as night-time recognition signals, and may also be an aid to camouflage by breaking up the outline of the owl's head. Softened flight feathers together with the low wing loading help an owl to move silently through the air—to hear other sounds while flying itself, and to avoid giving alarm to its prey. Fishing owls of the genera *Ketupa* in Asia and *Scotopelia* in Africa do not fly soundlessly, but, as they take underwater prey, the noisy wing beats do not seem to be of importance.

The bill and claws of owls are clearly suited to their predatory way of life. The bill is hooked, usually short and not conspicuously strong, directed downwards—a modification to reduce obstruction of the already limited visual field. As in the diurnal birds-of-prey, the nostrils are placed in a soft cere at the base of the bill, which is partly hidden by the feathers of the facial disc. The feet are always 4 toed, with the fourth toe reversible. The legs and toes are usually feathered, a protection against possible bites from prey. The fish-eating owls, *Scotopelia* and *Ketupa*, have bare legs and feet with rough spiny soles. All owls have sharp, strongly hooked, raptorial claws.

Habitat. As a group of birds owls are able to occupy all kinds of habitats: tundra, deserts, grasslands, marshes, swamps, woods, luxuriant rain forests, mountains and islands, but the majority of the species live in woodlands or forest edges. Only a few species, like the Arctic Snowy Owl and the desert-living species of North America (e.g. Elf Owl *Micrathene whitneyi*) prefer habitats where trees cannot grow. Some species are terrestrial and live in flat country or among rocks. Long-legged terrestrial species are known both in the Tytonidae (Common Grass Owl *Tyto capensis*, found in Africa and from India to Australia) and in the Strigidae (Burrowing Owl *Athene cunicularia*, found in North and South America). The recent decline of many owls with arboreal habits can be associated with the destruction of forest habitat. Some insular owls, e.g. Madagascar Owl *Tyto soumagnei*, Seychelles Owl *Otus manadensis insularis*, Sokoke Scops Owl *Otus ireneae* (living in a fairly small 'island' of inland forest on the Kenya coast), Anjuan Scops Owl *Otus rutilus capnodes* and Forest Little Owl *Athene blewitti*, are even threatened with total extinction, because of habitat destruction now occurring.

Distribution. On the whole, owls are successful birds, which have dispersed to all continents except Antarctica and several remote oceanic islands. The great majority of species occur in the tropics and subtropics. North America and the Palearctic zone of the Old World are inhabited by 33 species of owls, of which 8 species occur in both North America and Eurasia. The most common owl in the world is probably the Barn Owl which has almost world-wide distribution with at least 34 recognizable geographical forms. Barn Owls have been released in some Indian Ocean islands to control rats, and recently they have also colonized Malayan oil palm plantations. The Short-eared Owl is the other owl with a very wide range, mainly inhabiting boggy and marshy places in open country. The Marsh Owl *Asio capensis* is an ecological equivalent of the Short-eared Owl in Africa. The Snowy Owl is distributed throughout the Arctic tundra regions of the Northern Hemisphere. Throughout the zone of boreal coniferous forests of Europe, Asia and North America quite a number of other species are found; some of them are restricted to this zone, such as the Great Grey Owl, the Hawk Owl *Surnia ulula*, Tengmalm's Owl *Aegolius funereus* (known in North America as the Boreal Owl), the Ural Owl *Strix uralensis*, the Long-eared Owl, and the Pygmy Owl *Glaucidium passerinum*. The last two have a number of closely related forms in tropical America and Africa. The Eagle Owl *Bubo bubo* of Europe and Asia, ranging from the cold northern forests to the hot southern deserts, has allied species also in America (Great Horned Owl *B. virginianus*) and in Africa (Cape Eagle Owl *B. capensis* and Spotted Eagle Owl *B. africanus*). The Little Owl has a mainly Palearctic distribution, the Burrowing Owl from the steppe and desert regions of America being its present closest relative. The Little Owl has been introduced into Great Britain and New Zealand. The Tawny Owl and European Scops Owl *Otus scops* have both only Old World distribution. The Tawny Owl belongs to a widely distributed genus *Strix* which is absent only from Australia. *Otus scops* is the only European representative of the scops owls, which form a widespread group of about 33 species mostly living in the tropical regions of the world, except in Australasia where the genus is replaced by the hawk owls *Ninox* spp.

Populations. Studies of the territorial Tawny Owl (Southern 1970) have shown that there is a limit to the owl density in a given habitat, this being determined by territorial behaviour. In England Tawny Owl pairs had a territory of about 13 ha in closed woodland and 20 ha in mixed woodland and open ground (see TERRITORY). Fluctuations in food resources did not lead to changes in the number of adult owls in the woods. Failure to breed, the laying of fewer eggs than potentially possible, failure to hatch laid eggs, and mortality of the young in autumn and winter were the main factors keeping the numbers virtually constant from one year to the next. But quite the opposite population dynamic applies to the nomadic species. For instance, the Short-eared Owl alters the size of its territory from month to month according to the abundance of its main prey, *Microtus* voles. If food is scarce the species becomes nomadic and seeks new breeding and hunting areas.

Movements. Owls are mainly sedentary; regular migrations are known in respect of only a relatively few species. Among European owls some populations of Scops Owl migrate regularly to tropical Africa, while the northern populations of the Striated Scops Owl *Otus brucei* migrate to the Indus Valley and the Bombay region. Within eastern Asia the Oriental Scops Owl *Otus sunia* as well as the Oriental Hawk Owl *Ninox scutulata* migrate between temperate and tropical regions. The two most migratory species in Eurasia are some northern populations of the Long-eared and Short-eared Owls which are partially migrant also in North America. In several species (e.g. Snowy, Hawk and Great Grey Owls), nomadic winter movements or even irruptions occur more or less cyclically, triggered by fluctuations of rodent populations (see IRRUPTION).

Tengmalm's Owl *Aegolius funereus* has evolved a strategy of partial migration, adult males being resident and females and young being migratory. The periodical food scarcity favours the migration of females and young, and the urgency of guarding the nest-holes of good quality favours residence by the adult males.

Food. It has been fairly easy to analyse in detail what owls are eating at different seasons, because the smaller prey are generally swallowed whole, indigestible matter such as fur, feathers, bone, and chitin being regurgitated some hours later in the form of large PELLETS. Owls feed exclusively on animals. Small mammals like rodents and shrews predominate as food items for the majority of owls. Some species feed on birds, reptiles, amphibians, fish, crabs, earthworms and insects. Hunting methods vary according to the prey. A few species hunt actively on the wing, taking moths and other small creatures in flight. Semiaquatic fish-eating owls catch fish in their talons from the surface of rivers, or hunt crabs on shores and river shallows. But most owl species quarter the ground in silent flight, or scan it from a convenient perch, waiting and intently listening for ground-living insects and small mammals. Food is mainly consumed in the fresh-caught state; carrion is only occasionally eaten.

Behaviour. Most owls seem to be highly territorial, but some nomadic species, such as the Great Grey Owl and the Short-eared Owl, sometimes form loose colonies. Highly territorial owls (e.g. Eagle and Tawny Owls) are very aggressive towards other birds-of-prey, especially during the breeding season; birds of prey and smaller owls form often as much as 3–5% of the total food of the Eagle Owl.

Owls are generally monogamous, nesting in individual pairs, which are apparently permanent. But some males are known to be polygynous: at least, bigamous males of Tawny, Eagle, Snowy, Short-eared and Tengmalm's Owls have been discovered.

Owls usually hide away by day in holes, or in dark places in thick foliage, taking advantage mainly of their protective plumage. At least 80 species out of 134 hunt by night; others are known to be active at dusk or in full daylight. In northern latitudes the Snowy Owl and the Hawk Owl hunt during the light nights of the Arctic summer and in winter during the short hours of daylight. Some species seem to enjoy sun-bathing (Little Owl, Burrowing Owl).

Voice. Several species of owls sing, some very musically. In temperate regions it is the owls which in late winter or early spring fill the night with music, and in the tropics owls are just part of a formidable chorus of animal songs and calls. Throughout the world they have an extraordinary repertoire of shrieks, hoots and caterwaulings, in a range of frequencies which carry far on the night air. These announce their presence and the existence of occupied territories. Calls are completely diagnostic of species, and owls are as likely to recognize other individuals by voice as by sight during their travels in the dark. Individual Tawny Owls can be identified from sonagrams of their hooting.

Breeding. The weather and the food available influence the start of breeding activities and many species appear to make an assessment of rodent abundance; during good vole years they lay earlier and larger clutches than in poor ones. Late snowfalls may cause even advanced broods to be abandoned, while an abundant food supply and high temperatures can encourage reproduction by Barn and Short-eared Owls even in winter.

With minor exceptions, owls make hardly any nests themselves; instead, they use other birds' nests—such as the abandoned nest of a raptor or corvid—and holes in trees or rocks and a great variety of other places, including human habitations. Eagle Owls sometimes dig their nest cavities into uninhabited anthills. Owls of taiga and tundra nest on open ground or in low vegetation; they make a shallow scrape and even add some lining material to their nests (e.g. Snowy and Short-eared Owls). Desert species tend to live underground, taking over abandoned rodent burrows to escape the heat of the sun. Owls' eggs are chalky-white and roundish, the number varying from 1–14. Clutch-size is dependent on the food supply available, the differences from one season to the other being most notable in species which feed on rodents subjected to cyclic population fluctuations. Hence, in years of abundance, the Snowy Owl may have clutches of 10–14 eggs, and in years of food scarcity it may have clutches of 2–4, or not breed at all. Owls lay their eggs several days apart, and incubation starts with the first egg laid, resulting in marked differences in the size of the young in the nest. In good years all the young may survive, whereas in bad years the oldest progeny compete with their siblings for scarce food, and the clutch produces one well-fed fledgling instead of 3 or 4 starved weaklings. Such flexibility maximizes success in good years, while minimizing the risk of total failure in bad years.

Usually only the female incubates, while the male forages and brings food to the female; both sexes care for the young. The incubation period is long, being 32–34 days in the Barn Owl, 26–28 in the Long-eared Owl, and 34–36 in the Eagle Owl. The young are nidicolous after hatching, with ears and eyes closed and body lacking independent means of temperature regulation. After the natal down, the young acquire the so-called mesoptile feathers, which are followed by true feathers appearing on the same feather papillae (see PLUMAGE). Young owls become capable of breeding at about the age of one year; i.e. in the first spring after the year of birth. Owls have the reputation of reaching a great age, but records of their longevity are still inadequate. The life expectation of ringed Barn Owls in Switzerland has been found to be surprisingly short, being on average 16 months; only a few individual birds are known to have reached the age of 9 years. But in captivity one Tawny Owl has lived for 22 years and 2 Eagle Owls for 53 and 68 years respectively.

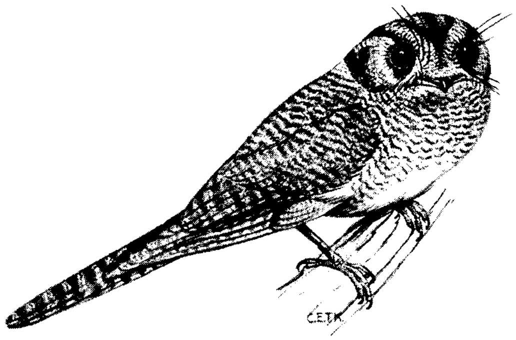
OWLET: term for a nestling OWL.



Owlet-frogmouth *Aegotheles cristatus*. (*C.E.T.K.*).

OWLET-FROGMOUTH: substantive name of the species of Aegothelidae (Caprimulgiformes, suborder Caprimulgi): in the plural, general term, alternatively 'owlet-nightjars', for the family.

Systematics and distribution. The group is related to the frogmouths (Podargidae) and consists of a single genus of small arboreal nightjars (in the ordinal sense) almost restricted to the Papuo-Australian area. One species has penetrated to the Moluccas and another is found in New Caledonia. New Guinea is inhabited by 5 species, of which *Aegotheles cristata* occurs widely in Australia. Extensive fossil remains of a closely allied form have been found in the Pleistocene to Recent in New Zealand, described as *Megaegotheles novaezealandiae* by Scarlett (1968).

Structurally, *Aegotheles* resembles *Podargus* but with several differences. The features in which it resembles *Podargus*, but which are not shared with true nightjars, include the desmognathous palate and the bronchial syrinx; the sternum has two foramina on each side instead of being double-notched. However, it possesses the two carotids normal in the order and an oil gland, and it lacks the powder-down tufts found in *Podargus*. It is unique in the order in not having caeca.

Characteristics. The body length is 20.5–24 cm. Plumage characters of mottled brown are similar to those of the frogmouths and true nightjars (Caprimulgidae). The frogmouth-like bill is shorter and weaker than in *Podargus* or *Batrachostomus*, and it is largely obscured by the forehead feathering. Stiff and partly erectile filoplumes occur on the forehead and lores, with a few softer recurved filoplumes on the chin. The bird sits with an upright, owl-like stance, but it does not adopt the rigid 'broken branch' stance, when alarmed, which is characteristic of *Podargus*. Generally, it is a more active bird than the comparatively lethargic *Podargus*.

Habitat. *Aegotheles* lives in forested and semi-open country, and has the same arboreal habits as *Podargus*.

Food. The feeding habits appear to be intermediate between those of the frogmouths and the true nightjars. Aerial hawking for flying insects has been described, but most hunting is done from the ground, the bird sometimes rising to take flying insects; most of the stomach contents analysed suggest that the bird feeds predominantly on terrestrial prey. Rich and Scarlett (1977) infer that the fossil New Zealand *Megaegotheles*, which tended to gigantism and 'may have been well on its way to becoming another of New Zealand's flightless birds', was a terrestrial insectivore.

Voice. The calls include a loud hissing note and a repeated churring call.

Breeding. Nesting takes place in hollow trees or occasionally in tunnels in banks. No actual nest may be constructed, or the eggs may be laid on a mat of dry leaves or mammal fur. The colour of the shell is white, as in *Podargus*, and the clutch is 3 or 4. The fledgling is covered with dense white down. The birds are readily flushed from their roosting or nesting hollows by tapping likely limbs or tree trunks. D.L.S.

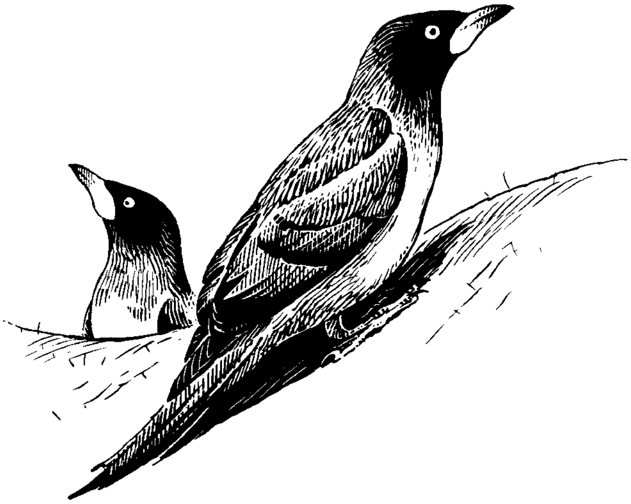
OXPECKER: substantive name of the 2 species constituting the subfamily Buphaginae of the Sturnidae (Passeriformes, suborder Oscines) (see STARLING); in the plural, general term for the subfamily. They are also called 'tickbirds'. The 2 species are similar (starling-like but with short legs) in size (18–19 cm long), and are very much alike with dull brown plumage; the sexes are similar, and the bill colouring is fully developed only in adults.

Characteristics, habitat and distribution. The Yellow-billed Oxpecker *Buphagus africanus* which has the terminal half of its broad bill red and the rump paler than the back occurs from west Africa through to western Ethiopia, east Africa and south to southern Africa. It became extinct in South Africa before 1914. The slightly smaller Red-billed Oxpecker *B. erythrorhynchus*, which has the whole narrow bill red and the back and rump concolorous, has a more restricted geographical range, from Eritrea and the south-eastern Sudan to South Africa and across to northern Namibia. It is an eastern species, its western limit being approximately 30°E except in the south of its range. In broad terms, therefore, *B. africanus* occupies the region west of the Rift Valley system, crossing it only in the area immediately to the north of Mount Kenya and in western Tanzania; it is absent from areas of dense forest, as is *B. erythrorhynchus*, though penetrating the open parts of the Congo. Both species are typical inhabitants of the African savanna.

Oxpeckers are notable for their special association with indigenous African ungulates and also domestic livestock (Artiodactyla and Perissodactyla). The birds are wholly dependent on their mammalian associates. Although the geographical ranges of the two species overlap in parts, their distribution and density are often patchy in accordance with their mammalian associates. In areas of sympatry the Yellow-billed Oxpecker associates more commonly with naked or sparsely furred mammals (e.g. the African Buffalo *Syncerus caffer*) than with mammals with moderately dense fur, including cattle, to which the Red-billed Oxpecker is then restricted. Both species, however, associate with a wide variety of mammals, including rhinoceros, giraffe, warthog, zebra and various antelopes, and both species prefer less densely furred mammals. The association is influenced by the behaviour of the mammals as well as that of the birds. Most ungulates are remarkably indifferent to the birds clambering over their bodies. However, waterbuck, reedbuck, hartebeest, tsesseby and steenbuck, for example, are intolerant of oxpeckers. Despite their naked skins, elephants, which are not ungulates, are not used by oxpeckers, apparently because elephants are intolerant of them.



Yellow-billed Oxpecker *Buphagus africanus*. (*D.A.T.*).

Populations. In the last few decades the distribution and numbers of oxpeckers have been greatly reduced, with the extension of regular dipping of cattle to control ticks. Successful reintroduction into a game reserve in Zimbabwe has been accomplished.

Food. Oxpeckers obtain nearly all their food from the skins of their mammalian associates. Despite the differences in bill morphology, both species seem to use the same techniques for foraging. Ticks, chiefly members of the genera *Amblyomma, Boophilus* and *Rhipicephalus*, comprise their main food and flies are a supplement. The birds progress on their hosts by walking and hopping, using their sharp, curved claws; their stiff, rather long tails are employed for bracing support when clinging to vertical surfaces. The birds' beaks are laterally flattened, facilitating a 'scissoring' feeding action in which the bill is opened and closed rapidly while being pushed through the pelage or over the skin of the mammalian host. This is the normal method of foraging. Plucking and pecking are also used in capturing ticks, and in feeding on scurf and open sores. The birds occasionally hawk flying insects, but are not very adept at this. At least in the case of the Red-billed Oxpecker, they feed mainly in the morning and late afternoon, resting in the middle of the day. They drink regularly, the host being used as a platform from which the birds descend to waterholes.

Voice. In addition to a variety of harsh starling-like calls, oxpeckers have a distinctive hissing alarm call given when disturbed on a mammal or at the nest. It is believed that they act as sentinels for their mammalian associates, particularly rhinoceroses, but this has yet to be critically evaluated.

Behaviour. More than a dozen birds can be found on a single large animal, such as a giraffe, but individual foraging groups generally are smaller. The birds roost communally, at traditional sites in trees, reeds, cliffs, buildings etc., the roosts, at which other species of starlings often also roost communally, comprising one or more individual groups of oxpeckers. The roosts decline in size with the onset of the wet season which is the start of the annual breeding cycle.

Breeding. Oxpeckers nest in tree cavities. All searching for nest holes is done from the mammalian hosts. Animal hair, dung, grass and rootlets are used for the nest. Up to 5 birds constitute a co-operative breeding group, and all collect nest material. Copulation occurs on the backs of the mammalian associates or on the ground. Only one female and one male actually breed, in that this pair is responsible for the production of fertile eggs (1–5 per clutch, most often 2 or 3) and their incubation (about 12 days). The eggs are pinkish white, with small red-brown, purple and lilac spots. In the daytime, the incubating birds relieve each other approximately every hour; the female incubates at night. All members of the group feed the nestlings which continue to be given food once they have left the nest, at about 30 days if undisturbed, and until they are about 3 months old. Up to 3 broods are raised in a season. Breeding overlaps with moult which is exceptionally long; the primaries are replaced over an 11-month period in the Red-billed Oxpecker. W.R.S. and R.K.B.

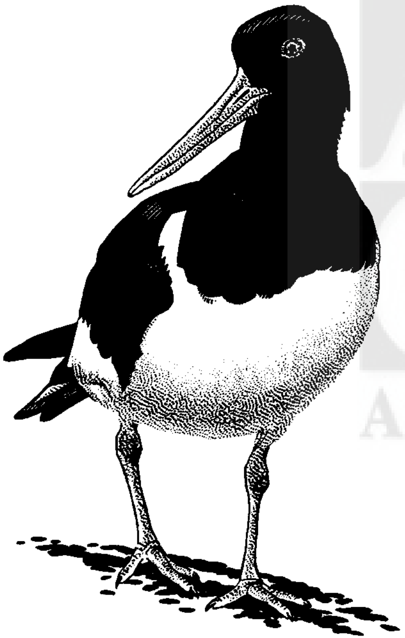
OXYRUNCIDAE: family of PASSERIFORMES, suborder Deutero-Oscines; SHARPBILL.

OXYURINI: see DUCK.



Oystercatcher *Haematopus ostralegus*. (*R.G.*).

OYSTERCATCHER: substantive name of all the species of Haematopodidae (Charadriiformes, suborder Charadrii); in the plural, general term for this small cosmopolitan family.

Characteristics. Oystercatchers, sometimes called 'sea-pies', are large waders (40–45 cm long) with either black-and-white or wholly black plumage. The powerful bill is characteristic—being long, stout, laterally compressed, and bright orange-red. It is specially adapted for opening the shells of bivalve molluscs but is also used for probing in mud, sand or turf. The rather thick legs are reddish; and each foot has 3 toes, slightly webbed. The tail is short; the wings are long and pointed. There are some slight seasonal and sexual differences, and the juveniles are more dark brown than black and have less brightly coloured bills and legs.

On the ground the birds normally walk but can run swiftly. They can swim well on occasion. The flight is rapid and direct, with rather shallow wing-beats. Oystercatchers are noisy and restless birds, often by night as well as by day, the characteristic call being a loud clear *klee-eep, klee-eep*.

Habitat. Oystercatchers are mainly birds of the seashore, and outside the breeding season they gather in flocks, sometimes of many thousands. Flocks of immature birds persist throughout the year, especially in certain favoured areas, for instance, in the British Isles, the northern coasts of the Irish Sea. It has been shown that the birds (at least of the European species) do not breed until 3 years old.

Distribution and populations. The family has no representatives breeding in very high latitudes or in tropical Africa or southern Asia. Otherwise, the distribution includes the coasts of most of both Old and New Worlds, and also certain inland areas to be mentioned below. Populations in higher latitudes tend to be migratory.

There is only a single genus, and the numerous forms comprised in it are grouped by different authors in from 3 to 6 or 7 species. The taxonomic position is complicated by the existence of melanistic populations, by some regarded as consisting of black mutants and by others as constituting distinct species. The Oystercatcher *Haematopus ostralegus* in various subspecific forms, some pied and some black, breeds from Arctic Europe to the coasts of the Aegean, Black, and Caspian Seas; on the Canary Islands and the coasts of temperate South Africa; and in Australasia from New Guinea to Tasmania and New Zealand. Further, the race *H. o. longipes* breeds mainly about inland waters from Kiev eastwards through southern and eastern Russia and Siberia to the Cis-Altai steppes, and is probably the race found breeding on the tributaries of the R. Euphrates in eastern Turkey, up to 1,900 m. The British race *H. o. occidentalis* has bred inland in Scotland for centuries and has recently begun to spread along the river valleys in the north of England. The form *H. o. unicolor* (*H. 'finschi'* of some authors) breeds far inland along the courses of the snow rivers of South Island, New Zealand. All these inland breeding birds apparently winter on the coasts.

Certain of the New World forms are treated by some as races of *H. ostralegus*. By others they are assigned to separate species, such as the Black Oystercatcher *H. bachmani* of western North America and the widely distributed American Oystercatcher *H. palliatus*.

Other species which have been recognized are the Sooty Oystercatcher *H. fuliginosus* of the coasts of Australia and two which both inhabit the coasts of southern South America and the Falkland Islands; of these last, *H. ater* is a black form while *H. leucopodus* is pied but with a black chest and under wing coverts, yellow (not crimson) eyelids, and other peculiarities of plumage.

Food. The food consists chiefly of molluscs, crustaceans, annelid worms, and insects, varying with the particular habitat (rocky or sandy shores, estuaries, river gravels, moorland, farmland). With their powerful bills, they can knock limpets off rocks. There is some evidence that birds on inland territories breed more successfully than those on coastal territories, probably because they can gather food for the chicks, which are dependent on their parents, unrestricted by the tides.

Behaviour and voice. The species present in Europe has an elaborate 'piping' ceremony in which 3 or more birds run about with 'shoulders hunched' and bills held pointing to the ground, while they utter together a rapid high-pitched trill. This behaviour is probably concerned with the separation of breeding pairs from the flock; both sexes take part and either may initiate it—and, apparently, immature birds do not pipe. As Makkink (1942) says, this ceremony is 'a mechanism which first enables the sexes to arrange themselves into pairs, and subsequently creates opportunities for the formed pairs to take up a position' against their fellows. Although this performance usually takes place on the ground, it sometimes occurs when the birds are in flight.

Breeding. The nest is a mere scrape in the ground, which is often decorated—rather than lined—with white shells, bones, stones, and other objects. The 2–4 eggs (usually 3 in the European species) are yellowish buff, heavily marked with dark brown or black. One clutch is laid and both sexes take part in incubation. The cryptic coloration of the eggs is highly effective, and the old birds avoid betraying the position; DISTRACTION BEHAVIOUR ('injury feigning') occurs, and also 'false brooding' at spots where no eggs lie. Incubation, in the European species, normally lasts for 26 or 27 days. The chicks run as soon as their cryptic down is dry; they are, however, fed by their parents for at least 6 weeks; they take about 5 weeks to fledge.

P

PACHYCEPHALIDAE; PACHYCEPHALINAE: family and subfamily of PASSERIFORMES, suborder Oscines; THICKHEAD.

PADDLING: see FEEDING HABITS.

PADDY: alternative name (plural 'paddies') for *Chionis* spp. (for family see SHEATHBILL).

PADDY-BIRD: otherwise the Indian Pond Heron *Ardeola grayii* (see HERON).

PAINTED SNIPE: substantive name for the 2 species of Rostratulidae (Charadriiformes, suborder Charadrii): the Old World Painted Snipe *Rostratula benghalensis* (colloquially 'painter') and the American Painted Snipe *Nycticryphes semicollaris* (called 'sleepyhead' in Argentina). Both superficially resemble snipe *Gallinago* spp. and, like the Jacanidae and Gruidae, have two notches on the posterior edge of the sternum.

Characteristics. Both species are unmistakable. Skulking and difficult to flush, they often run with lowered head, stopping to bob the head and neck if alarmed. They seldom fly far, with slow wingbeats and dangling legs, before diving into cover.

The plumage is spectacular, particularly in the females which are some 10% larger than the males. *R. benghalensis* (25 cm long) has longer legs, shorter bill and tail and broader wings than snipe. The bill is decurved at the tip, the nostrils lying in deep narrow grooves which extend over half-way along the mandible. The eyes lie towards the front of the skull, and the toes are un-webbed. The female has a chestnut face and black crown divided by a thin, buff stripe; diagnostic white spectacles surround the eyes. A white stripe over the shoulder separates the dark head and neck from the bronzy-green upperparts, whose dark vermiculations are only discernible at close range. The rump and rounded tail are browner, and marked with white spots, and the underparts are white, a black band running across the chest. The male is similarly patterned, though the colours are more subdued and less uniform. The chest, neck and coverts are barred, and the spots more obvious, creating a disruptive effect. The bill colour varies; generally it is pale brown, darker at the tip, becoming greenish towards the base. Juveniles resemble males and the downy nestling is striped. *N. semicollaris* (21.5 cm long) is smaller, with a more curved, terminally flattened bill. It has a slight web between the middle and outer toe, and the tail is wedge shaped. The sexes are similar, being deep chocolate brown above, finely barred with black. The head lacks spectacles, having superciliary stripes in addition to that on the crown. Two buff streaks form a V over the back and the coverts bear conspicuous white spots; the primaries are white on their outer edges. The underparts are white and the bill greenish or pink, tipped with red. Immatures are paler and more variegated.

Habitat. Low, swampy areas are preferred, with patches of open water interspersed with dense vegetation, as well as paddy fields and freshly flooded land. Birds may leave cover at dawn and dusk to forage on grassland and ploughed fields.

Distribution and movements. *R. b. benghalensis* inhabits Africa, the Middle East and southern Asia; *R. b. australis*, Australia; and *N. semicollaris* southern South America. Both species are generally sedentary, though *R. b. benghalensis* may make short migrations to follow the rains.

Voice. *R. benghalensis* is usually silent outside the breeding season. The voice of the female is deeper than that of the male due to a longer, convoluted trachea, which, during the breeding season, becomes less firmly held in the fat of the neck. The low mellow *vot* notes given during her display flight carry over long distances. When displaying on the ground to a male, mellow *booo* notes are given, reminiscent of the sound produced by blowing across a bottle. When confronting a rival or predator, throaty hissing and growling sounds are given by both sexes, and flushed birds may give a somewhat sharper alarm note.

Food. Omnivorous diet includes invertebrates, particularly Orthoptera, molluscs and earthworms, and seeds. They feed by probing soft mud or with scything movements of the bill in shallow water.

Behaviour. Being so secretive, few behavioural observations have been made, particularly on the American species. *R. benghalensis* usually occurs solitarily or in pairs, though after breeding flocks comprising several family groups may form. Males outnumber females and polyandry is the general rule, although in sparse populations, such as those in South Africa, monogamous bonds may form. Breeding is during the rainy season and the females take up territories within which they court several males in succession. They declare their territories and attract males with an advertisement flight not unlike the roding of Woodcock *Scolopax rusticola*. On the ground, one display is used both to woo males and during territorial disputes with other females. At low intensity the female stands sideways on, the far wing raised or extended, the tail fanned or depressed. At higher intensity she faces her opponent or mate, lowers her breast and extends and pronates both wings, bill pointed downwards and tail fanned. Females may actually fight each other in defence of their mates.

Breeding. The nest is a pad of woven plant material concealed in dense vegetation and is built by the male, though the female may be in attendance. The normal clutch is 4 (occasionally 5 or 6) pointed oval eggs, glossy cream or yellow marked with bold black blotches, speckles or lines. After laying the female leaves the male to incubate for *c.* 20 days and rear the young, and goes to court another mate. Bonds form rapidly, the second clutch often being laid before the first is hatched. The nests of one female usually form a loose group 4–10 m apart, and in Japan 2–4 clutches per female are usual. The males attend the nidifugous young and may use the head-on form of display to frighten off predators, as well as occasionally employing a rudimentary form of distraction display to lure observers from the chicks.

In the less well-known *N. semicollaris* the female incubates the eggs, though polyandry appears also to be normal and the male escorts the young. Single nests may be found, usually during July, though groups of 5 or 6 in an area of a hectare are most usual. The nests are also of woven plant matter, and the 1 or 2 eggs are white, evenly mottled with black, sometimes so densely as to appear wholly black. The call is a plaintive whistle. A.S.R.

PAIR: collective noun for, inter alia, two birds of opposite sexes, ordinarily used of adults (normally of the same species) believed to be mated together.

PAIR FORMATION: establishment of a special relation between two birds of opposite sex. Practically every type of relationship between the sexes occurs among birds. Some species, e.g. 'lek birds', have merely a temporary pair bond, the sexes meeting only for copulation (see LEK). More usually there is a lasting relationship, which may endure for days, weeks, or even years, and which may be monogamous, polygamous, or polyandrous (see MATING SYSTEMS; POLYANDRY). Monogamous relationships are most frequent, and it is with that type that this article is primarily concerned. Such relationships are of course normally heterosexual; although pairing between individuals of the same sex is common in captive birds, it is rare in the wild.

Pair formation implies that a number of social responses, potentially elicitable by any member of the species, become more or less limited to one individual; at the same time other responses (e.g. aggressive ones) become inhibited towards the partner. When paired, the mates often tend to keep together for much of the time, and may show a special type of searching behaviour if they lose contact.

Pair formation depends on an exchange of signals between potential mates over a period of time. These may be visual (e.g. colours or structures, often exhibited by courtship displays—see DISPLAY), or auditory (e.g. song—see VOCALIZATION). Since hybrids are usually at a selective disadvantage compared to their parental types, it is important that pairing should be intraspecific (see HYBRID). For this reason the signals usually differ markedly between closely related species living in the same area (see ISOLATING MECHANISM). Specific differences in courtship postures are shown in every comparative study, and the relevant plumage patterns usually differ between species more than the displays themselves. Sympatric closely related species also often differ markedly in song (e.g. Willow Warbler *Phylloscopus trochilus* and Chiffchaff *P. collybita*). The study of hybrids shows that such interspecific differences are usually polygenic, and are thus likely to be of adaptive value. That this value lies in the prevention of hybridization is suggested by the following types of evidence.

1. Divergence is most marked in those characters important in pair formation. Thus amongst cardueline finches, where there may be an interval of some weeks between pair formation and copulation, the early courtship displays differ between species more than do those immediately preceding copulation (see COPULATION).

2. Divergence is often greatest where hybridization is most likely, for instance in the overlap zone of potentially sympatric species.

3. Species characteristics often tend to disappear on oceanic islands, where no closely related species are present.

4. Divergence is more marked in males than in females. This is in harmony with Dobzhansky's view that since gamete loss is more serious for females than for males, it is primarily female preference that will be selected for; but the fact is also explicable in other ways, such as the maintenance of female uniformity by selection for cryptic coloration.

Mayr (1942) has shown that hybrids are more common in genera in which copulation is not preceded by an 'engagement' period (e.g. Paradisaeidae; some Tetraoninae), although hybrids do of course occur in groups that form lasting pair bonds. On the whole, however, hybrids are extraordinarily rare in nature, even among species that hybridize readily in captivity when conspecific mates are not available (see HYBRID).

Pair formation has been most studied in territorial song-birds (see TERRITORY). Where territorial establishment precedes pair formation and this occurs some time before copulation (e.g. Robin *Erithacus rubecula*, Snow Bunting *Plectrophenax nivalis*, Chaffinch *Fringilla coelebs*), the female is usually first attracted by the song or appearance of the male. The male normally responds aggressively to all intruders on his territory. If the intruder is a male, he flees or fights back. If it is a female not yet ready to pair, she flees. If, however, it is a female in condition, she usually stays around, often showing a 'submissive' posture, and the male's attacks gradually cease. The male then gradually ceases to be aggressive and begins to show courtship behaviour. The range of variations on this theme is of course enormous. For instance, the process may take anything from minutes to days; the stimuli to which each sex responds may be primarily structural, behavioural, or both; and the male's aggressiveness may cease almost at once or persist right up to copulation. Where pair formation precedes territorial establishment, it may start with the male's behaving aggressively to other members of the flock, although the process is fundamentally similar. Usually the increasing tendency of the male to behave sexually as the season advances is associated with a reduction in his aggressiveness towards his partner, who may then become dominant. Outside territorial song-birds, the diversity of behaviour is even greater. For instance, in some crows and ducks pair formation seems to involve a social ceremony. In most cases that have been studied in detail (e.g. Laridae), however, there seems to be a similar interplay between tendencies to attack, to flee from, and to behave sexually (or socially) towards the mate. The term sexually is, of course, to be interpreted rather widely, since in the early stages the consummatory situation is proximity to the mate rather than copulation, and the relation between male and female is little different from that between flock companions. It will be clear that the dominance relations during pair formation may be very complex; indeed many species pass through a phase in which the female attacks the male during courtship, but the male attacks her at other times, so that a distinction can be made between sexual and social dominance. Although pair formation is usually associated with changes in dominance, it is very difficult to make useful generalizations about the role that dominance plays (see DOMINANCE (2)).

Because of the diversity of the processes of pair formation, it is impossible to classify species into a limited number of types. Lorenz (1935) attempted a classification that depends primarily on whether the displays of the sexes are similar or different, on whether one or both sexes show 'releasers', and on whether males respond initially to other members of the species by aggression or courtship. Although his classification has been criticized by N. Tinbergen, D. Lack, and others, and it is clear that his categories do not represent inclusive groups, they are useful as types. R.A.H.

Tinbergen, N. 1959. Comparative studies of the behaviour of gulls (Laridae): a progress report. Behav. 15: 1–70.

PALAEOGNATHAE: a formerly recognized superorder.

PALAEOGNATHOUS: also 'palaeognathine' (Pycraft)—see PALATE.

PALAEOMONTANE: belonging to the fauna of the alpine or snow (nival) zones of the high mountains of the Palearctic Region.

PALAEONTOLOGY: the study of fossilized remains of animals and plants (see ARCHAEOPTERYX; EARLY EVOLUTION OF BIRDS; FOSSIL BIRDS).

PALAEOSPECIES: a species existing at an earlier level of geological time, possibly ancestral to one or more species of the present day but distinct from any of them; the ordinary criteria of a species are purely contemporary.

PALAEOTROPICAL: inclusive term used by Sclater for his three southern zoogeographical regions in the Old World, contrasted with the Palearctic Region (and on the other hand with the Neotropical); more generally, a term implying wide distribution in the tropical parts of the Old World (see DISTRIBUTION, GEOGRAPHICAL).

PALAEOXERIC: belong to the fauna of the steppes and deserts of the southern Palearctic Region.

PALAEO-XEROMONTANE: belonging to the fauna of the arid slopes of the low mountains of the southern Palearctic Region.

PALAEOZOOLOGY: the part of palaeontology that is concerned with forms ascribed to the Animal Kingdom.

PALATABILITY OF BIRDS AND EGGS: regarded both from the subjective human standpoint and, so far as possible, from that of the observed preferences of other animals. The inverse relation that is commonly found between palatability on the one hand and vulnerability and conspicuous coloration on the other is particularly considered.

Palatability of the flesh. It is well known that the flesh of birds differs widely in palatability. Some enjoy a high reputation in this respect, e.g. Quail *Coturnix coturnix*, Partridge *Perdix perdix*, Red Grouse *Lagopus lagopus scoticus*, Golden Plover *Pluvialis apricarius*, Woodcock *Scolopax rusticola*, Snipe *Gallinago gallinago*, Teal *Anas crecca*, Canvasback *Aythya valisineria*, Corncrake *Crex crex*, Bittern *Botaurus stellaris*, and Skylark *Alauda arvensis*. Others are unfit for the table, e.g. Kelp Goose *Chloephaga hybrida*, Smew *Mergus albellus*, Shelduck *Tadorna tadorna*, Oystercatcher *Ostralegus haematopus*, Egyptian Plover *Pluvianus aegyptius*, Hoatzin *Opisthocomus hoazin*, and various hornbills, kingfishers, and drongos. (See also UTILIZATION BY MAN.)

Attempts to assess relative palatability more exactly by experiments with meat-eating animals, and by observations of tasting panels, have extended knowledge to include a wide range of species not normally eaten by man, and have shown that among relatively vulnerable species, cryptic coloration, whether in the female alone or in both sexes, is generally associated with edibility, and conspicuous coloration with distastefulness. For example, in a series of experiments in which hornets were used in Egypt as assessors of the acceptability of the flesh of 38 species, the two rated as most acceptable (Wryneck *Jynx torquilla* and Crested Lark *Galerida cristata*) are also the two most cryptic in appearance; and those of lowest edibility (White-rumped Black Chat *Oenanthe leucopyga*, Mourning Chat *O. lugens*, Hooded Chat *O. monacha*, Pied Kingfisher *Ceryle rudis*, Masked Shrike *Lanius nubicus*, and Hoopoe *Upupa epops*) are all conspicuous and include the only three species in the series examined having exclusively black-and-white coloration. On available evidence other and quite unrelated tasters, such as cat and man, show generally similar preferences and aversions. Nauseousness is a common but not invariable attribute of conspicuous birds, for many highly conspicuous species are nevertheless relatively palatable, e.g. various albatrosses (Diomedeidae), storks, egrets *Egretta* spp., swans *Cygnus* spp., cranes, gulls, and macaws and cockatoos (Psittacidae); but such birds have no need of a nauseous deterrent, being otherwise protected—by large size, fighting strength, social habits, or ability to escape.

Tests recently carried out by members of a tasting panel in Zambia (Department of Game and Tsetse Control) confirm the above general conclusions. Samples of flesh were assessed on a scale from 9.0 (excellent) to 2.0 (inedible). Of 191 species examined, the 19 rated higher than 7.0 include 15 cryptic species, and in 10 of these the female or both sexes are highly cryptic (Quail *Coturnix coturnix*, the Kaffir (or African Water) Rail *Rallus caerulescens*, Corncrake *Crex crex*, African Crake *Crecopsis egregia*, Water Dikkop *Burhinus vermiculatus*, Senegal Bustard *Eupodotis senegalensis*, Black-bellied Bustard *Lissotis melanogaster*, Double-banded Sandgrouse *Pterocles bicinctus*, Yellow-throated Sandgrouse *P. gutturalis*, and Fiery-necked Nightjar *Caprimulgus pectoralis fervidus*. In contrast, of 14 species with plumage that is black, white, or a combination of both, only the White-breasted Cormorant *Phalacrocorax carbo lugubris* (7·0) was rated as palatable, and Little Egret *Egretta garzetta* (6.3), and Openbill Stork *Anastomus lamelligerus* (6.0) as moderate. Nine of the remainder are relatively or markedly distasteful, notably Pied Crow *Corvus albus* (4.9), White-winged Black Tit *Parus leuconotus* (4.8), Black (or Sooty) Chat *Myrmecocichla nigra* (4.5), Whiteheaded Black Chat *Thamnolaea arnotti* (4.5), Pied Kingfisher *Ceryle rudis* (4.1), Southern Black Tit *Parus niger* (4.1), and Black Cuckoo *Cuculus cafer* (3.0). The relation between visibility and distastefulness is also seen within the limits of restricted groups, for example: among 6 crakes examined, the only conspicuous species (Black Crake *Limnocorax flavirostra*) has the lowest edible rating (5.1); of 6 chats, the 3 most conspicuous are also the 3 most distasteful (all 4.5); the same relationship is found in 5 plovers, of which 2 (Blacksmith Plover *Vanellus* ('*Hoplopterus*') *armatus*, 5.1, and Long-toed Water Plover *Vanellus* ('*Hemiparra*') *crassirostris*, 4.8) are both relatively conspicuous and distasteful.

Colour conflict. The inverse relation between acceptability of the flesh and visibility of the plumage is of special interest in a connection with the concept of 'colour conflict'. It has been shown elsewhere (see COLORATION, ADAPTIVE) that concealing (cryptic) and revealing (phaneric) characters subserve many and diverse functions of adaptive value in the struggle for survival. Yet for optical-psychological reasons the two types of coloration, although both advantageous, are generally antagonistic and tend to be mutually exclusive.

The conflicting needs of effacement and of advertisement are reconciled in various ways. (*a*) Conspicuous characters, in birds of which the coloration is predominantly cryptic, may be revealed at special times by the momentary display of bright ornaments normally hidden (as in deflection displays, social recognition marks exposed only in flight, and the buccal feeding releasers of nidicoles, etc.). (b) Again, in many species, cryptic coloration is confined to the more valuable or vulnerable individuals, e.g. females in sexually dimorphic species where the males are conspicuous, e.g. many Anseriformes, Galliformes, and some territorial Passeriformes; and nidicolous young, where adults of both sexes are conspicuous, e.g. oystercatchers, some plovers (Charadriidae), gulls, and terns. (*c*) Relatively non-vulnerable species otherwise protected have no need for concealment; for them the road to conspicuousness lies open and has generally been taken by both sexes, e.g. cassowaries, gannets, pelicans, flamingos, some birds-of-prey, cranes, swans *Cygnus* spp., many gulls, and parrots. Such birds are not protected by distastefulness. (*d*) In many small and otherwise vulnerable birds the advantages of concealment have over-ridden those of visual advertisement, and cryptic coloration is developed in both sexes, e.g. in partridges *Perdix* spp., francolins *Francolinus* spp., quails *Coturnix* spp., coursers *Cursorius* spp., thickknees, nightjars, pipits *Anthus* spp., larks, warblers (Sylviinae). The palatability of such birds tends to render cryptic coloration of paramount importance. (*e*) Another line of evolution has led in the opposite direction, towards conspicuousness in both sexes, e.g. various plovers (Charadriidae), auks, turacos, Hoopoe *Upupa epops*, wood-hoopoes, kingfishers, barbets, shrikes, drongos, starlings, chats *Oenanthe* spp. etc. and tits. But this trend has been possible only for relatively defenceless species when it is associated with the counter-deterrent of repugnant taste. The advertising coloration of such birds is (in part) warning (proaposematic) in function.

Palatability of eggs. Experiments with egg-eating mammals of several orders (cat, ferret, mongoose, hedgehog, rat), and observations by members of a tasting panel (Low Temperature Station, Cambridge) afford results parallel in many respects to those considered above. Edibility and coloration are related to various factors that influence the availability of eggs to predators. Thus, eggs laid by larger birds, or in colonies, or in sites difficult of access, are in general more palatable than those laid by smaller birds, or by solitary nesters, or in accessible sites. Among otherwise vulnerable species, many eggs in the higher edibility grades are protected by cryptic coloration or are covered by a close-sitting cryptic parent, e.g. in many ducks, game-birds (Galliformes), bustards, rails, waders (Charadrii), sandgrouse. On the contrary, conspicuousness of the shell is often associated with a repugnant taste.

In a series of 212 species examined, the shells of the most ill-flavoured eggs were commonly either immaculate white or white with reddish spots: Red-faced Mousebird *Colius indicus* (3.5), Green Woodpecker *Picus viridis* (3.5), Verreaux's Eagle Owl *Bubo lacteus* (3.3), House Wren *Troglodytes aedon* (3.2), Wren *T. troglodytes* (2.7), Speckled Mousebird *Colius striatus* (2.5), Black Tit *Parus leucomelas* (2.0). Among eggs of low-grade edibility, the most widespread distasteful property is bitterness, which is highly developed in the flavour-pattern of Columbiformes, Cuculiformes, Strigiformes, Coliiformes, Coraciiformes, Piciformes, and Passeriformes. PALATE: the bony palate (Fig. 1) is made up of the same elements as are found in reptiles, except that the ectopterygoid or transpalatine is absent. Anterior are the premaxillae, which have shelf-like palatal processes fused in the midline at the front of the bill. Farther back these processes may be separated from each other by a cleft. There is often a large vacuity between them and the palatal processes of the maxillae, or

maxillopalatines, which may or may not be fused or closely approximated in the midline.

The vomers are usually fused into a single bone in the adult. On either side of these, and often separated by a gap on each side, are the palatines; behind these are the pterygoids, articulating posteriorly with the quadrates.

The internal nares lie between the palatines, the vomers and the maxillopalatines; but in kiwis *Apteryx* spp., where the palate is exceptionally complete, the internal nares are bordered by the palatines and vomers only, which approximate in front of the choanal opening.

Deeply placed in the midline of the palate is the rostrum of the parasphenoid. Posteriorly this bone widens out and is fused with the lower surface of the basisphenoid. The usually common opening of the Eustachian tubes (Tubae pharyngotympanicae) can be seen at the base of the rostrum.

In many birds the pterygoids articulate with the parasphenoid rostrum by means of movable joints. Movements of the quadrates are transmitted through the pterygoids and palatines to the BILL, which is thus raised or lowered (kinesis; see SKULL).

Taxonomic significance. Since T.H. Huxley's work (1867), the structure of the bony palate has been used as a basis for classifying birds into major groups. The following types of palate have been distinguished:

1. Palaeognathous, or dromaeognathous, characteristic of 'ratite' birds and tinamous (Fig. 1A). Vomers large and imperfectly fused, articulating anteriorly with the premaxillae and the maxillopalatines and posteriorly with the palatines and pterygoids (except for *Struthio*). Pterygoids in contact with the palatines along an unmovable suture and separating these from the parasphenoid rostrum. Well-developed basipterygoid processes set well back on parasphenoid. Complex pterygoid—quadrate articulation, involving the orbital process of the quadrate.

2. Neognathous, characteristic of carinate birds. Vomers often small and completely fused, sometimes absent. Palatines and pterygoids usually in contact with parasphenoid rostrum, and articulating with each other at a movable joint. Typical basipterygoid processes usually absent, but often replaced by facets on rostrum farther forwards (Fig. 1B).

Neognathous palates have been further subdivided as follows: (i) Desmognathous (Fig. 1B), as in Anseriformes, Pelecaniformes, Psittaciformes, most Accipitriformes and Falconiformes, Strigiformes, and some other groups. Vomers small and tapering. Maxillopalatines broad and meeting each other or the vomers in the midline. (ii) Schizognathous (Fig. 1C), as in Columbiformes, Galliformes, Sphenisciformes, Charadriiformes, and others. Vomers tapering in front. Maxillopalatines not meeting each other or vomers in midline, so that there is an extensive longitudinal cleft in the bony palate. The palate of woodpeckers (Picidae), to which the term saurognathous was applied to cover the (erroneously supposed) condition of paired and separated vomers is not distinguishable from the schizognathous condition (de Beer 1937). (iii) Aegithognathous (Fig. 1D), as in Passeriformes and a few other groups such as swifts (Apodidae) and nightjars (Caprimulgidae). Maxillopalatines separated, fused vomers truncated and broad in front, and forked behind, embracing the parasphenoid rostrum.

Today the taxonomic value of the different bony palate patterns is open to question. The various subdivisions of the neognathous condition partly merge into one another, and while these palatal types may be of value as a guide to the systematics of the smaller groups, they do not provide a reliable basis for major group classification.

McDowell (1948) denies that the distinction between the palaeognathous and neognathous types may be upheld any longer. Several authors have pointed out that during embryonic development some neognathous birds show an arrangement similar to the palaeognathous condition, with the pterygoid extending forward so as to articulate with the vomers. Later the front end of the pterygoids becomes detached from the rest as the 'hemipterygoid' and fuses with the palatine. Consequently the criterion of a palatine separating the vomer from the pterygoid, formerly thought to be characteristic of neognaths, is in some cases illusory.

The similarity in the embryonic arrangement of some neognathous birds may be interpreted as a recapitulation of an ancestral stage, or the palaeognathous palate in the ratites may be a neotenic structure, comparable to other features thought to be neotenic in these birds (see EARLY EVOLUTION OF BIRDS).

Fossil evidence adds no light to the problem. *Archaeopteryx* is claimed to be neognathous (schizognathous). The reconstruction of the skull of *Hesperornis* by Gingerich suggests a somewhat similar arrangement of the bony palate as in the palaeognaths, yet the vomer does not articulate with the pterygoid, and there is not the complex pterygoid-quadrate articulation.

In contrast with McDowell, Bock (1963) has clearly shown that in palaeognaths there is indeed a common morphological pattern and that

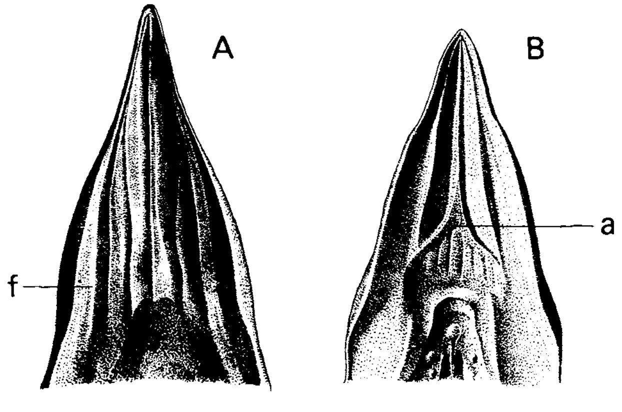

Fig. 2. View of the horny palate of *Fringilla coelebs* (A) and *Passerina ciris* (B). **a.** abutment; **f.** furrow.

the palaeognathous palate can be defined by the criteria mentioned above. He stresses its function in transmitting great forces for rhynchokinetic movements of the bill. Thus, the palaeognathous palate may indeed be of crucial importance for understanding of ratite evolution and relationship.

Horny palate. Apart from the bony palate there is a horny palate (Fig. 2) on the inner side of the rhamphotheca which covers the upper mandible. Normally this horny palate is a simple vault, but in several dietary specialists such as birds which remove the husks from the seeds before swallowing them (e.g. the granivorous songbirds and the parrots), the horny palate is highly structured with a characteristic system of furrows and longitudinal or cross tuberosities. The furrows lodge the seeds when they are cut open, the tuberosities serve as an abutment when the seeds are pressed off (Ziswiler 1965). In the granivorous songbirds and the parrots (Homberger 1980) the structure of the horny palate is species-typical and therefore of considerable taxonomic importance.

PALATINE: a paired bone of the SKULL.

PALEARCTIC REGION: or 'Palaearctis', name of zoogeographical region proposed by Philip L. Sclater (1858) (see DISTRIBUTION, GEOGRAPHICAL), comprising the whole of Europe, Africa north of the Sahara, and arctic, boreal and temperate Asia north of the Himalayas. The concept of a 'Holarctic Region' for all cold and temperate land masses of Eurasia and North America was introduced by Alfred Newton and followed widely, reducing the Palearctic and Nearctic (cold and temperate New World) to the rank of subregions. In spite of this, for the sake of convenience the term Region is still generally used. In zoogeography the stress has shifted from the static concept of a 'region' with fixed boundaries to the dynamic and more realistic state of a 'fauna'.

Features and boundaries. The main physical features of the Palearctic Region are a basically circumpolar arctic or tundra Zone, a virtually continuous belt of boreal, mainly coniferous woodland known as the taiga from Norway to eastern Siberia, an almost continuous chain of mountains from the Pyrenees, Alps, Carpathians, Caucasus, Elburz, to the Himalayas, and an almost continuous belt of desert from Morocco to Sinai, Arabia, Iran, Turkmenistan, Uzbekistan, Tibet, and Gobi. These features and their histories during the Pleistocene ice-age have exercised a profound influence on bird-life and its distribution.

The boundaries of the Palearctic Region are broadly defined in the west, north and east by the Atlantic, Arctic, and Pacific Oceans, separating it from the Nearctic. But in the south there is no clearly defined boundary with either the Afrotropical or the Oriental Regions.

Greenland, although geographically part of North America, is, on the evidence of plants, insects, and birds, biologically part of the Palearctic, probably in consequence of the ice-free condition of the arctic deserts in north-eastern Canada at least during the last glacial period and the amount of sea-ice in the North Atlantic in the post-glacial. Only 5 Nearctic species out of 55 have established themselves in Greenland as regular breeding birds, whilst 3 species have reached Iceland (Great Northern Diver *Gavia immer*, Harlequin Duck *Histrionicus histrionicus*, Barrow's Goldeneye *Bucephala islandica*).

The Atlantic has been an efficient barrier to avian dispersal. It is remarkable that no purely Palearctic passerine species has reached North America within the memory of man, save perhaps the Wheatear *Oenanthe oenanthe* in north-eastern Canada, whilst but a single non-passerine—the Cattle Egret *Bubulcus ibis* has recently established itself in the New World by crossing the Atlantic. In addition, the Black-headed Gull *Larus ridibundus* and the Lesser Black-backed Gull *L. fuscus* are busy establishing a foot-hold in eastern North America (via Iceland). Despite the hundreds of North American birds blown across the Atlantic or assisted by ships every year, not one species has yet established itself in Europe, though the Spotted Sandpiper *Actitis macularia* and Wilson's Phalarope *Phalaropus tricolor* have recently made an attempt.

In southern Europe the Mediterranean has been a less efficient barrier to dispersal than the Sahara. The northern and central Sahara are still predominantly Palearctic; but at both ends we find Palearctic species seeping down (e.g. Spoonbill *Platalea leucorodia* in the west and east, and Little Owl *Athene noctua* in the east) and Afrotropical species seeping up—some along the coast of Morocco and spreading east to Tunisia and even to Spain, e.g. the Little Buttonquail or Andalusian Hemipode *Turnix sylvatica* and the Crested Coot *Fulica cristata*, and several up the Nile Valley and into Lower Egypt and the Jordan Valley, e.g. the Palestine Sunbird *Nectarinia osea*. The bird faunas of the Canary Islands, Madeira, and the Azores are definitely Palearctic; so is the majority of the birds of the Cape Verde Islands.

Sinai is pure Palearctic. In Arabia many Palearctic forms reach the Yemen, as do a few Oriental forms across southern Arabia. At present, mountainous south-west Arabia is included by most biogeographers in the Afrotropical Region. In south-west Asia there are two remarkable cases of interrupted distribution, both Oriental kingfishers—the White-breasted Kingfisher *Halcyon smyrnensis* reaching westernmost Asia Minor and probably even south-eastern Europe, and the White-collared Kingfisher *H. chloris* reaching the southern Red Sea (outside the confines of the Palearctic), the latter's nearest relative being 3,200 km distant in India.

The avifaunas of the Persian Gulf and Iran are predominantly Palearctic with slight Afrotropical and Oriental elements; but farther east we find a more exact boundary between the Palearctic and the Oriental regions in the mountains of northern Baluchistan, the Afghan-Pakistan frontier, and then east along the higher levels of the Himalayas and into China about Szechuan and Hupeh, where the Yangtsekiang is usually considered a faunal boundary, but where in fact there is a large transition zone. North of the Hwang-ho the fauna is definitely Palearctic, as are those of Korea and Japan.

In Kamtschatka we find a close relationship with northern Alaskan birds. The narrow Bering Strait, which was land during each of the glacial periods, hardly acts as an efficient barrier for birds. Several Nearctic species have spread to eastern Siberia, e.g. the Grey-cheeked Thrush *Catharus minimus*, and some true Palearctic species have spread to Alaska, e.g. the Yellow Wagtail *Motacilla flava*, Wheatear and Arctic Warbler *Phylloscopus borealis*, while the Dotterel *Charadrius morinellus* has occasionally bred there.

Effects of Pleistocene glaciations. A large part of the north-western Palearctic has been subjected to arctic and sub-arctic conditions during the series of at least four alternating Pleistocene glaciations, which terminated some 10,000 years ago after persisting for almost 2,000,000 years. In fact, the present climatic condition of the Holarctic can be described as a post-glacial or even as a recent inter-glacial period. However, only small areas of the Palearctic were actually covered by ice-caps involving the complete extermination of bird-life. These included the whole of north-west Europe south to the British Isles, the Netherlands, the southern shores of the Baltic, central Russia, north-east to the Taimyr Peninsula, but not central and east Asia. (See also GEOLOGICAL FACTORS). There were minor ice-caps in the Atlas, Pyrenees, Alps, Himalayas, and mountains of north-east Asia. But even in glaciated regions small pockets of unglaciated land persisted as they do today in Greenland.

Far the greater part of the Palearctic Region was ice-free, though tundra and wind-swept cold deserts reigned in extensive peri-glacial areas. Warmer climates and more luxuriant vegetation prevailed, particularly in the east and south-east. In the western Palearctic all climatic vegetation zones were shifted south by a few thousand kilometres. Notably arboreal and forest birds were forced east, south-east and south, and this phenomenon has its counterpart in the post-glacial general return (expansion) westwards, north-westwards and northwards, continuing even today. During the last 100 years more than 28 Eurasiatic species have extended their range westwards and north-westwards, following the retreat of the Fenno-Scandinavian ice-cap and the surrounding tundra and steppes, the most spectacular extensions being those of the Grey-headed Woodpecker *Picus canus*, Greenish Warbler *Phylloscopus trochiloides*, and Scarlet Rosefinch *Carpodacus erythrinus*.

There are 66 species of birds breeding regularly in Britain that do not do so regularly in Ireland; the Magpie *Pica pica* reached Ireland only in 1676, the Stock Dove *Columba oenas* as recently as 1877, and the Black-necked Grebe in 1906 (but no longer breeds there).

Glaciation was the major influence in transforming many continuous into discontinuous distributions. Today we find the Blue or Azure-winged Magpie *Cyanopicus cyanus* in south-west Spain and again in China and Japan, the Twite *Carduelis flavirostris* in north-west Europe and again in the Caucasus and central Asian highlands; the Marsh Tit *Parus palustris* has two disjunct ranges in Europe and east Asia, the White Stork *Ciconia ciconia* has three disjunct ranges, in Europe, Turkestan, and east Asia. Also it was almost certainly the effect of glaciation that drove the Magpie *Pica pica* into Yemen, and some Palearctic species into tropical Africa; they left behind isolated populations when conditions in Eurasia allowed them to spread once more into the northern areas where the bulk of their numbers are now found. Examples are the Chough *Pyrrhocorax pyrrhocorax* in the Ethiopian highlands and the Bittern *Botaurus stellaris* in southern Africa.

Subdivisions. Bird-life in the Palearctic Region is by no means uniform; there are only 41 species in Korea that also breed in the British Isles; and there is still less uniformity among birds from Scandinavia and the eastern Himalayas. It may therefore be useful to suggest at least 7 zones of bird-life in the Palearctic Region, based on B. Stegmann's concept of faunal elements or faunal types.

1. Arctic Zone, with many circumpolar species, some of them extending south to the alpine levels of the European and Asian mountains, including the Tien Shan, but absent from the Himalayas and the Caucasus. The Ptarmigan *Lagopus mutus*, Snow Bunting *Plectrophenax nivalis* and numerous waders and waterfowl are typical of this zone. By its circumpolar nature and extreme climatic conditions the Arctic Zone is sometimes considered an independent Region or Sub-region. The Arctic Zone includes a more arid and colder high arctic and a moister and less extreme cold low arctic zone; characteristic species are Brent Goose *Branta bernicla*, King Eider *Somateria spectabilis*, Glaucous Gull *Larus hyperboreus* (part-arctic), Knot *Calidris canutus*, Sanderling *Calidris alba* (high arctic), Steller's Eider *Polysticta stelleri*, Bewick's Swan *Cygnus columbianus bewickii* (low arctic). The Arctic may include a sub-arctic zone, which is sometimes considered to have its own, independently derived vegetation and fauna. It is the zone of the low birch forest with fascinating tortured stems; characteristic species are Lesser White-fronted Goose *Anser erythropus*, Red-breasted Goose *Branta ruficollis*, Spotted Redshank *Tringa erythropus*, Pechora Pipit *Anthus gustavi*.

2. Siberian Zone, characterized by boreal coniferous forest, known as taiga, occupying a continuous belt from eastern Siberian into Scandinavia, with a gradual reduction of the number of species from east to west. Again there are isolated pockets of a Siberian fauna, including the Capercaillie *Tetrao urogallus* and the Nutcracker *Nucifraga caryocatactes*, in the sub-alpine zones of mountain ranges in Asia and Europe, such as the Alps and the Pyrenees. The Hawk Owl *Surnia ulula*, Siberian Jay *Perisoreus infaustus*, Redwing *Turdus iliacus*, and Brambling *Fringilla montifringilla* are typical species of the Siberian Zone.

3. European Zone of deciduous forests, narrowing to the southern Urals. A few species typical of this zone extend to Scandinavia, south-west Siberia, and recently even as far east as Baikal. Characteristic species are the Green Woodpecker *Picus viridis*, Robin *Erithacus rubecula*, Song Thrush *Turdus philomelos*, and Chaffinch *Fringilla coelebs*. The oak forests of North Africa and the mixed deciduous forests of the Caucasus and Turkestan contain others, such as the Jay *Garrulus glandarius*, several species of tit *Parus*, nuthatch *Sitta*, treecreeper *Certhia*, and thrush *Turdus*.

4. Mediterranean Zone, typified by xerophilous shrubs, steppe and semi-desert, and extending through most of lowland southern Europe, North Africa and south-west Asia to Iran and Afghanistan, with a few species extending north to southern England (Dartford Warbler *Sylvia undata*), central Europe and the steppes of southern Russia. The Cream-coloured Courser *Cursorius cursor*, bustards *Otis* and *Chlamydotis*, and many species of larks *Melanocorypha, Calandrella*, and warblers *Sylvia* are typical of the Mediterranean Zone.

5. Old World Desert or Eremian Zone, including the high Mongolian and low Turkestanian deserts, those of Iran and the Near East, with northern Arabia and Sinai, extending into Asia Minor and the northern half of the Sahara. Typical of this zone are sand partridges *Ammoperdix*, ground jays *Podoces*, various species of larks *Ammomanes, Alaemon, Ramphocorys*, wheatears *Oenanthe*, rock nuthatches *Sitta*, and the Trumpeter Finch *Bucanetes githagineus*. In the south-west of this zone there are many infiltrations from the Afrotropical Region, such as the Ostrich *Struthio camelus* in north Arabia and north-west Africa until quite recently, and several species of sandgrouse *Pterocles*.

6. Tibetan Zone, including the northern slopes of the high Himalayas. With the probable exception of the boreal forest zone there is no other continental area of the size of Tibet with such a distinct fauna. Typical are the Snow Partridge *Lerwa lerwa*, snowcocks *Tetraogallus*, Blue Grandala *Grandala coelicolor*, and various species of rosefinches *Carpodacus* and snowfinches *Montifringilla*; only the latter are restricted to the Tibetan highlands, the others include also Sino-Himalayan species, of which there are many.

7. Chinese Zone typified by the mixed broad-leaved forests of east Asia prevailing in southern Manchuria, Korea, Japan, and China and extending in the Himalayas as far as Kashmir and the Pamirs. Both the flora and the fauna of this area have maintained a high degree of diversity dating from pre-glacial times. The bird-life includes numerous forms and species that have died out in other parts of the Palearctic through the influence of the Pleistocene glaciations. Typical of the Chinese Zone are many species of pheasants *Ithaginis, Pucrasia, Lophophorus, Crossoptilon, Syrmaticus, Chrysolophus* and laughing thrushes *Garrulax* and *Pomatorhinus*.

Comparison with other regions. In size the Palearctic is roughly one and a half times as large as the Nearctic (*c.* 34 million km^2 against *c.* 21). However, computed per million km^2, the numbers of species occurring in these regions are almost alike, viz. *c.* 30 and 35, respectively. Compared with other continents and regions the numbers are low, as there are 85 species per million km^2 in the Afrotropical Region and up to 135 in South America (R.E. Moreau). These numbers may roughly indicate the relative diversity of ecological niches available, which is more restricted in the less hospitable temperate and cold areas than in the—for birds—more friendly humid tropics.

Of non-passerine species *c.* 443 occur in the Palearctic Region; of these 102 occur also in the Nearctic, 112 in the Afrotropical, and 105 in the Oriental Regions. Of passerine species *c.* 500 occur in the Palearctic Region; of these 16 occur also in the Nearctic, 30 in the Afrotropical, and 101 in the Oriental Regions.

There are 194 genera of non-passerine birds and 135 of passerine birds occurring regularly in the Palearctic Region. In the Nearctic Region these numbers are 180 and 111, respectively.

Characteristic forms. If we omit infiltrations from other regions, the Palearctic is more easily characterized by what it has not than by what it has; this applies particularly to its western half in which the devastating influence of the Pleistocene glaciations has been most severe. If we take the buntings *Emberiza*, we find 9 species in western Europe and 19 in Eastern Asia. We have 5 flycatchers *Ficedula* and *Muscicapa* in Europe and 14 in Palearctic Asia. On the other hand, of the 16 species of warblers *Sylvia* breeding in Europe and south-western Asia, not one occurs east of the Yenesei or in Japan; of the 6 species of *Phylloscopus* this number is, however, 4. Still, the Palearctic has 71 genera peculiar to it, and of these 27 are non-passerine (e.g. pheasant *Phasianus*, ruff *Philomachus*) and 44 passerine (e.g. crested lark *Galerida*, redstart *Phoenicurus*, long-tailed tit *Aegithalos*, wall creeper *Tichodroma*, chaffinch *Fringilla*).

A few groups require especial mention. Of the kingfishers (Alcedinidae) there are *c.* 87 species in the world and of parrots and parakeets (Psittacidae) *c.* 340; of these only 7 and 1, respectively, occur in the Palearctic, and 2 and 2 respectively, in the Nearctic. Among the larks (Alaudidae) only one species (Horned or Shore Lark *Eremophila alpestris*) occurs in the Nearctic, 24 in the Palearctic, and 49 in the Afrotropical Region. In the pipits and wagtails (Motacillidae) there are 5 species of wagtail *Motacilla* in the Palearctic, 3 in the Afrotropical Region, and only one, a geologically recent arrival, Yellow Wagtail *M. flava* in the Nearctic. There are 13 species of pipit *Anthus* in the Palearctic, 11 in the Afrotropical Region, and only 2 regularly in the Nearctic. The accentors (Prunellidae) with 13 species are virtually endemic to the Palearctic Region; none of them occurs in the Nearctic and only one marginally (Yemen, Arabia) in the Afrotropical Region.

The Horned Lark and Raven *Corvus corax* are noteworthy examples of truly Holarctic distributions: both species encompass the globe in its Northern Hemisphere, both extend from the Arctic to the tropics, and both breed from 5,500 m to below sea level.

Few birds have become extinct in the Palearctic in recent times.

Notable examples are Pallas' Cormorant *Phalacrocorax perspicillatus*, Great Auk *Pinguinus impennis*, a thrush *Cichlopasser terrestris* and a grosbeak *Chaunoproctus ferreorostris* from the Bonin Islands, Japan. (R.M.) K.H.V.

PALILA: *Loxioides bailleui*, one of the HAWAIIAN HONEYCREEPERS.

PALLIUM: the mantle (see TOPOGRAPHY).

PALMAR: pertaining to the ventral surface of the manus, or sometimes of the whole wing.

PALMATE: having three toes connected by webs (see LEG).

PALMCHAT: *Dulus dominicus*, sole member of the Dulidae (Passeriformes, suborder Oscines). It is confined to Hispaniola, West Indies. Some investigators place it in the same family as the WAXWINGS (Bombycillidae) and their presumed relatives the SILKY FLYCATCHERS (Ptilogonatidae)—others prefer classification as a separate family, principally because of the 'communal' nests but also because of the harsher plumage, which lacks the silky quality and blended coloration of waxwings.

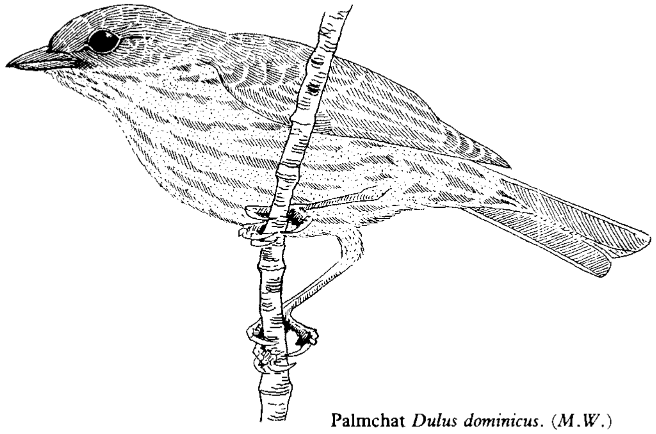
The total length is about 18 cm. The sexes are alike—greyish-olive (or brownish in worn plumage) above, and longitudinally striped with dark brown on a white base below. The head is darker than the back, the feathers having dark shafts; the rump is dark green. The tail is relatively long, the wings short and rounded, and the tenth primary rather long and thin, when compared with waxwings. Likewise the bill is stronger, more curved and compressed, and the nostril is exposed. The juvenile differs in having the throat and foreneck almost entirely dark brown, with only faintly paler edges, and a buffish rump.

The species is locally abundant throughout the island of Hispaniola (comprising Haiti and the Dominican Republic) except in rain-forest and at higher altitudes. On nearby Gonave Island the birds are slightly more local in distribution.

New nests are built, or old ones repaired or added to, during the spring months (March–June). These are usually large bulging structures—sometimes 1 m in diameter—of sticks and twigs, woven all about the smooth trunks of Royal Palms *Roystonea* and the bases of their fronds; when the fronds die, the nests fall. Pines are also used, but to a lesser extent, and nests built in them are smaller—used by one or two pairs.

Likening such nests to a block of flats is perhaps more apt than the word 'communal'. Pairs occupy their own compartments, to which they alone have access by passages from the outside. Each nest is lined with fine grass and shredded bark, and here the eggs are laid. Nests with central chambers and passages have been described. About 4 eggs are to be found in a clutch; they are white, heavily spotted and blotched with dark purplish grey or with a ring of this colour at the large end.

Berries (perhaps especially those of palms), as well as flowers of *Cordia* and other plants, are known to be staple foods. The birds are sociable and gregarious, even drawing together on the tree-limbs when roosting. No song has been recorded, but rather a noisy chattering in chorus as well as a variety of more or less pleasing notes. (J.C.G. Jr.)



Palmchat *Dulus dominicus*. (*M.W.*)

Wetmore, A. & Swales, B.H. 1931. The birds of Haiti and the Dominican Republic. U.S. Natl. Mus. Bull. 155: 345–352.

PALMCREEPER: substantive name of *Berlepschia rikeri*, a South American furnariid strictly associated with *Mauritia* palms (for family see OVENBIRD (1)).

PAMPA (PAMPAS): an environment of prairie type characteristic of southern South America (see PRAIRIE).

PAMPRODACTYL: having all 4 toes directed forwards or (the first being movable) capable of being so directed (see LEG).

PANCREAS: an unpaired organ lying within the loop of the duodenum (see ALIMENTARY SYSTEM). In addition to secreting digestive juices into the duodenum, it secretes insulin internally, i.e. into the blood-stream (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; NUTRITION).

PANDIONIDAE: family of ACCIPITRIFORMES; HAWK.

PANIC: in a special sense, a sudden wave of alarm that—often for no reason apparent to the observer—spreads very quickly through a flock of birds (especially waders) or colony (especially gulls Laridae and terns Sternidae). The birds rise and fly off together, usually returning soon; also called a 'dread'.

PANTROPICAL: of widespread distribution in the tropical parts of the world (see DISTRIBUTION, GEOGRAPHICAL).

PAPILLA, FEATHER: see FEATHER.

PARADIGALLA: substantive name of the 2 species of BIRDS-OF-PARADISE of the genus *Paradigalla*.

PARADISAEIDAE: a family of the PASSERIFORMES, suborder Oscines; BIRD-OF-PARADISE.

PARADISE BIRD: see BIRD-OF-PARADISE.

PARADISE-CROW: substantive name of *Lycocorax pyrrhopterus* (see BIRD-OF-PARADISE).

PARADOXORNITHINAE: see TIMALIIDAE; PARROTBILL.

PARAKEET: substantive name of some smaller species of Psittacinae with long, pointed tails (see PARROT).

PARALECTOTYPE: see TYPE SPECIMEN.

PARALLELISM: evolution in related stocks, producing similarity in ways which are not shown by the common ancestor, but derive from its genetic potential. Parallelism may in practice be difficult to distinguish from CONVERGENCE, which is never a sound basis for classification.

PARAMO: term applied to an altitudinal zone in the Andes, just above the limit of trees.

PARAPATRIC: occupying different but contiguous geographical areas.

PARAPHYLETIC: of a single evolutionary ancestry, but not including all the descendents of the common ancestor (see MONOPHYLETIC; POLYPHYLETIC). The term is necessary only in CLADISTICS, in which a monophyletic group is further defined as one which does include all the descendants.

PARASEMATIC: see under SEMATIC.

PARASITE: an organism that lives at the expense, so to speak, of another species and commonly in or upon it, without reciprocal advantage to the host—and indeed often with disadvantage. Birds have many parasites (see ECTOPARASITE; ENDOPARASITE; also DISEASE). No bird is itself wholly parasitic. A few, however, are parasitic in respect of parental care (see BROOD-PARASITISM); others are in a sense parasitic, as distinct from predatory, in their feeding habits (see PIRACY). True parasitism, in which the advantage is all on one side, is to be distinguished from associations that tend to be either neutral or mutually beneficial; thus, in 'commensalism' two species of organisms share the same food, while 'symbiosis' denotes a more intimate partnership (see NESTING ASSOCIATION).

PARASITISM: the exploitation by one organism of the resources of another. As a rule the relationship is between a more highly organized host and a less highly organized parasite; thus birds support many 'lower' parasites (see ECTOPARASITE; ENDOPARASITE), but are rarely parasites themselves. There are birds, such as skuas, which pirate the food catches of other birds (see PIRACY), while some other species such as the Cut-throat Finch *Amadina fasciata* (Estrildidae) usurp the nearly completed nests of ploceids such as the Masked Weaver *Ploceus velatus*, and a facultative parallel exists in the occupation of Black Woodpecker's *Dryocopus martius* nest-holes by Jackdaws *Corvus monedula*, or the burrows in Prairie Dog colonies by the Burrowing Owl *Athene cunicularia*. In south-east Asia some ploceids such as the Scaly-breasted Munia *Lonchura punctulata*, the Javan Munia *L. leucogastrioides* or the Java Sparrow *Padda oryzivora* regularly breed (sometimes several pairs together) in the side-walls of large raptor nests such as those of the Changeable Hawk-eagle *Spizaetus cirrhatus*, the Grey-headed Fish-eagle *Ichthyophaga ichthyaetus* or the White-bellied Sea-eagle *Haliaeetus leucogaster*, often when these nests contain eggs or young (see NESTING ASSOCIATION). A much more highly developed form of exploitation is found in birds which lay their eggs in the nests of birds of other species, and have evolved special adaptations, morphological and behavioural, promoting the acceptance and survival of their eggs and young in the hosts' nest (see BROOD-PARASITISM).

PARASPHENOID: a paired bone of the SKULL; PALATE.

PARASYMPATHETIC: see NERVOUS SYSTEM.

PARATHYROID GLAND: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

PARATREPSIS: term for DISTRACTION BEHAVIOUR.

PARATYPE: see TYPE SPECIMEN.

PARDALOTE: substantive name, alternatively 'diamond-bird', of *Pardalotus* spp. (for family see FLOWERPECKER).

PARDALOTINAE: see FLOWERPECKER.

PARENTAL ANTI-PREDATOR STRATEGIES: see DISTRACTION BEHAVIOUR; PARENTAL CARE.

PARENTAL CARE: the protection, feeding, and general care of young by one or both of the parents from the time of hatching to independence. For care of eggs see EGG; INCUBATION.

The amount of parental care expended by adults depends strongly on the mode of development of the young (see GROWTH). At one extreme are the ALTRICIAL species whose young are born naked (or nearly so) and unable to leave the nest. They therefore depend completely on the adults for food, brooding and defence from predators until they develop to independence. At the other extreme are such fully PRECOCIAL species as the megapodes, whose young lead an independent existence from the moment of hatching. Between are a series of intermediate forms of various abilities in respect of locomotion and thermo-regulation, of food finding and acquisition and of predator avoidance.

Hatching. Much of the hatching process is performed by the chick itself and the parents rarely assist. However, Eastern Bluebird *Sialia sialis* females have been seen to speed the hatching process by eating part of the shell and membranes of the pipping egg. Sanderlings *Calidris alba*, Stone-curlews *Burhinus oedicnemus* and other waders have also been recorded assisting hatching in this manner.

Eggshell removal. The majority of birds remove or eat the eggshell after hatching. Only in large ground-nesting species with large and precocial broods e.g. geese, ducks, game-birds and in some of the terns, are the shells left on the nest which is itself soon abandoned by the family. In large tree-nesting species, e.g. herons, the shells may be dropped over the nest edge. Stouter-billed passerines may eat some or all of the shell but slender-billed species and most of the Charadriiformes carry them away. The young Flamingo *Phoenicopterus ruber* is fed fragments of its shell by the parent, probably to increase its calcium intake for skeletal growth.

Eggshell disposal probably serves primarily as an anti-predator func-

Bittern *Botaurus stellaris* removing eggshell from nest. (*Photo: E.J. Hosking*).

tion. Field experiments show that nests with empty eggshells alongside attract predators e.g. crows, more frequently than do nests without shells. Study of the factors eliciting eggshell removal by Black-headed Gulls *Larus ridibundus* shows that the behaviour is not as simple as it first appears; rather it is under close control of a series of responses to the characteristics of the hatched eggshell which together ensure that the parent neither attempts to remove the shell prematurely whilst the young bird is still hatching or is so wet as to be vulnerable to cannibalism by conspecifics, nor tardily, exposing the nest to unnecessary predation risks. Such predation risks are particularly high for many ground-nesting species with precocial young and in these species eggshell removal tendencies peak around the time of hatching. Predation risks are often lower for species with altricial young, either because the parents sit tightly on the nest (thus concealing the hatched eggshells), as in doves, or because the nest sites are relatively inaccessible, e.g. hirundines. Nevertheless, eggshell removal occurs in such species and the removal tendency increases through the laying cycle. One possibility is that hatched eggshells in such species may otherwise slip over and encase the eggs not yet hatched, thereby reducing hatching success: in one study of Barbary Doves *Streptopelia risoria* 5 of 24 shells not removed within an hour of hatching interfered with other eggs in this way.

Nest sanitation. Disposal of the faeces by the parents, either by removing them or by swallowing them, is largely confined to the Passeriformes and the orders immediately related to them. The large broods of nidicolous young require a warm dry nest in the interests of hygiene and insulation and their vulnerability to predators requires distant disposal of excreta. In these species, therefore, the faeces are excreted within tough mucous sacs which can easily be carried away by the parent. Faeces are almost invariably produced only after feeding, the adult waiting for the nestling to lift its tail and produce the sac. The parent may prod the young bird near the vent to stimulate excretion. With very tiny young the sacs are immediately eaten by the adult, perhaps because digestion of ingested food is incomplete at this stage and the adult is tied to the nest by brooding requirements. With older young the sacs are carried away and disposed of. Passerines often wipe the material on to tree branches but some, such as swallows and martins, tend to drop them into water. Few go to the lengths of the female Lyrebird *Menura novaehollandia* which submerges the faeces in a nearby stream if she can and otherwise digs a hole and buries them. Young gulls and terns move away from the nest to defaecate but some tern species void their faeces around the nest where bird and substrate (e.g. sand dunes) are both white.

As the nestlings age, sanitation practices change. Sacs may be deposited on the nest rim or, in a roofed nest, in the entrance hole and are carried away by the parent after a feeding visit. In hirundines and other species with inaccessible nests, the young vent their faeces over the nest edge, leading to mounds of sacs outside or on the ground below. Young Kingfishers *Alcedo atthis* likewise have considerable competence in ejecting liquid faeces through the entrance of their tunnel nest. Woodpeckers and hornbills may void the faeces on to the floor of the nesting cavity where they are absorbed in the litter, to be periodically cast out by the female or young and the litter renewed.

Many of the larger species nesting in inaccessible sites, such as eagles, simply void their faeces in liquid form over the nest edge and do so from an early age. Some other species, notably the herons, have a nest of loose construction through which the liquid faeces fall. In hot climates this practice may be adaptive, the moist faeces falling on the twigs evaporating and keeping the nest cool. In broods of well-grown Blue Tits *Parus caeruleus* the faeces are also left in the nest; perhaps because the water they contain helps cool the crowded nest.

The young of some species are able to move from the nest although fed and cared for by their parents there, and some (e.g. Montagu's Harrier *Circus pygargus*, Nightjar *Caprimulgus europaeus*) do so to defaecate.

Brooding. Most young, altricial or precocial, are unable fully to regulate their body temperatures for some or many days after hatching (see GROWTH) and therefore require warming or brooding by the parents. Precocial young require only intermittent brooding but altricial young require almost constant brooding until their own temperature control develops. Figure 1 shows the typical pattern of brooding time in such species. Brooding frequency declines sooner in large than in small broods, because the large broods can conserve their body heat by huddling together.

The brooding rhythm of the adults is not endogenously controlled but depends on stimuli from the young. When Pied Flycatchers *Ficedula hypoleuca* were experimentally replaced by older nestlings, brooding frequency decreased, whilst when the growing young were successively replaced with younger ones brooding was substantially prolonged.

Protection from the weather. Adult birds normally shelter their young from rain, either by brooding them when small or by standing over them with spread wings when large. Precocial young may also seek shelter from their parents during rain. In prolonged rain the adult is unable to leave the young unattended and the chicks may suffer from starvation. In a few species, principally the aerial insectivores e.g. swallows, swifts, the adults may themselves be forced by starvation to leave their young unattended. Such species usually have sheltered nests (roofed, in crevices or tunnels, etc.) and the young are exposed to chilling rather than to wetting. Such young may have considerable tolerance of low temperatures, becoming torpid until the adults return. The European Swift *Apus apus* can survive a week or more in this fashion, from an early age.

Young birds have poorer physiological responses to overheating than to cooling and are dependent on their parents for shading during exposure to excessive insolation. Some herons defaecate over their young in extremes of sunlight, the resulting evaporative heat losses serving to cool the young. Tropical seabirds, notably terns, often dip to the sea surface to wet the breast feathers before sitting on the nest, thereby cooling eggs and young (see also BELLY-SOAKING).

Protection from predators. A very few species have young equipped to defend themselves against predators: the oil squirting of Fulmars *Fulmarus glacialis* and other Procellariformes, the odour glands of Hoopoes *Upupa epops* and the massive talons of young eagles being examples. Most young depend on their parents for warning and protection. Most will crouch and 'freeze' on hearing a parental alarm call. Mobile young may run and hide in the surroundings and gull chicks, for example, have individual refuges in the vicinity of the nest. Occasionally, adults may remove the young from danger by leading or carrying them to a safer site but their main tactics are to attack the predator directly or to attempt to distract it from the nest or young.

Direct attack on the predator is particularly common in colonial nesting species and many birds may combine to harass the intruder by swooping and screaming at it and even striking it with beak or claws. More solitary species, notably Charadrii, may rely on DISTRACTION BEHAVIOUR in which the bird appears to have been injured or otherwise incapacitated and flutters about near the predator but always just out of reach, until it has led the enemy far enough from the young for safety, whereupon it resumes its normal behaviour.

Hole-nesting species are occasionally threatened on the nest and may use a 'hiss' display to deter the predator at the nest entrance. The behaviour apparently simulates a hissing snake either by vocal means (Wryneck *Jynx torquilla*) or by wing movements (various tits). Adults disturbed on the nest may also adopt threatening postures and may attack the intruder with bill and claws or with regurgitated (and evil-smelling) food or oil secretions (Fulmars; coucals *Centropus* spp.) During dive-attacks, gulls and terns may defaecate on the intruder; and Fieldfares *Turdus pilaris* are notable exponents of this method of defence, their attacks sometimes leading to the death of the faeces-plastered victim.

Parents may also carry the young away from danger. A variety of waterfowl carry their young on their backs when swimming or with their beaks in flight, Woodcock *Scolopax rusticola* carry their young between their legs and body whilst in flight, and other species carry young using their feet (Red-tailed Hawk *Buteo jamaicensis*, Moorhen *Gallinula chloropus*). The American Finfoot *Heliornis fulica* has special pockets of skin under each wing in which to carry its young whilst swimming or in flight. Other species can walk away from danger carrying their young in their beak (*Rallus* spp.) or under their wings (African Jacana *Actophilornis africanus*).

Chinstrap Penguin *Pygoscelis antarctica* colony; Sheathbill *Chionis alba* eating penguin's egg. (*Photo: N. Rankin*)

Feeding. Some young receive no parental aid in food finding, the extreme being the megapode chicks which are fully independent from hatching. Amongst the more typical preococial species, however, the extent of parental involvement varies substantially. Most duck and shorebird (Charadrii) young are led to food sources but are left to feed themselves. Mute Swans *Cygnus olor*, however, will pull up submerged vegetation for their offspring and Quail *Coturnix coturnix* lead their young even to individual food items; they may also make food available by scratching the ground. Yet another group of semi-precocial species proffer food to very young chicks; older chicks of the same species feed at food regurgitated by the parents on to the ground in front of them. Fully altricial nestlings depend on their parents to deliver food into their open bills but semi-altricial raptor chicks can tear up and consume food brought to the nest after a period of fully altricial feeding by their parents.

Details of feeding behaviour are highly species-specific but a few broad generalizations are possible. Most parent birds feed their young on the same foods as they eat themselves but reserve the larger prey items for their young (except when feeding tiny young); they consume the smaller prey themselves. Presumably this trend reflects the relative economics of prey size and transport-to-nest costs. For the same reason various large seabirds with remote feeding grounds return to their young with a single large meal, often in conjunction with mate relief. Several seabird species feed their young by regurgitation of a thick stomach oil and doves and pigeons have evolved a similar ploy in the use of 'pigeon-milk' (see CROP MILK). In these and in other species, regurgitated food contains an increasing proportion of solid material as the young grow.

Feeding is most frequent in the early part of the day, presumably because the young are most hungry then after their overnight fast. But birds with unusually small broods have been noted to feed small young especially frequently in the middle and warmer part of the day, pre-

Blackbird *Turdus merula* female feeding young. (*Photo: E.J. Hosking*).

Sand Martin *Riparia riparia* feeding young at nest entrance. (*Photo: B. Huseby*).

sumably because they can then brood the young during the cooler mornings and evenings. The amount of food brought increases with the size of the brood but rarely proportionately, so young in large broods are frequently underweight and slower growing. This is apparently due to the inability of the parents to collect food fast enough over long periods: at one Great Tit *Parus major* nest studied, the parents of the over-large brood progressively 'tired' earlier each day as the nesting period progressed, collecting less food per unit time in late afternoon despite the greater food needs of their growing young.

Young are generally fed more frequently in cold weather, provided the food is available. This responds to the greater energy needs of the young. For other species cold weather results in reduced food availability and the parents may need to leave their young not only unfed but even un-brooded. In wet weather the general rule is to brood the young rather than to seek food for them.

Water supply. Most nestlings obtain their entire water requirements from the moisture content of their foods though, in the case of Bullfinches *Pyrrhula pyrrhula* and other species feeding their young by regurgitation, the young may well receive additional water in the mucus binding the food items together. Species breeding in hot areas, however, need large quantities of water for evaporative cooling and special behaviours have evolved to communicate these needs to the parents. Young Darters *Anhinga melanogaster*, for example, seek food by begging behaviours performed with the bill closed but seek water with the same behaviour performed after a feed and with the bill open; in response to such solicitation the adults fly to nearby water and return to regurgitate water into their offsprings' bills.

Most precocial young can travel to water but the Namaqua Sandgrouse *Pterocles namaqua* breeds in the Kalahari Desert 80 km or more from water. The adult male possesses specially modified ventral feathers with which to transfer a net 10–20 ml water from waterhole to chick over these distances. In this way the chick receives water over its 7 weeks of pre-flight life (see SANDGROUSE).

Care during nest departure. The extent to which the departure of the young from the nest receives parental care varies widely between species, from total absence in European Swifts to the elaborations of the 'water-call' and 'exodus call' of the Guillemot *Uria aalge* and Wood Duck *Aix sponsa* respectively. Young Swifts depart from their nest without parental attention, often doing so in the absence of the adult, and this is a common pattern amongst altricial species. Generally, however, fledglings are tended by their parents for the first few days of life outside the nest. In many such species nest departure is not synchronous and the parents may seek to encourage tardy young to fledge by withholding food: in Bluebirds *Sialia sialis* feeding rates are markedly reduced in the last day in the nest and more so when one young has left the nest, though feeding is resumed once the brood has fledged and re-united. In some cases adults seek to induce individual laggards to depart the nest by offering them food items from just outside it. In other species, however, the male and female divide the brood between them, one adult attending the new fledglings, the other those remaining in the nest.

Precocial young feed themselves to a large extent and the parents' major role is to warn and guard against predators once the brood has left the nest site after a short post-hatching period. In such species there may be a premium on the brood departing together, particularly where the chick feeding grounds are some distance from the nest-site. The adults frequently possess a distinctive nest exodus call, soft in terrestrial nesters but loud and well-developed where the chicks must jump from the nest, as in the tree-holes of the Wood Duck or the cliff ledges of Guillemots. Following a period of about 24 hours post-hatching during which she repeatedly utters the exodus call (thus familiarizing the young with her voice) the female Wood Duck reconnoitres the environs of the nest site and, if clear, summons the young from their cavity. Young Guillemots similarly leave their nest-ledges before developing full flight, descending on the 'lift' of their secondaries, and are prone to gull predation once away from the ledge. Hence the chicks 'fledge' predominantly at dusk following a session of reciprocal 'water-calling'—a loud clear whistling call—between parent and young, culminating in resumed contact between them on the sea below, the two swimming away through the dusk to offshore (and more gull-free) waters by dawn. The descent of the chick may be accompanied by an adult flying down behind it, providing physical obstruction to aerial predation.

Strength and duration of care. The duration and intensity of parental care are believed to represent a balance between (1) the reproductive potential of the parents on ceasing to tend the current young in favour of future broods and (2) their potential on continuing to invest further in the current attempt (giving the current young a better chance of surviving to reproduce). This has two consequences for the birds.

First, their willingness to provide care should increase through the nest

Great Crested Grebe *Podiceps cristatus* feeding feather to young on its back. (*Photo: E.J. Hosking*).

cycle since it will become increasingly difficult for them to get through a replacement cycle successfully. Thus, incubating eggs should be defended more vigorously than newly-laid eggs and hatched young should be defended more intensely than eggs. Empirical data testing these ideas are scarce but what are available support the hypothesis.

The second consequence of the theory is that fledglings should be cared for by the parents only whilst the return in reproductive output by doing so exceeds the return obtained by investing the same care into a fresh breeding attempt. In general terms this is the case, with species in which the young can quickly learn to forage for themselves having short periods of post-fledging care, as in small unspecialized passerines, whilst species with unusual (or very specialized) feeding techniques have long periods of post-fledging care. Terns have been found tending their British-born offspring whilst on their African wintering grounds, thus providing the young with the time and opportunity to acquire specialized fish-catching techniques with adequate levels of skill before being left to forage independently. However, another consequence of this inclusive FITNESS theory of parental care is that a period of conflict between parent and offspring as to the amount of care provided must arise, the offspring seeking more than the parent should optimally provide. Empirical data support this prediction for a variety of species. In a Bewick's Swan *Cygnus columbianus* study, for example, the proportion of cygnet movements going immediately unguarded by the adults increased from 52% to 87% over the first 4 weeks of cygnet life, even though the cygnets seek proximity to their parents for their protection during aggressive encounters.

Parental care and clutch-size. Precocial species have, on average, larger clutches than altricial species and this difference is frequently attributed to a supposed reduction in the need for parental care for self-feeding chicks. However, parental care in these species takes the form of guarding against predators and this has to be attained over the foraging area of the independently hunting chicks. When prey densities are low the chicks must hunt over larger areas than can in practice be adequately protected by the adults, thus limiting productive clutch size. For many arctic waders the clutch size is 4, suggesting some general limiting factor of this nature and, in one experimental test of the idea, artificially increased brood sizes of Semi-palmated Sandpipers *Calidris pusilla* fledged fewer young than did the natural broods of 4. Thus the provision of parental care even in the form of chick guarding can in practice be limiting to clutch size in the same way as can parental care through feeding (see also CLUTCH-SIZE).

Crèches. Chicks of several species normally spend part of their development period in groups or 'crèches' attended by a small number of adult birds which may or may not include the parents of the chicks present at the time. The behaviour was noted early in studies of penguins but also occurs in the 'crested' terns, pelicans, flamingos, and several waterfowl species, though the detailed features of the behaviour differ even within these species groups.

Sandwich Tern *Sterna sandvicensis* feeding fledged juvenile. (*Photo: D. Hosking*).

In some high latitude species the huddling together of the chicks into crèches undoubtedly serves to conserve heat by reducing the effective surface-to-volume ratio experienced by the chicks. But in the Eider *Somateria mollissima* and Shelduck *Tadorna tadorna* the chicks are actively guarded by the accompanying adults who are generally (perhaps always) successful breeders. On the Ythan Estuary in Scotland marked Eider ducks averaged only 4 days with their brood in a crèche before leaving to join adults feeding elsewhere on the estuary. These females have fasted to a substantial extent whilst incubating their clutches but the food they need to replenish their reserves—the edible mussel *Mytilus edulis*—is concentrated into parts of the estuary remote from the centres for the invertebrates required by their young—the amphipods *Corophium* spp., a

Great Black-headed Gull *Larus ichthyaetus* male, female and young. (*Photo: V. Siokhin*).

House Sparrow *Passer domesticus* male feeding fledged juvenile. (*Photo: J.B. & S. Bottomley*).

gastropod mollusc *Hydrobia* sp. and a winkle *Littorina* sp. Hence the ducklings in the crèches can be guarded only by the succession of females bringing their offspring to the brood-rearing areas over a period of time. Similar considerations have different consequences for local populations of Eiders on rocky (rather than estuarine) coasts; these do not form crèches but their young feed on the gammarids and other small crustaceans present in the seaweeds whilst the females take mytilids and littorinids present on the rock surfaces to which the seaweeds are attached.

Alternatively, crèching may have originated in normal parental caring at high brood densities. Broods then become mixed, either because both pairs of adults are fighting in defending their broods, which then scatter, or because a chick of one brood wanders closer to a foreign brood than to its own parents and joins the foreign brood when it is called together by its parents. Such mixing is most frequent when broods are less than a week old. Yet another explanation may lie with the adults resorting to crèching to share the costs of guarding young chicks amongst several adults: each adult can then spend a longer time feeding.

Skutch, A.F. 1976. Parent Birds and their Young. Austin.

Protection of eggs. As a general rule, breeding birds do not actively engage a predator—and thus put themselves at risk—unless it is relatively safe for them to do so, or as a last resort (though even then not to the extent of losing life or limb). Rather, they leave the eggs or young to the safety of their own camouflage or to that of the site as much as possible. In waders precautionary adaptations that enhance the camouflage of the eggs include siting them against a disruptive background (e.g. among cattle droppings) or concealing them, partly or completely, with nest debris; also the adoption of inconspicuous routines at the nest and the speedy removal of egg-shells as each chick hatches. The parents may also nest in loose association with other species that actively demonstrate, etc. against predators when breeding (see DISTRACTION BEHAVIOUR). If a predator appears, but does not immediately threaten the safety of the eggs or young, the attendant adult may react by flushing sooner or later (the timing being adaptably variable according to circumstances) or by adopting a concealing posture; it will depart furtively if necessary—in some species (such as Kittlitz's Sand-plover *Charadrius pecuarius*) after first speedily covering the eggs or even newly hatched chicks—and then remain inconspicuously in the general vicinity or depart entirely.

PARENTAL INVESTMENT: see PARENTAL CARE.

PARIDAE: a family of the PASSERIFORMES, suborder Oscines; TIT.

PARIETAL: a paired bone of the SKULL.

PAROTIA: substantive name sometimes used for the 4 species of *Parotia*, usually known as six-wired BIRDS-OF-PARADISE.

PARRAKEET: see PARAKEET.

PARROT: substantive name of most species of Psittacidae, sole family of the order Psittaciformes; in the plural, general term for the family and order.

Characteristics. Parrots share a number of characters which define the order: the upper mandible is strongly curved and fits over the shorter lower mandible; a cere surrounds the base of the upper mandible which articulates with the SKULL; the lingual and jaw musculature is highly developed and complex; the tarsometatarsus is short, the zygodactyl foot is covered with granular scales; the feather tracts are sparse among prominent bare areas; the moult of the primaries starts in the centre; the egg shell is white.

There is a wide variation in size from a total length of *c.* 8.4 cm for the Buff-faced Pygmy Parrot *Micropsitta pusio* to *c.* 100 cm for the Hyacinth Macaw *Anodorhynchus hyacinthinus*. In general, the male is slightly larger than the female; the opposite is true for some *Agapornis* spp. The plumage generally is brightly coloured, the prominent colour being most frequently green. Some species are less colourful, being mostly brownish-green, grey, black, or white. Most species are sexually monomorphic; in the dimorphic species the difference between the sexes varies from extreme, e.g. in *Eclectus roratus* to minimal, e.g. in the Budgerigar *Melopsittacus undulatus*. The juvenile is similar to the adult plumage, only somewhat duller; a distinct juvenile plumage is found in the ring-necked parakeets (*Psittacula* spp.), the Crimson Rosella *Platycercus elegans*, the Blue-crowned Lory *Vini australis* and others.

The wings can be elongated and pointed, as in the Swift Parakeet *Lathamus discolor*, or broad and rounded, as in the *Amazona* spp. Tails may be long and pointed or short and squarish. The central tail feathers are decorously elongated in the Papuan Lory *Charmosyna papou*; in the racket-tailed parrots (*Prioniturus* spp.) they extend beyond the tip of the tail as bare shafts terminating in spatules. Stiff shafts project from the tip of the tail feathers in the pygmy parrots (*Micropsitta* spp.) and *Nestor* spp. The crown feathers are elongated and form movable crests in cockatoos. Some lorikeets (*Vini* spp.) can ruffle their crown feathers, whereas the elongated crown feathers of the Horned Parakeet *Eunymphicus cornutus* cannot be moved. Elongated hind neck feathers are found in the Collared Lory *Phigys solitarius* and Hawk-headed Parrot *Deroptius accipitrinus*. The head is bare and covered only with bristles in the adults of Pesquet's Parrot *Psittrichas fulgidus* and the Vulturine Parrot *Gypopsitta vulturina*. Bristles are also found at the base of the bill of nocturnal parrots. The bill varies in length. It is very long and narrow in the Nestorinae, most Loriinae, the hanging parrots (*Loriculus* spp.), Pesquet's Parrot, the Long-billed Corella *Cacatua tenuirostris*, the Red-capped Parrot *Purpureicephalus spurius*, the Slender-billed Conure *Enicognathus leptorhynchus*, the Tepui Parrotlet *Nannopsittaca panychlora*, and *Brotogeris* spp. Short bills are found in the black cockatoos (*Calyptorhynchus* spp.), the pygmy parrots and *Poicephalus* spp., most broad-tailed parrots (Platycercini), *Ara* spp., and *Bolborhynchus* spp. The Palm Cockatoo *Probosciger aterrimus*, Great-billed Parrot *Tanygnathus megalorhynchus* and Hyacinth Macaw are known for their disproportionately large bills. The tongue is broad and fleshy. In pollen and nectar feeders, the tongue is elongated and bears epidermal papillae at the tip, e.g. in the lories, the Swift Parakeet, and the Philippine Hanging Parrot *Loriculus philippensis*. Most parrots have a well developed crop and a muscular gizzard. Both organs are reduced in pollen-nectar and fruit specialists.

Habitat. Parrots are found mainly in tropical regions but also in temperate zones. They are especially plentiful in lowland tropical forests. Some have conquered mountainous regions, e.g. the Derbyan Parakeet *Psittacula derbyana* in Tibet, or the Kea *Nestor notabilis*. Others inhabit more open country, mostly keeping close to waterholes and water courses in arid regions. A few species live on the sea shore, e.g. the Rock Parakeet *Neophema petrophila*, some subspecies of the Red-fronted Parakeet *Cyanoramphus novaezelandiae*. Three species are terrestrial, the

Kakapo *Strigops habroptilus*, the Australian Ground Parrot *Pezoporus wallicus*, and the Night Parrot *Geopsittacus occidentalis*.

Distribution. Parrots are found around the world, mainly in the Southern Hemisphere, i.e. Australasia, Pacific Islands, Africa, South and Central America, and the Caribbean Islands. The northernmost point of the distribution is reached by the Slaty-headed Parakeet *Psittacula himalayana* in Afghanistan, the southernmost point by the Austral Conure *Enicognathus ferrugineus* in Tierra del Fuego. The easternmost island of the Pacific, Henderson Island, is reached by Stephen's Lory *Vini stepheni*.

Movements. Most parrots are more or less sedentary, except for daily local movements between roosting and feeding places. Nomadic behaviour is especially common among inhabitants of arid regions, e.g. the Budgerigar and Cockatiel *Nymphicus hollandicus*. A few cases of seasonal migratory behaviour are known, e.g. the Swift Parakeet and the Orange-bellied Parakeet *Neophema chrysogaster*.

Food. The diet of parrots is mainly vegetarian and includes seeds, nuts, berries, fruit, tubers, roots, nectar, pollen, insects, and lichens. Specializations on either food have often been evolved several times independently. However, all parrots (except Pesquet's Parrot) eat some seeds (or nuts) which they always husk before swallowing. Food is often held in the foot when feeding.

Behaviour. Most parrots are gregarious. Many species live in pairs during the breeding season. The social behaviour of parrots is very complex with play behaviour, courtship and ritualized fighting. Mating is for life, and the pair bond is maintained (except in cockatoos) by mutual preening and partner feeding. The Kea is polygamous.

Voice. Parrot calls are mostly screeching, loud, metallic, and unmelodic. High-pitched whistles are characteristic for the Loriinae. Many species emit chattering vocalizations. Some parrots have a soft, almost melodic voice, e.g. the Purple-bellied Parrot *Triclaria malachitacea*, Bourke's Parakeet *Neopsephotus bourkii*. Vocal mimicry has been observed only in captivity.

Breeding. Nesting generally takes place in hollow trees without litter material. *Loriculus* and *Agapornis* spp. build a nest within tree holes. The Monk Parakeet *Myiopsitta monachus* builds huge colonial twig nests in trees. The Rock Parakeet and the Patagonian Conure *Cyanoliseus patagonus* nest in cliffs. The Australian Ground Parrot nests in tufts of grass. Some species nest in termite nests, e.g. the Golden-shouldered Parrot *Psephotus chrysopterygius*, the Red-faced Lovebird *Agapornis pullaria*, and the pygmy parrots. Depending on the species, 2–5 eggs are laid on alternate days, incubation, usually (except in cockatoos) by the female only, starting with the second egg. The chicks hatch after 16–32 days. The hatchlings are blind, naked or have sparse down. They are fed and brooded by the female during the first 5–10 days; later the male assists in the care of the young. After leaving the nest, the young usually remain with their parents until the next breeding season.

From early times parrots have been valued as pets because of their playfulness and mimicry of the human voice. In recent years, the lucrative pet trade has become, together with habitat destruction, a major threat to the survival of many species.

Systematics. Relationships of the Psittaciformes to other orders are unclear and hypothetical; most likely is a common ancestry with the pigeons. The first fossil parrot is known from the lower Miocene in France. The family comprises about 82 genera and 332 species. Eight subfamilies can be recognized.

Nestorinae. The single genus *Nestor* is endemic to New Zealand and adjacent islands. The 2 species are large, stocky birds. The Kea inhabits sub-alpine regions, whereas the Kaka *N. meridionalis* inhabits forests.

Strigopinae. The single species *Strigops habroptilus* is endemic to New Zealand. This heaviest parrot of all is flightless and nocturnal. The males display lek-behaviour (see LEK). The recent rediscovery of a small population on Stewart Island may save the Kakapo from imminent extinction.

Psittrichadinae. The single species *Psittrichas fulgidus* is endemic to New Guinea and inhabits high elevations. Its diet consists of fruit. It is the only parrot not known to eat seeds or nuts. It drinks with a suction-pump action of the tongue.

Cacatuinae. The cockatoos are found in Australia, New Guinea, and the islands adjacent to the Philippines. They are large birds with a movable crest, a short and high bill, and a narrow, stubby tongue. The plumage is white, pink, grey, or black, with various red or yellow markings. They are specialized seed and nut eaters and drink by scooping up water with their lower mandibles. The Cockatiel is much smaller than the rest of the group and has evolved in convergence to the broad-tailed parrots.

Rosy-faced Lovebird *Agapornis roseicollis*. (*K.J.W.*).

Micropsittinae. The pygmy parrots are endemic to New Guinea and the adjacent islands. These smallest of the parrots live in dense forests, climbing along the tree trunks. The bill resembles that of the cockatoos. The tarsometatarsus and the claws are long. Their food consists of lichens and, probably, insects.

Loriinae. The lories are found on the Pacific Islands, Australia, New Guinea and adjacent islands. They are medium-sized to small birds with extremely colourful plumage. They are pollen and nectar specialists, but eat also seeds and insects, and drink by dipping their brush-tipped tongue into the liquid.

Psittacinae. This group comprises 58 of the 82 parrot genera. It can be divided into 4 well-defined tribes, although the exact systematic position of some particular genera is not yet clear. The subfamily includes species of widely varying sizes, colours, appearances and feeding specializations. The group is characterized by a broad fleshy tongue with a spoon-shaped tip and by a drinking mechanism in which the tongue ladles water and swallows it by pushing the tongue against the palate.

(1) Platycercini. The broad-tailed parrots are restricted to Australia, New Zealand, New Caledonia, and Fiji. The group consists mostly of seed-eaters, but includes also the pollen feeding Swift Parakeet and the frugivorous shining parrots (*Prosopeia* spp.) All species have long tails.

(2) Psittaculini. This group has the most extensive distribution, from Australia to Africa. Size varies from the small *Agapornis* spp. to the large *Eclectus* sp. The appearance varies from stocky parrots with short tails to slim parakeets with extremely long tails. Most species have a coral-red bill.

(3) Psittacini. This African group consists of only 2 genera. The Grey Parrot *Psittacus erithacus* is more frugivorous than the seed and nut specialist *Poicephalus* spp. to which the Senegal Parrot belongs.

(4) Arini. This group is endemic to South America and comprises all Neotropical parrots (141 species of all 332 parrot species).

Loriculinae. Previously thought to be closely related to the *Agapornis* spp., the hanging parrots form a distinct group with the single genus *Loriculus*. They are small, green birds with a brilliantly red rump. Most species are highly specialized fruit, pollen, and nectar feeders. They drink with a suction-pump action of the tongue. They often roost and rest during the day hanging upside down, hence their name.

PARROTBILL (1): substantive name of most of the species of the subfamily Paradoxornithinae of the Timaliidae (Passeriformes, suborder Oscines); in the plural, a general term for the subfamily (sometimes called Suthoras or Crow-Tits). Certain aspects of the biology of this subfamily, including features of behaviour and moult, have prompted consideration that familial rank might be justified.

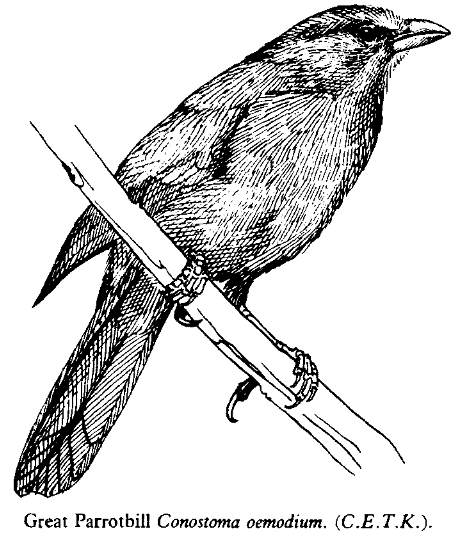
Characteristics. Parrotbills are small to medium-sized birds, ranging in total length from about 12–28 cm. Although somewhat like the tits (Paridae) in general appearance, they are with two exceptions distinguished from other Oscine birds by the peculiarly formed (usually yellowish) bill, which is shorter than the head, very much compressed, and with strikingly convex outlines. The culmen is curved strongly for its entire length, the gonys ascends sharply, and the cutting edges of both mandibles are more or less distinctly sinuous. The nostrils are completely covered in bristles, and the legs and feet are robust, with strong toes and claws. The plumage is very soft and loose.

Although numerous generic names have been proposed for the parrotbills on the basis of bill-shape, only 3, *Paradoxornis*, *Panurus* and *Conostoma* are currently accepted, the last 2 being monotypic. The Bearded Reedling or Bearded Tit *Panurus biarmicus* differs from the typical species in a number of particulars, e.g. in having a more normally shaped bill, in the sexes differing in plumage (with the juveniles resembling the female), and in laying larger clutches. The Great Parrotbill *Conostoma oemodium*, is much the largest of the subfamily, and has a bill intermediate in shape, though larger, between *Panurus* and *Paradoxornis*.

The sexes in *Paradoxornis* and *Conostoma* are alike in plumage, the coloration ranging from the almost uniform greys and browns of the larger species to complex patterns featuring orange-buff, pinkish-browns, and black and white. In most species the wings are short and rounded, but the tail is generally long and graduated. One species, the Three-toed Parrotbill *Paradoxornis paradoxus*, is remarkable among passerine birds in only having three toes, the outer one being a clawless stump attached to the middle toe.

Habitat. Parrotbills are birds of dwarf bamboo, rhododendron, and the lower levels of either deciduous or evergreen forest, while many of the smaller species prefer tall grass and reeds. The Bearded Reedling and one Chinese species are confined to reedbeds.

Distribution, populations and movements. The 19 species are essentially Sino-Himalayan birds, although several range widely in the Palearctic, and no less than 12 species extend into the mainland countries of south-east Asia, though not entering Malaysia. Amongst the typical parrotbills, the Vinous-throated *P. webbianus* is perhaps one of the most widely distributed, ranging in 7 races from Manchuria and Korea to Hainan and Burma. The Black-throated *P. nipalensis*, with 12 subspecies, ranges from Nepal to Taiwan and southwards into the Indo-Chinese countries. On the other hand, one of the most restricted species is *P. heudei*, a very distinctive intermediate-sized form, which only occurs in the reedbeds bordering an 80 km reach of the Yangtze river in the Chinese province of Kiangsu. The rather aberrant Bearded Reedling, is wholly Palearctic, and ranges in areas of reedbeds from England eastward into Manchuria. Most species are resident, though there is some seasonal and altitudinal movement in the Himalayas, and the western populations at least of the Bearded Reedling have, in the last 30 years, developed a new dynamism characterized by now annual eruptive dispersal and the colonizing of new sites.



Great Parrotbill *Conostoma oemodium*. (*C.E.T.K.*).

Food. Insects are commonly taken, as well as vegetable matter such as shoots, buds, berries and seeds, the strong and unusually shaped bill of many species also being well adapted for stripping bamboo stems.

Behaviour. All species are gregarious, and forage through tall grass or bamboo in small or large parties, keeping in touch with a continual twittering or cheeping. They fly reluctantly and rather feebly, but are quite agile and somewhat reminiscent of tits Paridae when foraging.

Voice. Some of the larger species are quite noisy, with both harsh chattering notes and more musical calls, and at least 2, including the Bearded Reedling, have rather metallic ringing notes. Most species have a variety of cheeping or chittering notes, and another is described by Stuart Baker as 'like . . . the plaintive bleating of a kid in distress.'

Breeding. The breeding habits of some species and subspecies remain undescribed; much is still to be learnt of the lives of some of the uncommon parrotbills of remote areas. Those whose nidification has been studied build compact cup-shaped nests of grass and strips of bamboo, often thickly lined with finer grasses and sometimes bound with cobwebs. The nest is placed in reeds or grass or among bamboo stems within 2 m or so of the ground. The eggs number 2–4, and may be unspotted blue, or white to creamy or fulvous with speckling and blotching of reddish, greenish-grey or purplish. Both sexes of the Bearded Reedling incubate the clutch of 5–7 eggs for 12–13 days; and the young, fed by both parents, may leave the nest in 9–12 days. Two broods are usual. (H.G.D.) M.W.

PARROTBILL (2): term sometimes applied, in the plural, to the Psittirostriinae (for family see HAWAIIAN HONEYCREEPER).

PARROT-FINCH: substantive name of *Erythrura* spp. (see ESTRILDID FINCH).

PARROTLET: substantive name of the Neotropical *Forpus* spp. (Psittacinae, Arini) (see PARROT).

PARSON-BIRD: alternative name for the Tui *Prosthemadura novaeseelandiae* (see HONEYEATER) and in Trinidad for the tanager *Tachyphonus rufus*.

PARTHENOGENESIS: production of a new individual from an egg not fertilized by a male gamete; from Greek *parthenos* meaning virgin and *genesis* meaning birth. In application parthenogenesis may be regarded as any mitotic activity in unfertilized eggs, or more conservatively, the development of a macroscopically detectable blastoderm.

Parthenogenesis may result in at least two cytological forms. Generative parthenogenesis occurs in animal groups in which chromosomes of the egg are reduced (through meiosis). Individuals that are produced are thus haploid. Automictic parthenogenesis occurs in animal groups in which chromosomes are initially reduced but diploidy is ultimately restored. The hypothesized mechanism for this restoration is suppression or re-entry of the second polar body during the second phase of meiosis.

Parthenogenesis appears to be relatively widespread in the animal kingdom. Using a definition of any mitotic activity in unfertilized eggs, parthenogenesis is probably very common. However production of viable offspring is much less common. Of all known cases 90% occur among invertebrate species.

Among birds mitosis may be initiated in the unfertilized egg but organization of the blastoderm generally fails. Naturally occurring parthenogenesis is usually abortive. The only documented cases of production of offspring by parthenogenesis are from domestic varieties of the chicken *Gallus gallus* and the Turkey *Meleagris gallopavo*. Automictic parthenogenetic development has been observed in 1% of the unfertilized eggs of standard and cross breeds of chickens; the frequency among various strains of domestic turkeys averages approximately 10%. Selective breeding programmes have increased the frequency of parthenogenesis indicating a genetic basis for the phenomenon. The presence of viruses appears to increase the frequency of parthenogenesis. Fowl Pox, Rous Sarcoma and Newcastle DISEASE have all been shown to play an active role in parthenogenesis in turkeys. Vaccinations using live virus have proven more effective than the killed form. Vaccination/selection programmes have resulted in frequencies of parthenogenetic development approaching 50%. In most cases development is aborted and production of viable individuals is rare. Those that have hatched have been male and of those surviving to maturity only 20% have produced viable sperm.

Parthenogenesis resulting in viable offspring in the wild has not been documented in birds. It is suspected in wild Turkeys because of its unusually high level in captivity. However, laboratory experience has shown that the parthenogenetically produced turkeys suffer from malposition in the egg and are generally less vigorous during pipping and hatching than normal young. In addition to poor hatchability, the birds show difficulties with locomotion and feeding during the early post-hatch phases. The probability of successful parthenogenetic production of offspring in the wild appears to be exceedingly low. W.F.P.

Olsen, M.W. 1975. Avian Parthenogenesis. US Department of Agriculture ARS-NE 65.

PARTIAL MIGRANT: term applied to species of which, in a given breeding area, some individuals are migratory while others are not, e.g. Song Thrush *Turdus philomelos* in Britain. (see MIGRATION).

PARTRIDGE: substantive name of species of Phasianidae in several genera (*Perdix*, *Ammoperdix*, *Alectoris*, etc.); also the tree partridges *Arborophila* spp. etc, the Snow Partridge *Lerwa lerwa*, and the bamboo partridges *Bambusicola* spp. etc. (see under PHEASANT).

PARULA: substantive name of the 2 species of *Parula* (see WARBLER (2)).

PARULIDAE: a family of the PASSERIFORMES, suborder Oscines; WARBLER (2).

PARVORDER: a taxonomic category which is a subdivision of an order, ranked between infraorder and superfamily. Used by McKenna (1975), Sibley and Ahlquist (in press). See also DNA AND PROTEINS AS SOURCES OF TAXONOMIC DATA.

McKenna, M.C. 1975. Toward a phylogenetic classification of the Mammalia. Pp. 21–46. *In* Luckett, W.P. & Szalay, F.S. (eds.). Phylogeny of the Primates. New York.

Sibley, C.G. & Ahlquist, J.E. In press. The phylogeny and classification of the passerine birds, based on comparisons of the genetic material, DNA. Proc. XVIII Int. Orn. Congr. Ilyichev, V.D. (ed.). Moscow.

PASSAGE MIGRANT: term, alternatively 'transient', applied to birds from the viewpoint of an observer in an area that they pass through on migration without remaining throughout either the summer or the winter; 'bird of passage' is sometimes used as an equivalent but is applied poetically to any migrant (see MIGRATION). For 'passage hawk' see FALCONRY.

PASSERES: used both as an ordinal name synonymous with 'Passeriformes' and (less commonly) as a subordinal name synonymous with 'Oscines' (see below). It was the name used by Linnaeus for his sixth order of birds.

PASSERIDAE: family of PASSERIFORMES, suborder Oscines, SPARROW (1).

PASSERIFORMES: an order comprising 2 suborders (1) the 'Deutero-Oscines' (with 12 families; name introduced by Voous, Ibis 119 (1977): 224); treated by Feduccia as an order of its own, Tyranniformes, with an independent origin from Coraciiform ancestors, and (2) the 'Oscines' (with 70 families) (see TABLE OF CLASSIFICATION). The families of 'Deutero-Oscines' are often referred to collectively as the 'Suboscine Passeriformes', but the name 'Suboscines' more precisely denotes the Australian Atrichornithidae and Menuridae which have syringeal differences in comparison to the remaining Oscines. The name 'Clamatores' is used alternatively for the Tyranni (but earlier had a wider connotation). The order can also be divided in accordance with the number and arrangement of the syringeal muscles (see SYRINX). In the terminology most lately used, the Tyranni or Clamatores (with which the Eurylaimi agree in the particular respect, although otherwise peculiar), are called 'Mesomyodi', and are subdivided into 'Tracheophonae' (= superfamily Furnarioidea) and 'Haploophonae' (= Tyrannoidea); the Menurae and the Oscines together constitute the 'Acromyodi'. There have been other variants of this scheme.

The Passeriformes, as an order, are often referred to as the 'perching birds', and the Oscines as the 'song-birds', and from the point of view of European ornithology these two common names are in practice synonymous, the Oscines being the only suborder represented in the Palearctic Region.

General characters. Perching and singing are functions reflected in the structure of members of the order. The foot is characteristic. There are always 4 toes, joined at the same level; the hallux is directed backwards and is not reversible. This form of foot is well adapted to perching by the method of gripping a slender branch, twig, reed, grass-stem or wire (see LEG). The toes are never webbed, even in the very few forms that have acquired aquatic habits (Cinclidae, and *Cinclodes* spp. in the Furnariidae). The syrinx is tracheal in a few (Tracheophonae—see above); otherwise it is in the common tracheo-bronchial position, but with various arrangements of its muscles as already mentioned. The quality of song varies greatly, even among the Oscines, but the order certainly includes the best musicians—and the most accomplished vocal mimics (see VOCALIZATION; and MIMICRY, VOCAL).

Among other morphological characters the wing is eutaxic and has either 9 or 10 distinct primaries. The tail most usually has 12 rectrices. The spermatozoa have a distinctive form, not found in other birds.

The form of bill shows various adaptations to the kind of food (see BILL). In body size, the members of the order range from very small to the moderate dimensions attained in the larger crows (Corvidae) and the lyrebirds (Menuridae). In feathering they range from inconspicuous drab hues and lack of adornment to brilliant colours and ornamental plumes.

Mode of life. The Passeriformes are land birds. Some particularly frequent the vicinity of fresh water, and a very few find their food in it; some live near, or visit, the seashore; but to them all the open sea figures only as a dangerous area to be crossed on migration. Many of them, especially insectivorous species breeding in high latitudes, are migratory in the highest degree; others perform shorter journeys, while others again are sedentary. Widely varying habitats are exploited, including desert, montane areas, man-made environments, roosting and nesting in buildings and making use of 'unnatural' food.

Breeding habits show a wide range of difference in nest sites, nests, eggs and so on. The young are nidicolous, being hatched blind, naked, and helpless. In general, parental care—by both sexes—is well developed; a few species, however, are parasitic in this respect (see BROOD-PARASITISM).

Distribution. The order is cosmopolitan, unrepresented only in polar latitudes and on the most forbidding islands. Indeed, its members predominate in the avifaunas of all but a few highly specialized types of environment. Some families of the Oscines are almost cosmopolitan, or are widespread in either the Old World or the New.

Familial taxonomy of the Oscines. This is a subject of the greatest difficulty and much speculation. The general resemblance is so high, and the effect of convergence on adaptive characters so great, that trustworthy evidence of relationships between groups is hard to find. As E. Mayr has pointed out, with the exception of the Alaudidae (absence of ossified pessulus in the syrinx) and the Hirundinidae (closed bronchial rings) none of the families can be defined unequivocally by anatomical characters—there is always a hint that these may be functional and not phyletic.

Many of the families are nevertheless reasonably distinctive—or at least appear to be so—and their validity as taxa has not been seriously challenged. Others are very unsatisfactory, and their boundaries are obscured by the existence of aberrant forms that may be included or excluded as a matter of opinion. Thus thrushes, warblers, flycatchers, and babblers have been considered by some authors to be so distinct as clearly to warrant the status of separate families, Turdidae, Sylviidae, Muscicapidae, Timaliidae, respectively. Many of the authors working on groups from the Old World Tropics, have treated them as subfamilies or tribes of the family Muscicapidae with all too numerous species and phenetic forms. Another classic area of special doubt includes the Fringillidae, Emberizidae, Thraupidae and other so-called nine-primaried (as opposed to the ordinary ten-primaried) Oscines. There are, in addition, instances which it is merely a matter of opinion, on degrees of difference, whether a few apparently nearly related groups should be treated as separate families or as subfamilies of one; such points are of minor importance.

Where it is difficult even to delimit many of the families, it is still more difficult to arrange them all in larger groups. Generally, the song-birds (again excluding the larks and swallows) are divided into 3 major assemblages; (1) Old World insect-eaters and relatives; (2) New World insect-eaters and finches; and (3) crows (Corvidae), birds-of-paradise (Paradisaeidae), and associated families. The remaining more peculiar and isolated families, as well as the Old World nectar-eaters, are then placed rather irregularly within this broad framework (see Mayr and Greenway 1956).

Whether or not any groups of families be expressly designated, it is necessary for practical purposes to arrange the families of the suborder in some sequence. Customarily, such a sequence purports to lead from the most primitive to the most specialized, or (chiefly in the past) vice versa. The same lack of real evidence, however, makes this equally in vain; the essential facts are just not known, and may perhaps never be ascertainable. In any event, even were it possible to construct an adequate concept of phyletic relationships, this could not be expressed in a linear sequence such as, for instance, the arrangement of any check-list or other systematic work requires. The most that a sequence can do is to keep together, here and there, a few families that are probably closely related; but it equally brings into juxtaposition other families between which no such near relationship can be supposed to exist.

Current views tend to favour a sequence that is traditional, and thus in some ways convenient. There may be reason for believing that the sequence is to some slight extent a 'natural' one, and that it at least serves to keep a few probably related families together—especially those that might perhaps equally well be brought under a single head as subfamilies, and are indeed so treated by some authors.

It should nevertheless be recognized and made abundantly clear that, apart from recent progress in biochemical and DNA research, the device is for the most part merely a convention. Thus, a conventional sequence of Passerine families was agreed upon by a committee appointed by the XI International Ornithological Congress (Basel 1954) and published by Mayr and Greenway (1956). This sequence has been followed by the editors and authors of the late James L. Peters' *Check-list of Birds of the World.* It follows the sequence (1), (2), (3) mentioned above and accepts the view that crows, as well as the whole corvid assemblage (group 3) are the most advanced and highly developed songbirds, a supposition which appears more or less based on the crows' intellectual capacities rather than on anatomical or fossil evidence and therefore has not failed to evoke refutation (Amadon 1957, Delacour and Vaurie 1957, Wetmore 1957, Mayr 1958, Storer 1959, 1971, Sibley 1970). Wetmore (1930, 1951, 1960) and most other Americans basically follow the sequence (3), (1), (2), whereas European authors, following Ernst Hartert's monumental work (1903–38) always have been more inclined to (3), (2), (1). As Storer's (1971) sequence, following (1), (3), (2), is thought to gain widest acceptance, it has been followed here with a few amendments as to the places of Motacillidae and Laniidae, in accordance with Voous (1977). It combines the views that the nine-primaried assemblage of New World insect-eaters, tanagers, finches, sparrows, cardinals and icterids are the most recently developed and diversified large group of birds. The evolution of the seed-crunching and seed-shelling fringilline and emberizine groups is thought to have been a geologically rather recent event, following the rapid and equally recent evolution of monocotyledonous plants. Sturnids, ploceids and allies are most advanced among the other groups of songbirds. The nectar-feeding birds form highly advanced groups of their own.

Among other authors, Sibley particularly (1976, 1983) has added a new aspect to the systematic arrangement of songbirds by expressing the view that many of the characteristic Australian songbirds have no direct relatives in the other continents, but instead represent ecologically diverse groups comparable to those found in the diversity of Australian marsupials. Similarities between many Australian birds and groups or families occurring in other continents therefore are to be considered as having resulted from parallel or convergent evolution. In addition to the main groups (1), (2), and (3), a fourth group of Old Australian Endemics (e.g. Maluridae, Acanthizidae, Neosittidae) has to be accepted. A secondary radiation of Australian crow-like Endemics (e.g. Callaeidae, Grallinidae, Cracticidae, Paradisaeidae) adds a further dimension to the basic group (3). Numerous details of this theory remain obscure, but the theory in itself is fascinating and illuminating. K.H.V.

See also references under CLASSIFICATION.

PASSERINE: appertaining to the order Passeriformes; commonly used substantively for species belonging to that order, members of all others being collectively called 'non-passerines' (see PASSERIFORMES). The form of the word would also admit of its being applied in a restricted sense with reference to the subfamily Passerinae, but to obviate confusion this is better avoided.

PASTOR: substantive name of the Rosy Pastor (or Rose-coloured Starling) *Sturnus roseus* (see STARLING).

PATAGIAL TAG: see MARKING.

PATAGIUM: see METAPATAGIUM; PROPATAGIUM; WING.

PATELLA: the 'knee-cap', not present in all birds (see LEG; SKELETON, POST-CRANIAL.

PATRISTIC: term sometimes applied in taxonomy to resemblances between forms due to common ancestry, as distinct from resemblances due to convergent adaptation (see CONVERGENCE).

PAURAQUE: substantive name of *Nyctidromus* and *Siphonorhis* spp. (for family see NIGHTJAR).

PEACOCK: see below.

PEAFOWL: substantive name of *Pavo* spp. and also of *Afropavo congensis* (and there are also 'peacock pheasants' *Polyplectron* spp.)—see PHEASANT. 'Peacock' and 'peahen' are special names for male and female, but the former may also be used irrespective of sex.

PEALEA PHENOMENON: the occurrence of 'spotting or streaking as variations from the normal plumage pattern' in some species of storm-petrels (Hydrobatidae). Specimens showing this and at one time ascribed to a supposed form '*Pealea lineata*' were later found to belong to 3 otherwise well known species.

Murphy, R.C. & Snyder, J.P. 1952. The 'Pealea' phenomenon and other notes on storm petrels. Amer. Mus. Novit. no. 1596: 1–16.

PECKING: see BEHAVIOUR, DEVELOPMENT OF.

PECK-ORDER: see DOMINANCE (2).

PECTEN: a structure on the retina of the avian eye (see VISION).

PECTINATE: provided with a serrated (comb-like) edge, as on the inner aspect of the claw on the middle toe of some species and on the sides of the toes in certain Tetraoninae (see under LEG).

PECTORAL: pertaining to the breast (see TOPOGRAPHY); for pectoral girdle see SKELETON, POST-CRANIAL.

PEDIONOMIDAE: see under GRUIFORMES; PLAINS-WANDERER.

PEDIUNKER: name for the Grey Petrel *Procellaria cinerea*, see PETREL.

PEEP: see SANDPIPER.

PEEWIT: see PEWIT; PLOVER (1).

PELAGIC HABITAT: see OCEANIC BIRDS.

PELECANI; PELECANIDAE: suborder and family of PELECANIFORMES; PELICAN.

PELECANIFORMES: an order, alternatively 'Steganopodes', comprising 3 suborders: Phaethontes, Pelecani, Fregatae; 6 families: Phaethontidae (TROPICBIRD), Sulidae (GANNET), Phalacrocoracidae (CORMORANT), Anhingidae (DARTER), Pelecanidae (PELICAN), Fregatidae (FRIGATEBIRD).

The order is one of mainly fish-eating birds of substantial size, characterized by having all 4 toes connected by a web (totipalmate), the hallux being turned forward and connected with the second digit. Except in the families first and last named above, the 8th and 9th of the 17–20 cervical vertebrae are so shaped that they articulate at an angle with those in front and behind.

PELECANOIDIDAE: family of PROCELLARIIFORMES; PETREL.

PELICAN: substantive name of all species of *Pelecanus* of the family Pelecanidae (Pelecaniformes, suborder Pelecani).

Pelecanus includes 7 species, divided into 3 groups: (1) Great White Pelican *Pelecanus onocrotalus*, Dalmatian Pelican *P. crispus*, Australian Pelican *P. conspicillatus*, and American White Pelican *P. erythrorhynchos*, all large, feed in groups, nest in dense colonies on ground, and never roost in trees; (2) Grey or Spotted-billed Pelican *P. philippensis* and Pink-backed Pelican *P. rufescens*, both smaller, usually feed singly, normally nest in trees in loosely packed colonies, and perch at roost in trees; and (3) Brown Pelican *P. occidentalis* which dives for its food. Sometimes *P. crispus* is included with *P. philippensis* but differences in nesting, feeding behaviour and morphology make this invalid.

Characteristics. Pelicans are large (140–180 cm) aquatic birds with a heavy body, long neck, large head and long, straight bill. The upper mandible is flat with a medium ridge, hooked at tip; the lower is loosely articulated and flexible with a suspended, extensible gular pouch. The wings are long and broad; the tail, short and rounded. Except for the Brown Pelican, the plumage is mainly white with areas of grey, brown and black. The face, throat and orbital area are bare. At courtship the American White Pelican develops a horn-like growth on the bill; the Great White Pelican has a swollen forehead, yellow in the male, orange-red in the female. All species develop startling secondary sex characters in the colours of the head, face and pouch. The sexes are similar, the male usually being larger.

Habitat. All inhabit inland fresh and brackish lakes and coastal waters except Brown Pelicans which are restricted to coastal marine habitats.

Distribution. Pelicans are pantropical and subtropical. In the New World, the Brown Pelican occurs along the Pacific coast from Washington to Chile and Galapagos and along the Atlantic from North Carolina to the Gulf of Mexico and Caribbean to Guiana. The American White Pelican is found from northern Alberta and Manitoba south to coastal Mexico and Guatemala east to Florida. In the Old World, Great White Pelicans range from Africa and south-east Europe to south-east China and the Malay Peninsula. The Dalmatian Pelican occurs from south-east Europe to Mongolia and northern China south to Iran and northern India. The Pink-backed Pelican occurs in Africa (south of about 20°N), Madagascar and south-west Arabia. The Grey Pelican inhabits India, southern China, and the Philippines south to the Malay Peninsula and Indonesia. The Australian Pelican occurs throughout Australia in suitable habitats, and in Tasmania and New Guinea.

White Pelican *Pelecanus onocrotalus*. (*J.B.*).

Populations. Colony size varies from a few individuals to many thousand pairs. Generally pelicans have declined markedly in range and numbers due to pesticides, drainage, and sensitivity to disturbance.

Movements. Pelicans fly in V-formation, in lines or single file, often travelling one behind the other with the leader beating wings or gliding, the rest doing likewise. Pelicans also circle high in thermals and soar for considerable distances. Certain pelican populations undergo post-breeding dispersal, with some travelling long distances.

Food. The diet is fish and sometimes crustaceans. Most species are surface-feeders, catching fish with the pouch. When the bird puts its bill into the water, the lower mandible expands into a broad scoop. The pelican traps the fish in the pouch under water, raises its head to drain water from the pouch, then swallows the fish whole. Sometimes pelicans transport fish in a partially digested state.

The Pink-backed and Grey Pelicans usually swim singly or in small groups and, upon sighting prey, dart out their head and neck to catch fish. The larger species often use a herding technique when groups of 5 to several hundred swim forward, often in U-formation with the open end directed forward towards the beach or shallow water. As the group moves along, several partly raise their wings and simultaneously plunge their heads into the water. Each successful bird raises its bill upward and swallows fish. The Brown Pelican dives to catch fish under water.

Behaviour. Pelicans are gregarious all year in groups of a few to several thousand individuals. Their non-breeding behaviour, as typified by the Brown Pelican, includes wing- and body-shake; tail-wag following landing in water or sitting on nest; bill-toss after preening; wing-flap for balance, comfort movement, or reaction to disturbance; wing-and-leg-stretching; glottis-exposure and bill-throw for stretching gular pouch and tissues of throat and upper breast; scratching head, neck, and pouch; bill-plunge to moisten gular pouch and to drink; head-rub to maintain head and neck feathers; preening; bathing; walking; swimming; gular flutter and spreading wings in response to temperature changes; and sleeping.

Pelicans appear to arrive at the nesting area unmated. In tree-nesting species the male occupies a potential nest site where he sways the head and bill through a figure-8 (head swaying); arches neck away from body and points bill downward (bowing); turns head from side to side (head turning); raises bill toward horizontal position, stretches gular pouch taut, spreads wings and sometimes opens bill (upright); and throws bill over back, thrashes wings and claps mandibles (bill-clapping, Pink-backed Pelican). The female initially selects the male, and also performs the above displays. No obvious behaviour precedes copulation. In ground-nesting species the displays are similar; in addition, males and females may swim, walk or fly in groups or walk along shore with head held high, sometimes with wings partly spread (strutting walk); males may gather in groups where they raise bills skyward (upright or head-up), make 'mooing' sounds, then thrust bills toward centre of group (bowing). The female selects the nest site.

Voice. Pelicans are usually silent except at breeding colonies. There some produce only an expulsion of air from the lungs during bowing and upright displays, while others produce *moo, ha-oogh* and deep grunts. Young make screaming and wailing sounds when soliciting food.

Breeding. Pelicans are colonial breeders, nesting in trees or on ground free of mammalian predators. Tree nests are large structures of dry sticks, sometimes 30 m above ground. Ground nests are small depressions, sometimes with sticks, leaves, reeds and pebbles. The male collects the nest material, the female builds the nest. In the tropics the nesting season may extend over several months, with some colonies peaking in rains, others in dry season. Usually 2–3 eggs are laid; they are large and elongated with a chalky coating. Incubation lasts 30–37 days, begins with the first egg, and is shared by both parents.

The newly hatched young are pink and naked, turn black or grey within 4–14 days, and thereafter develop a coat of white, grey or blackish down. After about 3 weeks, the young of ground-nesting species collect in crèches (pods). The young are cared for and fed by both parents. Small young are fed on partially regurgitated food; from about one week on, the young bird puts its head into the parent's pouch and feeds itself. Young pelicans take 70–80 days to reach the flying stage.

PELLET: a compact mass composed of those undigested portions of a bird's food that have been retained in the stomach by a mechanical barrier for a period before being regurgitated and ejected through the mouth, rather than evacuated as faeces; sometimes described as 'castings'. They vary considerably from species to species with respect to size, colour, shape, and the proportion of prey fragments that can be identified, but they form an important research tool for ornithologists when examining an individual bird's feeding tastes and variations in diet with season, year, region and habitat.

The physiology and mechanics of pellet formation have been examined using radio-active tags but there is scope for further studies. Pellets are composed of materials of relatively low nutritional value, while those produced by starved birds in captive conditions show a greater degree of digestion than is normal in the wild. Pellet ejection may be immediate and apparently 'effortless' or may take as long as an hour with apparent 'nausea'. The process often consists of several upward stretches of the head and neck—convulsive movements—followed by a lowering and, especially in passerines, shaking of the head, with the pellet expelled up to 1 m or more.

Pellets are most commonly associated with birds of prey (and notably owls) because their ability to digest bone is poor while the skeletal record in their pellets is good so that the diet may be accurately quantified. Pellet production has been widely observed in birds, covering some 330 species and more than 60 families (International Bird Pellet Study Group) including unlikely groups such as jays (Corvidae), flycatchers (Muscicapidae) and honeyeaters (Meliphagidae). Pellet ejection has also been recorded in certain mammals, reptiles and amphibians.

Most pellets produced by large birds comprise a central core of hard materials such as bones, beaks, claws, scales, teeth and chitin, enveloped by softer substances like fur, feathers and, less often, vegetable matter. Lengthy hard food fragments such as bird beaks, legs, and mammal long-bones tend to be aligned with the longitudinal axis, the majority of pellets being elongate and oval in shape, fewer rounded or segmented.

The contents of pellets are naturally determined first by the spectrum of food eaten; second, by the digestive ability of the species concerned. Owls usually swallow food items entire and their pellets contain the great majority of all bony elements and good evidence of most invertebrates eaten. Diurnal raptors are not so helpful to the analyst—they tear flesh and bone, digest much bone, frequently only partially consume a prey item, so that the pellet record is incomplete. Herons (Ardeidae) regurgitate fur castings with little or no bony evidence of fish, amphibian or mammalian foods. The pellets of other birds may be dominated by single items such as corn husks (Rook *Corvus frugilegus*), wax (Honey Buzzard *Pernis apivorus*), fish bones (Kingfisher *Alcedo atthis*), sand (Dipper *Cinclus cinclus*), chitinous insect hard-parts (Spotted Flycatcher *Muscicapa striata*), crustacean and mollusc fragments (some waders—Scolopacidae).

Pellets often also contain the unexpected. Scavenging gulls (Laridae) are notorious for the range of bizarre binding materials like cellophane, paper, plastic and rubber incorporated. Pellets can be important sources for the recovery of bird rings, especially those cast by regular small-bird feeders like Kestrel *Falco tinnunculus*, Short-eared Owl *Asio flammeus*, and Long-eared Owl *A. otus*. Other predators like the Barn Owl *Tyto alba* are very effective aerial 'samplers' of small mammal populations, indicating the presence of scarce or rare species and allowing large quantities of mammal bones to be collected far quicker than by normal trapping techniques.

The ease with which pellets can be collected varies greatly from species to species. For most passerines one needs to witness the characteristic 'retching' behaviour before searching. Regular visits to the loafing sites of homogeneous groups like gulls and waders can prove productive. Regular roosting sites and occupied nests are otherwise the best sources of material, the last resort being an examination of the stomach contents of dead birds.

Fresh pellets are usually damp and soft in texture with a surface mucous layer. This hardens quickly to produce a glossy varnished appearance (Barn Owl). Moisture may comprise 60% of the total initial pellet weight which is rapidly lost by evaporation. The rate at which pellets decompose depends on the species of bird, season, location and the micro-fauna and flora. Barn Owl pellets regurgitated in the protected environs of a dry barn may remain intact for many months, sometimes even years, while Tawny Owl *Strix aluco* pellets cast in damp woodland vegetation may be rain-leached or ice-shattered in a few days. Pellets composed of vegetable matter such as husks and seeds or fragments of insects, crustacea, or molluscs, are prone to an early breakdown.

The most important decomposers of fur and feather castings are certain tineid moths, trogid beetles, mites and saprophytic fungi. The insects especially feed in their larval form on the fur and feather matrix, and pellets may soon crumble into small piles of bones which are easily scattered or buried. A productive exercise is to scrape away earth at traditional nesting places or beneath pellet 'ejection posts' to reveal an historical layer of buried bones. 'Fossilized' pellets have been found during archaeological excavations and helped throw light on the past distribution of small mammals.

Pellets can be dissected in a dry or wet state, though most analysts prefer first to soak the material in a shallow tray of warm water before

Marsh Sandpiper *Tringa stagnatilis* bringing up a pellet. (*Photo: J.F. Reynolds*).

separating the contents with needles or forceps. A pocket lens or low-power microscope is necessary to identify the prey fragments with the aid of a reference key.

For large quantities of pellets a centrifuge may profitably be used to separate the hard and soft elements. Pellets are best preserved dry and entire by an early spray with a strong insecticide followed by several coats of a quick-drying polyurethane. The dissected contents may be stored in glass files or mounted on stiff cardboard. Pellets are excellent ecological tools for the educationalist wishing to demonstrate the principles of food preferences, food chains, and energetics. D.E.G.

PELVIC GIRDLE: see SKELETON, POST-CRANIAL.

PEN: special term for a female SWAN.

PENDULINE TIT: substantive name of *Remiz pendulinus* (Passeriformes, suborder Oscines); in the plural general term for the family Remizidae, formerly included in the Paridae (see TIT). There are 10 species in 4 genera.

Characteristics. The penduline tits are active birds from 8–14 cm long. They share many characteristics with the true tits, but have finer, more pointed bills and are even more acrobatic, being able to climb upside down along the underside of branches. The plumage of *Remiz* is basically pale buff, chestnut and black, and shows considerable variation within populations and between races. The kapok tits *Anthoscopus* are mostly brown and yellow, and the Verdin *Auriparus flaviceps* is yellow and grey with a rusty patch on the carpal area.

Habitat. Most species are found in open, scrubby areas where they are resident throughout the year, although some are nomadic outside the breeding season.

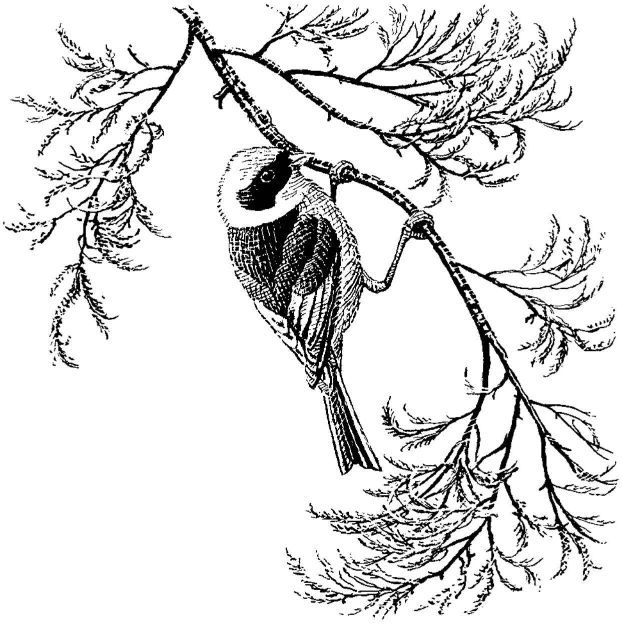
Distribution and systematics. *Remiz* (monotypic) is discontinuously distributed across the Palearctic from the Atlantic to the Pacific; the kapok tits (*Anthoscopus*, 7 species) are found in dry bush habitats over most of Africa south of the Sahara. In North America the Verdin is restricted to the semi-deserts of the south-western United States and northern Mexico. The Fire-capped Tit *Cephalopyrus flammiceps* is found in the evergreen forests of the Himalaya. Although structurally very similar to the other Remizidae and using the same highly developed acrobatic foraging and food-handling techniques (Löhrl 1967), its main affinities may lie with the true tits.

Food. All species mainly feed on invertebrate prey taken from the outer twigs and branches of trees and bushes, supplemented with seeds and fruit.

Behaviour. Most species are generally found in flocks, but the Verdins are solitary outside the breeding season, and it has been suggested that they may have closer links with the Bananaquit *Coereba flaveola* than with the Remizidae (Taylor 1970).

Voice. Songs are generally poorly developed but the species which flock have sharp, monosyllabic contact calls.

Breeding. The 2 widely distributed Old World genera, *Remiz* and *Anthoscopus*, build similar, pendulous domed nests of vegetable down and breed as groups rather than distinct pairs. *Remiz* nests are suspended from twigs and generally about 5 m above water. Nest-building is started by the male weaving a foundation loop of grasses and roots on which the felted nest is built over a period of weeks. The main material used is pappus from willow *Salix*, poplar *Populus*, reed-mace *Typha* or willow-herb *Epilobium*. The 5–10 white eggs, incubated by the female, hatch after about 12 days and the young fledge 16–18 days later. *Anthoscopus* nests have a prominent false entrance and dummy chamber with the real entrance capable of being closed by the birds. Vegetable down is generally the main nesting material but animal hair may also be used. The clutch consists of 3–6 white eggs, a few less than *Remiz*, and the hatching and fledging periods are a little longer. In both genera the breeding groups may roost together in the nest, and may have co-operative breeding. The Verdin does not have helpers at the nest, and only one of the 3 races uses vegetable down; the other 2 weave their nests from thorny twigs. All Verdins start nest-building from a platform lodged in the outer part of a bush and not from a hanging loop of pliable material. From 3–6 blue-green speckled eggs are laid and the young fledge some 3 weeks after hatching. The Fire-capped Tit lays a clutch of 3 or 4 pale blue-green eggs in a lined hole in a tree. C.J.M.



Penduline Tit *Remiz pendulinus*. (*D.W.*).

PENGUIN: substantive name of all species of Spheniscidae, sole family of the order Sphenisciformes. Penguins are flightless sea birds of the Southern Hemisphere highly adapted for marine life. They range in weight and stature from birds of about 1 kg and 40 cm body length to 30 kg and 115 cm.

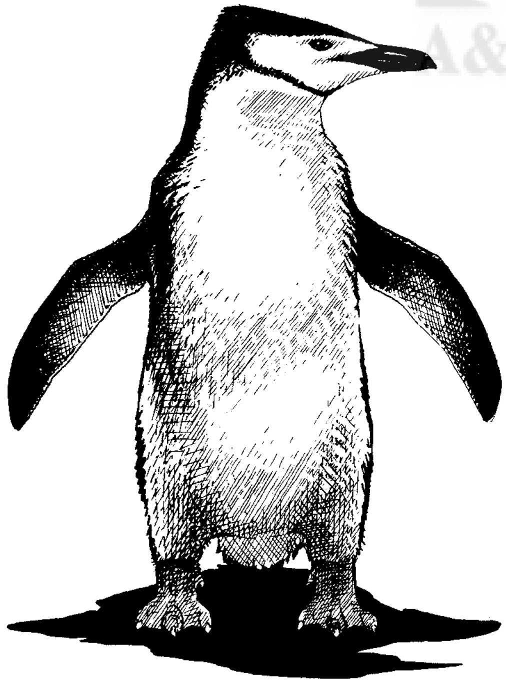
Characteristics. Despite their variation in size, and with breeding habitats ranging from the bare lava shores of equatorial islands through cool temperate forests, sub-Antarctic tussock grassland and beaches to Antarctic sea ice, penguins are remarkably similar in structure and plumage. They are all chiefly blue-grey or blue-black above and mainly white below; specific distinguishing marks are chiefly on the head and upper breast, visible while swimming on the surface. The main chick plumages are grey or brown uniformly or with one of these colours dorsally and white ventrally. Juvenile plumage is usually very similar to, but distinguishable from, that of adults. Most species are slightly sexually dimorphic; penguins of the genus *Eudyptes* notably so.

They lack defined feather tracts (unlike most birds; see PTERYLOSIS) and short specialized feathers closely cover the body surface. Their bodies are highly streamlined, the wings reduced to strong, narrow, stiff flippers, with which they swim rapidly. The feet and tarsi are short, the legs set well back on the body, being used, with the tail, as rudders. On land penguins frequently rest on the short tarsometatarsus (heel) with the stout rectrices forming a prop. The short legs induce a waddling gait but on ice penguins can move rapidly by tobogganning. Penguins have comparatively solid bones and they generally weigh only a little less than the water they displace, reducing the energy required to dive. The duration and depth of dives varies greatly but the Emperor Penguin *Aptenodytes forsteri* can submerge for 18 min and reach at least 265 m, while even small species may stay down for 6 min and reach nearly 100 m; typical values, however, are very much less than these. Swimming speeds probably range from 2–3 knots up to perhaps 15–20 knots in short bursts. Swimming often involves porpoising, whereby the bird breaks the surface with its momentum carrying it through the air for a metre or so before re-entering the water. This may facilitate breathing while travelling fast and may also confuse potential predators. The basic physical adaptations of penguins are thus concerned with swimming efficiently and also with thermal insulation. In addition to the dense waterproof feather coat, there is a well-defined fat layer and a highly developed vascular counter-current heat exchange system in the flippers and legs. All these are best developed in species of high latitude but are found even in temperate and tropical penguins which live in regions of cool water currents. When on land, however, these adaptations may lead to problems of overheating. It is significant that the species of warmer latitudes have relatively larger flippers and areas of bare facial skin as adaptations to dissipate excess heat. In addition they live in burrows to reduce direct insolation.

The fossil record of penguins begins in the late Eocene (45 million years BP) and about 32 species are currently recognized. Most were between 50 cm and 1 m tall (much as living species) but 2 or 3 species were probably about 150–160 cm tall and may have weighed 135 kg. Their distribution was similar to that of living species, with most specimens coming from (in order of importance) New Zealand, Patagonia, Antarctic Peninsula, South Australia and South Africa. The fossil record provides no direct indication of the origins of penguins (though they presumably passed through a stage combining flight and underwater swimming like the auks of the northern hemisphere which are their nearest ecological equivalent) but one firm line of evidence suggests a very distant relationship to the Procellariiformes.

The 16–18 living species (depending on whether the Royal Penguin *Eudyptes (chrysolophus) schlegeli* and the White-flippered Penguin *Eudyptula (minor) albosignata* are regarded as full species or not) are divided into 6 genera. Most species are currently found between 45°S and 60°S, with the greatest species diversity in the New Zealand area and the Falkland Islands; the main numerical concentrations, however, are around the coasts of Antarctica and on the sub-Antarctic islands. The biology and adaptations of 4 of the 6 genera are reviewed later; only the general patterns are summarized below.

Distribution. The genus *Aptenodytes* comprises the 2 largest penguins, Emperor *A. forsteri* and King *A. patagonicus*; they are completely allopatric, the former breeding on the sea ice around the Antarctic Continent, the latter breeding at most sub-Antarctic and cold temperate islands. The 3 species of the genus *Pygoscelis* include 2 circumpolar ones, Adélie *P. adeliae* around the Antarctic Continent and Gentoo *P. papua* at the sub-Antarctic islands. These 2 species overlap in the Antarctic Peninsula area where the third species, Chinstrap *P. antarctica*, occurs in considerable numbers, principally between the centres of abundance of the other 2.



Chinstrap Penguin *Pygoscelis antarctica*. (*B.P.*).

The Yellow-eyed Penguin *Megadyptes antipodes* is ecologically similar to the Gentoo and essentially replaces it at the New Zealand sub-Antarctic islands (not Macquarie Island where Gentoo occurs) and South Island mainland.

Of the crested penguins, 3, the Fiordland *Eudyptes pachyrhynchus*, Snares Crested *E. robustus* and Erect-crested *E. sclateri*, have allopatric breeding ranges and are confined to the same area as *Megadyptes* but the other 2 species, the Macaroni *E. chrysolophus* and Rockhopper *E. chrysocome*, have wide circumpolar distributions occurring together at several sub-Antarctic islands.

The 4 species of the genus *Spheniscus* span the greatest longitudinal range with the Galapágos *S. mendiculus* at the Equator, the Humboldt *S. humboldti* from equatorial Peru to central Chile (entirely within the cool Peruvian current), and the Magellanic *S. magellanicus* in southern South America and its off-lying islands, including the Falklands. The only African penguin, the Jackass *S. demersus*, is confined to the coast of South and South-west Africa, influenced by the cooler waters of the Benguela and Agulhas currents. The genus *Eudyptula*, ecologically similar to *Spheniscus*, has a single species, the Little Blue *E. minor*, the smallest of the family, throughout New Zealand and much of the south coast of Australia and a closely related species or subspecies, the White-flippered *E. albosignata*, on the east coast of New Zealand's South Island.

Movements. Winter distributions and movements are imprecisely known. The tropical and warm temperate species are sedentary. Most eudyptid species and southern populations of Gentoo and Magellanic Penguins disperse widely (and generally northwards) in winter but northern populations are chiefly resident. Antarctic species move at least to the pack ice edge in winter. Juveniles disperse widely after fledging and there are many records far from breeding sites.

Food. Crustaceans, fish and squid are the main prey of penguins. Fish are important in the diet of inshore feeding species, e.g. *Spheniscus* species, Little Blue and Gentoo Penguins and also of the deeper diving King and Emperor Penguins. Squid perhaps predominate in the food of the King Penguin and seem fairly frequently taken by Emperor and Rockhopper Penguins and some spheniscids. Euphausiid crustaceans (krill) are the principal prey of perhaps all pygoscelid and most eudyptid species and are certainly taken by all Antarctic penguins. When feeding chicks, individuals of most species are at sea exclusively or mainly during daylight hours but by diving they could follow any diel migration of their prey. The Little Blue Penguin is anomalous in not normally feeding its chicks until well after nightfall. As the smallest species it presumably has the shallowest diving capacity and may therefore be more dependent on crepuscular feeding, when a greater proportion of prey are near the surface. It may also be avoiding diurnal predators. Penguins may be assisted in prey detection by echolocation, using sonar based on cavitation clicks produced by their swimming movement.

Behaviour. Most penguins are highly social, both on land and at sea, and often breed in vast colonies, only defending the small area around the nest. Although all species have complex courtship and mate recognition behaviour, social behaviours are perhaps most developed in the densely colonial pygoscelid and eudyptid penguins. Of the latter, those species that breed in dense vegetation show less intraspecific interaction, presumably because, like *Megadyptes* also, their nests are farther apart. Despite living in burrows, spheniscid penguins, which usually breed in dense colonies, have fairly elaborate visual and vocal displays; *Eudyptula*, in which burrows are usually well dispersed, less so. Emperor Penguins, because of the physiological need to huddle when incubating, lack fixed territories and only defend their immediate living space (when not huddling). Individual recognition, whether of mates or offspring, is based mostly on calls but in burrowing species, and in others where chicks stay close to the breeding site after the brooding period ceases, nest site location is an important, if not a vital preliminary.

Breeding. Emperor Penguins breed in winter. King Penguin chicks overwinter at the breeding colony, but are rarely fed during this period and grow mainly during the previous and subsequent summers. Otherwise Antarctic and most sub-Antarctic and cold temperate penguins breed in spring and summer and their timing is highly synchronized within and between colonies. The Gentoo Penguin is least well synchronized and at Marion Island it lays in winter (June); this may reduce competition for food with the large number of eudyptid penguins there. The more temperate eudyptid species have a longer breeding season and its timing is more variable. In *Spheniscus* (except *S. magellanicus*) there are usually two main peaks of breeding but laying occurs in all months of the year. This is also true of most *Eudyptula* populations and in South Australia some pairs are able to raise broods successfully twice a year. Penguins usually mate with the partners of previous years: in a colony of Yellow-eyed Penguins 61% of pairings lasted 2 to 6 years, 12% 7 to 13 years and the overall divorce rate was 14% per annum; in a study of the Little Blue Penguin one pairing lasted 11 years and the divorce rate was 18% per annum. In a major Adélie Penguin study, however, no pairing lasted 6 years and the divorce rate was over 50%.

Royal Penguins breed first when at least 5 years old; Emperor, King, Gentoo and Adélie Penguins when at least 3 (♀) or 4 (♂) and Little Blue, Yellow-eyed and Jackass Penguins when at least 2 years old.

Only *Aptenodytes* penguins lay a single egg, the remainder normally laying 2 eggs, occasionally one (inexperienced birds where this is known) or 3. In the Yellow-eyed Penguin (and probably generally) age affected fertility so that hatching success in the study colony was 32%, 92% and 77% of eggs incubated by birds of age 2, 6 and 14–19 respectively. In eudyptids the first egg of the clutch is very much smaller than the second; only in Rockhopper and Fiordland Penguins do both eggs hatch and only one chick is ever reared. In other penguins hatching is also staggered and this can promote brood reduction, particularly in warmer water species, but even so 2 chicks are not infrequently reared.

All penguins have the capacity for storing substantial fat reserves (e.g. before the moult fast) but only the Emperor, King, Adélie and eudyptid penguins undertake long fasts in the courtship, incubation and brooding periods. During fasts lasting 110–115 days for male Emperor Penguins and 35 days for Adélie and eudyptid penguins up to 45% of initial body weight may be lost. By contrast Gentoo, Yellow-eyed, Little Blue and spheniscid penguins usually change incubation daily although in some species the female may incubate for more of each day. After the brooding period ceases the frequency with which chicks are fed increases. Intervals between meals are about 3 days for King and Emperor Penguin, about one day for Adélie and most eudyptids but in Gentoo, *Eudyptula* and *Spheniscus* both parents bring food each day. The rate of chick growth probably reflects the size of meals and the frequency with which they are delivered. This is presumably determined by food distribution and availability and it has also been suggested that intra-specific competition for food may affect both breeding success and the age (or level of experience) at which first breeding attempts are made. Reduction of interspecific competition between penguins is thought to be achieved by differences in prey type, foraging range and timing of breeding season. Chicks grow rapidly (though initially rather slowly in the Emperor Penguin), particularly in Antarctic species and the Macaroni Penguin among sub-Antarctic species. After 2 to 3 weeks (6 weeks in *Aptenodytes*) the chicks of species breeding in open areas form large aggregations (Adélie, Gentoo, *Aptenodytes*) or small ones involving a few chicks from adjacent nests (Chinstrap, Jackass, *Eudyptes* spp.).

Moult. In most species, once chicks are independent, the parents fatten quickly for a moult fast of 2–6 weeks depending on species. The daily energy cost of moult is about twice that of incubation. Jackass and Galapágos Penguins show a less well defined moult period; moult occurs at any time between breeding attempts. In other species immature birds usually complete moult before breeding birds start and at least in eudyptid penguins the timing of moult becomes later with age until the first breeding attempt is made.

Populations. Compared with other seabirds, annual survival of adult penguins is relatively low, being at least 69% for Adélie, 86% for Royal, 87% for Yellow-eyed and 86% for Little Blue Penguin, but 95% for Emperor Penguin. Longevity may well be inversely related to breeding success (including juvenile survival) which is high in most Antarctic species except Emperor Penguin, where only 19% of fledglings survive their first year of life. Some penguin populations in the Antarctic Peninsula area have increased substantially in numbers, e.g. Chinstrap Penguin has increased fivefold in 30 years at some established sites, while Adélie Penguin has doubled in the same period. This is attributed to greater availability of krill due to the drastic reduction in stocks of Antarctic krill-eating whales. In contrast Jackass and Humboldt Penguins have decreased markedly, chiefly because of human activities like egg and guano collection and commercial fishing. Yellow-eyed Penguins and some Adélie Penguin populations have declined due to increased human interference. J.P.C.

Aptenodytes. This genus comprises the 2 largest living penguins. The Emperor Penguin stands well over 1 m tall and weighs 20–40 kg; the King Penguin nearly 1 m tall but weights only 10–20 kg. Their plumage is very similar, blue-grey above, white (King) or yellowish (Emperor) below with conspicuous golden or bright yellow auricular patches and orange or violet-blue mandibular plates.

Both species have a circumpolar distribution. The Emperor Penguin has the most southerly distribution of any penguin (all colonies being south of 65°S), and as it breeds in winter, faces some of the most extreme climatic conditions for breeding of any bird. The low mean winter temperature (−10 to −20°C), high winds (mean 40 km h^{-1} but reaching 150–200 km h^{-1} at some colonies) and blown spindrift snow combine to produce an environment where heat loss can be critical. There are about 26 known colonies, mainly on the coasts of Enderby, Wilkes and Victoria Land; all but two are on fast sea-ice and most are backed by an ice-cliff providing shelter from wind. They range in size from Coulman Island with *c.* 25,000 pairs to the Dion Islands with only 500; the world breeding population is estimated at 200,000 pairs.

In contrast King Penguins lay in summer (but take a year to raise a chick) on flat or gently sloping ground at sub-Antarctic islands. The world breeding population is about one million pairs with the largest concentrations at the Indian Ocean sub-Antarctic islands (Prince Edward Islands, Crozet Islands) but they breed as far south as South Georgia and the recently re-colonized Heard Island.

Data on pelagic movements and distribution outside the breeding season are lacking. Emperor Penguins seem rarely to move outside the Antarctic Circle but stray birds (mainly immature) have reached Tierra del Fuego, Falkland Islands, southern New Zealand and many sub-Antarctic islands. King Penguins ringed at Iles Crozet have been retrapped at Macquarie and Marion Islands.

Both species have been recorded as eating squid, fish and crustaceans, but it is probable that squid and fish form the bulk of Emperor Penguin diet in the breeding season and of King Penguins at least in autumn and spring.

Both *Aptenodytes* species raise large chicks which become independent by the Antarctic mid-summer when food resources are at their most abundant. They have tackled this problem in quite different ways; the King Penguin by taking over a year for a successful breeding attempt and the Emperor Penguin by breeding in the cold, dark Antarctic winter. The latter is possible only with a remarkable conjunction of physiological and behavioural adaptations.

An Emperor Penguin's body size and shape combine to provide a relatively low surface to volume ratio (important for reducing heat loss) and in addition its appendages (flipper, bill) are 25% smaller in proportion than in any other penguin. Heat loss is further reduced by extreme proliferation of the vascular counter-current heat-exchange system and excellent insulation is afforded by the very long double-layered, high density feathers which even extend to cover the tibio-tarsi. All these combine to establish a lower ambient critical temperature (below which metabolic rate must be increased to maintain body temperature at a constant level) of −10°C with wind speed of up to 18 km h^{-1}.

Even though the size of the Emperor Penguin permits it to store proportionately large fat reserves, these would be insufficient to cope with the demands of long fasts in prevailing winter conditions. However a 25–50% reduction in individual heat loss is achieved by adults and chicks huddling in large groups (up to 5,000 birds at 10 per m^2) and reducing activity to a minimum. This behavioural adaptation is fundamental in permitting Emperor Penguins to breed during the Antarctic winter. Such social behaviour during breeding is unique among the otherwise highly territorial males of the family and is feasible only because of their ability to move with the egg on their feet and cover it (and the young chick) with the pouch-like fold of abdominal skin. Although King Penguins incubate in a similar fashion, they breed with constant inter-individual distance and also lack such extreme physiological specializations, presumably because temperature and wind chill effects rarely exceed their lower critical temperature of −5°C. Chicks, however, frequently form dense huddles in winter.

In the Emperor Penguin, in addition to sex-specific differences, there is a very clear individual variation in calls which, in a species lacking any fixed nest site or territory, is the basis for mate and parent-offspring recognition. In the King Penguin, which has a relatively fixed incubation site, although sex-specific differences are retained, individual variation of calls is much less marked.

For Emperor Penguins the breeding season commences with courtship and copulation in March-April, following 2 months at sea laying down substantial fat reserves. Females leave after laying in mid May, having lost 25% of body weight in the 6 week fast while ashore. Only males incubate (for 62–64 days) and also feed the chick for a few days (on an oesophageal secretion comprising 60% protein and 28% lipid) if the return of the female is delayed. During their 110–115 day fast males lose up to 45% of their initial body weight. The female broods the chick for 40 days and thereafter both parents rear the chick through the winter, the chicks themselves forming tight huddles. While losses at the egg stage are fairly consistent (4–16%) between years, chick losses are more variable (usually 4–30% but exceptionally up to 90%) and reflect the variation in winter conditions. Chicks depart in December at only 60% of adult body weight, the lowest figure for any penguin, presumably because the adults need the remaining time to moult and return to breeding condition by the end of the summer. Only 19% of fledglings survive their first year of life. However, Emperor Penguins may breed first at 3 years of age (although many do not do so until age 6) and mean annual survival from age 2 is 95%. Life expectancy from fledging is about 20 years.

King Penguins start laying in late November and continue until mid April although there are pronounced peaks at the beginning and towards the end of this period. Eggs hatch in 55 days and incubation duties are shared by the parents in 5-day shifts after an initial 14-day shift by the male. Early breeders raise their chick to 80% of adult weight by June and feed it sporadically (fasts of 2 months or so with a weight loss of about 40%) until September when regular feeding resumes until the chicks depart in November-December. The adults then moult and usually lay again in February-March. This time much smaller chicks overwinter (and many die) and finally fledge in January-February. Parents with this timetable cannot breed again until the following summer. After a breeding failure, however, many (but probably not all) birds postpone moult until the following September-October when it thus immediately precedes the next breeding attempt. This variety of breeding and moulting schedules ensures that in any colony at most times there are adults, eggs and chicks at many stages of moult, incubation and growth. The above account applies principally to South Georgia; at Iles Crozet it appears that most adults when successful breed only biennially. J.P.

Pygoscelis. A genus, of 3 species, with a circumpolar distribution in the Antarctic and sub-Antarctic. The species are *c.* 50–60 cm long and weigh between 4 and 8 kg. The Adélie Penguin breeds at numerous sites on Antarctica's coast and associated islands. Colonies range in size from less than 100 to at least 500,000 pairs and it is perhaps the most abundant of any penguin species. With the Emperor Penguin, it is the most southerly breeding penguin. The Chinstrap Penguin occurs in the northern Antarctic, principally in the region of the Scotia Sea and Antarctic Peninsula north of 65°S. The Gentoo Penguin has the most northerly distribution of the three. It breeds at a few Antarctic sites but mostly on sub-Antarctic islands near the Antarctic Convergence, for instance Crozet, Kerguelen, Marion, Prince Edward, South Georgia and Macquarie Islands. It is particularly abundant in the Falkland Islands.

Knowledge of the pelagic ecology of these species is virtually confined to the summer breeding period. In winter most populations of Adélie and Chinstrap Penguins must move north near to the limit of pack ice; their subsequent dispersion is unknown. The northern populations of the Gentoo, however, are relatively sedentary.

At all seasons the Gentoo Penguin is notably less pelagic than the others and the higher incidence of fish in its diet probably reflects this. Although some Adélie Penguin populations take many larval fish, euphausiids (particularly *Euphausia crystallorophias* around the periphery of the Antarctic continent and *E. superba* elsewhere) seem the most important prey for all 3 species and differences in foraging range and possibily size of prey eaten seem significant aspects of interspecific differences in feeding ecology.

More is known of the social behaviour of Adélie Penguins but most of their displays have somewhat similar counterparts in the other 2 species. Generally Chinstraps seem more aggressive and Gentoos more timid. In the Adélie Penguin breeding displays are most prevalent among young birds or older non-breeders; after egg laying breeders display rather little. The displays are affected by two important factors. First, these penguins are highly gregarious at sea and when breeding on land they maintain an almost inviolate individual distance and vigorously defend the space within pecking range of their nest. Second, partners associate for relatively few days in a breeding season shortened by the constraints of rigorous climate and high latitudes. There is thus a particular need for straightforward yet accurate communication. Within these constraints the repertoire of basic messages common to all higher vertebrates is present, with the possible exception of play. Individual birds vary greatly in aggression and this may relate partly to age. Some of the younger non-breeders who are physiologically mature enough to breed fail to do so until their social behaviour matures as well.

The breeding biology and behaviour of Adélie Penguins has been studied intensively. That of the other 2 pygoscelids is less well known but is probably rather similar, allowing for their more northern distributions and less intensive environmental constraints. Nesting is limited to snow- and ice-free areas and, because these are relatively rare in the Antarctic, there is much overlap in the type of terrain that the 3 species choose. Adélies seem to be the most selective, tending to build nests on exposed ridge tops. This may reflect the need in higher latitudes to avoid areas where drifting snow would cover nests or where melt water could inundate them. Chinstraps often prefer slopes, whereas Gentoos more often choose flatter areas closer to the beach, particularly at sub-Antarctic islands where drifting snow may be less of a problem.

Adélie Penguins arrive at their colonies a few weeks earlier in the spring than their relatives: September and early October in the Scotia Sea region, but late October in the Ross Sea which is much farther south. Males on average arrive a few days earlier than females. Unusually extensive pack-ice delays the arrival even of Adélies, since they walk over the ice much less rapidly than they swim.

Adélie Penguins fast throughout the territory establishment, courtship and egg-laying periods, thus reducing the number of times they have to walk between colonies and accessible feeding areas. Males remain for an additional 2 weeks to incubate eggs while females replenish their fat reserves by feeding at sea. Females incubate for about 10 days, then males for 5 or more days, and, at about the time the female next returns (about 35 days after the first egg was laid) the eggs hatch. With Chinstrap Penguins, which begin to nest after the pack-ice has become more broken up and has diminished in extent, the periods of fasting are shorter, and thus nest-reliefs more frequent, Gentoo Penguins have a daily change-over. The normal clutch for all 3 species consists of 2 eggs. A third egg will be laid only if the first is lost before the second is laid. Full incubation does not begin with the first egg; thus, although 2–4 days occur between laying of the eggs, the chicks hatch about 1–2 days apart.

If the pack-ice is more persistent than usual the returns of feeding Adélie Penguins are delayed, resulting in increased numbers of nest desertions as the fat reserves of incubating birds run low. This happens most often when the male is due for relief by the female at the end of his 5-week fast. The accelerating rate by which the ice disappears means that, even on the Antarctic Continent by early summer and the time eggs hatch, feeding trips take only 3 to 4 days and a week later are reduced to one to 2 days. The more frequent nest reliefs also correspond to the period of most rapid growth in the chicks. For the first 3 or 4 weeks one parent continually broods the chicks, but chick requirements become too great for one parent to sustain and both must forage simultaneously. Chicks then group together in crèches as a means to reduce predation from skuas *Catharacta* spp. At 7–8 weeks of age the chicks leave the colony of their own accord and go to sea. In most seasons each breeding pair averages less than one chick fledged. The fledging period is only slightly longer in the Chinstrap Penguin but is at least 12 weeks in the Gentoo Penguin whose actively swimming chicks are often still fed by their parents.

Age, and to some extent breeding experience, affect the breeding biology of Adélie Penguins. Very few one-year-olds visit the colony. Many 2-year-olds do so for a few days during the period of chick hatching, but most birds make their first visit as 3 and 4-year-olds and a few not until 5 years. With increasing age, up to about 7 including both breeders and non-breeders, birds arrive earlier in the season, make more visits and stay longer. Some females can first breed at 3 years of age, males at 4, but most females and males first breed at 4–5 and 5–6 years respectively. Most females have bred at least once by 5, but males have not all bred until 8. A year of previous breeding experience increases a bird's chances of breeding successfully. Birds that delay their first breeding to later years are often inept, breeding unsuccessfully or failing to breed more often than not. Most breeders are 5–10 years of age. Breeding is hazardous and only a few birds live as long as 18 years; the oldest birds even so tend to be those that first bred at a late age and to be non-breeders in several seasons thereafter. The high mortality among breeders (in which leopard seal *Hydrurga leptonyx* predation may be important) is apparently offset by high breeding success due to reliable and abundant food sources. D.G.A.

Eudyptes. A genus of medium sized (weight 2.6–6 kg), heavy-billed penguins differing from other members of the family in being highly sexually dimorphic, in having prominent yellow or orange crests on their heads, and in laying clutches of 2 eggs of very dissimilar size from which only a single chick is reared. There are 5 species (6 if the Royal Penguin *E. schlegeli* is considered a full species rather than a sub-species of the Macaroni *E. chrysolophus*) falling into 2 distinct groups: the large Royal and Macaroni Penguins (sometimes classified in the genus *Catarrhactes*) which have loose dull orange crests arising from the centre of the forehead and 14 rectrices, and the rest which are smaller, with more compact and lustrous yellow crests arising from superciliary stripes on either side of the head, and 16 rectrices.

All 5 species occur in the Australasian region and 3 are confined to New Zealand seas. The other 2 species, Rockhopper and Macaroni/Royal have a circumpolar breeding distribution at sub-Antarctic islands although the Rockhopper Penguin occurs further north (to Tristan da Cunha) and the Macaroni further south (to the South Shetland Islands).

Most species nest colonially in the open either on the coast or inland up to about 300 m. The exception is the Fiordland Penguin, which nests in dense, wet forest north of the Subtropical Convergence on the west coast of the South Island of New Zealand. In this forest environment it experiences considerably less extreme temperature and exposure compared with nesting in the open.

The more widespread species are very numerous and one world estimate for the Rockhopper Penguin was 4¾ million pairs. Some 2 million Royal Penguins nest at Macquarie Island and about 5 million pairs of Macaroni Penguins breed at South Georgia. Least abundant is the Snares Crested Penguin, estimated to have not more than about 50,000 birds at its sole breeding place on the Snares Island, south of New Zealand.

After moulting the non-breeding season is spent at sea. Some birds wander far, e.g. an Erect-crested Penguin from New Zealand to the Falkland Islands and a Rockhopper of the northern race to the Chatham Islands, New Zealand.

All species probably eat krill and *Euphausia superba* forms 80% by weight of the diet of Macaroni Penguins at South Georgia. It is possible that the difference in bill size of males and females may result in prey of different sizes being taken. Fish and squid make up the remainder of the diet and are of greater importance to the Rockhopper Penguin. In most species the chick is fed daily, on average, indicating that that the parents are able to forage extensively in continental shelf and slope waters.

All species are highly colonial on land and social at sea, only the Fiordland Penguin nesting in a rather dispersed pattern, but this is probably a consequence of the use of a forest habitat and there is nonetheless much vocal interaction among nearby nesting pairs. Crested penguins show a marked philopatry: young birds returning as yearlings usually to that part of the colony where they were born and breeding birds return to the same nest and partner during successive years, although some divorce does occur. A complex system of displays and vocalizations is used, including nearly 20 distinct displays.

Breeding takes place in the southern summer except for the Fiordland Penguin which lays in late winter. Maturity is delayed and each successive age group comes ashore earlier and stays longer. Few Royal Penguins less than 6 years old attempt to breed, success appearing to depend upon the parents' age and weight on arrival, and few birds less than 10 years old regularly rear young successfully. The breeding cycles all involve long fasts at the nests before laying (male arriving before female), followed by 10–15 day incubation stints when the on-duty bird again fasts. In all but the Fiordland Penguin the female incubates first, having been ashore for less time than the male. Hatching occurs after 31–37 days and with all the species the male then remains to guard the chick, not feeding it, but fasting for 2–3 weeks. The female alone brings food to the chick during this guard stage. The chick then enters a small crèche and the male leaves for the sea. Thereafter the chick is fed by both sexes, but still mainly by the female, for a total of about 60–75 days depending on species. The parents then depart to sea for between 14 days (Macaroni) and 70 days (Snares Crested), laying down fat reserves nearly equivalent to their original body weight, before a moult fast at the breeding colony lasting *c.* 25 days. All birds then go to sea, some having reached their minimum weight during the season.

Unique to this genus is the laying of first a small and then a large egg. For example, the second eggs of the Rockhopper, Snares Crested and Macaroni Penguins are 46%, 29% and 71% larger respectively than the first eggs of those species. Both eggs are viable but only one chick is reared. In contrast, the difference in egg size is only 17% with the Fiordland Penguin and in this species twins are often reared for a few days. Thereafter, as with the other species, the smaller chick dies; usually, but not always, the chick hatched from the smaller egg. Such a system may exist to cope with the high egg loss consequent on the considerable amount of fighting between neighbours, which in turn results from sexual selection favouring aggressive males. That the eggs are of different sizes ensures that if both hatch—as quite often occurs in the less concentrated colonies of the Fiordland Penguin (where fighting is correspondingly reduced) only one chick survives for long. If the eggs were of similar sizes then many similar sized twins might survive to the guard stage only for both to die when their food needs exceeded their parents' abilities to supply it. J.W.

Spheniscus. A genus of 4 medium sized (*c.* 3 kg weight) species of essentially low latitudes: the Galapágos Penguin breeding on two islands of this archipelago at the Equator, the Humboldt Penguin in Peru and Chile from 6°S to 34°S, the Magellanic Penguin breeding north to 32°30′S in western and 48°S in eastern South America and the Jackass Penguin breeding from southern Africa (35°S) north to 16°30′S on the west coast and 26°S on the east coast. They are basically sedentary species but southern populations of the Magellanic Penguin migrate northwards after breeding. This account is taken mainly from recent studies of the Jackass Penguin and the Galapágos Penguin.

All *Spheniscus* species breed in burrows dug with the feet in sand or under rocks and bushes but densely packed surface colonies of Jackass Penguins also occur. They are inshore feeders, restricted to continental shelf areas and their diet is mainly fish, often anchovy *Engraulis* sp. and pilchards *Sardinops* sp., though squid are also taken, at least by Jackass Penguins. At sea, Jackass Penguins forage in small groups and dive synchronously, often after a head-bobbing signal.

Diving depths or actual foraging techniques are unknown but deep dives are unlikely since they feed mainly on surface-shoaling fish. Two species, the Jackass and the Humboldt, occur in high productive upwelling systems that support large fishing industries. Populations of these 2 species have decreased alarmingly, initially due to egg removal and guano collection, subsequently due to competition for food; the fishing industries of the west coasts of South America and South Africa both 'prey' on the same species of fish as do the penguins. The survival of these 2 species is inextricably linked to the presence of the anchovy and pilchard and therefore to a compromise between exploitation and conservation.

The breeding displays of the Jackass Penguin resemble those of other non-*Aptenodytes* penguins. Adaptation for hole-nesting appears to have resulted in particularly loud raucous vocalizations. *Spheniscus* penguins engage in 'ecstatic displays' and 'mutual ecstatic displays' as do most penguin species. 'Beak-slapping', an aggressive display, occurs in Jackass and Galapágos Penguins and may be restricted to the genus; during 'beak-slapping' 2 birds (often mates) face each other and shake their heads rapidly so that the beaks slap together.

The Magellanic Penguin, with the most southerly distribution, has the most restricted breeding season and moult follows chick fledging. By contrast Jackass Penguins may breed in all months but 2 peaks a year are usually noticeable, the first following the annual summer moult. Galapágos Penguins may breed and moult twice a year (but sometimes not at all); again breeding follows moulting, an unusual pattern in birds.

Clutch size is one or (usually) 2 and 2 young may be reared. There is little difference in size between first and second laid eggs. Asynchronous laying and hatching leads to brood reduction by starvation of the younger sibling if the food supply is inadequate.

Being inshore feeders, *Spheniscus* penguins have no breeding fast; changeover at the nest is usually daily; prolonged incubation bouts of several days normally result in desertion. Jackass Penguin chicks may be fed several times a day, typically in the late afternoon or evening. When older, they are often left alone during the day and may form small crèches (usually not more than 5 chicks), and are then fed daily by both parents.

The chick-rearing period in the Jackass Penguin varies by as much as 40 days. The younger chick often stays at the nest for as long as 2 weeks after its elder sibling has left. During this period it is able to 'catch up' and even exceed its sibling's weight. Breeding success in Jackass Penguins varies with nest habitat and has been reduced historically by removal of the GUANO 'cap' in which birds once burrowed; surface nests are less successful, due mainly to enhanced predation. A similar trend has apparently occurred in the Humboldt Penguin. The Galapágos and probably the Humboldt Penguin's breeding season and success is related to the occurrence of warm water influxes (El Niño) and a decrease in upwelling. Similar changes in the degree of upwelling may affect the Jackass Penguin in parts of its range.

Jackass Penguins fledge at approximately ⅔ the weight of adults and undergo a juvenile dispersal to warmer waters, returning to moult into adult plumage at about one year of age—though this varies by many months. Breeding does not take place in the first year of adulthood, and not always in the second.

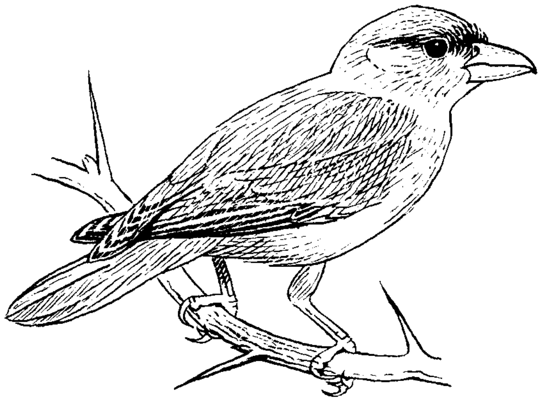
PENIS: male copulatory organ, present in a few kinds of birds (see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM).

PENNA: alternatively 'pennaceous feather', one in which the barbs form a coherent vane (see FEATHER; and compare PLUMA).

PEPPER-SHRIKE: substantive name of the 2 species of the subfamily Cyclarhinae of the Vireonidae (Passeriformes, suborder Oscines); in the plural, general term for the subfamily. This is a Neotropical group usually placed among (as here) or close to the vireos. Pepper-shrikes are heavily built birds, 15–18 cm long, with large heads and powerful bills strongly hooked at the tip. The wings are short and the flight is weak; the plumage is loose in texture. The better-known species, the Rufous-browed Pepper-shrike *Cyclarhis gujanensis*, has a wide range from southern Mexico south to Uruguay; the other, *C. nigrirostris*, is confined to Colombia and Ecuador.

The Rufous-browed Pepper-shrike is greenish above, with a red-brown steak through the eye, grey crown, and yellow breast. It is a bird of open woodland, cultivation, and second growth; it lives in pairs and is sedentary. The food consists mainly of insects and other invertebrates, which the birds search for among the foliage of the middle levels and tops of trees. Pepper-shrikes hold down large prey with the foot and pull it to pieces with the bill, which is also well adapted for tearing open cocoons adhering to leaves and bark. The commonest call is a melodious but monotonous phrase of set pattern, like that of an Old World oriole (Oriolidae); this is uttered repeatedly from leafy cover where the bird itself is often difficult to see. The alarm calls are loud and extremely harsh.



Rufous-browed Pepper-shrike *Cyclarhis gujanensis*. (*P.J.K.B.*).

The nest is a semi-pendent hammock slung, like that of a vireo, from a fork of a tree or tall bush. The eggs, 2 or 3 in number, are pale cream or pinkish, spotted and blotched with brown. The part played by male and female in incubation is uncertain, but both sexes feed the young.

D.W.S.(1)

PERCHING: loosely, the act of standing (sometimes sitting) on some more or less elevated object, especially one providing only exiguous space; more particularly, doing this while gripping the perch with the feet. The Passeriformes are sometimes referred to as the 'perching birds' because their toes, and the flexor tendons actuating these, are notably adapted to gripping a small branch or similar object, e.g. taut wire (see LEG). Many other birds, however, are well able to perch, although lacking the particular specialization of foot structure. Others again can only stand on an object flatfooted, as they do on the ground, and have therefore limited powers of perching; some, of course, make no use of any kind of narrow perch, if indeed they stand in elevated positions at all. A few birds, e.g. nightjars, commonly perch along the axis of a branch instead of transversely. Distinct from perching is clinging to the roughnesses of a vertical or overhanging surface; to this action some birds are particularly adapted, e.g. swifts—which are unable to perch in the ordinary sense—woodpeckers and nuthatches among others. The hanging parrots or 'bat parrots' *Loriculus* spp. have the habit of hanging head downwards, by their feet, from branches.

See photo overleaf.

PERCHING BIRDS: see PASSERIFORMES.

PERDIZ: name used in Latin America for *Rynchotus* spp. (see TINAMOU).

PEREGRINE: *Falco peregrinus* (see FALCON).

PERICARDIUM: see HEART.

PERIODICALS, ORNITHOLOGICAL: see under ORNITHOLOGY.

PERIODICITY: see PHOTOPERIODISM; RHYTHMS AND TIME MEASUREMENT.

PERIOSTEUM: see SKELETON, POST-CRANIAL.

PERIOTIC: a paired bone of the SKULL.

PERITONEUM: membranous lining of the abdominal cavity and reflected over the outer surfaces of organs lying therein.

PERNINAE: see HAWK.

PERVIOUS: as applied to nostrils, see NARIS.

PESSULUS: see SYRINX.

Sandwich Terns *Sterna sandvicensis* perching on log. (*Photo: J.B. & S. Bottomley*). See PERCHING on previous page.

PESTICIDE: a chemical agent used by man to control living organisms which are inimical or believed to be inimical to his interests. The term covers herbicides, fungicides, insecticides, rodenticides, chemosterilants and growth retardants. The term is sometimes used in a more restricted sense as a synonym for insecticide. Most pesticides are synthetic organic substances, but some are inorganic or naturally occurring organic ones. See TOXIC CHEMICALS.

PESTS, BIRDS AS: wherever man has established settlements he has found that some of his resources are shared by birds. With most bird species this is acceptable but a few conflict with man's interests. The result of this conflict is some kind of damage, where the term 'damage' infers a direct loss, ultimately in terms of money, or causes expenditure to counteract the problem. In some instances, however, this definition cannot be strictly applied. A farmer who sees his fields apparently devastated is not prepared to wait until harvest time to see whether his yield is in fact reduced. In other words, if a farmer thinks that birds are causing damage, he will take steps to prevent it whether or not a real loss is incurred. Even where damage does occur, it is often very difficult to estimate the financial losses. The equation is rendered even more difficult by the capacity of some of the pest species to confer potential benefit by their consumption of insect pests. Estimates of damage that are available for some species in some situations indicate that losses can be considerable (Jackson and Jackson 1977) and in developing countries severe damage may result in loss of human life. Damage to crops is usually local, however, and although individual farmers can lose a high proportion of their yields, expressed in national terms birds generally consume only a small proportion of total production.

Kinds of damage. Bird problems fall in several areas: agriculture (including horticulture and fisheries), forestry, urban and aviation are those which attract most attention.

Damage to agricultural crops occurs mainly at sowing/germination and at ripening, the seeds being the target food; but the foliage is also grazed by some birds, notably pigeons and sometimes by larks, pheasants and geese. The seeds of cultivated crops such as maize, barley, wheat, sorghum, millet and rice are eaten by a wide variety of birds, especially certain sparrows, weavers, starlings, parakeets and New World blackbirds (Icteridae). Damage to sown and germinating seeds is, owing to the compensatory capabilities of the plants, generally less serious than damage to ripening crops. Following recent changes in animal husbandry, where cereal grains are fed to cattle in the open, post-harvest losses due to starlings and New World blackbirds have become serious in some countries. These birds, together with some crows, can also be responsible for losses of pelleted animal foods where these are presented in the open.

Many fruiting plants have evolved dispersal mechanisms involving birds and mammals, and cultivated fruits inevitably suffer the attentions of starlings, thrushes, finches, parrots and many others. The decline of the cherry industry in some areas of Europe is blamed partly on predation by Starlings *Sturnus vulgaris*. Olives in North Africa and grapes in Europe, North America, parts of Africa and elsewhere also suffer severe bird damage, and a wide variety of other fruits is attacked. Fruit blossoms may also be eaten (though some species that attack flowers may be important pollinators e.g. sunbirds Nectariniidae), and Bullfinches *Pyrrhula pyrrhula* can cause extensive damage by eating the buds of certain cultivars of apples, pears, plums and blackcurrants.

Claims that seabirds can compete with commercial marine fisheries seem to be unfounded, declines being attributed largely to the industry itself. At fish farms, bird predation is of great concern to the owner since financial losses can be high. Herons, gulls, Ospreys *Pandion haliaetus* and others take fish while Mute Swans *Cygnus olor* have been blamed for taking fish eggs.

Damage in forestry is due mainly to large concentrations of birds such as European Starlings and American Red-winged Blackbirds *Agelaius phoeniceus* roosting in young plantations. The weight of birds can break off branches, possibly leading to subsequent mis-shapen growth of the trees, and trees may even be killed by the large deposits of guano.

While birds are generally welcome around human habitations, some cultures regard them, or at least some species, as harbingers of ill omen. In some places the breeding and roosting of birds in or on buildings can necessitate expensive cleaning or repair or can cause public health problems. The guano stains beneath House Martin *Delichon urbica* nests constitute a relatively minor problem but the nesting of some species can cause structural damage. The construction of bulky nests in roof spaces by various starlings and by Jackdaws *Corvus monedula* can lead to subsequent dangers of damp, while in aircraft hangars nest material and faecal droppings can result in expensive and dangerous problems when they fall into the air intakes of jet engines; occasionally, nests are even built inside aircraft. Woodpeckers have been recorded drilling holes in wooden roofs, telegraph poles and even, in Israel, irrigation pipes. Where thatching is a common roofing material, nest-building in the thatch by birds such as sparrows (*Passer*) and Indian Mynahs *Acridotheres tristis* can destroy insulative and water-proofing properties of the roof. Recent inland foraging of various gulls is being accompanied by their breeding on buildings, leading to problems of fouling and unacceptable noise, especially in early morning. Roosting by gulls on buildings has also resulted in damage to roof materials, especially where expanded polystyrene insulation is used. Fouling by roosting Starlings and Feral Pigeons *Columba livia* in cities results in degradation of masonry, dangerously slippery roads and pavements, and possible dangers of disease. In North

America, the main problem associated with roosts of icterids and starlings near conurbations lies in the guano providing a growth medium for *Histoplasma capsulatum*, the causative agent of endemic histoplasmosis in humans. Some pigeon populations have a high incidence of avian tuberculosis *Mycobacterium avium* and the roosting of gulls on reservoirs increases their potential to transmit salmonellae to man. Psittacosis (a form of ornithosis) can be contracted as a result of close contact with birds, especially parrots and their allies. Wild birds are sometimes claimed to act as vectors of diseases of domestic stock e.g. foot and mouth disease and transmissible gastroenteritis of pigs, but conclusive evidence of the involvement of birds is often lacking.

Collisions between birds and aircraft—'bird strikes'—range from relatively minor to catastrophic. Slight structural damage can be expensive to repair but the ingestion of birds by jet engines, leading to engine failure, can result in loss of the aeroplane, sometimes with loss of life. Most bird strikes occur near airfields when aircraft fly low, in the airspace most frequently occupied by birds; it is at take-off and landing that sudden loss of power can be most serious. The species most frequently involved are those, like certain gulls, corvids, plovers (Charadriidae) and starlings, that inhabit open grassy areas.

Damage prevention. The two basic approaches are to reduce the population of bird pests by killing them or to make the resource being damaged, or from which damage occurs, less attractive to the birds.

Attempts to reduce populations form the basic philosophy of damage reduction of many farmers. Most bird pests are, however, extremely numerous and successful. They have a high annual mortality and population turnover and their 'natural' mortality must be exceeded to achieve effective population reduction. Traditional methods of killing, e.g. by shooting or trapping, fail to achieve the desired level of mortality and even agents of mass destruction using poisons, flame-throwers, explosives (see QUELEA CONTROL; Tahon 1980), stupefying chemicals or surfactants (feather wetting agents—Lefebvre and Seubert 1970) have not reduced general population levels. Mass destruction can provide sufficient reduction to permit alleviation of local damage in some instances (e.g. Quelea and European Starling). In the United States, urban roosting icterids and starlings are killed rather than dispersed to prevent the establishment of new roosts whose guano deposits might act as foci of infection of histoplasmosis. In the western world the growing protectionist lobby is forcing a more critical approach to mass killing of birds and to the techniques that may be employed, and damage prevention measures that do not involve killing will inevitably play a greater role in future.

One approach to damage is to let it continue and offer compensation to the farmer. This is done in Canada where the damaging birds are wildfowl, themselves a valuable sporting resource (Boyd 1980). There are obvious difficulties in deciding the level of compensation and who should meet the cost. Another approach, involving similar financial problems, is to provide alternative attractive food for the bird pests, on the farm or in refuges (Owen 1980).

More commonly used approaches involve rendering the place where damage occurs less attractive. This can be done in several ways but most techniques rely on the presence of an alternative resource to which the birds may be driven. This is especially true of attempts to drive birds away from vulnerable areas (see SCARING and REPELLENTS, CHEMICAL) rather than of physical modifications to the crop or habitat. The ultimate form of physical modification is to exclude birds totally from a vulnerable resource. Cages to exclude birds are commonly used over fruit in domestic gardens but this form of protection is less frequently adopted in commercial horticulture. Disposable plastic netting is now draped over large areas of vineyards in Europe, while more permanent forms of netting are sometimes used over cherry orchards in Britain and New Zealand: the development of dwarf forms of cherry tree will make this form of bird protection easier in the future. A similar approach has been applied where cattle are fed indoors: a mixture of plastic and wire netting and strips of heavy duty PVC is used to cover entrances to buildings through which birds might otherwise have access (Feare and Swannack 1978).

Less complete protection can be afforded by other forms of habitat modification. Good and Johnson (1976) were able to manipulate the positions occupied by Brown-headed Cowbirds *Molothrus ater* in their roosts by thinning the roosting trees, and Brough and Bridgman (1980) showed that the bird populations of airfields could be reduced by allowing the grass to grow tall. A degree of crop protection may also be achieved by growing cultivars that are less susceptible to attack by birds in areas where damage is anticipated. For example, Bullfinches eat certain cultivars of fruit buds in preference to others and some cereal crops have long-awned cultivars that possess some resistance to bird attack (see QUELEA CONTROL). The mechanism of the Bullfinch's selection is not known but, as with scaring devices and chemical repellents, the efficiency of these 'bird resistant' forms is likely to diminish when acceptable alternative foods are absent. PETREL: whole or part of the substantive name of many species in 3 of the 4 families of the order Procellariiformes (Tubinares); in the plural a general term together with 'tubenoses' for the order. It comprises the families Diomedeidae (albatrosses), Procellariidae (fulmars and shearwaters), Hydrobatidae (storm-petrels) and Pelecanoididae (diving-petrels); in the past some authors have treated the Hydrobatidae as a subfamily of the Procellariidae, but they differ in their serum proteins among other characters. The order forms a group of totally marine species which share a number of distinctive characteristics.

Characteristics. The Procellariiformes are distinguished by deeply-grooved, markedly hooked bills. Their long tubular nostrils are associated with a marked development of the olfactory part of the brain. They all have a distinctive musky smell, and it appears that the whole order is adapted to locate either their feeding-area, food, each other or their breeding-places by smell. Most or all species collect and store in their stomachs large quantities of oil from the energy-rich food-stores laid down by marine organisms. This oil is used as food for their young, and is also spat out as a defence against predators. They are very helpless on land, most species being clumsy and walking only with difficulty. The larger ones bite viciously.

The tubenoses appear to be a very ancient group, perhaps of southern origin, although several modern genera are already present in northern deposits dating at least as far back as the Miocene. They appear to be most closely related to another southern order, the penguins (Sphenisciformes), the petrels having developed as aerial seabirds while the penguins developed as aquatic ones. The two between them show the most advanced adaptation for a marine environment now found among birds. There are some 23 genera and 80 to 100 species distributed throughout the oceans; one family, the Pelecanoididae, and about half the genera and species are still restricted to the Southern Hemisphere with progressively fewer species in the North Pacific, North Atlantic, Indian Ocean and Mediterranean.

Tubenoses all have very similar life histories adapted to the relatively stable, secure, uniform marine environment with its exposure to the weather. They have a long period of immaturity, a long breeding cycle and low reproductive rate adapted for slow formation of the egg and growth of the embryo and chick while the parents travel widely in search of food. They have a long expectation of life in an environment relatively free from predators. They show more variation in other characters adapted for the exploitation of different aspects of the marine environment, notably either from the air or by diving under water, and for the avoidance of interspecific reactions, including size, structure, markings, patterns of distribution and migrations, and timing of breeding seasons and moult.

The albatrosses (70–140 cm in length) are among the largest and the storm-petrels (12–25 cm in length) the smallest seabirds. Within several of the larger groups closely related species of different sizes, habits and appearance are found in the same area. In some cases, such as the albatrosses, prions *Pachyptila* and gadfly petrels *Pterodroma* and *Bulweria*, they are all very similar in structure; in others, such as the fulmars, shearwaters and storm-petrels they show a marked variation in structure adapted for different types of flight or methods of feeding. Many species show a simple counter-shaded colour pattern, dark above and light below, sometimes with contrasting markings on the head, wing-coverts, tail-coverts or flight-feathers; but pale, mottled, or uniformly dark variations are common even among closely related forms. Many species are markedly polymorphic and most show traces of polymorphism. The species nesting in high latitudes tend to be white all over, or grey or pale brown above and white below, with yellow, pink, green or blue and black bare parts; those breeding in warmer climates tend to be brown or black above with less or no white below and red and black or entirely black bare parts. Some groups of closely related species or races show great geographical variation in conformity with this trend.

The peripheral markings often provide interspecific recognition characters, including the brightly coloured bills and complex wing-markings of the larger species which display by day, and the white faces of many gadfly-petrels and some shearwaters, and the white rumps of many storm-petrels, which display by night. Closely related species which occur at the same breeding places often show contrasting markings or occur in different colour phases, and races of the same species may show differences in appearance which can be related to the occurrence of species with which they might come into conflict. In general, representative species tend to be smaller, but races of species larger, in lower latitudes, but there is much variation, which can often also be related to the local competitive situation. Some well-defined larger superspecies may have closely related smaller 'shadow species' breeding in the same area at another season, as in the case of the Manx and Little Shearwater *Puffinus puffinus* and *P. assimilis* and the Hawaiian and Bonin Petrels *Pterodroma phaeopygia* and *P. hypoleuca* and their allies.

Marked variation in appearance with age and sex is only found in the largest species, the albatrosses and giant petrels, in which the young birds tend to be dark while male Wandering Albatrosses *Diomedea exulans* become whiter than the females. Young birds may also show more marked pale feather-edges above in some other species, including the small Hydrobatidae, and at first have soft, undeveloped bills. Their appearance contrasts markedly with that of the senile individuals which are not uncommon in these long-lived species, with more rugged bills, scaly legs, worn or missing claws, and dishevelled plumage. Males tend to be larger than females in most groups, but may be smaller in the Hydrobatidae; marked variation in the amount of sexual dimorphism may occur even among races of the same species. Dwarf individuals sometimes occur, possibly birds which were fed inadequately as chicks; one such runt examined had aspergillosis.

Habitat. All species are totally marine, feeding alone or in groups dispersed over the open ocean according to the distribution of their food, more birds and larger flocks occurring in the areas of upwelling and marine turbulence associated with plankton production along the lee shores of the continents and around the convergences between water masses at sea.

Distribution and movements. Most species appear to be more or less closely restricted to distinct circumpolar zones of surface water at sea. Some are comparatively sedentary or disperse throughout the habitat outside the breeding season, and others perform more or less complex migrations between good feeding areas in different zones in the same or opposite hemispheres. Some populations appear to perform circular movements, either around the world in the circumpolar belts of winds in the higher latitudes of the Southern Hemisphere, or around the anticyclones stationary in the middle latitudes of other oceans, so that they are assisted by following winds throughout their migrations. These travellers may often be largely young birds, while the adults make more direct movements. The movements of closely related species often appear to have a complementary pattern, so that their distribution forms a mozaic, as for example in the large shearwaters and gadfly petrels.

In general, the species occurring in high latitudes of either hemisphere usually appear either to be sedentary or to move into lower latitudes in the winter. The species occurring in middle latitudes may either be sedentary, or move into the tropics or the comparable latitudes of the opposite hemisphere in the winter; and the tropics are occupied either by residents, or by wintering populations of birds breeding in the higher latitudes of both hemispheres and which replace each other at different seasons. Most species breed in the highest latitudes of their range in the local summer, but some in the lowest latitudes in the winter, possibly either because there are no suitable breeding places in higher latitudes, or because there are too many competitors there, or because they originated in the other hemisphere. Where a number of similar species feed or breed in the same area they are thus often found to avoid competition for food or conflicts at the nest-sites by occurring at different seasons.

Populations. The welfare of many species has been affected in recent centuries by human activity. Some have been reduced by past exploitation for food, feathers, or fish bait, but few are known to be killed directly by man now except where their chicks are harvested on a limited scale in Australasia and at Tristan da Cunha, and where they are lost accidentally in fish-nets in northern seas. Many populations have also been seriously reduced by the loss of habitat and predation due to imported mammals such as rats, cats, rabbits, goats, hogs, and mongooses at island breeding sites. A number of species including the Short-tailed Albatross *Diomedea albatrus*, 2 shearwaters, and 5 gadfly petrels were 'lost' for long periods of years and found to be reduced to small vulnerable populations when they were rediscovered. So far only one species is definitely thought to have been exterminated, the Guadelupe Storm-petrel *Oceanodroma macrodactyla*, which was lost in the early decades of the 20th century from an island off Lower California invaded by cats. On the other hand, many species including albatrosses, large shearwaters, and the Northern Fulmar *Fulmarus glacialis*, which is spreading all round the temperate North Atlantic, have profited greatly by feeding on the offal discarded by fishing boats.

Food. The natural food of tubenoses consists of the larger zooplankton, cephalopods, fish and sometimes other birds. Many species now follow ships for refuse or food turned up in the wake, and some avoid them. The different groups specialize in catching different foods under different conditions at different distances from the shore, so there is a considerable series of representative forms exploiting different zones of surface water in different oceans.

Behaviour. All species normally keep well away from land when not engaged in breeding activities, but may come inshore when the visibility deteriorates and sometimes appear inland in large 'wrecks' after gales. Usually there appears to be some underlying factor such as the failure of the food supply or disease, since they can ride out most bad weather.

Birds normally come ashore only to breed, though the more sedentary species may visit the breeding stations at intervals for much of the year.

Adults start to re-establish their territories and renovate their nest sites weeks or months before laying. They then usually depart again for a 'honeymoon' lasting days or weeks during which time they appear to feed separately before the female returns to lay and the male to take the first spell of incubation.

Voice. There are complex vocal displays at the breeding sites, the larger species also rattling their bills, behaviour carried out both in the air overhead and at the nest. Repertoires include a variety of wailing, moaning, screaming, cackling and squalling noises, often with a weird effect at night so that the birds have been mistaken for evil spirits. At sea they are usually shy, quiet and undemonstrative except when fighting over food.

Breeding. Nesting is usually social, sometimes in vast, dense colonies running into hundreds of thousands of pairs, though others are more widely scattered. Most nest on oceanic and offshore islands, but some species may use mainland cliffs and headlands, mountain tops and deserts, and even buildings, if they are undisturbed. The smaller species usually nest in a chamber at the end of a long burrow which they dig for themselves, but sometimes in holes among rocks or concealed in vegetation, and usually come ashore by night, apparently to avoid aerial predators which appear to be their worst natural enemies. The larger species visit more open nests by day.

Large nests are built on the ground by the southern albatrosses and poorer ones by the giant petrels, possibly because they are normally compelled to nest in waterlogged situations. Other species may collect any material which is within reach around the nest. They normally lay one comparatively large white egg with a coarse shell and sometimes fine reddish spots, but never well developed markings. The female has a distended cloaca for weeks afterwards (the only indication of her sex for many species). Two eggs have been recorded, probably often the work of 2 females or replacement after an egg is lost, but this appears to be very rare. The incubation period is long, nearly 6 weeks in the smallest storm-petrels, 2 months or more in the larger species, and the chick is hatched blind, but covered in long, thick down. While incubating the egg and brooding the chick, the parents relieve each other at intervals of days. The chick is soon left alone and only visited to be fed at equally long intervals. Both parents feed the chick by regurgitation with a mixture of half digested food and oil which is derived from it, and if well fed the chick soon becomes very fat. The frequency of feeding is liable to vary greatly with the weather and possibly the experience of the parents, and sometimes individual chicks or even whole colonies may starve. The successful chicks eventually become much heavier than their parents, though the weight falls again as the feathers grow, and at fledging they usually weigh much the same as the adults. It has been suggested that the parents eventually abandon the chick before it fledges, but in some species at least it may be fed irregularly until it leaves, and some parents may even continue to return to the nest afterwards. Some weakly and backward young, possibly the offspring of dead or incompetent (immature or senile) birds, may certainly be abandoned in the nest, especially in migratory species, but may do well if they are then given supplementary feeds.

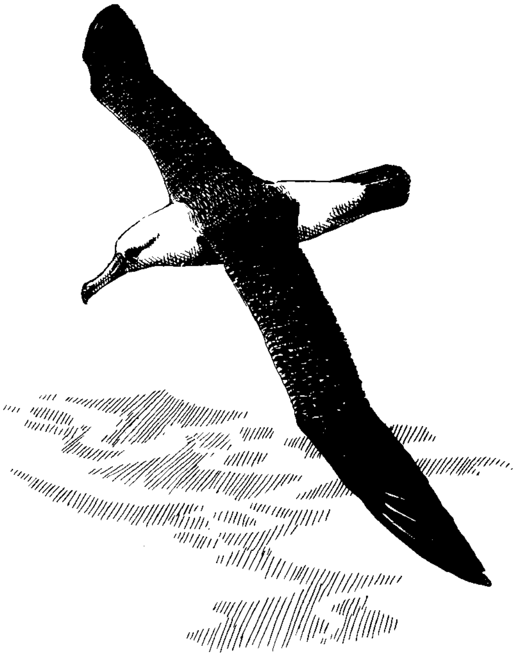
The fledging period is very long, some 2 months in the storm-petrels, 3–5 in the medium sized species, 9–12 in the largest albatrosses. The young sit quietly in the nest at first, but start to move about and exercise themselves by flapping their wings as the time to leave approaches. Most chicks eventually appear to fly directly from the nest, especially if it is situated inland. They are liable to make abortive flights and land in unsuitable places or come to village lights at night at first, and weakly young may swim out to sea if they can reach the water. Strong young fly well on fledging and probably never see the nest or their parents again; some transequatorial migrants immediately set out on long migrations, which must include a further period of starvation as they cross the tropics, and wrecks are particularly liable to occur at this time. Ringed birds have been recovered in the opposite hemisphere within days of the probable date of fledging.

Young birds fend for themselves on leaving the nest and spend their early years at sea, sometimes congregating in 'nurseries' where there is a good food supply. Later, they start to return to land for increasing periods in the breeding season, and also leave to start the annual moult early. During this time they often appear to wander and prospect new sites, though most eventually return to their natal colony. They then spend more years displaying and excavating nests before they start to breed, which the smallest storm-petrels may attempt at 2–3 years, but the largest albatrosses not until they are 5–10 years old, with poor success at first. Once they have started to breed, most species attempt it annually, though within the tropics some species may return at shorter intervals, while the largest albatrosses require 2 years for a successful cycle.

Some southern storm-petrels have only one coat of nestling down, but most have two. The juvenile plumage usually appears to be moulted at sea when the birds are about a year old, often in the 'nurseries'. Some of the larger species start a slow body-moult during the breeding season, Snow Petrels *Pagodroma nivea* completing it, but most species delay the moult of the flight-feathers until they have finished breeding for the year. The migrants may then complete it rapidly in some good feeding area in their winter quarters, though the more sedentary species are slower and start to return to the breeding places before it is finished. The power of flight may be impaired for a time when the moult is rapid, notably in some of the large shearwaters, and may be lost entirely by some of the diving petrels which moult the flight feathers simultaneously.

Albatrosses. The family Diomedeidae includes the 14 largest species (length 70–140 cm) in the order, with a vast WING SPAN (2–3 m), long, hooked bills with separate nostrils, short legs on which they can stand well and run to take off, and short, round tails in the 11 members of the genus *Diomedea*, but long, pointed tails in the 2 sooty albatrosses of the genus *Phoebetria*. They achieve continual effortless gliding flight by making use of the updraughts above the waves and the slopes of their breeding islands, and tend to settle on the water when the wind drops. They appear to feed mainly on large cephalopods caught or found disabled at the sea surface, perhaps largely at night, but they can also dive, and take fish and other marine animals. The sooty albatrosses in particular also catch birds, while the other species are among the seabirds which appear to profit most from scavenging around fishing-boats.

Albatrosses nest colonially in the open on remote islands, and one of the largest species, the Royal Albatross *Diomedea epomophora*, colonized Taiaroa Head on the east coast of the South Island of New Zealand when it was protected with a fence. They all have spectacular displays at the nest in which they stand with the wings opened and tail fanned while the head is stretched out and thrown up and the tip of the bill buried in the plumage of the back between the scapulars, to the accompaniment of gurgling and braying sounds. The members of the genus *Phoebetria* which tend to nest on cliffs also carry out aerial displays in pairs accompanied by screams. Two of the great albatrosses, the Wandering *Diomedea exulans* and the Royal, have more complex social displays in which the males (which arrive first at the breeding colony) gather around a female with their vast wings spread, rattling their bills.



Black-browed Albatross *Diomedea melanophris*. (*B.P.*).

It seems likely that there was once a community of primitive albatrosses in the circumpolar Tethys Ocean of the Northern Hemisphere during the Tertiary, since fossil remains of an early form, the English Albatross *Diomedea anglica*, have been found on both sides of the North Atlantic, which is now only visited by stray individuals of the southern species; while the northern species are now confined to the North Pacific. It seems possible that the Galapagos Albatross *Diomedea irrorata*, which occurs over the cold Peruvian Current within the tropics, is the most primitive surviving form, since it has a simple grey coloration with a paler head and bill and builds no nest. Three rather similar species with contrasting markings breed together at the central North Pacific archipelagoes, the Black-footed Albatross *D. nigripes*, which is dark brown with a paler face and base to the tail when adult, the Laysan Albatross *D. immutabilis*, which has a white body with a dark eyebrow, upperwing, back and tip to the tail, and the Short-tailed Albatross *D. albatrus*, now reduced to a population of a few score birds nesting on islands south of Japan; it is dark when young but becomes white with dark wing-tips when adult.

The fact that the northern albatrosses nest in the local winter suggests that the group was originally of southern origin, and they show their greatest development in the Southern Ocean, where there are now 3 distinct groups of species each of which has plumage comparable to one of the northern species, with the addition of distinctive head and wing markings, although they do not appear to be particularly closely related to the northern forms, and differ from them in building nests. The simplest situation and basic pattern of variation is found in the genus *Phoebetria*, which includes 2 small, dark, agile, long-tailed species with dark plumage and a distinctive incomplete white eye-ring, the Sooty Albatross *P. fusca* with a dark brown body and yellow stripe on the lower mandible in the subtropical South Atlantic and Indian Ocean, and the Light-Mantled (Sooty) Albatross *P. palpebrata*, with a paler body and blue stripe on the bill, further south and in the South Pacific.

The 3 great albatrosses are much larger than the other species, with an exceptionally long breeding-cycle, so that eggs laid in one summer give rise to chicks which are fed through the winter to fledge a year later. The Royal Albatross is largely white with dark upperwings and breeds in the New Zealand area, dispersing around the world to South America.

The populations of the Wandering Albatross which breed alongside it are largely dark, like the young Short-tailed Albatross, and never become very white, but the old birds of the populations breeding elsewhere throughout the Southern Ocean become whiter when adult, some of the southern males becoming as white as Royal Albatrosses. A third dark species *D. amsterdamensis* has recently also been found breeding in very small numbers on Amsterdam Island in the southern Indian Ocean.

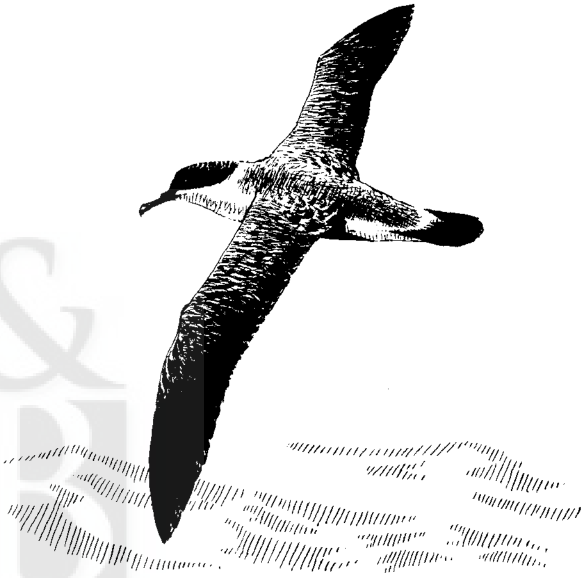
The height of complexity is found with a group of medium-sized species with dark brows, backs and tails similar to those of the Laysan Albatross known as 'mollymawks' from the old sailor's name for fulmars. The most familiar species is the Black-browed Albatross *Diomedea melanophris*, which has a simple black and white plumage pattern and yellow bill when adult. It behaves like the Wandering Albatross, breeding abundantly throughout the subantarctic zone and migrating north in the winter, when it sometimes reaches the northern hemisphere, including Britain, and may become marooned there. In contrast to this, 3 highly-distinct races of Shy Albatross *Diomedea cauta* retain as adults the more or less grey head and bill found in young mollymawks, and behave like the Royal Albatross, breeding around New Zealand and Tasmania and migrating east and west. Finally, 3 allies of the last group, having grey heads and black bills with distinctive yellow stripes, behave like the sooty albatrosses, breeding on oceanic islands in the subtropical South Atlantic and Indian Ocean (Yellow-nosed Albatross *Diomedea chlororhynchos*), subtropical South Pacific (Buller's Albatross *D. bulleri*) and the subantarctic zone of the Southern Ocean (Grey-headed Albatross *D. chrysostoma*) and disperse throughout these zones of surface water.

Fulmarine petrels and shearwaters. The family Procellariidae includes the main body of medium- to large-sized petrels (30–70 cm) totalling some 12 genera and over 50 species. They may be divided into 2 subfamilies, the Fulmarinae, largely aerial species with skulls strengthened by fusion of the lacrhymal bone to facilitate seizure of their food from above the surface (except in the small primitive northern genus *Bulweria*) and the Procellariinae, more aquatic species with longer bills rendered mobile by retention of a separate lacrhymal bone used for seizing fish under water. The Fulmarinae can be subdivided into 3 further specialized groups, the fulmars, prions, and gadfly petrels.

The fulmars include 5 highly distinct species or superspecies of different sizes with a heavy build, short tails and a gliding and flapping flight characteristic of high latitudes. Three monotypic genera are restricted to the Southern Hemisphere, where there are also sibling species of giant petrel *Macronectes* in the subantarctic and subtropical zones of surface water, while there are closely-related species of *Fulmarus* in both the Northern and Southern Hemispheres. The Southern Giant Petrel *Macronectes giganteus* and Northern Fulmar *Fulmarus glacialis* are polymorphic and may be either dark or pale, the Cape Pigeon *Daption capensis* and Antarctic Petrel *Thalassoica antarctica* are chequered brown and white, the pale phase of the Northern Fulmar and its southern representative *Fulmarus glacialoides* are grey and white, and the Snow Petrel *Pagodroma nivea* of the antarctic ice is pure white, and remarkable for the possession of 2 races of very different size. All species have broad bills with distensile gular pouches, and all except the Southern Fulmar have some sort of filtering plates or lamellae in the bill. Most probably they once fed mainly on plankton, though the giant petrels at least have always been scavengers and predators; but they have taken readily to feeding behind fishing-boats. They nest in the open or in shallow niches, visiting the nest by day, and have developed oil-spitting as an effective defence.

The prions *Pachyptila* spp. are a group of some 12 very closely-related species and subspecies of small petrel adapted to feed directly upon the smaller organisms in the surface water by straining it through lamellae fringing the bill. They are all very similar in size and appearance, blue-grey above and white below with darker ear-coverts, 'W' markings on the back, and tips to the tail-feathers, and an erratic, mobile, skimming flight; they differ mainly in the size of the bill and its lamellae. The different forms appear to replace each other ecologically in different zones of surface water, feeding in large flocks along the marine convergences at sea and breeding underground on the subantarctic islands in dense warrens which they visit by night. The Blue Petrel *Halobaena caerulea* is a superficially similar species with a smooth narrow bill and white tips to the tail feathers which appears somewhat intermediate in its structure and behaviour between this group and the next one.

The gadfly petrels *Bulweria* and *Pterodroma* spp. are a group of some 24 rather similar medium-sized petrels with long wings and short, stout, heavily-grooved and markedly-hooked black bills; they live far from land in the centre of the oceans. The smaller species, including the primitive northern genus *Bulweria*, are lightly-built, with fairly long wedge-shaped tails, and a graceful mobile, soaring flight, while the larger members of the genus *Pterodroma* are sturdy, with shorter rounded tails and a forceful flight in great arcs, between which they may tower in the air. They vary greatly in their coloration and many are polymorphic, but in general they tend to be grey or brown above and may have either white faces and underparts or be equally dark below, though in all plumages they tend to show characteristic wing markings. Comparatively little is known about their biology, but some have a remarkable twisted gut apparently adapted to absorb the oil from cephalopods caught largely at night. They have very long breeding cycles. Some of the larger species visit nests in the open by day on remote southern islands, but most nest in burrows which they visit by night, often in forested mountain slopes far inland. Young birds tend to wander great distances, and, in the Pacific, some appear to carry out transequatorial migrations.



Great Shearwater *Puffinus gravis*. (*B.P.*).

The shearwaters are another large group of some 15 species distributed throughout the oceans, though they tend to be commoner near land. They have longer, more slender bills with smaller hooks, and may also be either dark above and light below or uniformly dark, and some are polymorphic. They may be divided into 2 groups with different flight and feeding habits. Some, including the White-chinned Petrel *Procellaria aequinoctialis*, Cory's Shearwater *Calonectris diomedea* and their allies, and the Wedge-tailed and Grey-backed Shearwaters *Puffinus pacificus* and *P. bulleri*, are adapted for an aerial way of life, fishing on the wing in the centre of the ocean, which is associated with the development of long wings, tails and legs. Others such as the Grey Petrel *Procellaria cinerea*, Manx Shearwater *Puffinus puffinus*, and the remaining members of the genus *Puffinus*, are adapted for a more aquatic existence diving on fish-shoals offshore. This is associated with the development of shorter wings, tails and legs with flattened tarsi. One species, the Christmas Island Shearwater *Puffinus nativitatis*, nests more or less in the open on islands in the central Pacific, but they often breed in large, dense colonies of burrows, which they visit by night, near the coasts of offshore islands, though they may also use hills inland. Many species have long and complex migrations between well defined feeding areas in the same or opposite hemispheres.

Storm-petrels. The family Hydrobatidae includes 8 genera and over 20 species of small petrel (12–25 cm) adapted to catch small marine animals at the water surface. They are all more or less dark above with paler wing coverts, and often white rumps, and vary in colour below. They all breed more or less socially in crevices and burrows, usually on islands, though they may use mainland cliffs or travel inland to nest in deserts. Many carry out considerable migrations, the species from opposite hemispheres replacing each other at different seasons as winter

Wilson's Storm-petrel *Oceanites oceanicus*. (*B.P.*).

visitors to the tropics. They may be divided into 2 subfamilies characteristic of different hemispheres, with a wide overlap in range in the intervening area.

The Oceanitinae include some 7 more or less highly differentiated forms characterized by the possession of short, rounded wings, nearly square tails, long tarsi and short toes. They are adapted for a distinct mode of progression, walking or hopping along the surface of the water between the waves, picking organisms from the surface as they go. They occur in 2 colour-phases, dark or white below, all species being polymorphic to some degree. Most are restricted to the Southern Hemisphere, but the White-throated Storm-petrel *Nesofregetta fuliginosa* (= *N. albigularis*) is resident in the tropical Pacific, the White-faced Storm-petrel *Pelagodroma marina* has colonized the North Atlantic, and Wilson's Storm-petrel *Oceanites oceanicus* is a transequatorial migrant which breeds in the antarctic and winters in the northern oceans.

The northern Hydrobatinae include some dozen closely-related species which may be derived from Wilson's Storm-petrel, since they also normally occur in the dark phase but may have white rumps. They show a progressive development of a very different type of flight adapted for calmer northern seas, swooping over the surface like terns, which renders them more vulnerable to wrecks. An early stage of development is shown by the British Storm-petrel *Hydrobates pelagicus* which breeds around the west coast of Europe and winters off South Africa. It reaches its climax in the Pacific, where a minute wedge-tailed species, the Least Storm-petrel *Oceanodroma microsoma*, occurs off California and a swarm of fork-tailed species of the genus *Oceanodroma* of different sizes and colours frequent the areas of upwelling there and off Japan and Peru, some migrating to winter in the tropics.

Diving-petrels. The family Pelecanoididae contains one genus *Pelecanoides* which includes 4 or 5 small aquatic petrels (16–25 cm) belonging to 2 superspecies which may have originated in South America and Australasia, though they have now developed an overlapping distribution in the Southern Ocean. They are known on Tristan da Cunha as 'flying pinamins' or penguins, and are also remarkable for their similarity to the smaller northern auks, especially the Dovekie or Little Auk *Alle alle*, which replaces them in the North Atlantic. They are only easily distinguished by their possession of the characteristic tubular nostrils of the Procellariiformes. The resemblance provides an outstanding example of evolutionary convergence in a similar environment, because not only are the 2 groups extremely similar in size, appearance and proportions, both being black above and white below with short bills, wings and tails; they both have a similar whirring rather than gliding flights and dive straight from the air into the water where they use their wings in pursuit of small marine organisms which they collect in gular pouches. Some alcids behave like the diving-petrels in breeding socially overlooking the sea in holes which they visit by night and where they lay white eggs.

The South American group of diving-petrels possess a pointed arch to the lower jaw and comparatively raised, rounded nostrils. They include the largest species, the Peruvian Diving-petrel or Potoyunco *Pelecanoides garnotii*, which feeds in the cold Humboldt Current and nests on the adjacent guano islands. Further south it is replaced by the medium-sized Magellanic Diving-petrel *P. magellani* in the channels between the mainland and offshore islands and in the Falklands, and by the Small Georgian Diving-petrel *P. georgicus* in the subantarctic islands, including South Georgia, Marion and Prince Edward Islands, the Crozets and Kerguelen, and probably Macquarie and other islands south of New Zealand, where there is a colony in the Foveaux Strait. It feeds upon krill *Euphausia superba* and breeds late in the summer in holes in the sandy upper parts of islands.

The New Zealand group is distinguished by the possession of a rounded arch to the lower jaw and flattened, elongated nostrils, and tend to nest early around the vegetated lower slopes of islands and feed upon copepods. They include an uncertain number of forms, notably the medium-sized Common Diving-petrel *P. urinatrix*, breeding around the Bass Strait in south-east Australia and the main islands of New Zealand, and a number of very similar small populations breeding at the same sites in the subantarctic islands as the Georgian Diving-petrel and also Tristan da Cunha, Gough Island, the Falklands and probably around southern South America, where it occurs alongside the Magellanic Diving-petrel as well. It seems possible that there may be some overlap in the distribution of the large and small forms of Common Diving-petrel, notably in the Chatham Islands, in which case the small form would rank as a distinct species *P. berard*.

Common Diving-petrel *Pelecanoides urinatrix*. (*B.P.*).

PEWEE: substantive name (in some cases 'wood-pewee') of *Contopus* ('*Myiochanes*') spp. (see FLYCATCHER (2)).

PEWIT: common alternative name (from the call, and variously spelt) in Britain for the Lapwing *Vanellus vanellus* (see PLOVER (1)); formerly used also for the Black-headed Gull *Larus ridibundus*.

PEZOPHAPIDAE: family of extinct birds. See under COLUMBIFORMES; SOLITAIRE (now in Pezophapidae, previously 'Raphidae', see DODO).

pH: a symbol followed by a value that is a logarithmic expression of the hydrogen ion concentration of a solution, and thus an index of its reaction. The pH of a neutral solution is 7; above 7 alkalinity increases, below 7 acidity increases.

PHAENICOPHAEINAE: see CUCKOO.

PHAETHONTES; PHAETHONTIDAE: suborder and family of PELECANIFORMES; TROPICBIRD.

PHAINOPEPLA: generic name used as common name of *P. nitens* (see SILKY FLYCATCHER).

PHAINOPTILA: generic name often used as common name of *P. melanoxantha* (see SILKY FLYCATCHER).

PHALACROCORACIDAE: see under PELECANIFORMES; CORMORANT.

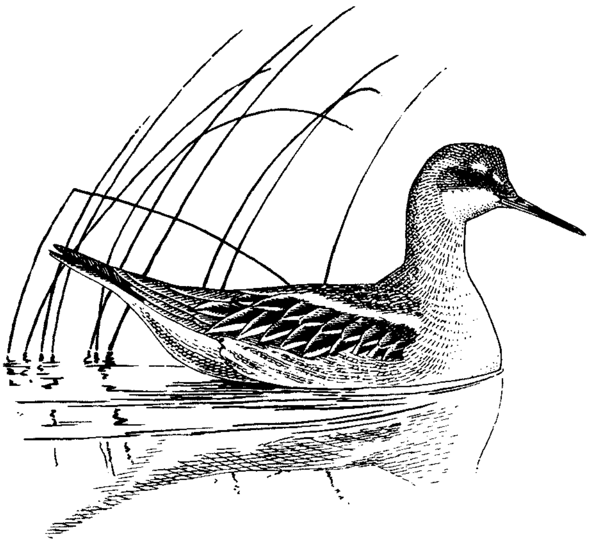
PHALANX: a bony element (plural 'phalanges') of a digit (see LEG; SKELETON, POST-CRANIAL; WING).

PHALAROPE: substantive name (coined by Brisson in 1760) of the 3 species of Phalaropodinae (Charadriiformes, family Scolopacidae). They are small, swimming 'sandpipers', breeding in northern latitudes, with dense breast plumage which provides a raft of air on which they float lightly. There are short webs between the bases of the front toes and all 4 toes are expanded and fringed with contiguous convex scales; the tarsus is laterally compressed. Two of the species become seabirds during the 9 non-breeding months; and it is characteristic of all 3 that the sexual roles are reversed, the female being larger and in nuptial plumage more brightly coloured than the male.

They are assigned to a distinct subfamily because of their aquatic adaptations, and all 3 have mutually diverged so much that they are placed in separate genera by New World taxonomists. They are Wilson's Phalarope *Phalaropus tricolor*, the Grey (or Red) Phalarope *P. fulicarius*, and the Red-necked (or Northern) Phalarope *P. lobatus*; the alternative English names are those in use in the Americas—the 'Grey' being descriptive of most autumn migrants and the 'Red' of the breeding plumage.

Characteristics. Wilson's is slightly the largest (length 23 cm); it has very long legs and a long needle-like bill, and its toes are evenly fringed, whereas those of the other two are lobed, with a waist at each joint. The Grey (length 20 cm) is apparently the most numerous; it has a short bill, unusually broad for a wader. The Red-necked is the smallest and most delicate (length 18 cm), has the most broadly lobed toes and a bill as fine but not as long as that of Wilson's; in spite of its former American name it is a less northern breeder than the Grey. The Grey and Red-necked in all plumages have dark rumps and show a white wing-bar in flight, whereas the rump of Wilson's is white and there is no wing-bar.

All have decorative nuptial plumages, acquired late in spring and, in most individuals, lost before autumn. The various combinations of bay or maroon with white, black, light grey and buff put the females among the most colourful of the Charadrii; the male plumages are more subdued, and cryptic when the bird sits on the nest. They are unremarkable vocalists, often repeating single soft high notes, *tik* and *peep* (also heard at sea); the Grey has additional disyllabic and twittering calls.



Red-necked Phalarope *Phalaropus lobatus*. (*A.H.*).

Distribution and habitat. The Grey and Red-necked are circumpolar breeders, the former mainly in the arctic biome, the latter in the sub-arctic or boreal, but there is some overlap. The Grey is more confined to coastal habitats and often breeds on inshore islands, but both frequent shallow freshwater ponds and lakes; a minority of Red-necks breed far inland. The Red-necked is a rare and rather insecure breeder at several sites on the mainland and islands of Scotland, and until 1971 it bred in western Ireland. The Grey in the British Isles is a sporadic, chiefly autumn, migrant along western coasts, and more rarely elsewhere.

In contrast, Wilson's Phalarope is a temperate-zone breeder confined to the interior of North America, from Alberta (probably to 60°N) to California (37°N) and east to Ontario. It enjoys a warm summer but many of the ponds and marshes it frequents dry up. It is a bird of inland shores and waters at all seasons, wintering in South America.

Movements. The females remain at the breeding colonies only a few weeks, those of the hot-summer species Wilson's being least, and those of the high-arctic Grey most, in a hurry to be off; in all species the majority have left before the peak date of hatching arrives. After the chicks have emerged, the males accompany and brood them; but, only 3–4 weeks after the females have left, the males also aggregate and depart, some of them allegedly deserting small young. Each exodus of adults must relieve the pressure on the food supply, to the benefit of those that stay behind. Finally, after another similar interval, the young themselves are ready to start their long migration.

The adults of all species begin their moult before or soon after they leave their breeding places. Most Greys complete it at sea before going south on migration. They are rarely found in the interior of either Asia or North America, and reach their traditional ocean winter resorts near or beyond the equator virtually undetected en route, no doubt largely by sea. An exception is the 4,000 km fringe of the north-west Atlantic, where large numbers are found in autumn feeding and moulting, from Baffin Bay to Nova Scotia, up to 300 km offshore; south of that they disappear. Some may possibly fly non-stop from arctic Siberia to resorts in the Arabian Sea (> 5,000 km).

The Red-necked, on the contrary, is a conspicuous overland migrant in Asia, funnelling southward in autumn across the steppes, visiting well-known feeding places, and finally crossing the plateau of Afghanistan/West Pakistan and Iran to reach the Indian Ocean. It returns by the same routes in spring (Dementiev *et al* 1969). In Canada, a less massive overland migration is restricted to the prairies and British Columbia. Red-necks also migrate by sea-routes. Being very light birds, both species are subject to occasional 'wrecks' when caught by gales on migration at sea.

At sea both species frequent regions where the mingling of water-masses, or strong offshore winds, lead to turbulence and the appearance of streaks and slicks on the surface, with concentrations of plankton immediately beneath them (Brown 1979; also OCEANIC BIRDS). The 2 species often keep apart, though by no means wholly. The winter resorts in which the Greys predominate are in the enriched waters off Cape Verde and Angola (Africa), and off Chile (20–40°S); the Red-necks are most numerous off the Arabian Peninsula and south of Baluchistan, and over a wide region extending south roughly from Japan to New Guinea, and also off Peru (0–20°S) and Argentina.

Wilson's Phalaropes migrate overland and southward along the Andes to winter chiefly east of the Cordillera, between the mountains and the Atlantic coast, and especially on the pampas of Argentina. Vagrants have been appearing not infrequently in Britain since they were first detected in 1954, chiefly at migration times.

Food. Although in summer phalaropes feed partly ashore, most food is taken at the water surface when they are swimming or wading, and consists largely of insects and small crustacea. All 3 species share the habit of spinning round and round on the water, supposedly to stir up or activate their prey; no doubt the movement is facilitated by having legs amidships, rather than far back like most swimming birds. Sometimes they up-end like ducks, but submerging seems difficult. In the non-breeding season the Grey and Red-necked live at sea in the tropics or further south, feeding on plankton.

Behaviour. All are sociable breeders, usually dispersed in small diffuse groups centred on particular feeding areas or prairie sloughs. In some districts the habitats are extensive, and in suitable parts of south-west Baffin Island and coastal eastern Siberia the Grey Phalarope may be among the commonest birds, reaching 30–200 pairs per km^2 (Kistchinski 1975). Apart from defending the actual nest or mate, the females are non-territorial; they make solitary advertising flights over the colony, and there are also aerial chases, usually with one or several females chasing a male. But Schamel and Tracy (1977) also saw mixed chases and chases of a female by males of the Grey Phalarope, which suggests that the roles change when the males have an unmated surplus. Courtship swimming occurs, and copulation with the female swimming on the water can occur in all species; it apparently always does with the Red-necked, and in most instances with Wilson's, whereas the female Grey is normally on her feet either in shallow water or on land. Incidentally the Red-necked and Grey are so tame as to be easily studied at close range.

Breeding. Single pair-bonds are the norm. The nest is a scrape with a varying amount of lining. The clutch is 4 eggs, less often 3. Nests are commonly well separated though clumping has been recorded in all species. Incubation (18–24 days) is by the male who alone has brood-patches; their development depends on the typically female hormone prolactin, more of which is secreted by male than female phalaropes. Likewise the female's bright plumage is conditioned by testosterone, normally a male hormone. Depending in part on sex-ratios, single females may frequent the immediate nest-area for much of their mate's incubation period, or they may flock with other females remaining in the neighbourhood (indicating a short-lived pair-bond), or the flocks they join may quit the district.

It was long assumed that phalaropes would turn out to be polyandrous, but this has only recently been confirmed, for the Red-necked in Finland and Sweden (Hilden and Vuolanto 1972; Raner 1972), and for the Grey at Barrow, Alaska (Schamel and Tracy 1977). Breeding conditions in the Arctic are notoriously variable, and it appears now that only some females are 'diandrous', and only when there is an excess of males. Graul *et al* (1977) postulate that reversed sex-roles have evolved in various nidifugous birds which breed in ecosystems where feeding is usually so sparse (and the season so short) as to prevent the female from meeting the cost of incubating the eggs as well as producing them; but, if the male can take over the hatching unaided, the population can still remain viable. Once that has been achieved, it will benefit all concerned still more if, in a spring when feeding is better than usual, a female can attract two batchelors in quick succession and lay each of them a set of eggs, so as to give both enough time to rear their families.

PHALAROPODINAE: see PHALAROPE.

PHANERIC: term applied to coloration or other characters that are the opposite of cryptic in that their purpose is to be conspicuous (see COLORATION, ADAPTIVE).

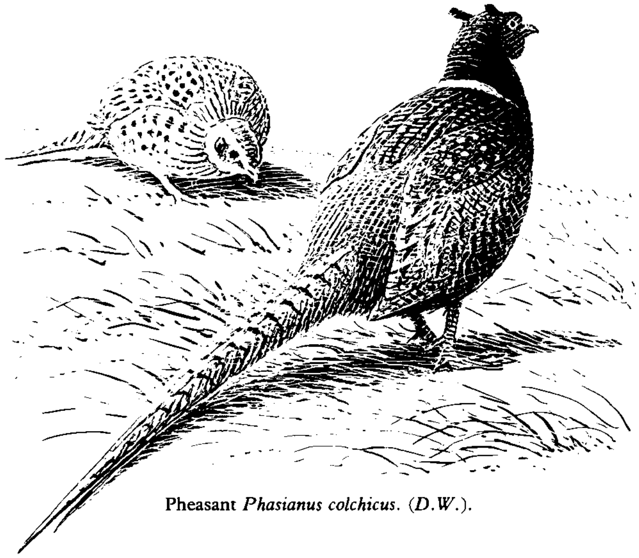
PHARYNX: the cavity of the throat, behind the buccal cavity and leading to the oesophagus and trachea respectively (adjective 'pharyngeal').

PHASE: equivalent of MORPH (see also POLYMORPHISM).

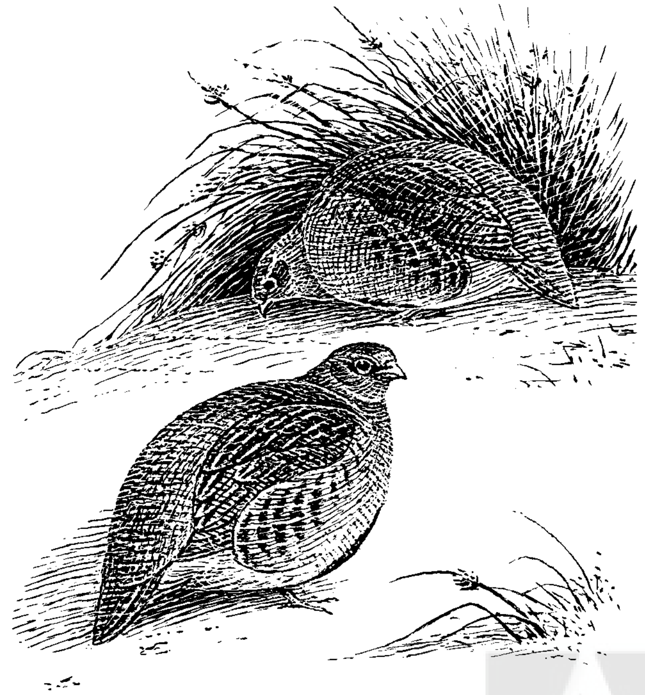
PHASIANIDAE: see under GALLIFORMES; PHEASANT.

PHEASANT: substantive name of many species of Phasianidae (Galliformes, suborder Galli); used without qualification in Britain for *Phasianus colchicus*; in the plural serves as a general term for the family. In the pheasants, called by that name, the males have bright colours or elaborate markings; the duller species, mostly a great deal smaller and with shorter tails, are given such names as 'partridges', 'quail', 'francolin', and 'snowcocks', but are not differentiated by any important characteristics, there being in fact a gradual transition between them. American quail are placed in a separate subfamily or tribe, the Odontophorinae, as distinct from the Phasianinae of the Old World.

Characteristics. The family is one of terrestrial birds which as a rule feed and nest on the ground, but in the majority of cases roost on trees at night. They are heavy birds; their wings are short and rounded, curved and fitting closely to the body, making them capable of a powerful, fast flight, but—except in some migratory quails—one that cannot be sustained for long (see FLIGHT). The legs are strong, with 4 toes (the hallux inserted somewhat higher than the others) armed with heavy claws, and adapted to scratching; the tarsus often shows a spur, or even 2 or more. The bill is short and thick, the upper mandible overhanging the lower. The tail varies from short to very long, the longest tail feathers being



Pheasant *Phasianus colchicus*. (*D.W.*).



Grey Partridge *Perdix perdix*. (*D.W.*).

those of Reeves's Pheasant *Syrmaticus reevesi* and Crested Argus *Rheinartia ocellata* which reach over 1½m in length. The plumage is ample and soft; the sexes are alike in some species, different in others.

Most pheasants are easily kept in captivity and are well known as ornamental birds. The most useful domestic bird, the common fowl, derives from a pheasant, the Red Junglefowl *Gallus gallus*. Other species such as peafowl *Pavo* have been kept in complete or semi-captivity for centuries; but they have not yet changed in size or characteristics, although mutations have occurred, such as the 'Black-shouldered Peafowl', 'Melanistic Pheasant', and the 'Yellow Golden Pheasant'.

A few of the more spectacular pheasants have figured prominently in myths and legends. This is particularly true of the peafowl which are sacred birds in much of India and appear in Buddhist, Hindu and various pagan mythologies including that of the ancient Greeks. The Buddha is sometimes depicted riding on a displaying peacock, and early Christians used the peacock as a symbol of immortality. A peacock competes with the Crested Argus for identification as the model for the Chinese Phoenix, the Fung-whang, while the Golden Pheasant *Chrysolophus pictus* has been suggested as the original of the Phoenix itself (see FABULOUS BIRDS). Concrete examples of such myths are to be found in the famous peacock throne of the Moghul and later the Persian emperors, in the heraldic use of peacocks in medieval Europe, or in the use of peacock feathers to denote rank among Chinese mandarins (the long tail feathers of Reeves's Pheasant, worn on the cap, are used to this day in Chinese opera to signify military characters.)

For convenience the pheasants are divided into 4 main groups:

American quail (18–36 cm). These comprise 36 species in 10 genera, of small rotund birds, distinguished from the Old World members of the family in having a stronger bill, the tip and edges of which are sharp and more or less serrated, and by other important anatomical features. Otherwise they resemble the partridges of the Old World and have similar habits. They are, as a rule, brightly and elaborately marked with brown, buff, yellow, reddish, grey, black and white. The tail varies from short to moderately long. The tarsi carry no spurs. The head is often crested and in most species the sexes are different.

Old World quail (14–20 cm). This group includes 10 species usually placed in 3 genera; they are very small and rounded, and appear tailless with weak bill and legs. The sexes are dissimilar in most species, the males heavily, and in some cases, colourfully marked with blue, brown, black and white.

Partridges (16–72 cm). The partridges (84 species in about 17 genera) are a large and diverse group of Old World birds with larger bills, stronger legs and longer tails than the preceding groups. The group includes bush quail, francolins, spurfowl, snowcocks and pheasant-grouse as well as grey-, red-legged-, sand-, snow-, stone-, tree-, wood-, and bamboo-partridges. In most species the sexes are similar and cryptically patterned. In a few forest species, notably the Roulroul *Rollulus roulroul*, the male is brightly coloured and crested. They vary in size from the quail-sized bush quail *Perdicula* to the Himalayan Snowcock *Tetraogallus himalayensis* which may weigh up to 3 kg.

Pheasants (40–235 cm). The pheasants proper comprise 48 species in 16 genera, of large but generally more slender birds, often with long, pointed tails and giving lateral displays. In all but one genus, the eared pheasants *Crossoptilon*, the sexes are different, the males being boldly and sometimes iridescently patterned with blues, reds, greens, and whites, and often adorned with elaborate structures used in display. The group includes Junglefowl *Gallus*, Peafowl *Pavo*, and several species well known from captivity such as Golden Pheasants and Silver Pheasants *Lophura nycthemera*, as well as the 'true' or 'game' pheasants *Phasianus*.

Distribution and habitat. The family in general is distributed throughout the world with the exception of a number of oceanic islands and the polar regions. Most members are natives of the Old World, and apart from artificial introductions, the family is represented in the New World only by the American quails. These are found in the temperate and warm parts of North, Central and South America, from the northern United States (one reaches southern Ontario in Canada) to Peru, Bolivia, Paraguay, and southern Brazil. They are particularly numerous and diverse in the southern United States, Mexico, and Central America. Some live in forests, others on woody or bushy plains and deserts, and a number are found on cultivated land, for example the Bobwhite *Colinus virginianus*. Some are adapted to life at a high altitude, although they never transcend the limit of the trees.

The Old World quail are widely distributed in all the continents of the Old World from Australia to Europe and Africa. There are separate species on Madagascar and New Guinea, but the New Zealand species is now extinct. Quail are typically birds of open country, preferring grassy plains but adapting to cultivated land as well. At least some species roost in tight circles, heads pointing outwards.

Partridges are found from Europe to Indonesia, their distribution centred on southern Asia with many species in India, Burma, and Malaysia. Francolins are found mostly in Africa, with only one other (monospecific) genus, the Stone Partridge *Ptilopachus* present south of the Sahara. Although most partridges live in grassland, scrub and farmland, they inhabit a wide variety of habitats from desert and alpine meadows to dense tropical rainforest.

Pheasants are almost entirely confined to Asia. The startling exception to this is the Congo Peacock *Afropavo congensis* which is restricted to the rainforests of central Africa, where it was only discovered in 1936. Several species have been successfully introduced in other parts of the world, notably *Phasianus colchicus* which is now established in Europe, North America and New Zealand. Most pheasants inhabit forests, either in the mountains of central Asia and China, or in the tropical rain forests of south-east Asia. A few species are adapted to forest edge (e.g. *Gallus*), open woodland (e.g. *Syrmaticus* spp., *Pavo*), or scrub (e.g. *Chrysolophus*, *Crossoptilon*). *Ithaginis*, *Lophophorus* and *Catreus* inhabit scrub, woodland and open grassland on steep, rocky hillsides, and *Phasianus* prefers patches of dense cover such as tamarisk, scrub or reedbeds, near cultivation, in steppe or in desert.

Populations. Pheasants, partridges and quail are of great importance to man as game-birds, providing sport and food. Wild populations are hunted and in Europe and America are sometimes protected and managed. Pheasants (*Phasianus*) and sometimes partridges (*Alectoris* and *Perdix*) are raised in captivity and released to supplement wild populations in some areas.

Most species are fairly numerous, but hunting pressure and habitat destruction have already exterminated 2 species (*Ophrysia* the Indian Mountain Quail, and *Coturnix novaezealandiae* the New Zealand Quail) and have seriously threatened the survival of at least 16 other species. Most of these are pheasants from tropical and montane forests. However, a number of the endangered species can be bred in captivity and in certain cases (for example the Cheer *Catreus wallichii*) captive-bred stock has been reintroduced to the wild. There are rumours, too, of rediscovery of the Indian Mountain Quail.

Movements. Most pheasants are sedentary in habits and often show strong local attachments. Some mountain species migrate up and down hill at different seasons, and Bulwer's Wattled Pheasant *Lophura bulweri* is said to be nomadic in search of fruiting trees, but only a few quails of the genus *Coturnix* are truly migratory. *C. coturnix* migrates from Europe and central Asia to Africa and India, an astonishing feat for such heavy, round-winged little birds, and Harlequin Quail *C. delegorguei* of Africa periodically invade suitable areas in large numbers, deserting them again after breeding.

Food. The family is mainly vegetarian, but the amount of animal protein taken varies from none to a large proportion of the diet. Pheasants are catholic feeders and rarely specialize on one type or species of food. Important foods include seeds, shoots, berries, roots, bulbs, and insects. Those living in grassland or scrub eat mainly seeds and shoots, while in woodland berries may be more important. In tropical forests, fallen fruit and invertebrates such as grubs and termites are the main items of diet, while at high altitudes in particular, some species (notably eared *Crossoptilon*, Cheer *Catreus*, and monal *Lophophorus* pheasants) are adapted to unearthing bulbs, roots and worms with their feet or bill (*Lophophorus* uses only its bill and is capable of excavating holes up to 30 cm in depth in search of bulbs). Peafowl are known to eat lizards and snakes. Desert-dwelling partridges may depend on grasshoppers and locusts, but most partridges and quail are vegetarian as adults. However, the chicks of almost all species in the family are raised on insects and other invertebrates (an exception being snowcock young, which feed on legumes). The current decline of Grey Partridges *Perdix perdix* in Britain is attributed largely to the increased use of pesticides which kill chick food.

Behaviour. A variety of patterns of social organization is found in the family, depending largely on habitat. Most of the American quail and the partridges, living in scrub and open country, are highly gregarious, found for much of the year in 'coveys' comprising one or more family parties. Typically these number between 4 and 10 but in some species living in very bare habitats, such as *Callipepela*, *Colinus*, *Ammoperdix*, *Tetraogallus*, *Lerwa*, and *Francolinus* spp., such groups may amalgamate to form flocks of 20–40 birds. Most partridges and American quail are monogamous, pairs being formed and maintained all year round; in spring these pairs leave the coveys and remain dispersed during breeding, but they do not defend territories. Some partridges do not gather in coveys, but remain in pairs all year, the broods fragmenting on reaching maturity. These are generally birds such as *Rollulus* and *Melanoperdix* that live in dense tropical forests.

Except on migration most Old World quail are solitary. Some, however, live, like partridges, in coveys. On the breeding grounds, the males occupy territories which they defend against other males, and in which they sing to attract females who then nest within the territory; they are sometimes polygynous. On migration, they may travel in coveys or larger temporary flocks.

Among the pheasants, social patterns are varied and often poorly understood. Those that live in open scrub or open woodland are found in coveys like those of partridges, and are monogamous. Eared (*Crossoptilon*) and blood pheasants (*Ithaginis*) often gather in larger flocks of up to at least 20. Coveys break up into pairs in the breeding season. Species living in dense scrub or around the edges of forest are often found in single sex groups or are organized into harems with one male defending each group of females, and surplus males remaining in bachelor groups (for example junglefowl). Alternatively, the males may defend territories in which live one or more females (for example true pheasants *Phasianus* and long-tailed pheasants *Syrmaticus*). Peacocks *Pavo* defend small aggregated territories resembling leks. Most species are polygynous, and the males take no part in rearing the young. Species that live in dense forest tend to be more solitary and secretive. Some live in pairs (for example tragopans and the Congo Peacock *Afropavo*) but others are solitary, and the sexes meet only briefly during the mating season, when males attract females to special display grounds or seek them out (for example argus and peacock pheasants *Polyplectron*). In some gallopheasants *Lophura*, the sexes live separately for most of the year, each bird in its own home range, but may gather in flocks at other times.

Display and voice. In the quail and partridges, displays are relatively simple affairs; courting males strut around the females with body feathers erected, wings lowered, and tail spread. Patches of colour on the face or flank may be exaggerated by the adoption of special postures or the crest may be raised and spread. Such display precedes pairing and is not generally repeated before copulation. American quail are on the whole noisy birds; those that live in open country have harsh, repetitive, staccato voices used in alarm calls, choruses at dawn and dusk, or for advertisement by unmated males. Forest species give whistles or hoots, the most elaborate forms being the loud, hooting choruses of the tree quails *Dendrortyx* and the piping, nocturnal song of the singing quails *Dactylortyx*. Old World quail are more silent except in the breeding season when males give their distinctive song to advertise their territories and attract females (the song is a series of high-pitched whistles, *quit quit quit* repeated many times). Partridges are talkative birds with loud alarm calls, and they are fond of choruses at dawn and dusk. They make a variety of sounds: low, grating creaks (*Perdix*, *Ammoperdix*); harsh, staccato sounds, as suggested by the name 'chukar' (*Alectoris*); cackles (*Galloperdix*); sharp, high-pitched creaks and twitters (*Francolinus*, *Perdicula*, *Bambusicola*), and low, melodious whistles (*Tetraogallus*). Forest partridges give shrill, piping whistles, and some species are fond of duetting, for example *Rhizothera longirostris* the Long-billed Partridge, and *Caloperdix oculea* the Ferruginous Wood Partridge.

In pheasants, displays are elaborate, colourful and varied. The males of most species display laterally, that is by presenting one flank of their body to the female, with the body feathers and wing lowered on that side, raised on the other, and the tail spread vertically either, in species with flat tails such as tragopans, Koklass *Pucrasia* and true pheasants, by opening the tail and tilting it on one side, or, in species with compressed arched tails such as gallopheasants, by opening the tail vertically. Such displays exaggerate the size of the performer and reach their most extreme form in the Crested Argus in which the enormous tail feathers (the largest feathers in the world, 15 cm wide and reaching over 1.5 m in length) are spread, like a sail, in front of the female. Lateral displays are also used in, for example, *Phasianus* to intimidate other males. Some species do not display laterally or have in addition, different methods. Eared pheasants have simple partridge-like displays, and in long-tailed pheasants *Syrmaticus* the males strut in front of the females with the feathers of the neck and head erected to give a swollen appearance. Peacock pheasants have both lateral and frontal displays. Monals *Lophophorus* also display in flight. But the most spectacular displays of all are the great frontal shows of some of the larger, flat-tailed species. In these the tail is erected over the back and spread like a fan, while the wings are lowered or spread and the head is retracted between the shoulders. The effect is to show off the colours of the back (e.g. *Lophophorus*), wings, tail or tail coverts: in peacocks the latter are enormous and beautifully patterned with metallic ocellae. In the Great Argus *Argusianus argus*, the secondary feathers are very long and broad and in display they are spread over the back, with the head hidden behind them, so that the bird looks like a huge painted fan.

As well as lateral and frontal displays, many pheasants use so-called 'tid-bitting' ceremonies to call their mates to proffered items of food, over which they then display. Displays are often enhanced by the use of special structures, notably bare patches of skin on the face which can be enlarged or flushed at moments of sexual or aggressive excitement. These are normally red, sometimes, in forest species, blue. The commonest forms are the red wattles or facial 'roses' of the true, eared and gallopheasants. In junglefowl, a 'comb' is also present on the crown of the head, and in Bulwer's Wattled Pheasant, the blue facial wattles can be extended beyond the head in front and behind, which, together with the enormous white tail gives this species a bizarre and spectacular display. Tragopans have erectile, bare horns on the head and lappet below the face which can be greatly expanded in display to form a large, blue or yellow bib, patterned with orange, which resembles a brightly coloured piece of silk. Other species possess crests or ruffs used in display. The long, double crest of the Koklass *Pucrasia macrolopha* can be raised vertically and out from the head, as can the short 'ears' of true pheasants, while in *Chrysolophus* (Golden and Lady Amherst's Pheasants) the lateral display is enhanced by a beautiful yellow or white ruff, boldly marked with black, which can be spread from the nape to the bill, completely hiding one side of the face.

Some pheasants, particularly gallopheasants *Lophura*, long-tailed pheasants and tragopans, whirr their wings in advertisement displays to announce territory ownership or attract females. Others have loud advertisement calls which may be harsh and grating (*Chrysolophus*), raucous and deep (*Phasianus* and *Pucrasia*), high-pitched and whistling (*Ithaginis*, *Lophophorus*, *Lophura*, *Polyplectron*), or a plaintive, musical wail (*Tragopan*, *Pavo*, *Argus*, *Rheinartia*). The crowing call of the junglefowl is the well known sound of the domestic cockerel. Apart from crowing calls, some pheasants are talkative and noisy, particularly those that are gregarious like *Ithaginis*, *Catreus*, *Gallus* and *Crossoptilon*, and make continual clucking or crooning sounds. Others are very silent or like *Syrmaticus* have weak, quiet voices. Male true pheasants have a raucous, repetitive alarm call, the well known *cock cock cock* . . . .

Breeding. The nest is very simple, usually placed on the ground, perhaps protected by a rock or bush, or situated at the foot of a tree; it may be lined with grass or leaves but not with feathers. In the Crimson-headed Wood Partridge *Haematortyx sanguiniceps* the nest may be raised on a tussock to avoid flooding, and wood quail *Odontophorus* of South America are reported to build domed nests; tragopans are unique in building bulky nests in trees. The eggs are plain (white, buff, olive green) or spotted. Clutch size is highly variable: argus and peacock pheasants lay only 2 eggs and most tropical species of all groups lay 3–5 eggs in a clutch. But open country birds lay larger clutches, typically about 8–12; some species lay even more and the Grey Partridge lays probably the largest clutch of all birds, at least 20 eggs in many cases. Clutch size is complicated in *Phasianus* by egg-dumping habits (several birds may lay in one nest) and in *Alectoris* by 'double-clutching' where the male sometimes incubates a second clutch. There is normally only one clutch in a season, but nest predation is often heavy and birds may re-lay several times. In most cases the males take no part in incubation, although in monogamous species they may help to rear the young. In at least 2 species, the Golden Pheasant and the Great Argus, the female incubates continuously without ever leaving the nest, even to feed or drink, and without moving for much of the time. The chicks of all species are born fully covered with down and they leave the nest soon after hatching; some have well-developed wing feathers and are soon able to fly and to roost up at night with the mother. Most species mature in their first year, but in a few large pheasants maturation of males in particular is deferred for one or more years and in certain cases (peacocks and argus pheasants) full adult male plumage is not attained for 3–5 years. Such species are often long lived, and one Great Argus survived for more than 30 years in captivity.

PHEASANT, CROW-: see CROW-PHEASANT; and for family see CUCKOO.

PHENETIC: term applied in taxonomy to a grouping or arrangement based on observable resemblances that may or may not also be evidence of phyletic relationship.

PHENOLOGY: literally the study of visible appearances, and thus used in respect of seasonally recurring events in animate nature, such as—in the ornithological field—first arrival of a migratory species, first laying of a species, last singing of a species, and the relation of these with meteorological data.

PHENOTYPE: the group in which an individual falls by reason of its appearance, which is the result of interaction between external factors and the GENOTYPE; see also GENETICS.

PHILEPITTIDAE: see under PASSERIFORMES, suborder Deutero-Oscines; ASITY.

PHILOPATRY: fidelity to home area—a term introduced as the English equivalent of ORTSTREUE (see DISPERSAL).

PHILYDORINAE: see OVENBIRD (1).

PHOEBE: substantive name of *Sayornis* spp. (see FLYCATCHER (2)).

PHOENICOPTERIDAE: see under PHOENICOPTERIFORMES; FLAMINGO.

PHOENICOPTERIFORMES: an order, comprising the sole Recent family Phoenicopteridae (see FLAMINGO). In Wetmore's system treated as a suborder Phoenicopteri of the order Ciconiiformes, but other authors consider them more closely related to the Anseriformes, and, more recently, to the Charadriiformes, suborder Charadrii, next to the Recurvirostridae.

PHOENICULIDAE: family of CORACIIFORMES; WOOD-HOOPOE.

PHOENIX: see FABULOUS BIRDS.

PHORESY: transport of one species of organism by another that is not parasitic upon it; the term is applied particularly to insects, e.g. Mallophaga carried by louse-flies on a bird (see ECTOPARASITE).

PHORORHACI: see under FOSSIL BIRDS.

PHOTOGRAPHY: as applied to birds—a comparatively young aspect of ornithology. Although its pioneers were active in the 1890s, it was in fact only during the first decade of the present century, and especially after the First World War, that its impact became important and its practice widespread, until today the camera may be regarded, in varying degrees and with different purposes, as a tool of ornithologists. At one extreme, its object may be purely scientific; at the other, merely recreational—a field sport as it were, with the bird taking second place to the artistic effectiveness of the result.

Whilst it is for its scientific value as an aid to ornithology that the camera appeals to the serious student, it is of wide importance in more general directions. Fundamentally, the ornithologist is a collector, as are all naturalists. The museums and private collections are the foundation stone of the science. But as these grew more and more complete, interest turned to the living bird, and with the advent of conservation, as we know it today, aimless collecting fell into disrepute. Here it was that the camera came into its timely own, for with it the instincts of the collector could be satisfied without the need to take life.

Again, if today the public is much more 'bird-minded' than even 20 years ago, photography, more than scientific awareness, is one of the main causes. Ornithology, once the hobby of the few, was the interest of those to whom leisure and opportunity gave access. Today it is shared, with vastly differing degrees of seriousness, by all the many who subscribe to societies and clubs that serve birds and their observers (see BIRD-WATCHING).

Illustration. In this minor revolution of our age the bird photographer has played a decisive part. Without illustration it was of little avail to write about, or appeal for, an unknown bird with some strange name. The photograph has added reality and substance to the written word; and the ease with which it can be reproduced has made it available to the public press. Its rise has been at the expense of, or at least has coincided with the decline of, the coloured Plate, and none would for a moment fail to regret that fact. The age, however, of the stately coloured Plate was the age of patronage, and with its passing the photograph filled a vital gap. Moreover, the skill of the painter was confined to the gifted few; the ability to take a photograph, albeit with different degrees of perfection, was open to all capable of mastering its fundamental technique. Thus those who visit distant places are able, either by illustrated books or lectures, to convey visually to the layman their experiences, the countryside, and its birds. This has been the case especially with the moving film, and the influence of bird photography on the public has reached a new peak with its adoption by television. In short, photography in all its guises—monochrome, colour, and cinematography—has gained for birds a very wide audience, not necessarily knowledgeable, but sympathetic and interested; and it is largely from this pool that has sprung modern 'ornithomania' and the general acceptance of the concept of conservation.

Scientific applications. In the scientific field, the camera stands supreme in recording bird behaviour, e.g. displays and the like. However vivid the written word, it can never compete with the visual record, with the possibility of frame-by-frame analysis. Electronic flash has enabled the student of avian aerodynamics to see in detail wing positions too fast for the human eye to register. Its ability to stop all movement has assisted in the exact identification of insect food brought by birds to their young.

Photography can also give valuable aid in the enumeration of birds, e.g. sea birds breeding densely on a cliff-face, or flocks of birds such as Anatidae in the open photographed from the air (see CENSUS). Mention may also be made of the photography of radar screens showing birds flying overhead (see RADAR). In systematic work, monochrome or colour photographs of a series of skins are often useful to illustrate an author's point.

Trends. Heralded at its advent with acclaim, bird photography has with its increasing popularity come under the fire of criticism. Today pictures of outstanding merit and technical excellence have become the rule, so that the serious ornithologist tends to be scornful of the man who uses a camera but, too often, in his eyes, fails to make any biological contribution along with the photograph. Moreover, photography at the nest, which has for long been the chief focusing point, does entail disturbance. The fact that correct technique and due care of approach can minimize this danger was satisfactory so long as bird photographers were few in number and therefore of little importance. But today many have adopted the pursuit as a field sport, and with numbers the element of possible disturbance becomes of more significance, particularly in the case of rare birds which by their very rarity present a challenge to the photographer. To counter this danger recent legislation has made it an offence deliberately to disturb birds at the nest, and permission for any such photography in Britain has now to be obtained from the Nature Conservancy Council. Consequently there has been a marked reaction from bird-at-the-nest portraits to bird-in-habitat—waders on the tide-line, carrion-eaters at bait, birds in flight—in short to illustrate activities rather than to make portraits.

Equipment. Until the 1960s most serious bird photography was undertaken with large camera, large lens, and large film or plate and with its going went the infinite beauty of the delicate tones in monochrome and the superb detail of plumage. Such equipment was not easy to use, was cumbersome and heavy and limited in its use. But with the advent of the 35 mm camera bird photography was revolutionized. Small and lightweight bodies, high definition lenses with a great variety of focal lengths ideal for either nest or wait-and-see photography; electronic flash now coupled with the metering system on the camera giving accurate exposures whether used as the main lighting source or as a fill-in to soften harsh shadows; high resolution films in colour and in black and white, with faster speeds making it possible to take photographs that would have been impossible before. Who knows what the future holds in store with the continued rapid advance in photographic technology? One thing is certain: that the computer and video-tape will replace many of the methods used today and these developments will give bird photography new life, new purpose and new areas to conquer. PHOTOPERIODISM: the use of the daily light/dark cycle as a source of predictive information, chiefly in the regulation of seasonal changes in physiological conditions and behaviour. At a given latitude, predictable changes in daylength allow its use by birds and other animals as a proximate factor controlling annual cycles of, for example, breeding, moult and migration in many non-equatorial species. Some species respond directly to increases in photoperiod, beginning the development of, for example, reproductive condition when daylength reaches a threshold value, so that it may be completed in time for the production of young at an opportune season (see BREEDING SEASON). In other species, the seasonal changes in photoperiod may serve also, or only, as a synchronizer for circannual rhythms (see RHYTHMS AND TIME MEASUREMENT). (See also ENERGETICS; MIGRATION; MOULT). Most photoperiodic species become insensitive at a certain time of year to photoperiods which normally would stimulate reproductive development. This phenomenon is described as photorefractoriness and its adaptive value is to prevent breeding at seasons when it is disadvantageous. The complex endocrine events associated with photostimulation are reviewed in Murton and Westwood (1977).

Baker, J.R. 1938. The evolution of breeding seasons. *In* de Beer, G.R. (ed.). Evolution. London.

Murton, R.K. & Westwood, N.J. 1977. Avian Breeding Cycles. Oxford.

PHYLETIC: used in the same sense as 'phylogenetic' (see PHYLOGENY).

PHYLOGENETIC TAXONOMY: see TAXONOMY.

PHYLOGENY: sometimes written 'phylogenesis', the evolutionary history of a taxon—contrasted with 'ontogeny', the development of an individual within its own life-span; both 'phylogenetic' and 'phyletic' are used as adjectives. (See TAXONOMY).

PHYLUM: a taxonomic category higher than class (see ANIMAL KINGDOM).

PHYSIOLOGY: the science of bodily function. The use of chemical and physical methods for this study involves the disciplines of biochemistry and biophysics; or the subject may be divided, according to the particular function studied, into such specialities as neurology and endocrinology. The physiology of birds is dealt with in this work under the names of the various systems of the body, and under other special heads, e.g. HEAT REGULATION; METABOLISM; NUTRITION.

PHYTOTOMIDAE: see under PASSERIFORMES, infraorder Tyranni; PLANTCUTTER.

PIAPIAC: *Ptilostomus afer* (see CROW (1)).

PICAE: the second order of Linnaeus.

PICARIAE: formerly used as the name of an order, placed next to the Passeres, which included a motley assemblage of groups now placed in the Piciformes, Apodiformes, Caprimulgiformes, Coraciiformes, and Cuculiformes (and by Stresemann in a still greater number of orders), and originally also the birds now placed in the Psittaciformes.

PICATHARTINI: see BABBLER.

PICI; PICIDAE: see below.

PICIFORMES: an order, alternatively 'Pici', comprising 2 suborders, Galbulae, Pici; 6 families: Galbulidae (JACAMAR), Bucconidae (PUFFBIRD), Capitonidae (BARBET), Indicatoridae (HONEYGUIDE), Ramphastidae (TOUCAN), Picidae (WOODPECKER). The Galbulae are here divided into 2 superfamilies comprising 5 families; but some authors prefer to place all but the first 2 families in the suborder Pici. The Picidae are divisible into 3 subfamilies—Picinae (typical woodpeckers), Picumninae (piculets), and Jynginae (wrynecks). The relationship of the families is indicated by certain anatomical characters common to all. These include a zygodactyl foot, with a distinctive arrangement of the flexor tendons; also, except in the Galbulidae, absence of down plumage at any age in most species. A specialized form of bill is characteristic of each family. Other characters shared by all of them include those of the bony palate, the rather weak structure of the plate of the breast bone and the general appearance of arboreal birds, reminiscent of early arboreal Passerines, to which they may be actually related. Their wide ecological radiation suggests long periods of development and hence the antiquity of all the families in this order.

PICULET: substantive name of Picumninae spp. (see WOODPECKER).

PICUMNINAE: see WOODPECKER.

PIE: see MAGPIE; TREE-PIE (for family see CROW(1)).

PIEDTAIL: substantive name of *Phlogophilus* spp. (for family see HUMMINGBIRD).

PIGEON: substantive name, with 'dove' as a frequent alternative, of the species of Columbidae (Columbiformes): in the plural general term for the family. In popular speech in England 'dove' is used for the smaller and 'pigeon' for the larger forms, but this usage has not been followed by ornithologists; thus, the Stock Dove *Columba oenas* is a typical pigeon in every way.

Characteristics and distribution. Pigeons vary in size from the Diamond Dove *Geopelia cuneata* no bigger than a Skylark *Alauda arvensis* to the crowned pigeons *Goura* spp., which are nearly as large as hen Turkeys *Meleagris gallopavo* (*c.* 17–90 cm). They have soft, dense plumage with feathers that detach easily, and plump, compact bodies with rather small heads. The wings are usually medium sized but may be rather short and rounded or rather long. The tail may be square ended, rounded or pointed and of variable length. The bill is usually rather small, hard at the tip but soft at the base and with a naked cere over the nostrils. The legs are usually short but are longer in some of the terrestrial species. In most species the female is slightly duller than the male; in some the sexes are alike, but in others the male differs strikingly in colour from the female.

The family has been divided into numerous genera, 43 are recognized here; 12 of these are monotypic. The subfamily Columbinae includes not only all the more typical pigeons and doves but also the various superficially partridge-like forms such as the quail doves *Geotrygon* spp. of Central and South America, the Pheasant Pigeon *Otidiphaps nobilis* of New Guinea, the many rather small South American doves, and the Australian bronzewings (see later). Most members of this subfamily are primarily seed-eaters; they differ much in colour, but are mostly clad in soft shades of brown, grey or vinous in various combinations. Often they have iridescent, white, or black areas on the neck, wings, or tail that are exhibited in display or when the bird takes wing.

The subfamily Treroninae consists of a probably bi-phyletic and possible polyphyletic assemblage of arboreal fruit-eating species. Among them are the green pigeons *Treron* spp. of the Afrotropical and Oriental regions. These are primarily soft green in colour, often with beautiful yellow, orange or mauve markings and brilliantly coloured eyes and ceres. Unlike other fruit pigeons they have hard, muscular gizzards, and digest the seed of the wild figs on which they largely feed. The often brilliantly coloured fruit doves of the genus *Ptilinopus* and the larger imperial pigeons *Ducula* spp. differ from each other in size and in the more diverse colours found in the smaller species; they are widespread in the Indo-Malayan and Pacific areas, a few species reaching India proper and Australia. The New Zealand Pigeon *Hemiphaga novaeseelandiae* and the very distinct Top-knot Pigeon *Lopholaimus antarcticus* of eastern Australia are probably related to them, as the blue fruit pigeons *Alectroenas* spp. of the islands of the Indian Ocean almost certainly are. All these forms have a broad gut and void intact the (often large) seeds of the fruits which they swallow whole.

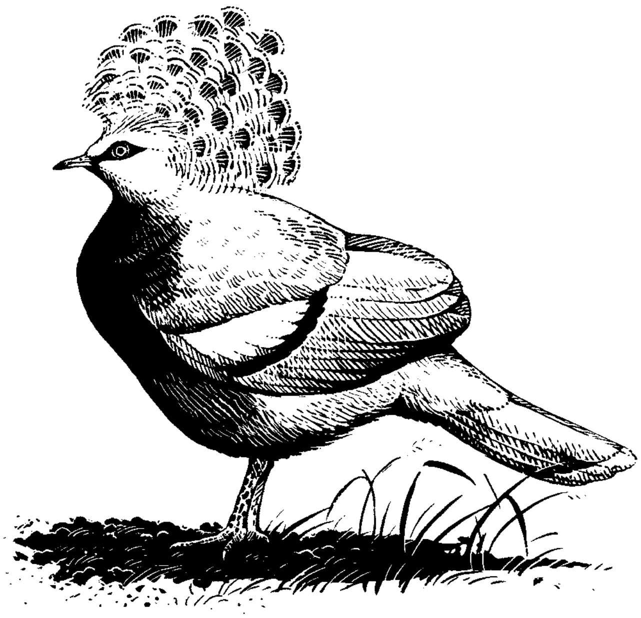
The subfamily Gourinae consists of 3 closely related crowned pigeons *Goura* spp. of New Guinea. They have large, laterally flattened crests of lacy-looking disconnected or spatulate-tipped feathers.

The subfamily Didunculinae comprises only one species, the Tooth-billed Pigeon *Didunculus strigirostris* of Samoa.

Only a few of the more noteworthy of the 255 species of pigeons can be mentioned individually here. The Rock Pigeon or Rock Dove *Columba livia*, a native of Europe, western Asia, India and north Africa, is the ancestor of the many breeds of domestic pigeons and of their feral descendants now common in towns (and often also in the country) throughout most of the world (see DOMESTICATION; HOMING PIGEON). The wild form is bluish grey with two black wing bars and an iridescent neck. It roosts and breeds in caves and on sheltered cliff ledges and feeds on the ground, usually in open areas.

The long-tailed Passenger Pigeon *Ectopistes migratorius* of eastern North America was remarkable for its extreme gregariousness, nesting and migrating in enormous flocks. Unfortunately this made it very vulnerable to human predation and it was exterminated in the wild by 1894 after a long period of relentless exploitation by man (see EXTINCT BIRDS). A closely related but smaller and less brightly coloured species, the Mourning Dove *Zenaida macroura*, is still common, ranging from Alaska to Panama.

The African Collared Dove *Streptopelia roseogrisea* is the ancestor of the domesticated Barbary Dove or Blonde Ringdove and its white variety the so-called 'Java Dove'. A related Asian species, the Collared Dove *Streptopelia decaocto*, has recently spread across Europe in a remarkable manner; the first one to be seen in Britain was in 1952; now it is a common and characteristic bird of lowland villages, suburbs, farmsteads and some towns, throughout Britain.



Victoria Crowned Pigeon *Goura victoria*. (*D.A.T.*).

The little Masked or Namaqua Dove *Oena capensis* of Africa and Madagascar frequents open country and is of nomadic habits. It has a very long, graduated tail and shows marked sexual dichromatism, the male having a black face and breast bordered with pale grey, while these areas are light drab in the female. Another strongly dichromatic species, with a most unusual type of sexual difference, the Flame Dove or Orange Dove *Ptilinopus victor* of Fiji is unique in colour: the male is vivid orange with an olive-yellow head, and the female dark green but with her head the same colour as her mate's.

The Australian bronzewing pigeons of the genera *Phaps*, *Geophaps*, *Ocyphaps* and *Petrophassa* are good examples of adaptive radiation. Although they have diverged greatly in the course of their speciation and adaptation to different biotopes, their colour patterns and behaviour still show their close phylogenetic affinities. They include the only 2 genera, *Ocyphaps* and *Geophaps* (subgenus *Lophophaps*), which have long, pointed crests.

Habitat. Pigeons, of different species, inhabit many types of country, from rocky uplands and scrub-grown semi-desert to tropical forest. Most species are at least partly arboreal but a few are terrestrial or cliff-dwelling. The family is almost cosmopolitan, being absent only from the Arctic, sub-Arctic, Antarctic and sub-Antarctic areas and some oceanic islands. Feral populations of *Columba livia* now exist in some places where no wild species lives or is thought formerly to have done so.

Food. Seeds, fruits, berries, flowers and young leaves are the main foods of pigeons but many species also take small snails and/or other invertebrate animals. Some, perhaps most or all, also take such mineral substances as salt-impregnated earth and crushed shell. Most pigeons have strong, muscular gizzards and long, narrow intestines, but in some of the fruit-eating species, the stomach is designed for rubbing off the pulp or pericarp of fruits rather than grinding seeds and the gut is short and wide. These latter birds digest only the pulp of the fruits they eat, voiding the stones intact. Pigeons drink by immersing the bill and sucking, a habit shared with some estrildid finches but one which many species that do not habitually practise it, can and do use when necessary.

Behaviour. Most pigeons are strong flyers and some are migratory or nomadic. Some species, however, spend much of their time on the ground and make use of their wings only in an emergency or to fly up to perch on a branch or rock. Most of the species whose behaviour is known are to some extent gregarious when not breeding, some gathering into large flocks. Some species often or usually breed colonially; and in others large numbers of individuals may congregate at good feeding places even in the breeding season.

An old writer on domestic pigeons noted that 'These birds have many pretty and whimsical gestures when that they are salacious'. It would be difficult to make a more succinct and yet appreciative statement. Suffice to say that courtship displays are often similar to, though seldom identical with, those used in threat and that, as in other birds, they exhibit bright or striking parts of the plumage or soft parts to best advantage. Pigeons pair at least for the duration of a nesting cycle, in most known cases for an entire breeding season and sometimes for life. In many species the male drives his mate away from potential sexual rivals during the period that she is sexually receptive. The copulation ceremonial may be comparatively short and simple as in the doves of the genus *Streptopelia* or surprisingly involved and 'complicated' as in some of the Australian forms such as the Diamond Dove *Geopelia cuneata*.

Voice. Typically pigeons utter cooing, crooning or booming calls and inflate their necks when so-doing. Some utter whistling, screaming, harsh or cackling cries in lieu of or additionally to cooing. Some usually or often punctuate their display flights with loud wing-clapping. Rather similar, but less deliberate-seeming, more rattling or clattering wing claps may be made (by some species, including the Rock Pigeon and its feral descendants) when the bird suddenly takes wing in alarm or when it intends to fly fast for some distance, for example to a feeding site some miles away.

Breeding. All species whose behaviour is known build a shallow, usually slight but often strongly interwoven nest of twigs, wiry stems, thin roots or similar materials; species that nest on the ground, on ledges or in holes may sometimes dispense with nesting material although more usually they build some sort of nest. One or (in a majority of species) 2 white or (less often) buffish, unmarked eggs are laid. From these hatch helpless nestlings clad sparsely in coarse down which is usually yellow or buff in colour. The young insert their soft bills into their parents' mouths and are fed by regurgitation. They grow rapidly as a rule; some of the smaller species can fly before they are 2 weeks old. Some of the larger species, such as the New Zealand Pigeon, take longer than most and the Nicobar Pigeon *Caloenas nicobarica* is said to grow astonishingly slowly, not fledging until 3 months old (Nicolai 1969). The female usually does most or all of the building, the male bringing her materials. Both sexes share in incubation (from 14–18 days) and care of the young. Both produce 'pigeon's milk', a nutritious curd-like substance formed by the proliferation and sloughing off of the cells of the lining epithelium of the crop (see CROP MILK); for the first few days this constitutes the sole food of the young. The fledged young are fed by both parents, or by their father only, until at least some days after they are strong on the wing. D.G.

PIGEON, CAPE: sailors' name for the Pintado Petrel *Daption capense* (see PETREL).

PIGEON, HOMING: see HOMING PIGEON.

PIGEON MILK: see CROP MILK.

PIGMENT: see COLOUR; EGG; PLUMAGE.

PIGMENTS, VISUAL: see VISION.

PIHA: substantive name of *Lipaugus* spp. (for family see COTINGA).

PILEATED: crested or capped, referring to the shape of the crown-feathers.

PILOT-BIRD: *Pycnoptilus floccosus* (for family see WREN (2)).

PINEAL BODY: see NERVOUS SYSTEM (Fore-brain).

PINFEATHER: a growing feather still in its sheath.

PINION: poetical word for a wing; sometimes applied to the part of the wing comprising the primary feathers, or even to a single one of these.

PINIONING: rendering a captive bird permanently incapable of flight by cutting one wing at the carpal joint and so removing the basis from which the primary feathers grow (compare CLIPPING). This procedure makes it possible to keep waterfowl and reasonably large ground-birds in the open; it is the lopsidedness, more than the reduction in wing area, that is effective.

PINKFOOT: colloquial short name (plural 'pinkfeet') for the Pink-footed Goose *Anser fabalis brachyrhynchus* (see under DUCK).

PINTAIL: substantive name of certain *Anas* spp.; used without qualification for *A. acuta* (see DUCK).

PIOPIO: native name for *Turnagra capensis*, also known as the New Zealand Thrush, a bird of uncertain affinities but usually placed in the Turnagridae (see THRUSH, NEW ZEALAND).

PIPIT: substantive name of species of *Anthus* and related genera (see under WAGTAIL).

PIPPED: see HATCHING.

PIPRIDAE: see under PASSERIFORMES, suborder Deutero-Oscines; MANAKIN.

PIQUERO: alternative name for *Sula nebouxii* (see GANNET).

PIRACY: term describing a range of inter- and intraspecific food-stealing activities (also called clepto- or kleptoparasitism). Food items procured by one individual (the 'host') are forcibly stolen by another (the 'pirate' or kleptoparasite). What distinguishes piracy from the many other types of feeding interaction is the fact that the host is usually harassed, often violently and for long periods, into giving up items of food. The pirate may snatch food from the host's grasp or the host may drop an item on being chased. Frequently, however, the host is harried into regurgitating food which has already been swallowed. Several pirates may harass one host individual at a time and may steal food from each other once it has been secured. 'Piracy' of nest material also occurs, but this article is only concerned with food-stealing.

The distribution of piracy among birds. Piracy occurs in many animal groups but it is particularly widespread among birds. Its distribution across the various orders, however, is far from random. Only one duck, the American Wigeon *Anas americana*, is a regular pirate although ducks are frequently found in mixed species flocks and are themselves hosts for a number of pirate species. Piracy has never been recorded among the seed and fruit-eating Galliformes, Columbiformes and Psittaciformes and is sporadic among passerines even though these constitute the vast majority of bird species. On the other hand piracy is extensive among the Accipitriformes, Falconiformes and Charadriiformes (particularly the families Stercorariidae and Laridae). These 3 orders together contain 60% of recorded pirate species but only 7% of the known bird species of the world. The frequency of piracy within an order is therefore not simply a reflection of the number of species it contains but appears instead to depend on particular ecological conditions which make piracy profitable. Species of some orders encounter these conditions more often than those of others and the pirate individuals are favoured by natural selection.

Conditions favouring piracy. Regular association of one type or another is an obvious prerequisite for the development of piracy. When raptors pursue prey the latter may drop or regurgitate food to avoid capture. Raptor species may then begin to harass rather than capture 'prey' to obtain already immobilized food. Turkey Vultures *Cathartes aura*, for example, which commonly prey on young Great Blue Heron *Ardea herodias* chicks, sometimes attack older nestlings. As part of their (successful) defence mechanism, older chicks regurgitate food which the vultures then feed to their own offspring. Various raptor species have also been recorded snatching food from one another including one observation of a triple piracy where a Sparrowhawk *Accipiter nisus* was robbed by a Merlin *Falco columbarius*, the Merlin by a Honey Buzzard *Pernis apivorus* and the Honey Buzzard by a Peregrine Falcon *Falco peregrinus*. Piracy is commonest in mixed species colonies of seabirds. In tern colonies, adults steal both from each other and from feeding chicks, and gulls nesting in the colony steal from the terns and from conspecifics. In colonies of Puffins *Fratercula arctica* and Black Guillemots *Cepphus grylle*,

Arctic Skua *Stercorarius parasiticus* parasitizing Lesser Black-backed Gull *Larus fuscus*. (*Photo: P. Munsterman*).

Jackdaws *Corvus monedula*, gulls and even terns operate as ground-based pirates while skuas (*Stercorarius* spp.) and some gulls attack the auks as they return with food to their burrows. Other associations in which piracy is common are single and mixed species feeding flocks (e.g. Black-headed Gulls *Larus ridibundus* robbing Lapwings *Vanellus vanellus* of earthworms), and associations based on scavenging and predator mobbing responses. The mobbing response appears to be the origin of Magpies *Pica pica* stealing from Golden Eagles *Aquila chrysaetos* and of crows stealing from harriers, falcons and kites. Pirates are most likely to attack when food carried by the host is large, visible, of high quality or is scarce and when the host is unlikely to escape.

Many species which show piracy are dietary opportunists. In these cases piracy is one of many feeding strategies which may be employed at different times. For example the omnivorous House Sparrow *Passer domesticus* has been recorded stealing immobilized katydids (Orthoptera) from female digger wasps (*Sphex* spp.). Several gull and egret species are similarly opportunistic pirates. Some species, however, obtain a large proportion of their food through piracy. The frigatebirds (*Fregata* spp.), skuas and jaegers (*Stercorarius* spp.) are probably the best known 'professional' pirates. Specializations for piracy in frigatebirds include a vestigial uropygial gland which greatly reduces the amount of oil in the feathers and the largest wingspan: body-weight ratio of any bird species. These features enhance aerobatic flight but they also mean the birds can no longer enter the water from which most of their food originates.

PISCIVOROUS: fish eating.

PISHING: squeaking (see HUMAN IMITATION OF BIRD SOUNDS).

PITOHUI: substantive name of the 7 species of Australasian pachycephaline flycatchers of the genus *Pitohui* (see THICKHEAD).

PITTA: substantive name of the species of Pittidae (Passeriformes, suborder Deutero-Oscines, infraorder Pittae); in the plural, general term for the family. The pittas comprise a rather uniform family of 29 species, usually placed in the single genus *Pitta*. They are mostly confined to the Old World tropics, with their centre of diversity in South-east Asia where 22 species are found.

In 1876 the pittas were placed with the New World Deutero-Oscines on the basis of syringeal morphology, but it is a simple type of syrinx and now considered to be unreliable as an indicator of relationships. However, the result of recent anatomical and biochemical studies is that the pittas occupy an isolated and highly enigmatic position nearest to the New World Deutero-Oscines. Further to this, the latest volume of Peters' 'Check-list of birds of the world' (1979) chose to include the Pittidae in the suborder *Incertae Sedis*. The wing has 10 primaries, the outermost long, and 12 rectrices. The tarsus has a long anterior and a posterior plate.

Characteristics. Pittas' size range is 15–28 cm; weights vary between 42 and 218 g. Fifteen male Fairy Pittas *Pitta nympha* collected on Taiwan in May had a range of 67.5–155 g and a mean of 109 g. They are stocky, long-legged, short-tailed birds and in the field some species might be confused with ground thrushes, the group with which they were originally placed. They have also been called 'ant-thrushes' or 'jewel-thrushes'. The plumage of many pittas is highly colourful. Much of the bright coloration, however, is on the underparts, while the more protectively patterned upperparts effectively conceal them in the dim light of the tropical forest floor. Nine species are sexually dimorphic, 4 with brightly coloured males and drab females. Juvenile birds are more brownish and mottled or spotted.

Habitat. Moist evergreen or deciduous forests, bamboo groves, mangroves, dense secondary scrub and wooded ravines in more open areas; up to 2,500 m.

Distribution. Widespread in the Oriental Region as residents and/or migrants, extending north to Japan (one species), east to Australia (3) and the Solomon Islands (one) and also tropical Africa (one).

Populations. Many forms are considered rare, but this is partly due to their retiring habits; pittas may be locally common.

Movements. Generally sedentary, with local or seasonal dispersal, also altitudinal. Eight forms are migratory, including the Indian Pitta *P. brachyura* from the Himalayan region to southern India and Sri Lanka, the Fairy Pitta from Japan to Borneo and the African Pitta *P. angolensis* in east and central Africa. Some long distance vagrancy has been recorded, e.g. the Blue-winged Pitta *P. moluccensis* has reached NW Australia. Pittas are nocturnal migrants and their attraction to lights has provided many records. A study of migrating birds at Fraser's Hill, West Malaysia, revealed the following periods for the 2 regular migrants, the Blue-winged Pitta and the Hooded Pitta *P. sordida*: 25 September–22 December and 7 April–9 May.

Food. Insects, spiders, worms and particularly snails; small shrimps, crabs, lizards or snakes may also be taken. Other food has seldom been recorded, e.g. the Garnet Pitta *P. granatina* on Borneo taking large seeds and Schneider's Pitta *P. schneideri* of Sumatra taking vegetable matter. A captive Hooded Pitta studied for one month ate approximately its own weight in food each day.

Behaviour. Normally all pittas live singly or in pairs, but larger groups may occur during migration. Pittas spend most of their time foraging on the ground where they hop about, often flicking and bobbing their tails. If disturbed, they will hop away or fly a short distance, keeping near the ground; in some commoner species this reveals a conspicuous white wing patch. When foraging, pittas flick the leaves and other vegetation over with their strong bills and may sometimes use slight wing flicking movements to flush small prey ahead of them. A stone or log is used as an anvil to break snail shells. An ability attributed to pittas of locating prey by smell is supported by a study of their olfactory system, with the largest olfactory ratio among the Passeriformes. This is exemplified by the captive Hooded Pitta mentioned above that actively sought worms by digging the entire bill into the soft earth provided. Pittas are shy and retiring birds and often only located by calls, an imitation of which will usually bring them into view; outside of the breeding period they may be more silent. When calling, pittas have been observed up to 10 m above the ground and short looping flights may be performed from a perch. At night pittas usually roost in trees. An aggressive display observed in a few species involves crouching with fluffed out feathers, wings spread and bill pointed upwards. The distinctive Eared Pitta *P. phayrei* has long plumes at the side of the nape that may have a special function, as all species have erectile crown feathers, elevated when excited.

Voice. A short series of variably pitched whistles, often dissyllabic, is characteristic; also trilling, rolling sounds. Calls may be heard during the day from some species but most often at dawn and dusk, before rainstorms, and on moonlit nights, when some neighbouring birds may call against each other or in chorus.

Breeding. The breeding season is variable. In distinctly seasonal areas, pittas are summer breeders, especially the migratory species. Otherwise, as in South-east Asia, they breed in all but the wettest months. The nest may be found up to 8 m above the ground, but usually under 3 m or even on the ground. Sites include stumps, amongst root buttresses of large trees, against banks or fallen trees, in tangled clumps of vegetation or rock clefts. The nest is an untidy globular or elliptical structure of twigs and rootlets often decorated with moss, lined with finer materials and with a low side-entrance. A doormat of animal dung outside the nest is made by the Australian Noisy Pitta *P. versicolor*. Average dimensions for some nests of the Blue-winged Pitta were: external diameter 20 cm, internal 16 cm, depth 7.5 cm, and entrance 10 cm wide. When disturbed, the bird may cover the entrance with a small, leafy twig. So far as is known, both sexes share in nest building, incubation and the care and feeding of the young. The clutch size is 2–7 eggs, but usually 3–5; they vary from a broad blunt oval to a spheroidal shape, some with a large amount of gloss, and are white or buffish with reddish or purplish spots or speckles and fine grey or lilac undermarkings. Fifty eggs of the Indian Pitta measured 23.3–28.2 × 20.0–22.4 mm, with a mean of 24.7 × 21.2 mm; average egg weight from a clutch of the Blue-winged Pitta was 5.2 g. The incubation period for a captive Hooded Pitta was 17 days. This was for the first breeding in captivity by J. Delacour (1934). Pittas are difficult to keep and have seldom been bred, partly due to their pugnacious nature. The young hatchlings are fleshy or purplish coloured, sometimes with tufts of natal down on the upperparts. M.D.B.

PITTA, ANT-: see ANTPITTA; ANTBIRD.

PITTIDAE: family of PASSERIFORMES; suborder Deutero-Oscines; PITTA.

PITUITARY GLAND: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM; NERVOUS SYSTEM.

PITYRIASIDIDAE: a family of PASSERIFORMES, suborder Oscines; BRISTLEHEAD.

PLAINRUNNER: substantive name of *Coryphistera alaudina* and *Clibanornis dendrocolaptoides* (see OVENBIRD (1)).

PLAINS-WANDERER: alternatively 'Collared Hemipode', *Pedionomus torquatus*, sole member of the Pedionomidae (Gruiformes, suborder Turnices). *Pedionomus* is placed apart from the buttonquails (Turnicidae) on account of the persistent hind toe, the pyriform instead of oval eggs, and the persistence of paired carotid arteries: but many consider separation as a subfamily (Pedionominae) sufficient.

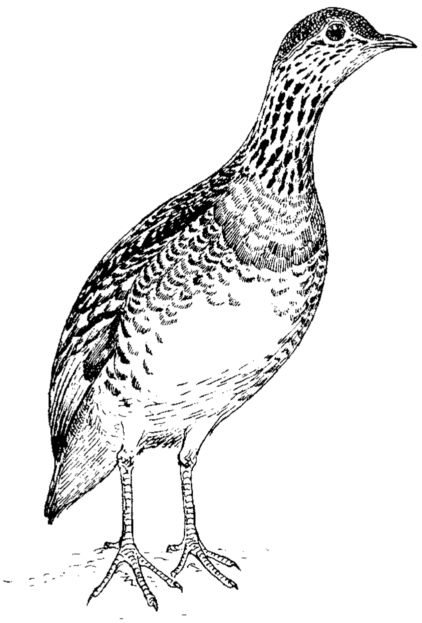
Characteristics. The Plains-wanderer is a small bird (male *c.* 10 cm, female *c.* 12 cm). Although superficially like a buttonquail *Turnix* sp., the Plains-wanderer typically does not exhibit the crouching posture but stands erect like a bustard (Otididae); an interesting photograph published by Purnell (1915) shows clearly the bird's habit of standing 'elevated on its toes' so as to achieve a wide view of the surroundings.

The bill is slender and of medium length. The wings are short and rounded, the tail is very short, and the whole body is compact. The plumage shows a cryptic pattern of reddish-brown, buff, and black, paler below; there is a 'collar' of black spots on a white ground. Sexual dimorphism is marked, the female having a chestnut-coloured breast. They are usually loth to fly, preferring to run or 'freeze', and have on occasions been caught by hand. They have a whirring flight like that of a buttonquail.

Habitat. Plains-wanderers inhabit open grasslands and plains of south-eastern Australia, where they keep to open areas and avoid the scrubby sections and stubble that are favoured by most buttonquail species.

Distribution. The breeding range is from Duaringa, Queensland, in the north, to western New South Wales, Lake Frome (one or two records) and south-eastern South Australia. Most recent records are from Victoria. D'Ombrain (1926) has reviewed certain aspects of the scanty knowledge of the habits of the species, speculating about the reason for its rarity in modern times. Recent records in South Australia, Victoria and New South Wales are widely dispersed but uncommon. Alteration of habitat due to sheep, rabbits, and fires, and the introduction of the fox and feral cat, have undoubtedly contributed to the numerical reduction of the species.

Food. Such stomach analyses as have been carried out disclose the presence of insects, seeds, vegetable matter, and sand.



Plains-wanderer *Pedionomus torquatus*. (*C.J.F.C.*).

Breeding. The breeding season is described as being from September to January. The nest is a slight depression in the ground, and 4 eggs make up the clutch; they are pale yellowish or greenish, spotted with grey and olive. The male incubates the eggs and raises the young. (A.K.) H.J.F.

PLAINTAIN-EATER: substantive name (unfortunately misleading) of some species of Musophagidae (see TURACO).

PLANTAR: pertaining to the posterior surface of the tarsus (equivalent to the sole).

PLANTCUTTER: substantive name for 3 species of Phytotomidae (Passeriformes, infraorder Tyranni); in the plural, general term for the family. *Phytotoma* is a single, polytypic and purely neotropical genus, its 3 species being very alike.

Characteristics. Plantcutters are heavily built finch-like birds about the size of an European Hawfinch *Coccothraustes coccothraustes* (18–19.5 cm), having short wings, rather long tails and with crown feathers pileated to form a slight crest. The plumage on the upper parts is plumbeous and/or brown, in the male streaked more heavily with black. The throat, breast and underparts of the female are light buff and dull ochre with dark streaks; these colours being replaced in the male by bright rufous and chestnut. The males of all species present a conspicuous white wing-bar. Tails in *Phytotoma rutila* and *P. raimondi* are blackish with white tips; in the case of *P. rara* they are black-tipped with chestnut coloured inner webs. Immatures tend to look like females. Legs are short and feet large in comparison; the bill is stout, short, conical and finely serrated in both mandibles. Eyes are bright amber or yellow in both sexes.

Habitat and distribution. Plantcutters are typical of bushy and low woodland, preferring rather open country; also well adapted to cultivated fields and orchards where they may cause damage. They are found from about 3,000 m in Andean valleys down to the coast. They have enlarged their range and, locally, their numbers due to increasing cultivation. But intensive pesticide spraying on parts of this artificial habitat may eradicate a whole population.

The genus is mainly distributed in western and southern South America. The smallest species, *Phytotoma raimondi*, the Peruvian Plantcutter (total length *c.* 18 cm) is confined to the coastal fringe of northern Peru between Tumbes and Lima. The Chilean Plantcutter *Phytotoma rara*, the largest representative (19.5 cm), has been observed in Chile from Atacama to Magallanes and along the Andean foothills of Argentina from Neuquén to northern Chubut. The Red-breasted Plantcutter *Phytotoma rutila* (19 cm) is distributed in SE Bolivia, Paraguay, Uruguay and Argentina south to Río Negro.

Movements. Plantcutters are generally sedentary in lowlands, but high-level and southern populations migrate respectively down and/or north during autumn and winter seasons.

Food. The genus is entirely vegetarian. The bill is admirably adapted for plucking buds, shoots, tender leaves and different fruits. The birds, being provided with such an instrument of destruction, are considered one of the worst enemies to fruit and horticultural plantations.

Behaviour and voice. Plantcutters are commonly observed in pairs and, at the end of the breeding season, family groups are typical. Small flocks of 6 to 12 individuals may be observed flying or foraging together in loose association. They tend to be territorial during the breeding season, males making their presence known by an oft-repeated rasping metallic wheeze. When approached they fly off with an undulating rather sluggish flight to perch on top of another nearby shrub and utter again their unmusical rattle.

Breeding. Nesting starts in October and continues into January for Andean populations. The nest is loosely made, flat, untidy and built almost entirely with root fibres. It measures about 10–12 cm in diameter and is usually placed in the fork of horizontal branches near the top of low trees or shrubs. Clutch-size 2–4 eggs; these are greenish-blue, sparsely dotted with dark markings which have a tendency to zone at the broad end. (J.D.G.) R.P.S.

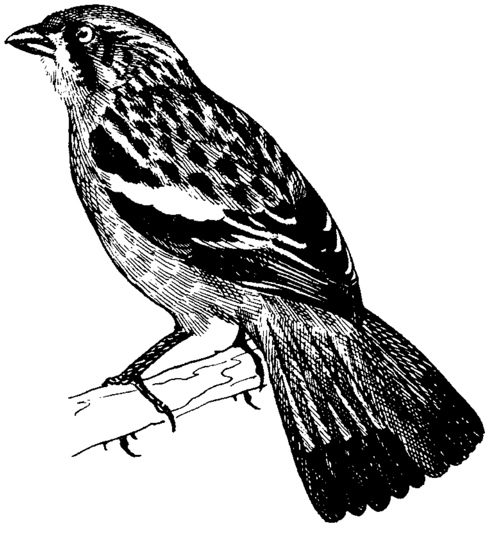
PLATALEINAE: see SPOONBILL.

PLAY: an activity performed by a wide variety of bird species; although probably less common in birds than in mammals (Kilham 1974; Ficken 1977). Playful behaviour in young animals may be important in the development of social behaviour and social relationships and may also be useful in the development and/or 'polishing' (or practising and learning) of specific motor skills (but see BEHAVIOUR, DEVELOPMENT OF.) Also, play may result in increased flexibility of behaviour (Ficken 1977). Some birds, as do many mammals (Bekoff and Byers 1981), even use play invitation signals to solicit play from other individuals. Play behaviour in birds may take on a number of different forms including mock-fighting, sexual behaviour and courtship, reciprocal chasing and fleeing, and the performance of rapid motor sequences such as 'nose-diving' at other birds or performing somersaults in water, and may involve playing with food objects or even making snowballs (Kilham 1974; Keller 1975; Ficken 1977). Social play is probably less common than object play.



Chilean Plantcutter *Phytotoma rara*. (*C.E.T.K.*).

Young raptors have been observed to make hunting movements towards inedible objects and Red-bellied Woodpeckers *Centurus carolinus* will try to put miscellaneous objects such as bent nails in crevices otherwise used to store food (Kilham 1974). Young Christmas Island Frigatebirds *Fregata minor minor* will swoop at, pick up, and then drop, leaves and other objects floating on the surface of the sea. Vocal play also may occur. Subsong shows some close similarities with characteristics of nonvocal mammalian play (Ficken 1977).

Play by adults is more difficult to understand than is play by young (as is the case in many mammals). Rooks *Corvus frugilegus* will commonly indulge in tumbling acrobatics; Ravens *C. corax* have been described as carrying up twigs or pieces of heather, which they drop and then catch again in the air. Various aquatic birds, e.g. Eider *Somateria mollissima* and Black Guillemot *Cepphus grylle*, have been seen to disport themselves in swift currents in a way that suggests that the birds are 'having fun'. Similarly, Adélie Penguins *Pygoscelis adeliae* have been described as riding in vociferous parties on small iceflows in a tide race, only to swim back to the starting point and begin once again. That play may indeed be enjoyable has been suggested for mammals as well (Bekoff 1976). Adults (and probably young) seem to play most when they are undisturbed and when other more pressing needs (such as food, shelter, warmth) have been satisfied. As in mammals, play rarely occurs when individuals are disturbed or stressed.

In many cases it is very difficult to separate playful from non-playful activities, regardless of how amusing the behaviours appear to the human eye. More quantitative data are needed regarding avian play and it would be useful if a list of play criteria could be developed. One should not expect *a priori* that avian play will necessarily be very similar to mammalian play. Avian play should be studied as an entity in itself before detailed comparisons are made with mammalian play, especially concerning its structure (what animals do when they play), function(s), adaptive significance, development, and evolution. PLAYBACK: refers to the broadcasting of recorded songs or calls, usually in the field. Since portable recording equipment became available in the 1950s, this technique has been employed increasingly for research on bird sounds, for censusing, viewing, photographing and capturing birds, and as a control method where birds are regarded as pests. It is suitable for use with any kind of bird which uses any sort of sound for communication. Although birds often respond to poor recordings, playback of good quality and adequate volume is important for most applications. Portable equipment is usually sufficient. Although there is little evidence that playback is harmful, it should be used with restraint. Birds are protected by their tendency to lose interest in repeated sound signals.

Alone or with visual models, playback enables researchers to use experimental methods to investigate the meaning of sound signals by observing responses of listeners. The investigator can vary the location, time of day, stage of the breeding cycle, type of listener to be studied and the individual whose signal is to be broadcast. Various studies have shown that birds can distinguish between sounds of their own and other species and may recognize sounds of mates, parents, offspring and individual territorial neighbours. In certain cases responses between species have been demonstrated. By playing altered or artificial sounds, it is possible to determine which features are sufficient to elicit a particular response. Thus, the acoustic basis of species and individual recognition has been investigated. For most purposes, brief playback experiments are more meaningful than prolonged exposure of birds to an unresponsive sound source.

Playback is especially valuable in the study of territorial behaviour. For example, territory-holders have been removed and recordings played in their territories to investigate the role of song as a 'keep out' signal. Birds that advertise by song usually respond aggressively if recorded songs are played within their territories. By moving the loudspeaker, their defended boundaries can be mapped. Where territories are contiguous, mapping by playback provides an accurate census of the breeding population. However, if members of a species are few and far between, a bird may follow a loudspeaker far beyond the area it normally occupies. Playback is useful for locating rare, inaccessible or nocturnal species. Song or distress calls can be played near traps or mist nets to capture particular individuals. This is useful in studies of breeding birds.

Since playback may attract birds which are otherwise difficult to approach, it facilitates close observation, sound recording and photography. It is most effective early in the breeding season (often prior to mating) and when the recording is of the bird's own voice or that of an unfamiliar member of the same population. If the response wanes it may be restored temporarily by changing songs or locations.

As a control method, alarm or distress calls have been broadcast to disperse undesirable roosts, reduce bird hazards at airports, and to protect crops. The effectiveness of such measures may diminish with prolonged use. J.B.F.

PLENARY POWERS: of the International Commission, see NOMENCLATURE.

PLOCEIDAE: a family of the PASSERIFORMES, suborder Oscines; WEAVER; also SPARROW (1)).

PLOCEPASSERINAE: see SPARROW-WEAVER AND SCALY-WEAVER.

PLOVER (1): substantive name of the majority of species of the Charadriidae (Charadriiformes, suborder Charadrii); in the plural, general term for the family. The other substantive name widely used in the group is 'lapwing', but not all the species that are generically lapwings are in practice so called. A few members of the family have particular names, and one of these, 'dotterel', is sometimes used also as a substantive name of other species of Charadriidae, especially in Australia and New Zealand.

Characteristics. Plovers are birds of from small to medium size (15–40 cm long), compactly built and thick-necked, with large eyes. They run swiftly and fly strongly. The bill is usually straight, fairly stout, and of only moderate length compared to the size of the head—not showing numerous specialized forms such as are found in the Scolopacidae (see SANDPIPER). The wings are long, the tail is short to medium, the legs are of various lengths, and with or without a vestigial hallux. The plumage differs from that commonly found in the Scolopacidae in that it shows bold colour patterns (in brown, olive, grey, black, and white), but it is nevertheless cryptic owing to the disruptive effect. Common features are a white band on or behind the nape, a dark thoracic band or area, and a dark terminal or subterminal band on the tail. The downy chicks of most species have the white band on the nape, and also a dark cap. A few species show pronounced seasonal change; the sexes are alike or nearly so, and the juvenile plumage is also not strikingly different.

Bock (1958) recognized about 50 species of plovers, with a few others doubtfully belonging to the group. They can be broadly divided into the lapwings, recognized by Bock as a single genus *Vanellus* comprising 24 species; and the true plovers, 5 genera comprising 26 species. This classification amalgamated many genera recognized hitherto, the majority of them monotypic. The earlier classification had been based on characters of doubtful validity—notably the shape of the skull, which is in fact particularly affected by the size of the nasal glands, this in turn depending on adaptation to a fresh-water or saline environment. The classification adopted here recognizes some subdivision of the lapwings at a generic level.

Of additional forms sometimes included in the Charadriidae, *Phegornis* is retained here on the basis of relationship with the dotterels *Eudromias* spp. (see Storer in Burton 1974); and the Australian Dotterel *Peltohyas* *australis*, sometimes included with the coursers, is treated as a plover on the basis of the review by Maclean (1976); but the turnstones (Arenariinae) are firmly placed in the Scolopacidae (see SANDPIPER) (Jehl 1968, Burton 1974); and the MAGELLANIC PLOVER *Pluvianellus socialis* has been removed from the Charadriidae and placed in a monotypic family Pluvianellidae by J.R. Jehl.

The plover family is cosmopolitan in its distribution, but whereas the Scolopacidae are predominantly native to the Northern Hemisphere, the Charadriidae are to a large extent tropical.

Lapwings. Although the general appearance of the several species of *Vanellus* is diverse, the tail is always white basally and usually has a broad black band distally, while the wing always has black primaries and usually a broad white stripe. Characters frequent among the lapwings, but not found in other plovers, are a crest, facial wattles, and wing-spurs; the last correlate with the aggressive nature of the birds, and in species which have no actual spur on the carpal joint a bony knob is present beneath the skin. Africa has the largest number of species. North America has no lapwings, apart from the occasional occurrence of vagrant individuals or flocks of the European *Vanellus vanellus*; South America has 3 species, probably descended from birds crossing directly from Africa. New Zealand had none, even as regular visitors, until its successful invasion by an Australian form (*V. miles novaehollandiae*).

The English name was originally given to the Lapwing *Vanellus vanellus* and refers to the rather slow wing-beat. It is a crested species native to middle Palearctic latitudes. The Sociable Plover *Chettusia* ('*Vanellus*') *gregarius* has a circumscribed inland breeding range on both sides of the Ural mountains. The handsome Spur-winged Plover *Hoplopterus* ('*Vanellus*') *spinosus* is found in south-eastern Europe, the Middle East, Egypt and tropical Africa (mostly north of the Equator); in eastern Africa its range is largely allopatric with that of the Blacksmith Plover *V. armatus*, which replaces it to the south, though the 2 species are patchily sympatric in Kenya where they have both been recorded nesting around the same water hole. Africa seems to have been the centre from which the lapwings have radiated, as judged by present-day distributions and specializations. Separation in eastern Africa by altitude is found between *V. lugubris* and *V. melanopterus* and by habitat between *V. tectus* (in arid thorn scrub) and *V. coronatus* (on grassland). The former is also a more northerly species, but the ranges are sympatric in Kenya, though with a fair degree of ecological separation. Amongst further habitat specializations may be cited the jacana-like habits of *V. crassirostris*, which makes a floating nest, and the exploitation of rivers with extensive sandbanks by *V. albiceps* and other plovers during the dry season.

Of the smaller number of species in the Oriental Region, the Red-wattled Lapwing *V. indicus* and the Yellow-wattled Lapwing *V. malabaricus* are well-known birds in India, where the latter often nests on flat roofed houses. The River Lapwing *V. duvaucelii*, ranging from India to S. China, is often considered conspecific with the Spur-winged Plover *Hoplopterus* ('*V.*') *spinosus*. Australia holds the Banded Plover *V.* ('*Zonifer*') *tricolor* and 2 subspecies of the Masked Plover *V. miles*.

Golden Plovers. The 4 species of *Pluvialis* are exceptional in their plumage pattern; the white band on the nape is not present even in the downy chick, and the colour of the back is 'spangled' instead of uniform. These 'spangles', pale feather edgings, often wear off during the winter months. The under parts are largely black in the breeding season in the 3 northern species. They are relatively larger birds than the sand plovers (see below).

The Golden Plover *P. apricaria* (northern and southern races) breeds in northern Europe and the extreme north-west of Asia, reaching the Mediterranean countries and northern India on migration; the southern race is present throughout the year in Britain. The closely related Lesser or American Golden Plover *P. dominica* (Atlantic and Pacific races) is native to high latitudes in North America and Siberia east of R. Yenesei. Its migrations extend as far as Australia, Argentina and East Africa (e.g. Ethiopia and Somalia). The Grey Plover *Pluvialis* ('*Squatarola*') *squatarola*—called Black-bellied Plover in America—has a Holarctic breeding distribution at very high latitudes; and migrations extending as far as Chile, Cape Province, and Australia. The so-called New Zealand Dotterel *P. obscurus* has reddish-brown underparts in the breeding season; it is restricted to New Zealand, and one may suppose it to be descended from migrant ancestors of the northern species remaining in the south to breed.

Sand plovers. This is sometimes used as a convenient general term for the species here regarded as constituting the genus *Charadrius*, often termed 'dotterels' in Australia. They are mostly rather small plovers, but some are of medium size. In general the plumage is brown or grey above and white below except for some expression of a pattern of darker markings that is characteristic of the genus—a dark band across the breast, a black forehead, and a black line from bill to eye.

Bock recognized 24 species and divided them into (a) a typical group; (b) sand plovers in the narrow sense; (c) mountain or plains plovers; (d) a number of aberrant forms. The genus is cosmopolitan in its distribution. Of group (a), the familiar Ringed Plover *Charadrius hiaticula* of Europe also breeds in Greenland and arctic Canada, where it has been known to interbreed with the Semipalmated Plover *C. semipalmatus* of North America; they are often considered to be conspecific. The Kentish Plover *C. alexandrinus* of Europe (Snowy Plover of North America) is a small and pale species with only an interrupted breast-band. It is practically cosmopolitan, in different subspecific forms, the most colourful being the Red-capped Dotterel of Australia. The Killdeer *C. vociferus*, which is larger than those just mentioned, has two breast-bands; it is a bird of inland pastures and breeds from Canada to Peru. Another species with 2 black bands (leaving 3 white areas) is the Three-banded Plover *C. tricollaris* of Africa South of the Sahara, including Madagascar. The Double-banded Dotterels *C. bicinctus*, which breed in New Zealand, and some of which then visit Australia, have an upper black band and a lower chestnut one.

Typical of group (b) is the Great Sand-plover (or Large Sand Dotterel) *C. leschenaultii* which has no black on the chest, but a broad band of rufous in the male only; it is a notable migrant, breeding in Central Asia and reaching South Africa and Australia. Amongst group (c), the Mountain Plover *C.* ('*Eupodia*') *montanus* inhabits semi-arid plains in the southern area of the Rocky Mountains, and is notable for its flexible mating system (see later), a supposed adaptation to unpredictable food supplies which vary in quantity from year to year. The Caspian Plover *C. asiaticus*, which may be conspecific with the larger Oriental Plover *C. veredus*, breeds in the eastern Palearctic and reaches South Africa and Australia on migration. It seems closely related to the Winter Plover *C. modestus* of South America.

Other genera. In similar habitats to the montane plovers are found the Dotterel *Eudromias morinellus*, a native chiefly of northern Europe and western Siberia, migrating to the Mediterranean and south-western Asia, and the congeneric *E. ruficollis* of South America. Also found in South America is Mitchell's Plover *Phegornis mitchellii*, a bird of the edges of mountain torrents, where it feeds on animal prey picked from aquatic plants. The Wrybill Plover *Anarhynchus frontalis* of New Zealand, breeding in the South Island and migrating to the North Island, is unique among birds in having a laterally deflected bill, the distal quarter being turned to the right; with this it probes for insects under stones on beaches.

Habitat. Lapwings are found in a wide variety of habitats during the breeding season, from areas of human habitation (*V. malabaricus* in India, *V. miles novaehollandiae* in Australia), through farmland, both arable and grazed pasture (*V. vanellus* in Europe), sparsely vegetated ground (*V. tricolor* in Australia), thorn scrub (*V. tectus* in E. Africa) to sandbanks in major African rivers during the dry season. The 3 species of golden plovers that breed in the northern hemisphere do so in sparsely vegetated mountainous areas or on the arctic tundra. Of the sand plovers, some breed on sandy or pebbly seashores, often nesting only a short distance above the tide-line (*C. hiaticula* in Europe, *C. alexandrinus*), whereas others of the same species may nest inland on shingle beds in rivers or beside lakes, as well as on stony tundra (*C. hiaticula* in Greenland). *C. pallidus* breeds around soda-lakes in East and SW Africa. Other species frequent open ground, often far from water, whilst breeding: either lowland fields (*C. vociferus*) or dry prairies at higher altitudes (*C. montanus*).

Movements. Those species breeding at high latitudes are migratory, some of them performing journeys of up to 10,000 km. Immature birds of the larger species may stay south of the arctic breeding grounds for 1 or 2 years. The migrations of the golden plovers, particularly *P. dominica*, involve long sea-crossings e.g. from Alaska to Hawaii, and consequently require the storage of large quantities of fat before departure and an accurate navigation system which can be used over the open ocean. In temperate latitudes, many species migrate towards the Equator in autumn but few cross it. Some populations of some species are partial migrants, e.g. the British population of *C. hiaticula*, and the New Zealand *C. bicinctus*. In tropical regions, most species move only short distances, though this may involve a change of habitat e.g. from riverine sandbanks to nearby ricefields in Nigeria when the large rivers come into flood. European species that feed inland on damp pastures or ploughed land in the non-breeding season, e.g. *V. vanellus*, move west or south during severe weather in winter or during very dry summer weather, when their foods become unavailable.

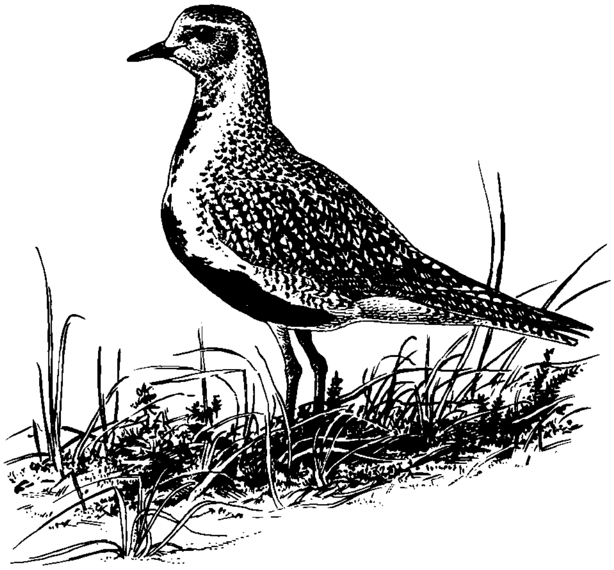
Food. Plovers forage in a characteristic way, by repeated runs of a few metres at a time, interrupted by pauses spent in an upright or 'head-lowered' attitude. A peck at the ground often follows a pause, with a change from the upright to the 'head-lowered' attitude sometimes intervening. Successive runs may involve changes in direction of more than 90°, presumably because birds have detected prey to the side of, or behind, them. Although it has been claimed that plovers hunt by auditory cues (and have been shown to be able to do so in the laboratory), it is unlikely that these are of major importance in field conditions, where sight is used almost exclusively (Pienkowski 1983). Plovers can detect prey when these are active on the surface of the substratum, and they may use foot-trembling to make prey move. They do not search by probing, as do many sandpipers. Their food is mainly animal. On coasts and estuaries, it comprises the larger intertidal polychaetes, small crustacea and small bivalves and gastropods, swallowed whole. Terrestrial plovers take many annelids, dipteran larvae and carabid beetles. Many species feed at night, some probably obtaining a greater proportion of their daily food intake then than by day, as a result of the greater variety and size of invertebrates that become active at the surface of the substratum by night.

When feeding, plovers space out much more than sandpipers, and often feed away from the water's edge, even in intertidal areas. In this way, they are able to reduce physical disturbance to the substratum, which might otherwise make prey unavailable. (When disturbed, many prey either become immobile or move to depths beyond the range of a plover's bill.) Some individuals of some species, e.g. *P. squatarola*, defend feeding territories during the non-breeding season, partly to reduce disturbance to prey, partly to conserve food resources and sometimes to ensure sheltered sites in which to feed during gales (Townshend *et al* 1984).

Behaviour. Many plovers are also territorial during the breeding season, though some species, e.g. *V. vanellus* in Europe and *V. tricolor* in Australia, form what have been termed 'loose colonies', in which nests are well spaced, but some co-operation occurs between adjacent pairs in mobbing potential predators. (These loose colonies appear to be determined only in part by suitability of habitat.) Outside the breeding season, plovers tend to be gregarious inland in Europe (e.g. flocks of thousands of *P. apricaria* and *V. vanellus*) though never in such large numbers on coastal sites, nor inland in Africa. On the coast, birds that have been feeding while well-dispersed over many sq km of mudflats usually come together to roost, often with sandpipers.

Display and voice. Territorial plovers display on the ground at the boundaries of their territories and in the air above them, particularly at the beginning of the breeding season. When in flight, with slow butterfly-like wing-beats, they often 'sing' with melodious long trills. Call-notes, which are usually short whistles or shrill cries, are often reserved for flights to and from roost and feeding areas, and are not always given when birds are disturbed. Other displays connected with nesting include injury-feigning to distract predators from the vicinity of nests (e.g. by shore-nesting plovers such as *C. hiaticula*), and attacks, by jumping with spread wings, in the faces of large herbivores approaching nesting areas, as shown by African vanellids. *V. vanellus* in Europe will mob and dive-bomb corvids alighting near their nests.

Breeding. Plovers employ a variety of mating systems—monogamy (as in *C. hiaticula*, although the mate may be changed from one year to the next); polyandry, associated with sex reversal in dotterels, in which the female is brightly coloured and the male incubates; polygyny; and polygamy involving mate-changing by both sexes, as found in *C. montanus*. Many monogamous species attempt to raise only one brood per year, but this may involve many layings, since predation of the ground nests is heavy. Most breeding habitats are open, either bare or thinly vegetated, and the nests are mere scrapes with little or no lining. Several *Charadrius* spp. partly cover their eggs with sand when leaving them, a habit most fully developed in the African *C. pecuarius* which, in a few seconds, completely covers its eggs by stereotyped kicking movements. Tropical plovers may also damp the eggs and substrate with water brought in their belly feathers (see BELLY-SOAKING). Two to 5 eggs are laid; in many temperate species very consistently 4, in African *Charadrius* spp. equally consistently 2. They are buff, brown or grey, heavily marked with black, and well camouflaged. In monogamous species, both parents usually incubate and share care of the brood after hatching. First breeding may occur at one-year-old in smaller species, but often not until 2 or 3 in larger species. The chicks are downy and nidifugous, and losses to predators occur chiefly during the first 10 days after hatching, which takes place after 3–4 weeks incubation. Fledging takes from 3 weeks in the smaller to 5 or 6 weeks in the larger species. Annual survival of adults in high, especially of larger species e.g. 80–90% for *P. squatarola*.



Golden Plover *Pluvialis apricaria*. (*A.H.*).

PLOVER (2): used as substantive name of certain species not included in the Charadriidae—Egyptian Plover *Pluvianus aegyptius* (see COURSER); Norfolk Plover (or Stone-curlew) *Burhinus oedicnemus* and Stone Plover *Esacus magnirostris* (see THICKKNEE); Upland Plover (or Bartram's Sandpiper) *Bartramia longicauda* (see SANDPIPER); Crab-plover *Dromas ardeola* (see CRAB-PLOVER); and, not even in the Charadriiformes, Quail-plover *Ortyxelos meiffrenii* (see BUTTONQUAIL).

PLOVERCREST: *Stephanoxis lalandi* (for family see HUMMINGBIRD).

PLOVER, MAGELLANIC: see MAGELLANIC PLOVER.

PLOVER, QUAIL-: see BUTTONQUAIL.

PLOVER, SAND: see SAND-PLOVER; for family see PLOVER (1).

PLUMA: alternatively 'plumage feather', one in which the barbs are free instead of forming a coherent vane (see FEATHER; PLUMAGE; and compare PENNA).

PLUMAGE: also called 'ptilosis', the aggregate of which the feather is the unit, and the outstanding character distinguishing the Class Aves from all others (see FEATHER). While the general nature of plumage is constant for all birds, differences in its characteristics are found between one species and another, and to a minor extent between populations of a species (whether sharply separable into races or not); and certain broad differences are common to particular taxonomic groups of species. Further, there are differences related to age, sex and season. There is also individual variation, strongly marked in some species; and occasional abnormalities occur (see PLUMAGE, ABNORMAL). The plumage of the individual bird is periodically renewed (see MOULT).

Functions. The plumage constitutes a mechanical and thermal protective covering for the body. Parts of it are essential components of the organs of flight—the wings, and to a lesser extent the tail (see FLIGHT). In addition, the plumage helps to streamline the body, reducing friction during movement on the ground, in the air, and—in the aquatic environment of many species—on or below the surface of the water. For all these it combines high efficiency with minimal weight. It exerts its influence on the energy economy of the body (see HEAT REGULATION) partly through the insulation provided by the air trapped among the feathers and partly by its coloration. During incubation the plumage has a special role in that the feathers and associated brood patches of bare skin are important in maintaining the eggs at optimum temperature (see INCUBATION).

Other functions of the plumage are: to make aquatic birds waterproof (but the feathers of cormorants (Phalacrocoracidae) soak water, which has the function of reducing buoyancy), to carry water (see BELLY-SOAKING; SANDGROUSE), to facilitate the catching of insects in flight and as tactile organs (bristles), to collect acoustic energy and direct it into the ear (the ear coverts of owls (Strigiformes)) and to facilitate the escape from a predator by the sudden shedding of part of it, in analogy with a lizard shedding part of its tail ('fright moult').

The plumage is also the most important element in the external appearance of the bird. As such, the differences which it shows play a great part in determining recognition of other members of the same species. In some, also, the plumage is mainly responsible for a cryptic, mimetic, or aggressive appearance of the bird (see COLORATION, ADAPTIVE). In very many it includes the principal manifestations of the secondary sexual characters and parts of the plumage are often specially adapted for use in DISPLAY. Apart from providing visual stimuli, feathers—sometimes specially modified—play a part in the production of auditory signals (see MECHANICAL SOUNDS). In all these relations to behaviour the plumage is important for the perpetuation of the species.

Terminology. A bird which attains maturity has, in succession, a number of plumages. The plumages of a temperate zone bird, which has a breeding plumage differing from that outside the breeding season, the latter being identical at 1½ years old with that at 2½ years old, can be named in one of the following two ways:

(Dwight 1900)	(Humphrey and Parkes 1959)
Natal	Natal
Juvenile	Juvenal
1st non-nuptial	1st basic
1st nuptial	1st alternate
Adult non-nuptial	Definitive basic
Adult nuptial	Definitive alternate

If the plumage is the same during and outside the breeding season it is termed annual or basic. If there are three plumages per cycle the third may be termed supplemental.

Plumages may also be defined with respect to the age of the bird, the season of the year or the brightness of the feathers. In most cases, especially in technical studies of plumage succession and moult, the terminology of Humphrey and Parkes probably is to be preferred (see MOULT for further explanation), but it was criticized by E. Stresemann. Humphrey and Parkes also defined the plumage in a new way, namely as a single generation of feathers that is brought about by a moult. The aggregate of feathers of a bird at a given time is then termed the feather coat, which may consist of one or several 'plumages' (= feather generations); e.g. a 4 month old domestic hen has three 'plumages'. There is, however, a very long tradition for using plumage either in a general way to describe the feather coat or the appearance of a given bird at a given time, and this is adhered to here.

Natal plumage. The plumage of the chick on hatching is downy. But in many species, e.g. pigeons (Columbiformes), parrots (Psittaciformes) and passerines, this is sparse, providing virtually no covering, and in some, e.g. kingfishers (Alcedinidae) and woodpeckers (Picidae), it is entirely absent; in others e.g. ducks (Anatidae) and waders (Charadriiformes), it is thick, soft and beautiful—and in these instances often of cryptic coloration. In some species, e.g. cormorants, the nestling is naked at hatching, but later develops down. A few groups of birds, e.g. penguins (Spheniscidae) and owls, produce a second set of down or semiplumes. The two successive sets may be termed protoptile and mesoptile, respectively. In the megapodes (Megapodiidae) the natal plumage consists of contour-like feathers, not down (Becker), and the young are able to fly almost at once.

Juvenile plumage. This is the first plumage in which contour feathers are present. Usually the growing juvenile feather bears the preceding natal down on its tip, but soon the down falls off. It was formerly held that the natal down and the juvenile feather comprised only one feather generation, the natal down being merely the downy tip of the juvenile feather. This view has been abandoned.

Juvenile feathers are simpler in structure than corresponding adult ones (fewer barbs per unit length, fewer barbules with hooklets, etc. (Göhringer 1951)).

Where sexual dimorphism occurs, the juvenile plumage of both sexes usually resembles quite closely the plumage of the adult female. There are exceptions to this rule, for in the Koel *Eudynamus scolopacea* and the Somali Chestnut-wing Starling *Onycognathus blythii* the juvenile birds of both sexes resemble the male.

In some species, e.g. the Gannet *Sula bassana*, where the adults show no broad differences between the sexes, the juvenile plumage differs totally from that of the adult. In others, the juvenile plumage resembles that of the adults, but is nevertheless distinguishable, e.g. in the Kingfisher *Alcedo atthis*, where the young have similar colouring but lack the brilliance of the adults.

Yet another pattern, in which the young have a distinctive dress, is exemplified by the Great Spotted Woodpecker *Dendrocopos major*; juvenile birds of both sexes have the top of the head red but, after moulting from the juvenile plumage, they acquire the distinctive sexual dimorphism of the parents, i.e. the black crown in both and the red nuchal band that distinguishes the male. This may be an instance of ontogeny repeating phylogeny, indicating that an ancestral form had at one time the red crown both in adults and in the young, and that the present sexual dimorphism represents a later specialization.

Spotting and longitudinal striation is often more marked and cryptic in juvenile than in adult (definitive) plumages. The cryptic effect can be related to the juveniles' lack of environmental experience and consequently greater vulnerability to predators. In a few species, e.g. the Red-backed Shrike *Lanius collurio*, two similarly coloured juvenile plumages follow each other.

Plumage change with age. In many species (passerines in particular) the plumage that follows the juvenile plumage is so similar to that of the adult bird in the same season, that close inspection is necessary to disclose a difference (e.g. in European Robin *Erithacus rubecula* some rectrices tend to be more pointed and some wing-coverts tend to have larger bright spots in first year birds). In a few instances, e.g. the Shore (or Horned) Lark *Eremophila alpestris*, there may be no observable distinction at all, so that the definitive basic plumage is assumed direct from the juvenile plumage. In other species, e.g. the male European Blackbird *Turdus merula*, this second plumage is clearly intermediate between those of the juvenile and adult birds. Often flight and tail feathers belonging to the juvenile feather generation are retained for the succeeding plumage.

In small birds, in general, the plumage does not change appreciably with age after the bird is about 1½ years old. In male Pied Flycatcher *Ficedula hypoleuca*, however, the brown or black plumage colour continues to intensify up to an age of perhaps 5 years (Winkel *et al* 1970). Also many larger species e.g. geese *Anser*, show only minor plumage changes after their first year to year and a half.

In some species the plumage succession may extend over a span of years. Examples are provided by albatrosses (Diomedeidae), gannets, large birds of prey and the larger gull *Larus* species, but also by some passerine birds, such as the males of some species of birds-of-paradise (Paradisaeidae) with their elaborate display plumages. In the Twelve-wired Bird-of-Paradise *Seleucidis melanoleuca* the period may be as long as 7 years (at least in captivity).

The attainment of the final plumage roughly coincides with the age at which breeding starts, but the correlation is not always close. In the European Sea Eagle *Haliaeetus albicilla* breeding starts when the birds are about 4 years old, by which age the dark brown juvenile plumage has changed through gradually lighter plumages into the light grey-brown plumage of the adult; the tail also has changed from brown to predominantly white, but it may be several more years before it becomes pure white. In captivity the Bald Eagle *Haliaeetus leucocephalus* may take 10 years to reach the definitive plumage.

The plumages intervening between the juvenile plumage and the adult or definitive plumage are most precisely termed first, second (etc.) basic/non-nuptial and alternate/nuptial. Collectively the less accurate term 'immature plumage' may be used; for the later stages also 'sub-adult plumage'.

Seasonal plumage changes. In species with a seasonal change of plumage, the plumage worn outside the breeding season is the non-nuptial or basic, while the plumage worn during the breeding season is the nuptial or alternate.

The non-nuptial or basic plumage is usually duller than the nuptial or alternate plumage, and the term 'basic' stems from considering the dullness primitive (Humphrey and Parkes). To give an example, the basic plumage in many waders is characterized by white under parts as opposed to black or red in the alternate plumage.

Striking nuptial plumages and accessories are assumed by both sexes in the grebes (Podicipedidae), the divers (Gaviidae) and the herons (Ardeidae)—the plumes of the head, mantle and other regions of the last-named forming most impressive additions to the breeding dress. SEXUAL DIMORPHISM is very common and usually more marked in the alternate i.e. breeding plumage, than in the basic plumage. Where a dull basic/non-nuptial plumage is worn for only a short period, as in ducks and some sunbirds (Nectariniidae), it is sometimes referred to as eclipse plumage (see MOULT); but it is not certain that this plumage corresponds to the basic/non-nuptial plumage of other birds. Some sunbirds have a bright plumage the whole year. If this corresponds to the annual/basic plumage of other birds, the eclipse plumage of some sunbirds must be regarded as a specialized interpolated plumage serving a protective function (E. Stresemann).

In some species, e.g. the Sharp-tailed Sparrow *Ammospiza caudacuta*, there are two nearly identical plumages per year. This may be related to abrasion caused by the species' habit of foraging in wet vegetation.

The length of the period during which each plumage is worn varies with the species; in the Dunlin *Calidris alpina* the basic plumage is present for 7–8 months (September–April) while in the Mallard *Anas platyrhynchos* it is worn for only 2–3 months.

Other terms for the basic/non-nuptial/eclipse plumage are off-season, non-breeding and winter plumage, though in northern temperate dabbling ducks the 'winter' plumage is actually worn during the later summer months. The alternate or nuptial plumage is also termed breeding, nesting or summer plumage.

Some species have more than two plumages annually. In the adult male Long-tailed Duck *Clangula hyemalis* four plumages are recognized: transitional autumn, winter, transitional summer and full non-breeding. It is assumed that the first two correspond to the nuptial plumage of other ducks, the latter two to the non-nuptial plumage, but some tracts bear three feather generations in a year. The major moults are not continuous, but interrupted or halted for several weeks, so that annual plumages are produced.

In ptarmigans *Lagopus* as well as in the male Ruff *Philomachus pugnax* three annual plumages are present. In the Ruff the third plumage is related to display, while in the Long-tailed Duck and ptarmigans the plumage succession probably favours camouflage in changing habitats.

Component units. Outwardly, most birds appear to be uniformly covered with contour feathers. In most species, however, the feathers, other than down, grow only from definite tracts (pterylae) of skin (see PTERYLOSIS).

The total number of feathers usually runs into thousands (see FEATHERS, NUMBER OF), but the plumage weight usually equals only 5–7% of the body weight. More than 95% of the plumage volume consists of air.

The plumage comprises feathers of several different types (for details of development and structure see FEATHER):

1. *Contour feathers.* Except for the natal plumage, these constitute the most important element of the ordinarily visible plumage. They include the primary and secondary remiges of the wings and the rectrices of the tail, the coverts that—above and below—cover the bases of the remiges and rectrices and also cover the ear orifices, and feathers on other parts of the body (see TAIL; TOPOGRAPHY; WING).

2. *Down.* Except in the natal plumage, down rarely contributes to the appearance of the plumage, being hidden from view as a separate layer beneath the contour feathers, where it forms an undercoat in many species. Sometimes down is partly visible, as at the neck in vultures, where the contour feathers have become suppressed as an adaptation to the method of feeding. Some groups of birds entirely lack down in the adult plumage, e.g. ratites, pigeons, and coraciiform birds except kingfishers. In such cases the downy portion of the contour feathers fulfils the corresponding function; but contour feathers with downy portions are present as well as down in many species.

3. *Semiplumes.* These, like adult down, are hidden from view by the contour feathers. They are often abundant in the abdominal region.

4. *Filoplumes.* Although these are normally associated with and concealed by the contour feathers they may be visible in some species, e.g. Chaffinch *Fringilla coelebs*, at the nape. They are seen very strikingly on the nape and back of the Hairy-backed Bulbul *Hypsipetes criniger*. The white feathers found on the heads, necks and thigh patches of some cormorants are presumably also filoplumes.

5. *Bristles.* In a few species bristles are found on the toes, but otherwise bristles are confined to the neck and to the head, most frequently at the base of the bill (rictal bristles), the lores, the eye, the malar and the gular regions. Those above the base of the bill and on the lores are sometimes known as 'vibrissae'. Bristles specialized as eyelashes and other bristles in the eye region may serve to keep foreign particles out of the eye.

Most groups of birds possess bristles, but some groups, e.g. tubenoses (Procellariiformes) and flamingos (Phoenicopteridae), seem to lack them (Stettenheim 1974).

6. *Powder feathers.* Where these are densely packed in patches, they may be recognized outwardly in the plumage, e.g. on the Kagu *Rhynochetos jubatus* and herons (Ardeidae). In other species, e.g. some pigeons and parrots, they are dispersed among the contour feathers and so hidden from view. Powder feathers are widespread among birds, but many groups lack them, including nearly all passerine families. Their function is not well understood; the powder may contribute to making the plumage waterproof or to changing the plumage's colour, so that it becomes more bluish grey.

Adaptive differences. Some degree of specialized adaptation can be recognized in practically all the feathering of a bird. Most important of all is the modification of wing feathers to serve the vital function of flight, to which they are most perfectly suited. Minor examples are the beautifully graded and shaped feathers of the facial disc and 'ears' of many owls and the curious rosette of feathers surrounding the uropygial gland (see OIL GLAND).

During the course of evolution, notable differences of plumage quality have become established between different taxonomic groups. Contrast, for example, the scale-like feathers of penguins—a character already discernible in embryonic life—and the soft, abundant feathering of owls, in which flight as near silent as possible is essential to the birds' mode of predation. Take again the water-resistant property of the feathering of the Anatidae and other aquatic birds, which is primarily a structural adaptation: the barbules bear many relatively long outgrowths (E. Rutschke), which, together with the barbules themselves, break up the interface between the surrounding water and the air in the plumage into numerous minute areas. Due to its surface tension, the water is not able to displace the air present in these minute areas and a stable water–air interface is produced. Probably the main function of uropygial gland secretion as a water-repellent is to impregnate the feather substance of the barbules and their outgrowths so that they retain their flexibility and do not break or become disordered.

Plumage variation. Individual birds of a given population normally differ from each other slightly with respect to plumage characteristics. Corresponding feathers may vary between individuals in length, shape, pattern of pigmentation and colour, and in at least two *Accipiter* hawks there is evidence that these features are constant over the years, so that they can be used for the recognition of individual birds (Opdam and Müskens 1976).

In addition to this normal, continuous variation there are more striking types of variation. A given plumage of a species may show several colour phases (see POLYMORPHISM) or individuals may show abnormalities (see PLUMAGE, ABNORMAL).

A further type of variation appears to have phylogenetic significance as an atavistic manifestation. The study of the subject received a great stimulus from the classical experiments of Darwin in back-breeding fancy varieties of domestic pigeon to the similitude of the original stock, the Rock Dove *Columba livia*. Another example is provided by the occurrence, in the Britsh race of the Robin *Erithacus rubecula melophilus*, of a variant in which the breast pattern approximates closely to that found in the Japanese Robin *Luscinia akahige*.

A recurring character in the gulls of the genus *Larus*, namely an oblong white patch in the region of the carpal joint, has been noted in individuals of Heermann's Gull *L. heermanni*, the Herring Gull *L. argentatus* and the British race of the Lesser Black-backed Gull *L. fuscus graellsii*, indicating the extremely close affinity of these three forms.

A white neck ring, which is a constant character in the drake Mallard, and which can occur also in the duck of that species, occurs on occasions in the Gadwall *A. strepera* both in immature and adult drakes, in the Shoveler *A. clypeata*, in the Wigeon *A. penelope*, in the Yellow-billed Teal *A. flavirostris* and in the European race of the Teal *A. crecca crecca*, although in the last two it is at best vestigial and incomplete; it also occurs in some Pintail *A. acuta* drakes in eclipse plumage.

In all the above examples interspecific hybridization is not involved. Where this has been the case, more striking instances have occurred (see also HYBRID). An example is provided by the progeny of a drake European Teal and a duck Shoveler *A. clypeata* in which appeared the striking facial bridling that is the most characteristic feature of the drake Baikal Teal *A. formosa* when in adult nuptial plumage.

A summary of plumage variants in the Anatidae is given by Harrison and Harrison (1963).

Associated behaviour. Some species make use of their own or other down and feathers as nesting material. The habit of plucking their own breast down to use as a nest lining is well developed among ducks. In the bowerbirds (Ptilonorhynchidae) any available bright feathers are among the objects used for decorative purposes in the surroundings of the bower (see BOWERBIRD).

There is also the physiological value of ingested feathers. Among birds of prey feathers are taken in the course of ingesting avian prey and facilitate pellet formation (see PELLET). In grebes the feathers are apparently plucked from the bird's own body surface, but subserve the same purpose.

Preening, ANTING, DUSTING, SUNNING and flirting with smoke and fire form part of the behaviour of a bird towards its own plumage (see COMFORT BEHAVIOUR). ALLOPREENING is a social response in some species, while mutual preening by a pair occurs in the normal relations between the sexes. An apparent perversion is the feather picking indulged in by domestic fowls and by game-birds (Galliformes) in captivity. (J.M.H.) J.D.

PLUMAGE, ABNORMAL: plumage abnormalities may be due to changes in the amount and distribution of the pigments normally present, chemical changes in the pigments producing abnormal colours, changes in feather patterning, or changes in the structure of feathers. Such abnormalities are in many cases extremes of tendencies apparent in the individual variation of a species. They are, of course, to be distinguished from normal differences in colour and pattern resulting from geographical variation or POLYMORPHISM.

Abnormal pigmentation. This is the most frequently occurring type of plumage abnormality, at times affecting most of the commoner pigments, the melanins—black or grey Eumelanin, brown or buff Phaeomelanin and chestnut-red Erythromelanin—and the red and yellow lipochrome pigments.

Atypical pigmentation. The more extreme variations of this type are sometimes grouped under the term 'heterochroism'. Occasional individuals of a wide range of species, from penguins to passerines, show a marked reduction or loss, or a considerable increase, in the pigments normally present. Although often referred to as chance mutations, in the form in which they occur they are remarkably consistent, genetically controlled and usually recessive, and can predictably be produced by subsequent controlled breeding.

Under natural conditions individuals showing such variations are usually at a disadvantage and short-lived, mainly because their greater conspicuousness makes them more liable to predation. In addition, reduced pigmentation weakens the feather structure, causing accelerated abrasion and wear, particularly of flight feathers, and this may affect mobility. Loss of pigmentation also affects the retina of the eye and can lead to impaired sight in bright light. There is evidence in some species of a failure to recognize abnormally-coloured individuals as potential partners in pair-formation. In captive Greenfinches *Carduelis chloris*, nestlings with variant plumage are at a disadvantage compared with normal youngsters in the same brood and often fail to survive until fledging.

Of variations resulting from an increase in the pigment present, the best-known is probably 'melanism' in which the amount of black and/or brown melanin present increases, and may spread to parts of the plumage which normally lack melanin, masking other colours where these are present. The bird usually appears entirely black or dark brown or a mixture of both. Apparent melanism is sometimes due to a staining of feathers by industrial wastes, soot or oil. The term 'erythrism' is sometimes used for cases in which chestnut-red replaces other melanins. 'Flavism', an excess of yellow pigment spreading into parts of the plumage where it does not normally occur, is rare in the wild, but is apparent in some domesticated strains of the Canary *Serinus canaria* and Budgerigar *Melopsittacus undulatus*.

Partial loss of pigment, affecting all the colours present and reducing them in intensity, is rare. It is called 'dilution' by bird breeders and 'leucism' in scientific writings, although the latter term is also used at times for various forms of schizochroic loss (see below) of single pigments which make the plumage appear paler. The complete loss of feather pigment is more common. This may occur as true 'albinism' in which pigment is absent throughout the body, a condition resulting in red eyes and pale pink legs and bill. In other cases, genetically different from true albinism, pigment is absent from the plumage but the normal body colours are retained. In species in which some or all of the plumage is normally white, the normal condition can often be distinguished from these white variants by the presence of small amounts of greyish pigmentation in the downy bases of the white feathers.

Partial whiteness, usually in the form of one or more asymmetrical patches of plumage, is more frequent than total whiteness. It is controlled by recessive genes which appear to carry the capacity for partial loss of plumage pigmentation, but not to control its location on the body, resulting in individual differences also apparent if the variation is passed on to offspring. However, within any group of related species, partial whiteness is likely to occur more consistently on some areas of plumage than on others. The amount of white may increase in area on an individual with successive moults, but it appears not to have been established whether this is an aspect of ageing due to a hereditary factor or the result of some increasing physiological disorder.

Schizochroism. The other major source of colour abnormality is a phenomenon sometimes called 'schizochroism'. In this a pigment normally present in the plumage is absent, or several pigments may be missing. This changes coloration or affects patterns by leaving white areas on feathers where the missing pigments would normally be present, unless another pigment also occurs on this part of the feather and now appears alone.

The predominant colour of many bird plumages is a dull brown formed by a mixture of both brown and black melanin. In the non-eumelanic form of schizochroic plumage abnormality only the black colour is lacking, and the bird appears a pale buffish-brown, with white markings where black alone was present. If other pigments are normally present they will be unaffected. In captive birds this condition is usually described as 'buff', 'fawn' or 'cinnamon'. It is controlled by a sex-linked gene and is usually found only in females in the wild.

The non-phaeomelanic variation is less frequently seen. It usually appears mainly ash-grey, and is sometimes referred to as a 'silver' variety. It is under different genetic control from the last, being apparently autosomal, and birds showing it are as likely to be male as female. In both types of loss the feathers, with reduced quantities of melanin, are subject to more rapid abrasion than are normal feathers, and also bleach rapidly. By the time that they are due to be moulted, the normally-exposed portions of feathers may have lost their melanin, and the bird may appear white unless closely examined.

The chestnut-red melanin, when present, seems little affected in such variant plumages. The loss of both black and brown with retention of chestnut-red is known in the Zebra Finch *Poephila guttata*, and has been recorded once in the Waxwing *Bombycilla garrulus*. Loss of chestnut-red with retention of other melanins seems unknown in wild birds but occurs in the 'penguin' strain of the domesticated Zebra Finch.

Schizochroic variants in which all melanins are lacking from the plumage appear albino or white-feathered except where red and yellow pigments are also present, the latter persisting as coloured areas on otherwise white plumage. Such variations are known in the finches (Fringillidae), waxbills (Estrildidae), and weavers (Ploceidae); while loss of black in normally green parrots such as the Budgerigar and the Ring-necked Parakeet *Psittacula krameri* produces yellow individuals in which normally dark markings are white. In some cases loss of melanin reveals a more extensive distribution of red or yellow, which is normally masked by other pigments.

The converse of the last variation produces individuals having the normal melanin pigments, with white areas where red or yellow would occur, and modification of areas of mixed pigmentation. In parrots this produces blue forms, lacking the yellow pigment which would make them appear green, and with the black melanin modified to blue by Tyndall scattering (see COLOUR). Other examples lacking red and yellow pigments are known in the finches and in the Yellow Wagtail *Motacilla flava*.

Once the general pigment distribution in the plumage of any species is known, it is usually possible to predict what potential plumage abnormalities there might be, and their likely appearance; but unexpected abnormalities sometimes occur. The distinctive patterns which are characteristic of the display plumages of males of many species appear to be to some extent under independent genetic control and not necessarily responsive to changes in the pigmentation of the remainder of the plumage. This is particularly true of the patterns on head and breast; thus in what would otherwise be recognized as non-eumelanic variants of the House Sparrow *Passer domesticus* and Painted Quail *Coturnix chinensis*, these parts of the plumage retain much of the black patterning.

Pigment replacement. Rarely, one colour is replaced by another. An abnormal change to chestnut-red melanin occurs in individuals of some wader species (Charadriiformes), particularly in the Woodcock *Scolopax rusticola* and Common Snipe *Gallinago gallinago*. It is also found in gamebirds (Phasianidae), as in the rufous or 'montana' variant of the Grey Partridge *Perdix perdix*. The abnormal replacement of red by orange has occurred in individuals of the Red-eared Waxbill *Estrilda troglodytes* and Senegal Firefinch *Lagonosticta senegala*, in the latter proving to be a recessive inherited character.

Gynandromorphs. A striking abnormal variation in pigment distribution results from a possible chromosomal accident which produces an individual that is visually half-male and half-female, possessing both an ovary and testis. In sexually dimorphic species the two sides show the different plumage colours and patterns of the two sexes (and differences in other characters such as wattles, if present), joining abruptly along the mid-line. This phenomenon has been recorded in a number of passerine species, and in the Pheasant *Phasianus colchicus*, Flicker *Colaptes auratus* and Budgerigar. In species with marked sexual size dimorphism, this abnormality may produce an individual with dissimilar legs and wings and with distortion of the bill and other medial features.

Pigment deficiency. Plumage abnormalities sometimes very similar to those of genetic origin, already mentioned, may be the results of deficiencies or excesses in diet. They occasionally occur in wild birds but are more often seen in captive individuals. Some may be distinguished from genetic variants in that they are temporary and may be partially or wholly corrected in later life. Others are permanent and may be the outward evidence of pathological disorders. The former are sometimes evident in hand-reared birds which show a lack or excess of normal pigment in the plumage, corrected when the individual has greater opportunity to select its own food and moults into adult plumage.

Inadequacy of diet is likely to be cumulative in its effects, and during feather growth is sometimes apparent as a gradual reduction in pigmentation, producing feathers that are increasingly whitish towards the bases. The white bases to remiges occurring on some individual wild Carrion Crows *Corvus corone* and Rooks *C. frugilegus* have been ascribed to diet deficiencies but may be of genetic origin. An initially deficient but gradually rectified diet may produce pale-tipped feathers. Brief or intermittent periods of starvation may produce one or more narrow transverse bands across feathers, indicating the extent of growth during the period of deficiency. Such inadequacies of diet will not affect feathers once they are fully grown. On a nestling where all feathers are growing simultaneously, pale transverse bands may occur in similar positions on most feathers, creating a plumage pattern similar to some of genetic origin. Such barred patterns have been described for young crows *Corvus* spp. White transverse bands of this type have been experimentally induced by hormone injections during moult.

Abnormal white feathers may appear when injury to individual feather follicles or to areas of skin results in follicles continuing to produce feathers but unable to produce melanin. An abnormality of unknown origin in the African Grey Parrot *Psittacus erithacus* results in the replacement of normal grey body feathers by red ones lacking melanin and similar to those normally present in the tail.

Unsatisfactory diet in captive birds may produce melanism which is in some instances irreversible. In captive finches this has been attributed to an excess of oily seeds, particularly hemp seed. It may result in wholly black plumage but in the early stages the melanin is sometimes irregularly distributed, affecting only some feathers and producing an asymmetrical spotted appearance.

Excess of red-pigmented material in the diet may affect the appearance of the plumage. Prior to the production of Red Factor canaries in which red and orange colour is genetic in origin, powdered red peppers were fed to give an orange tint to yellow canaries. Orange-tinted plumage in wild birds has been recorded for a Yellow Wagtail feeding around a red palm-oil effluent, and in Greenfinches feeding on yew berries.

Diet deficiency, particularly a lack of carotene, may result in a reversible reduction or loss of red and yellow pigments in feathers. Birds showing a complete loss of these colours may resemble some schizochroic variant forms. This most frequently occurs as an abnormality of captive birds. Blue-grey and white plumage may replace green and yellow, and a bronzy tint occur instead of red. The red colour of captive flamingos (Phoenicopteridae) is largely lost if the diet lacks a substitute for the crustaceans from which this is normally derived.

A similar effect may occur in some species due to loss of fugitive pigment from plumage after a period of exposure to light, without any deficiency of diet. A pink tint on freshly-moulted white plumage of some gulls (Laridae) and ducks (Anatidae) is soon lost; and in some tropical bee-eaters (Meropidae) and kingfishers (Alcedinidae) the green feathers of the plumage fade to a light blue through loss of yellow pigment by the time that they are moulted. In the Hunting Cissa *Cissa chinensis* the normally bright green plumage rapidly becomes light blue in captive birds and also in stored museum skins.

Pattern variations. The patterns created by variations in melanin distribution on feathers are a distinctive plumage character of many species, and within populations marked variation in visible pattern is unusual. From a study of the pigment patterns on feathers it seems probable that the patterns apparent on the plumages of many species have undergone a series of progressive changes in the past to evolve that which is now present, and that a uniform colouring may mask earlier patterns. The occurrence on feathers of markings differing from simple transverse bars, such as those induced by experimental hormone injection in some game birds and domestic fowl, may therefore be due to the revelation, when complete pigmentation is inhibited, of earlier evolved patterns.

Similarly, earlier patterns on areas of plumage may have been lost, but the genetic potential for their production may remain. This would appear to be the underlying cause for the appearance on some hybrid birds of patterns not apparent in either parent but present on closely-related species. The bimaculate face patterns of some *Anas* duck hybrids may be an example of this. Variant individuals showing elements of pattern or colour characteristic of other subspecies or related species occur sporadically in a wide range of taxa, and these variations may be of similar origin. In some instances a recurrent variation is not a character of any extant species, as in the case of the white carpal patch which has been noted on individuals of several different species of gulls.

In normal plumage the appearance is controlled not only by direct genetic factors but also by the relative levels of hormones which determine the occurrence of sexually dimorphic plumages and the seasonal breeding and non-breeding plumages. Any imbalance of the endocrine system is likely to have a noticeable effect on plumage, and in some instances this has been studied in experimentally created conditions, as well as in individuals showing changes which are of pathological origin.

In some gamebirds such as the Pheasant and the domestic fowl a reduction in the level of the female hormone may result in females assuming male plumage. This may also occur through the atrophy of ovaries from age or disease. It may not necessarily imply a loss of all female functions since exceptionally individuals have laid eggs when in male plumage. This can occur in other species and there is a record of a male-plumaged Common Redstart *Phoenicurus phoenicurus* laying eggs in the wild. Female birds have only a single ovary on the left side of the abdominal cavity and if this is removed a mixed gland (ovotestis) develops in a similar site on the right hand side. In game birds the plumage assumed by the castrated female is of a male type and becomes increasingly male with successive moults. Conversely, in castrated Pheasants the male assumes a plumage resembling that of the female. In some breeds of domestic fowl most of the males are hen-feathered. Paradoxically, if such birds are castrated, a more typical male plumage is produced. The hen-feathered condition is controlled by the testes but appears to be hypersensitive to such female hormones as are normally present in the sexually active male.

In the House Sparrow, the male of which retains the sexually dimorphic plumage throughout the year although it is partially concealed by dull feather edges in winter, the sexual plumage is under genetic control, but a character affected by hormone levels and lost through castration is the black bill colour of the male breeding dress.

Feather structure abnormalities. Abnormalities of feather structure occur infrequently and in wild birds are usually lethal. Like pigment abnormalities, they may be the result of disease or temporary food deficiencies, or may be genetically determined and can be maintained by controlled breeding in captive birds.

The more rapid abrasion and loss of portions of plumage deficient in melanin has been mentioned above. Structural abnormalities may have a similar effect. An abnormal weakness of structure resulting in rapid wear of the distal part of the feather vane with retention of a tapering rachial zone, to give a 'needle-tailed' effect to the rectrices, has occurred on both rectrices and remiges of individuals of the Guillemot *Uria aalge* and Black Guillemot *Cepphus grylle*. A complete breakdown of the structure of these feathers, resulting in flightlessness, has been recorded for the Eurasian Jay *Garrulus glandarius* and Shelduck *Tadorna tadorna*.

Abnormally loose and fluffy plumage may be produced by failure of the interlocking barbule structure, or absence of the necessary barbicels. If the abnormality affects the remiges and rectrices, such a variation is usually lethal in the wild. In captivity hereditary strains of a similar type have been selected to produce the 'silky' form of the domestic fowl, domestic pigeon *Columba livia* and Barbary Dove *Streptopelia roseogrisea*. A similar breakdown of feather structure associated with reduced pigmentation, possibly resulting from disease and producing plumage with a 'hairy' appearance, has been noted in the Eurasian Jay and the Moorhen *Gallinula chloropus*.

A structural defect resulting in a twisting of the rachis of contour feathers to produce a frizzled effect occurs at times in captive finches, and hereditary strains have been established. Hereditary strains with a complete absence of all feathers have been produced in the domestic fowl and domestic pigeon but have failed to survive for long.

Although most of these structural abnormalities are rare, one type of defect is of more frequent occurrence. If a bird undergoes one or more days of inadequate diet when feathers are growing, the deficiency may result in a narrow transverse zone or line of weakness across the vane of the feather. (As already mentioned, pigmentation may also be affected.) This transverse line of defective structure is usually referred to as a 'hunger trace' or 'hunger fault'. Feathers with such faults are liable to break off after a time along the line of weakness, and if this occurs on a number of flight feathers it may make flight difficult or impossible. It was particularly a matter of concern to man in the early practice of falconry.

PLUMAGE MIMICRY: see MIMICRY.

PLUMAGE VARIATION: see PLUMAGE.

PLUMBEOUS: lead coloured.

PLUME: a feather, usually long and showy, developed for the purposes of display.

PLUMELETEER: substantive name of *Chalybura* spp. (for family see HUMMINGBIRD).

PLUMULA: a down feather (see PLUMAGE). Natal or nestling down plumage, when present, is called 'neossoptile'.

PLUNGING: see SWIMMING AND DIVING.

PLUSHCROWN: substantive name of *Metopothrix aurantiacus*, a South American furnariid (for family see OVENBIRD (1)).

PLUVIANELLIDAE: see under CHARADRIIFORMES; PLOVER, MAGELLANIC.

PNEUMATIZATION OF BONE: a term denoting the air-holding properties of the skeleton or parts of the skeleton. Aerated bones are characteristic of the class Aves, but also occur in the skull of crocodiles and, according to Bellairs and Jenkin (1960), were very probably features of the fossil pterodactyls. Since very light and hollow bones are also found in dinosaurs, it is not inconceivable that the origin of pneumatization is to be sought in the early archosaurs, from which all these groups stem (see EARLY EVOLUTION OF BIRDS). Pneumatized bones are hollow, the hollow parts communicating with the air-sac system. Air is supplied to the cranial bones via the air-sacs of the nasal and tympanic cavities, and to the postcranial skeleton via the air-sacs of the respiratory apparatus proper (see RESPIRATORY SYSTEM).

Skull pneumatization. The extent of pneumatization can easily be examined in the skull-roof. Unpneumatized parts (so-called windows) appear featureless and more or less translucent. They consist of a single layer of bone. Pneumatized parts of the skull-roof appear speckled in passerines and have a labyrinthine conformation in non-passerines. They consist of bilaminate bone, the two layers sandwiching the spongiosa, bony tissue rendered cancellous by action of bone-excavating cells. The extent of pneumatization can vary markedly both between and within different orders, families and species. No universally applicable rule can be formulated about this. Skulls which are for the most part weakly or not at all pneumatized are seen in e.g. kiwis (Apterygiformes), divers (Gaviiformes), herons (Ardeidae) and auks (Alcidae). Quite varied development of pneumatization occurs e.g. among wildfowl (Anseriformes), raptors (Accipitriformes, Falconiformes), gulls (Laridae) and woodpeckers (Picidae). Predominantly strongly or even fully pneumatized skulls are possessed by e.g. ostriches, rheas and cassowaries (Struthioniformes), pigeons and doves (Columbiformes), parrots (Psittaciformes) and nightjars (Caprimulgidae). The only two orders in which all members pneumatize completely are the owls (Strigiformes) and—apart from a very few exceptions—the passerines (Passeriformes). Numerous examples of the amount of pneumatization of the skull-roof in various groups of birds are given in papers by Harrison (1957), Verheyen (1953) and Winkler (1979).

In young birds the available studies show a different process of development of pneumatization in non-passerines and passerines. This phenomenon is closely correlated with differences in brain-development: in non-passerines the brain grows evenly to its adult volume and in most species the pneumatization-process terminates with attainment of the ultimate body-size. In the few non-passerines in which pneumatization continues beyond this point, additional bone is laid down on the outer surface of the skull, as Stork (1972) has established for pigeons. Pneumatization on the inner surface would cause pressure on the brain. But in young passerines the brain goes through an overweight phase, after which it shrinks to the adult volume. For this reason the skull in this group remains unpneumatized until maximum brain-volume is attained. The pneumatization process only sets in when the brain begins to contract to its adult volume. This point approximately coincides with the fledging of the passerine nestling. In contrast to non-passerines, pneumatization takes place against the internal skull-surface. Its function here is to fill out the gap between the unpneumatized skull-roof and upper brain-surface left by the shrinkage-process of the brain.

Pneumatization of skull-roof and ageing. In passerines the state of pneumatization of the skull-roof has long been used in establishing age. Since Baird (1963) first demonstrated how the state of pneumatization can be examined through the skin even in live birds, this method of ageing has become important in bird ringing. As nearly all passerines are fully pneumatized when adult (exceptions are noted in Winkler), all incompletely pneumatized birds can be recorded as immatures. However fully pneumatized individuals may only be definitely termed adult during the part of the year in which no juveniles with completed pneumatization can be expected. The dates from which fully pneumatized juveniles can occur have been given by Wood (1969) for certain North American passerines and by Winkler for European species. Depending on species the pneumatization process takes 2 to 8 months, beginning in the occipital region and finishing over the forehead. Among European species pneumatization takes least time in the Willow Warbler *Phylloscopus trochilus* (2 months) and longest in the Yellowhammer *Emberiza citrinella* (over 8 months). Occasionally the latter fails to achieve complete pneumatization.

In general the stage of pneumatization in non-passerines cannot be employed as an ageing criterion.

Pneumatization of postcranial skeleton. This has been far less well studied than that of the skull-roof and again is far more extensively developed in some species than in others. Diving birds like penguins (Spheniscidae), divers *Gavia* spp. and cormorants *Phalacrocorax* spp. are more poorly pneumatized than large flying birds like albatrosses (Diomedeidae) and eagles *Aquila* spp. A number of examples are contained in Bellairs and Jenkin and in Stresemann (1934). Generally the skeleton of large species in a related group appears to be more highly pneumatized than that of smaller species. As demonstrated both by Bellairs and Jenkin, and Stresemann, pneumatization of the postcranial skeleton begins with the penetration of developing bone by fine air-sac diverticula. The air-sac diverticula follow the resorption of the bone marrow and expand through the interior of the bone until they occupy its entire cavity.

Function of pneumatization. It is obvious that pneumatization primarily serves to save weight and so enhance flying ability. In addition, a pneumatized bone proves to be structurally more stress-resistant than an unpneumatized one. However, the great differences in extent of pneumatization between different orders of birds remain unexplained. Adaptations to specialized modes of life certainly play an important role here. Thus Harrison comments on the fact that almost all deep-diving birds are but very poorly pneumatized. They thereby minimize the natural tendency to buoyancy during diving. Stork ascribes a function of brain-insulation to the pneumatization of the skull. Winkler considers the significance of skull-pneumatization to lie in, among other things, its balancing out the two functions of the skull-roof, namely on the one hand to enclose securely the brain and on the other to provide insertions for musculature and sockets for the large eyes. Since pneumatization has above all a functional character, its extent cannot be employed as a taxonomic criterion. R.W.

POCHARD: substantive name of some *Aythya* spp. and of *Netta* spp.; used without qualification in Britain for *A. ferina*; in the plural, general term for the tribe Aythyini (see DUCK).

PODARGIDAE: see under CAPRIMULGIFORMES; FROGMOUTH.

PODICIPEDIFORMES: an order, comprising only the cosmopolitan family Podicipedidae (see GREBE). The ordinal name, which on the basis of a different view of the etymology of the type genus *Podiceps* was for a short time called Podicipitiformes, is derived from the family name Podicipedidae, which in its turn was validated in Opinion 981 of the Bulletin of the International Commission on Zoological Nomenclature 29 (1) 1972: 152. Before 1956 the name of the order used by the American Ornithologists' Union was Colymbiformes, for which see COLYMBIDAE.

PODICIPITIFORMES: obsolete term, see PODICIPEDIFORMES.

PODOTHECA: the horny covering of the unfeathered parts of the legs and feet (see LEG).

POETRY, BIRDS IN: for birds, as for man, the dominant senses are those of sight and hearing; the world of their experience seems, therefore, more comprehensible than one perceived mainly through scent or touch. Their form is often elegant and their colours attractive; the songs of some have long pleased man; their power of flight is enviable. Some build their nests not only in gardens and orchards but even in man's farm buildings and houses, so that these are familiar to man as no other wild animals are. Their domestic behaviour—the nests they build, the care they give to their young—are, again, not remote from human experience. And yet they are rendered mysterious and a cause of curiosity by their migrations. All in all, birds are a natural source of myth and of poetry; but the amount of actual observation of their lives which is available to a poet is necessarily limited.

Perhaps the earliest folk-song of Europe to survive was that sung by Rhodian boys to welcome the Swallow, but 7 or 8 centuries earlier a Minoan artist on Santorini had painted a Spring fresco of Swallows, with a pair rising beak to beak against a background of rocks and lilies. Hesiod, Simonides, Aristophanes and other Greek poets associated the return of the Swallow with spring, for even three and a half millennia ago it nested about man's buildings and so made itself more noticeable than other summer migrants. ('Swallow' for the poets often included the House Martin and the Red-rumped Swallow, both of which nest on buildings. The poets are always 'lumpers' not 'splitters'.) But the Swallow's twitter, which has pleased many an English poet—Sir John Davies even preferred it to the Nightingale—seemed to the Greeks no more than a barbarous gabble.

The Cuckoo's call—for Shakespeare, with his love of puns, a 'word of fear unpleasing to a married ear'—was a sign of spring to Hesiod, and Aristophanes recognized in it a warning to be off to work in the fields. The spring arrival of these birds was noted, but they were not, like storks and cranes, observable while on migration. Homer compared the clamour of the Trojan host to the noise of migrating cranes, and Hesiod and Aristophanes took the sound in autumn to be a sign that it was time to plough and to sow; Euripides seems to have been more impressed by the spectacle of the long-necked birds in flight 'passing beneath the Pleiads and Orion in the night', probably the first mention of moon-watching. And the winter quarters of cranes were not, like those of Swallows, beyond the limits of the known world.

The song of the Nightingale has evoked the charmed response of poets from Homer to our own time, and from Persia to Britain. Some of them—Aristophanes, Nashe, Lyly, Barnfield—have even attempted to transcribe its song into human syllables. Dafydd ap Gwilym addressed a poem to the Nightingale in the Birch Grove (was this in Wales?) and Milton saluted the bird

> 'that on yon bloomy spray
> Warblest at eve when all the woods are still',

in the earliest of his sonnets, and often referred to it elsewhere. His friend Marvell, whose poetry gives precise descriptions of birds, observed that

> 'Low Shrubs she sits in, and adorns
> With Musick high the squatted Thorns.'

And Izaak Walton, their elder contemporary, shows that he had chosen to listen to the song: 'He that at midnight, when the very labourer sleeps securely, should hear, as I have very often, the clear airs, the sweet descants, the natural rising and falling, the doubling and redoubling of her voice, might well be lifted above earth, and say, "Lord, what music hast thou provided for the Saints in Heaven, when thou affordest bad men such music on Earth!"' Collins noted Sophocles's 'peculiar fondness for the song' which he heard at Colonus, and Peacock also referred to this. Keats, hearing the song at Hampstead, was prompted to write perhaps the best known of all poems in its praise, and Robert Bridges wrote a sensitive lyric on the song. Throughout the bird's range the poets have celebrated its song: in English and Welsh, in German and Italian, in Greek and Persian; no other bird has been so universally admired.

Much of the poetry about the Nightingale derives from the primitive and savage myth of Tereus, Procne and Philomela (the Hoopoe, Nightingale and Swallow), on which Sophocles wrote a tragedy, of which only a fragment remains. Ovid retells the myth in *Metamorphoses* VI (the source of later versions) but with Philomela now the Nightingale not, as in Greek sources, the Swallow. For the poets the Nightingale was feminine, and she sang her sad song 'leaning her breast against a thorn.' But these things are the effects of myth, not of observation. Another myth, of Aedon who murdered her child Itylus in error and prayed to be changed into a Nightingale, was known to Homer: in the *Odyssey* Philomel

> 'in bow'ry shades unseen
> To vernal airs attunes her varied strains,
> And Itylus sounds warbling o'er the plains.'

Swinburne's poem is the best known version of this story in English. Probably more English poets knew the myths than had ever listened to the song, and one cannot help questioning whether the bird whose song Cowper heard on New Year's Day, 1792, was, as he supposed, a Nightingale.

No other song-bird has attracted so much myth as the Nightingale, and poetry about Song Thrush, Blackbird and Skylark owes rather more to personal observation. Robert Browning, in *Home Thoughts from Abroad*, recalled the song of the Chaffinch and of

> 'the wise thrush; he sings each song twice over
> Lest you should think he never could recapture
> The first fine careless rapture.'

The same characteristic repetition was noted by Tennyson and, 250 years earlier, by William Browne of Tavistock. John Clare, a most observant countryman who mentions many birds, heard

> 'a merry thrush
> Sing songs of rapture,'

and he watched her skilful modelling of her nest, where Marvell noted with pleasure how he might

> 'through the Hazles thick espy
> The hatching *Throstles* shining Eye.'

Spenser, in *The Faerie Queene*, singles out the refreshing quality of the song when Calepine, released from captivity, and now regaining strength,

> 'Upon a day he cast abrode to wend,
> To take the ayre, and heare the thrushes song.'

And the song made a similar appeal to Hardy, when 'every spirit upon earth seemed fervourless as I',

> 'At once a voice arose among
> The bleak twigs overhead
> In a full-hearted evensong
> Of joy illimited;
> An agéd thrush, frail, gaunt, and small,
> In blast-beruffled plume,
> Had chosen thus to fling his soul
> Upon the growing gloom.'

Michael Drayton, who has some claim to be the best ornithologist among English poets, said 'Of all birds, only the blackbird whistleth', and with 'the blackbird whistles from the thorny brake' Thomson recognized the same quality. Theocritus, 2,000 years before, had remarked the clarity of its notes, and poets in the Greek Anthology leave no doubt of their preference for its song to that of the thrush—in Greece, no doubt, the Mistle Thrush.

The 'early, cheerful, mounting lark' both by its conspicuous song-flight and by the quality of its song makes a strong contrast with the Nightingale singing its plaintive song at night in 'verdurous glooms and winding mossy ways', and it has delighted many English poets. Wordsworth drew the contrast in a poem addressed To a Skylark:

> 'Leave to the nightingale her shady wood;
> A privacy of glorious light is thine;
> Whence thou dost pour upon the world a flood
> Of harmony, with instinct more divine;
> Type of the wise who soar, but never roam;
> True to the kindred points of Heaven and Home!'

When Romeo must leave Juliet she says:

> 'It was the nightingale, and not the lark,
> That pierced the fearful hollow of thine ear;
> Nightly she sings on yond pomegranate-tree:
> Believe me, love, it was the nightingale.'

But Romeo is not convinced:

> 'It was the lark, the herald of the morn,
> No nightingale: look, love, what envious streaks
> Do lace the severing clouds in yonder east:
> Night's candles are burnt out, and jocund day
> Stands tiptoe on the misty mountain tops.'

Gray, like Wordsworth, notes song-flight and song:

> 'the skylark warbles high
> His trembling thrilling ecstasy;
> And, lessening from the dazzled sight,
> Melts into air and liquid light.'

Meredith attempted to describe the song:

> 'He drops the silver chain of sound,
> Of many links without a break,
> In chirrup, whistle, slur and shake ...
> A press of hurried notes that run
> So fleet they scarce are more than one.'

In the finest of all the poems inspired by the Skylark, which Shelley heard 'while wandering among the lanes' near Leghorn, he devised a stanza to represent its continuous, trilling melody:

> 'Sound of vernal showers
> On the twinkling grass,
> Rain-awakened flowers,
> All that ever was
> Joyous, and clear, and fresh, thy music doth surpass.'

Shelley heard his Skylark 'on a beautiful summer evening', but most of the poets associate the song with break of day. This is especially the time for song, before the busy human world has filled the air with discordant sounds, and the dawn chorus must have delighted many when getting up with the lark was the normal custom. The best description of this is Michael Drayton's in *Poly-Olbion*, where he writes of the birds of his native Warwickshire greeting the dawn in the Forest of Arden—where else, indeed, should a friend and neighbour of Shakespeare choose?—and he names many birds which

> 'with their cleere open throats
> Unto the joyfull Morne so straine their warbling notes
> That Hills and Valleys ring, and even the ecchoing Ayre
> Seemes all compos'd of sounds.'

Among these he names the Woodlark, which Gerard Manley Hopkins made the subject of an unfinished poem, where he transcribes the song:

> '*Teevo cheevo cheevio chee*:
> O where, what can that be?
> *Weedio-weedio*: there again!
> So tiny a trickle of song-strain.'

William Browne has a description of 'a musical concert of birds' no doubt in his native Devon:

> 'The lofty treble sung the little wren;
> Robin the mean, that best of all loves men;
> The nightingale the tenor, and the thrush
> The counter-tenor sweetly in a bush ...
> The crow was willing they should be beholding
> For his deep voice, but being hoarse with scolding,
> He thus lends aid; upon an oak doth climb
> And nodding with his head, so keepeth time.'

Poets of the greatest age of English music, in the 16th and 17th centuries, were especially responsive to the song of birds. Henry Vaughan, different from other poets as always, thought of a bird waking from sleep:

'Hither thou com'st: the busie wind all night
Blew through thy lodging, where thy own warm wing
Thy pillow was. Many a sullen storm
(For which course man seems much the fitter born,)
Rain'd on thy bed
And harmless head.
And now as fresh and chearful as the light
Thy little heart in early hymns doth sing.'

John Clare may rival Skelton and Drayton for the number of birds whom he mentions, among them some which seldom enter poetry, such as the Snipe, Yellowhammer, Blue Tit, Sand Martin, Corncrake and Firetail (Redstart) which, apprehensive when a hedger stops a gap near her nest in a hollow tree,

'Of everything that stirs she dreameth wrong
And pipes her "tweet tut" fears the whole day long.'

And, when his mind had broken, he could still delight in the birds he knew:

'Little trotty wagtail he went in the rain,
And twittering, tottering sideways he ne'er got straight again.
He stooped to get a worm, and looked up to get a fly,
And then he flew away ere his feathers they were dry.'

But it is not the province of the poet to contribute detailed knowledge of the lives and habits of individual species and it is often pointless to try to make precise identifications.

One of the strangest legends about the song of birds is of the swan-song—the song which the swan was said to sing only as a prelude to its own death. Certainly the Greeks, among whom the legend arose, would not have differentiated between Mute and Whooper Swans, both of which occur in the north, but it is tempting to suppose that the species which gave rise to the legend was the Whooper. Alcaeus said that swans transported Apollo to the land of the Hyperboreans, to the uttermost north, and Aristophanes said that the birds 'clattered their wings together in praise of Apollo, and through an aery cloud came their cry.' Perhaps someone noticed the musical cry of Whoopers before they left in the spring and, not seeing them again, devised the legend of the swan-song. The unrelated myth of Zeus taking the shape of a swan to woo Leda, who laid the egg (or two eggs) from which hatched Helen of Troy and the Heavenly Twins, was first told by Euripides and has attracted many painters and poets since his time, including W.B. Yeats who wrote a fine sonnet—his only sonnet—on the theme. But that story cannot reward ornithological research. *The Wild Swans at Coole* shows Yeats watching unmythical birds at a favourite place of his, and yet imagining them to have that timelessness which Keats imagined for his Nightingale. Birds' lack of individual characteristics seems to deprive them of those personal qualities whose passing is the source of so much human grief.

Swans are large and conspicuous not small and retiring like so many song-birds, but these man has long kept in cages and aviaries, where the poets have praised or lamented them. Catullus' address to and elegy on Lesbia's sparrow are probably the most famous of these, but by no means the earliest. The Greek Anthology includes a number of epitaphs on tame partridges—Alcibiades kept a pet Quail—or on song-birds, some of which had been killed by cats, and Catullus knew Simias' epitaph on a partridge. Some have doubted whether Lesbia's pet was a humble sparrow, but it chirruped (*pipiabat*) and sparrows are still kept as pets in Italy, as in England in the 16th century. Skelton wrote a long poem, and his best, when Jane Scrope's pet sparrow was killed by the nunnery cat, and though he was more interested in Jane than in her pet there is no reason to doubt that it was a sparrow: indeed the lecherous disposition of sparrows was something that Skelton could exploit. Sidney pretended to be jealous of Stella's pet sparrow which, like Jane Scrope's and George Gascoigne's and like himself, was called Philip. Skelton, who names 75 birds in his poem—far more than Shakespeare in all his works—followed the medieval tradition of birds attending a requiem mass, as does Shakespeare in *The Phoenix and Turtle*; but this tradition derived ultimately from Ovid who, in his elegy on a parrot (*Amores* II.6) summoned the birds to its funeral.

'Psittacus, Eois imitatrix ales ab Indis,
occidit: exsequias ite frequenter, aves;
ite, piae volucres, et plangite pectora pinnis
et rigido teneras ungue notate genas.'

Later Statius also wrote a lament for a dead parrot. They were fashionable pets in Imperial Rome.

If the poets' sympathies are usually with the owners of the pet birds there are, nevertheless, some whose imagination is touched by the bird's imprisonment in a cage. Everyone knows Blake's

'A robin redbreast in a cage
Puts all Heaven in a rage,'

but the exaggerated violence of expression is far less acceptable than Chaucer's gentle understanding:

'Tak any brid, and put it in a cage,
And do al thyn entente and thy corage
To fostre it tendrely with mete and drinke,
Of alle deyntees that thou canst bithinke,
And keep it al-so clenly as thou may;
Al-though his cage of gold be never so gay,
Yet hath this brid, by twenty thousand fold,
Lever in a forest, that is rude and cold,
Gon ete wormes and swich wrecchednesse.
For ever this brid wol doon his bisinesse
To escape out of his cage, if he may;
His libertee this brid desireth ay.'

Thomas Hardy, seeing a caged bird whose eyes had been put out, and hearing it singing, made a subtle contrast with man by adapting St Paul's words on charity:

'Who hath charity? This bird.
Who suffereth long and is kind,
Is not provoked, though blind
And alive ensepulchred?
Who hopeth, endureth all things?
Who thinketh no evil, but sings?
Who is divine? This bird.'

Cowper, who wrote an elegy *On the Death of Mrs Throckmorton's Bulfinch* (which was killed by a rat) wrote a better poem *On a Goldfinch starved to death in his cage*:

'Time was when I was free as air,
The thistle's downy seed my fare,
My drink the morning dew;
I perch'd at will on ev'ry spray,
My form genteel, my plumage gay,
My strains for ever new.'

But man's cruelty and neglect brought this happy liberty to an end. A more unusual epitaph, for this is on a wild bird, is Samuel Rogers' On a Robin-Redbreast, which was 'inscribed on an urn in the flower-garden at Hafod.'

'Tread lightly here, for here, 'tis said,
When piping winds are hushed around,
A small note wakes from underground,
Where now his tiny bones are laid.
No more in lone and leafless groves,
With ruffled wing and faded breast,
His friendless, homeless spirit roves;
—Gone to the world where birds are blest!
Where never cat glides o'er the green,
Or school-boy's giant form is seen;
But Love, and Joy, and smiling Spring
Inspire their little souls to sing!'

Poems about Robins are innumerable, for it is familiar in most English gardens where its confiding nature and attractive song, which is repeated in autumn when most other birds are silent, endears it to man. The nursery rhyme, *Who killed cock robin?* has been known to generations of children, probably from the 15th century on; and the strange legend that the robin 'fynding the dead body of a Man or Woman, wyll cover the face of the same with Mosse', was attached to the story of the Babes in the Wood, and so again made known in the nursery. Both the ballad and the legend date from the late 16th century, if not earlier. Only a bird as well known to man as the Redbreast could have acquired a nickname, which indeed has now become its usual name, just as 'Jackdaw' has supplanted the older 'daw'. The rascally repute of this bird has also been established by the Ingoldsby Legend of *The Jackdaw of Rheims*, one of the most amusing poems about a bird. By contrast with such anthropomorphic accounts of birds Marvell has a vivid description of the Hewel (Green Woodpecker) who

'walks still upright from the Root,
Meas'ring the Timber with his Foot;
And all the way, to keep it clean,
Doth from the Bark the Wood-moths glean.'

Clearly he had enjoyed watching a wild woodpecker about its daily life.

Emigrants from Britain to the New World were seldom poets, but Alexander Wilson, the Scottish pedlar poet author of the *American Ornithology* (1808–14), wrote of American birds which had not previously been celebrated in verse: the Ruby-throated Hummingbird which

'Sips with inserted tube the honeyed blooms,
And chirps his gratitude as round he roams.'

And he notes the iridescence of the plumage, where

'Each rapid movement gives a different dye.'

He has poems descriptive of other American birds, among them the Blue Jay and the tyrant flycatcher or Kingbird. This then was persecuted and Wilson sought to dispel prejudice by presenting the reader with a short poetical description of its life-history. Edna Millay's *Bobolink* is more about herself than the bird, and Robert Frost's charming poem *On a Bird Singing in its Sleep* does not identify the species. Poe's *Raven* has the traditional, sinister qualities but is as mythical as Coleridge's albatross.

Men have kept birds not only as pets, for the beauty of their plumage and the charm of their song, and for food, but also for sport, especially the noble sport of FALCONRY which provided imagery for medieval poets and for Shakespeare. In *2 Henry VI* there is reference to flying at the brook, and Michael Drayton, again, provides the best poetic account of this sport in the Norfolk section of *Poly-Olbion*, where the quarry is wildfowl. Drayton clearly had first-hand knowledge of the sport through Sir Thomas Monson and Sir Henry Goodere, both of whom he knew well, and both of whom were noted falconers. The later and less aristocratic sport of shooting has also been noted by the poets, perhaps best of all by Pope in *Windsor-Forest*, though the prey here would not all be at risk from modern sportsmen:

'With slaught'ring Guns th' unweary'd Fowler roves,
When Frosts have whiten'd all the naked Groves;
Where Doves in Flocks the leafless Trees o'ershade,
And lonely Woodcocks haunt the watry Glade.
He lifts the Tube, and levels with his Eye;
Strait a short Thunder breaks the frozen Sky.
Oft, as in Airy Rings they skim the Heath,
The clam'rous Lapwings feel the Leaden Death:
Oft as the mounting Larks their Notes prepare,
They fall, and leave their little Lives in Air.'

Thomson's humanitarian sentiment deflected him from describing the sport:

'These are not subjects for the peaceful muse,
Nor will she stain with such her spotless song—
Then most delighted when she social sees
The whole mix'd animal creation round
Alive and happy.'

The ancient Japanese custom of fishing with trained cormorants has been celebrated in tankas and it may be that the training of cormorants demands similar patience and skill to the training of falcons.

Hopkins' poem *The Windhover* is a masterpiece on a falcon (Kestrel) but has no reference to the sport; there are few poems about birds of prey outside the context of falconry, though Alexander Wilson has one on the Osprey. Even eagles have not found much favour with the poets, apart from their legendary ability to gaze at the sun and their identification in Greek myth with Zeus as was fitting for the 'feathered king'. Tennyson's six lines, which recall the legend, surpass all others:

'He clasps the crag with crookèd hands;
Close to the sun in lonely lands,
Ringed with the azure world, he stands.

The wrinkled sea beneath him crawls;
He watches from his mountain walls,
And like a thunderbolt he falls.'

Seabirds are as remote from man as eagles, and the most famous of them in poetry, the Ancient Mariner's albatross, is a symbol rather than a bird—a bird which Coleridge had never seen. As we might expect, it is poets from the highland zone of Britain who have written of seabirds: Dafydd ap Gwilym has an elegant cywydd to a snow-white gull on the margin of the sea, and in the Anglo-Saxon *Seafarer* there is mention of the clamour of Gannets and the crying of 'sea-mews'. But the finest description is James Thomson's in *Autumn*:

  Or, where the Northern Ocean in vast whirls
Boils round the naked melancholy isles
Of farthest Thule, and th' Atlantic surge
Pours in among the stormy Hebrides,
Who can recount what transmigrations there
Are annual made? what nations come and go?
And how the living clouds on clouds arise,
Infinite wings! till all the plume-dark air
And rude resounding shore are one wild cry?

Thomson's birds are immersed in activities which have nothing to do with man. In Norway, too, Ibsen has some well-observed poems about seabirds. With these one might place Shakespeare's well-known lines about a Dabchick, which he had clearly observed, though, as usual, he requires it only for a simile for human behaviour:

'Like a dive-dapper peering through a wave,
Who, being looked on, ducks as quickly in.'

The nocturnal owls, remote from man in another way, have, by their stealthy flight and eerie cries, always seemed sinister, and this has perhaps been enhanced by their facial discs and frontal gaze, 'the staring owl' of Shakespeare, which has some human suggestion. The 13th century poem of *The Owl and the Nightingale*, in which the two birds debate the matter of what benefits they confer on man nevertheless has some natural charm of observation though the two birds are very anthropomorphic.

Aristophanes' comedy *The Birds*, first produced at Athens in 414 BC, remains the most comprehensive and in many ways most remarkable of all European tributes to birds. It exhibits man's world seen through the eyes of birds, and, inevitably, seen as comic, an ornithomorphic view of man, so to say. It includes 'scraps of birdlore culled from every quarter—from history, poetry, legend, fable, proverb, and personal observation,' from all the varied responses of man to the fascination of birds. It could only have been written by a man who enjoyed looking at and listening to birds, and perhaps better than any other piece sums up what European poets for nearly 3,000 years have been writing about birds. POIKILOTHERMAL: 'cold-blooded', opposite of HOMOIOTHERMAL (see HEAT REGULATION).

POINTED-TAIL: substantive name of *Berlepschia rikeri* (see OVENBIRD (1)).

POISONING: see TOXIC CHEMICALS.

POISONING, LEAD: see DISEASE; and under GRIT.

POLIOPTILINAE: see GNATCATCHER.

POLLINATORS: agents—avian in this context—in the pollination of plants. Birds may be predators on plants or they may be used by plants as agents of pollen flow or SEED DISPERSAL. In the latter cases, the plants have adaptations for attracting birds and often for restricting less efficient visitors. There has evidently been a long history of co-evolution between birds and plants, in the course of which mutual adaptations have been acquired.

In typical bird-pollinated flowers the corolla tube is long and generally narrow, the ovary is inferior, and the nectar, which is produced mostly during the day when the flower is open, is stored at the base of the corolla. The colour is very often (but by no means always) red. Bird-flowers usually do not produce a scent or have nectar guides that might facilitate insect visits. Within bird-flowers there are even more refined specializations that limit the range of bird species that can visit each flower efficiently.

Birds of a wide variety of families (hummingbirds, honeyeaters, sunbirds, orioles (Icteridae), tanagers, finches, estrildid finches, flowerpeckers etc.) visit flowers and, at least sometimes, remove nectar. Not all of these visitors effect successful pollination. Some birds (e.g. estrildids and finches) remove and mandibulate the flower to force nectar out; others, such as some honeycreepers (Thraupidae), may probe into the nectar chamber through the corolla wall, contacting neither the stigma nor stamens. These nectar thieves have probably been important selective agents for the evolution of thick corollas and inferior ovaries.

Birds adapted for feeding on flower nectar often have relatively long bills, and extensible tongues with fringed bifurcated tips. The tongue of sunbirds and hummingbirds has a longitudinal trough in which nectar moves by capillary action. In neither group is the trough sufficiently enclosed to permit a 'soda straw' sucking action. Other, less specialized nectar feeders among birds have fringe-tipped tongues (e.g. the 'brush-tongued' parrots), but generally lack the bifurcated tip. Legitimate visitors to flowers probe through the distal corolla opening to reach the nectar chamber at the base of the corolla, at the same time either depositing or removing pollen. The position of stamens and stigma differs in different bird-flowers, and this may help to ensure that the pollen removed by a bird is transferred to another flower of the same species. The pollen of bird-flowers is generally sticky and may coat the bird's surfaces.

There is very little evidence that birds regularly eat pollen (though this may be an important source of amino acids for some insects and bats) or are searching for insects in the flowers that they probe (despite categorical statements in the earlier literature). They visit the flowers only for the nectar, which in the case of specialized nectarivores provides their main energy source.

The composition of floral nectar includes (in addition to water) sugars, usually composed primarily of sucrose, glucose and fructose; small amounts of polysaccharides; and small quantities of other substances (see below). Nectar in bird-pollinated flowers varies at least from 10% to about 50% sugar concentration by weight, the majority being in the range 15–25%. Insect-pollinated flowers tend to have somewhat higher concentrations of sugar, and also nectar that varies widely in concentration through time as a result of evaporation from the more open flowers.

The other substances contained in nectar include amino acids, proteins and lipids. While some of these are of some nutritional potential for birds the concentrations tend to be lower in bird-pollinated than insect-pollinated flowers. The few hummingbirds that have been tested in the laboratory either reject or show no preference for sugar solutions containing amino acids at approximately natural concentrations. It seems to be the general rule that nectarivorous birds derive most non-energetic nutrients from insects captured away from the flowers.

Most hummingbird-pollinated plants do not have perches that provide direct access to the flowers. Hummingbirds must usually hover while feeding, although where possible they will use an available perch, such as an adjacent leaf. Most other nectar specialists visit plants with convenient perches. Large nectar feeders such as orioles and parrots are facultative visitors although some tropical trees may use orioles as their principal pollinators.

Nectarivorous birds may increase the benefit from foraging by preferentially visiting flowers that have accumulated the largest amounts of nectar. Sunbirds, Hawaiian honeycreepers (Drepanididae) and hummingbirds have been shown to organize their visits so as to make the nectar reward per flower more than could be expected from random foraging. This probably involves some memory of locations in a foraging area. Long-term memory has been recorded in hummingbirds that, for example, return to the location of a feeder after a migratory absence.

Foraging patterns by nectarivores influence gene flow among the plants at which they feed. Non-random foraging (see above) will tend to equalize the visitation rate to each potential pollen donor and recipient. Behavioural interactions among the pollinators will also influence gene-flow between plants. Thus a territorial bird, defending a concentrated group of flowers, will generally carry pollen only over short distances, while a bird that feeds on flowers that are too sparse to be suitable to defend as a feeding territory will carry pollen over longer distances. The effect on the plants will depend on the degree of local adaptation. For at least one insect-pollinated plant, *Delphinium nelsoni*, there is evidence that pollen flow over relatively short distances increases individual reproduction. Shorter or longer distances of pollen movement may disrupt local adaptations and lower reproductive success through reduced seed set or reduced viability of offspring.

Colour, especially red, is often assumed to play an important role in attracting bird visitors to flowers. However, hummingbirds will visit flowers (and feeders) displaying colours from near ultraviolet to red, provided that they obtain nectar rewards. The importance of red may lie in the contrast with green foliage as well as in the ability of birds to discriminate red wave lengths. Some insects, at least, are less capable or incapable of red discrimination, so that colour may function to restrict insect visitors to hummingbird-flowers.

POLYANDRY: general term for mating systems in which individual females regularly mate with two or more males in the course of a breeding season. Polyandrous mating systems are confined to a few groups of non-passerine nidifugous birds, in nearly all of which each nest is tended by a single parent—in most cases the male only, in a few cases by the male and female at separate nests. It is often combined with a reversal of the usual sex roles in courtship, the female being larger and more brightly coloured than the male and playing the dominant role. In contrast to POLYGYNY, which is characteristic of seed-, fruit- and nectar-eating birds, polyandrous species mostly eat animal food.

The main feature of typical polyandrous breeding systems is that the male takes charge of the eggs laid by his mate, thus freeing her to lay another clutch for another male. Hence polyandry is normally successive (or serial). Simultaneous polyandry is known in two species of hawks, one species of jacana, the Tasmanian Waterhen *Tribonyx mortierii*, and the Noisy Miner *Manorina melanocephala*, a honeyeater with a highly developed group breeding system.

The reasons for the original reversal of the sex roles in families in which polyandry is the rule are not known. When the contributions of the two sexes to the care of the nest and young are unequal, the female will normally be expected to take the greater part, as her investment in the reproductive effort is the greater (see MATING SYSTEM). Whatever the original causal factors in the various groups in which it occurs, polyandry is clearly adaptive in making possible an increase in the reproductive output, especially when conditions suitable for breeding are short-lived. In principle it can easily be derived from a monogamous breeding system in which the female lays 2 clutches of eggs, the first of which her mate incubates while she takes charge of the second.

The following treatment is systematic, and includes all groups of birds in which polyandry has been reliably reported.

Ratites. The Australian Cassowary *Casuarius casuarius* practises successive polyandry. Pairs are formed, but after laying the female leaves the clutch to the male and may mate with one or more further males. (The nesting behaviour of the Emu *Dromaius novaehollandiae* is similar, but females apparently do not normally pair with a second male.) In the Greater Rhea *Rhea americana* successive polyandry is combined with harem polygyny. The male collects a harem of females, all of whom lay in his nest. He then takes sole charge of the nest and eggs and the females move on and mate with another male. Mating systems vary geographically in the Ostrich *Struthio camelus*; in the East African race at least (*S. c. massaicus*), females mate promiscuously with several males.

Tinamous. The breeding systems are varied in this family, but in all species that have been studied in detail the male takes charge of the nest and its contents. Some species are monogamous; in others there is successive polyandry, and in at least 3 species successive polyandry is combined with harem polygyny (see POLYGYNY).

Hawks. The Galapagos Hawk *Buteo galapagoensis* practises what has been called 'co-operative polyandry' (Faaborg *et al* 1980). One to 4 males mate with a single female, and all males help in the care of the eggs and young. Polyandrous groups apparently breed more successfully than monogamous pairs. Less complete evidence indicates that the breeding system of Harris's Hawk *Parabuteo unicinctus* of desert areas of North America is similar. In these cases polyandry seems to be an adaptive response to breeding in habitats where food resources are poor or unpredictable.

Partridges. In the Red-legged Partridge *Alectoris rufa* in captivity, after pair formation the female lays a clutch of eggs which her mate incubates and then a second clutch which she herself incubates. In the wild, however, there is evidence that females may lay clutches for successive males.

Buttonquail. Successive polyandry appears to be the rule. There is some evidence for it also in the related Plains-wanderer *Pedionomus torquatus* (sole member of the Pedionomidae), and in one of the 3 species of mesites (Mesitornithidae), another related family. Possibly therefore the system evolved early in the evolutionary history of this section of the Gruiformes.

Rails. The Tasmanian Waterhen lives in groups, each female associating with one to 3 males. All of them mate with her and help to raise her young.

Jacanas. Successive polyandry is the rule in the Indian species *Hydrophasianus chirurgus*, and probably in *Metopidius indicus*. The Neotropical species *Jacana spinosa* has a system of simultaneous polyandry. Each female has from one to 4 males which hold sub-territories within her own territory. Females are generally larger than males in all species; in *Jacana spinosa* the difference is extreme, females weighing 75% more than males.

Painted snipe. Successive polyandry is the rule, at least in the Old World species *Rostratula benghalensis*. The female is larger and more brightly coloured than the male.

Sandpipers, plovers and phalaropes. Most sandpipers and plovers seem to be normally monogamous, but successive polyandry occurs in a number of northern and montane species. The initial stage in the evolution of polyandry in this group is probably shown by Temminck's Stint *Calidris temminckii*, a species which seems normally to be monogamous: the female lays 2 successive clutches, the first of which is incubated by the male and the second by the female. A similar system probably occurs in the Little Stint *C. minuta*, Sanderling *C. alba*, and Mountain Plover *Charadrius montanus*. In the Spotted Sandpiper *Actitis macularia* polyandry is more advanced, females laying a succession of up to 4 clutches for different males, the last of which they help in incubating. In the Dotterel *Eudromias morinellus* the system seems to be essentially the same, but females are not recorded as laying more than 2 successive clutches. In the phalaropes the mating system has long been controversial. Polyandry (successive) was assumed, and recent research has confirmed it for the Red-necked Phalarope *Phalaropus lobatus* and Grey Phalarope *P. fulicarius* (see PHALAROPE).

Honeyeaters. The Noisy Miner of eastern Australia has a highly developed communal breeding system (Dow 1978). Females may mate with several males of the group to which they belong, and as many as 14 different males have been seen feeding the young in one nest. Though the system qualifies as polyandrous, it is rather one of promiscuity modified by the dominance relations obtaining among the males, the dominant male of a group achieving most of the copulations. (See also references under MATING SYSTEM.)

POLYBOROIDINAE: see HAWK.

POLYGAMY: see MATING SYSTEM.

POLYGYNY: general term for mating systems in which individual males regularly mate with two or more females in the course of a breeding season; thus excluding the cases of occasional bigamy recorded in many normally monogamous species. For general considerations of the part played by the two sexes in the care of eggs and young, see under MATING SYSTEM.

A clear-cut classification of the many forms of polygyny is hardly possible, partly because of their variety and variability and partly because of inadequate knowledge of the biology of many of the species concerned. A distinction is usually made between (1) harem polygyny, in which a male maintains simultaneous pair-bonds with two or more females, (2) successive (or serial) polygyny, in which a male pairs with two or more females in succession, and (3) promiscuity (often associated with LEK displays), in which the male mates with as many females as offer themselves to him, and no pair-bonds are maintained. 'Promiscuity' is, however, not a very suitable term, as females of such species are by no means promiscuous but highly selective in their choice of mates, though males may be relatively undiscriminating. The term 'polybrachygamy' (many brief matings) has been proposed by Selander (1972). In some ratites and tinamous harem polygyny is combined with POLYANDRY. A distinction may also be made between 'resource-based' polygyny, in which the male makes some resource, over which he has control, available to the females with which he mates, and polygyny that is not based on any resource, in which the male contributes nothing but his genetic material to the reproductive effort of the females with which he mates. This distinction is biologically important, but in particular cases it is not always possible to decide, on the evidence available, whether a system is resource-based or not. A further difficulty arises, in some cases, in attempting to distinguish polygyny from promiscuity in species which have not received detailed study with marked individuals.

One of the main preconditions for the evolution of polygyny is that the female should be able to tend the eggs and young single-handed, or with only a small amount of assistance from her mate. This condition is met in several of the groups of birds in which polygyny occurs (e.g. game-birds, waders, hummingbirds), but it applies less obviously to polygynous species in passerine families in which monogamy is the rule. In these cases it seems that polygyny results from certain features of the habitat and associated food resources. It is found especially in species that exploit highly productive but structurally simple habitats, in which food is concentrated in a narrow spatial range (e.g. some marsh birds), or habitats that offer widespread feeding areas but restricted nest-sites (e.g. some colonial tree-nesters). In such conditions some males may be able to control territories in which two or more females may be able to breed successfully, while less successful males may obtain suboptimal or unsuitable territories, or none at all. A further factor favouring polygyny may be a domed or hole nest, which reduces the energetic costs of incubation and feeding the young and so may make it easier for the female alone to tend the nest (e.g. wrens, dippers).

Since the functional classification is difficult, for the reasons given above, the following treatment is systematic, and includes all groups of birds in which polygyny has been reliably reported. Lek species are mentioned but not dealt with in detail; for a fuller treatment see under LEK.

Ratites. In the Greater Rhea *Rhea americana* the male collects a harem of up to 15 females, all of whom lay in his nest. He then takes sole charge of the eggs and young while the females move on and lay for another male (harem polygyny combined with successive polyandry). In the Ostrich *Struthio camelus* mating systems differ in different populations. Males of the southern race (*S. c. australis*) collect a harem of females who all lay in one nest, but the dominant female helps the male in incubation and all the females help in care of the young. In the E. African race (*S. c. massaicus*) several females lay in one nest but a harem is not formed; only one female, the 'major' female, remains associated with the male and his nest. (In the Emu *Dromaius novaehollandiae* monogamy seems to be the rule.)

Tinamous. In at least 3 species (*Nothocercus bonapartei, Nothoprocta cinerascens* and *Crypturellus boucardi*) the breeding system is essentially the same as in the Greater Rhea: the male collects a harem of several females, which lay in his nest and then move on to another male. Other tinamous are monogamous or serially polyandrous; in all of them the male takes charge of the nest and its contents.

Bittern. Males of the Bittern *Botaurus stellaris* (and possibly other *Botaurus* spp.) may have several females nesting within their territories. Presumably this is a case of harem polygyny, but it needs further study. Nothing comparable has been recorded in other members of the Ardeidae.

Ducks. In contrast to the great majority of the species, the tropical ducks of the closely related genera *Cairina* and *Sarkidiornis* (Muscovy and Comb Ducks) are reported to be promiscuous, each drake copulating with several females. The Musk Duck *Biziura lobata* of Australia is also promiscuous. The evidence comes mainly from birds in captivity, and more detailed observations on wild birds are needed. Harem polygyny may be involved.

Harriers. Polygyny is regular in the Hen Harrier *Circus cyaneus*, Montagu's Harrier *C. pygargus*, and probably Marsh Harrier *C. aeruginosus*. In the Hen Harrier as many as 7 females have been recorded breeding in an area occupied by a single male.

Game-birds. Several species of grouse (Tetraoninae) and the Great Argus *Argusianus argus* and Crested Argus *Rheinartia ocellata* (Phasianidae) have lek displays. In the Common Pheasant *Phasianus colchicus*, and probably many other pheasants with pronounced sexual dimorphism, the system is one of harem polygyny; the male contributes to the reproductive success of his mates by feeding them in the period before egg-laying, and they may benefit by nesting within his defended territory. Mating systems in the Phasianidae need further study, ranging as they do from monogamy (e.g. partridges) to lek systems; almost certainly there is wide variation in the development of polygyny, linked with the extent of the male's contribution to the reproductive effort of his mates. The Turkey *Meleagris gallopavo* (Meleagridae) has a system of harem polygyny in which the male apparently contributes nothing except genetic material.

Bustards. In the Great Bustard *Otis tarda* males display in leks and are either promiscuous or perhaps form temporary bonds with particular females; in either case they are polygynous. The Little Bustard *Tetrax tetrax* has been reported to be polygynous and monogamous; the Houbara *Chlamydotis undulata* is said to be monogamous. Mating systems in this family need much more study.

Waders. Several species that breed at high latitudes in the north are polygynous. In 4 species, the Ruff *Philomachus pugnax*, Great Snipe *Gallinago media*, Buff-breasted Sandpiper *Tryngites subruficollis*, and Pectoral Sandpiper *Calidris melanotos* the males are promiscuous, the first 3 of these displaying in leks or 'exploded leks' (see under LEK) to which the females come for mating. Harem polygyny is found in 2 species (Curlew Sandpiper *Calidris ferruginea* and White-rumped Sandpiper *C. fuscicollis*) and possibly a third (Sharp-tailed Sandpiper *C. acuminata*). The Eurasian Woodcock *Scolopax rusticola*, a woodland breeder, practises successive polygyny (see RODING).

Hummingbirds. Polygyny is probably general throughout the family; there is no convincing evidence for monogamy in any species. In the great majority of the species the males contribute nothing except genetic material to the reproductive effort of the females with which they mate. Lek displays occur in several species; in many others males display solitarily. In a few hummingbirds, however, resource-based mating systems occur. In the Anna Hummingbird *Calypte anna* and the Fiery-throated Hummingbird *Panterpe insignis* males are territorial over flower clumps rich in nectar, and allow access to these food sources to females with which they have mated, and possibly also to their young. Males of the Hairy Hermit *Glaucis hirsuta* hold territories along stretches of forest stream, within which up to 3 females may nest. In this case it seems that competition for specialized stream-side nest-sites is so strong that the help of the male is needed for effective defence of the nest against conspecifics.

Honeyguides. A resource-based mating system of a special kind is found in the Orange-rumped Honeyguide *Indicator xanthonotus* of the Himalayan foothills. Males defend the huge combs of the bee *Apis dorsata*, and feed on the wax. Females mate only with comb-holding males, and they and later their young are allowed access to the comb of the male with which they have mated. Casual observations suggest that some African honeyguides may have similar mating systems.

Lyrebird. Polygyny is apparently regular in the Superb Lyrebird *Menura novaehollandiae* of south-eastern Australia. It is not certain whether females form any sort of pair bond with the males with which they mate, but it is known that they may visit more than one displaying male before mating.

Cotingas and manakins. Many members of these 2 families are polygynous. The males display either in leks or solitarily, mating with the females that they attract to their display areas. Frugivory seems to be the main predisposing factor in the evolution of polygyny in this group. Thus in the related family Tyrannidae, most of whose members are insectivorous, monogamy is the general rule, but one of the more markedly frugivorous species, *Pipromorpha oleaginea*, has a lek system analogous to but less highly developed than the lek systems of cotingas and manakins.

Dippers. Polygyny appears to be regular in the American Dipper *Cinclus mexicanus*, and may be expected to occur in other species.

Wrens. Four northern species are regularly polygynous, but so far as known no tropical species are. In the European Wren *Troglodytes troglodytes*, polygyny is most prevalent in the habitats that are richest in food, and the same is probably true of the Marsh Wren *Cistothorus palustris* of North America. It seems that in this family polygyny is likely to develop when the food supply is rich enough for the female to be able to feed the young effectively single-handed; the male can then increase his reproductive output by acquiring more than one female and reducing the assistance that he gives to each of them.

Old World flycatchers. In the Pied Flycatcher *Ficedula hypoleuca* and Collared Flycatcher *F. collaris* a proportion of the males are bigamous. The adaptive basis of polygyny is probably essentially the same as in the wrens.

Old World warblers. Polygyny is regular in Cetti's Warbler *Cettia cetti* and the Great Reed Warbler *Acrocephalus arundinaceus*. In the former, the largest males tend to acquire most females. In the latter, males that occupy territories that are especially rich in food tend most often to be polygynous, and the adaptive basis seems to be the same as in the wrens.

Penduline tits. In the Eurasian species, *Remiz pendulinus*, males build a succession of nests, attracting a female to each one in turn. This system seems to be essentially similar to that of the weaver-birds dealt with below.

Buntings. In the Dickcissel *Spiza americana* a proportion of the males are bigamous. The Corn Bunting *Miliaria calandra* has also been claimed to be polygynous, but the evidence is conflicting.

American orioles etc (Icteridae). Two groups of species in this family, all colonial breeders, are regularly polygynous, the marsh-living blackbirds (*Agelaius*, *Euphagus*, *Xanthocephalus*, and probably other genera) and the tropical tree-nesting caciques (*Ostinops*, *Cacicus*, and related genera). In the former group, the main predisposing conditions seem to be that food is generally very plentiful in the best habitats and that a proportion of the males can occupy the best areas and exclude the other males (cf. the Marsh Wren, above, in which similar conditions obtain). The latter group of species are mainly frugivorous, and nest-colonies are in traditional (presumably safe) trees away from feeding areas. Males are much larger than females and take no part in nesting. Successful males may mate with several different females; whether they are promiscuous, as is usually thought, or dominate a part of the colony and mate with the females in that part, needs further investigation.

Weavers. Successive polygyny occurs in 3 colonially nesting genera, *Ploceus*, *Bubalornis* and *Euplectes*. Males build a succession of nests, displaying at each newly completed nest to attract a female and then building another as soon as the previous one is occupied. There is an evident correlation between polygyny and diet in this family; thus the polygynous species are all seed-eaters, while the insectivorous species are monogamous.

Australian magpies (Cracticidae). In *Gymnorhina tibicen*, a group breeder, a male may mate with one to several females in his group. Mating and other relationships within this and other group-breeding species are dealt with more fully under CO-OPERATIVE BREEDING.

Birds-of-paradise and bowerbirds. Polygyny is the rule in most members of these 2 families. Males display either solitarily or in leks and take no part in the nesting duties. As in the cotingas and manakins, a mainly frugivorous diet seems to be an important predisposing condition for the evolution of polygyny. D.W.S. (1)

POLYMORPHISM: term that was defined by Ford (1945) as the coexistence in one interbreeding population of two (dimorphism) or more distinct and genetically determined forms, the least abundant of which is present in numbers too great to be due solely to recurrent mutation. The frequency of the rarer form has been variously defined as 1–5% by subsequent authors. The commonest use of the term for ornithologists occurs in relation to distinct plumage colour variants (strictly polychromatism) which have a genetic basis and which are not merely sexual, seasonal or developmental plumage variations. Examples would be the dark and light colour morphs of the Arctic Skua *Stercorarius parasiticus* or the red and grey morphs of the Screech Owl *Otus asio*. In recent years, however, polymorphism has been investigated in birds and other organisms at the molecular level using electrophoresis and other techniques to detect discontinuous genetic variation in enzyme systems.

The essence of Ford's definition is that the morphs must firstly be phenotypically distinguishable with discontinuities in the phenotype, since polymorphism must not be used to include continuous or quasi-discontinuous variation. These discontinuities, however, need not be obvious to the eye, since enzyme polymorphism requires considerable biochemical manipulation for its detection. Secondly, the phenotypic variants must be genetically distinct and there should be some understanding of the genetic basis of the polymorphism. Minimally it should be demonstrated that there is allelic segregation at at least one gene locus.

The difference between discontinuous and continuous genetic variation, while easy to understand conceptually, is often difficult to distinguish in practice. Huxley (1955) considered clutch-size differences in birds to be an example of polymorphism, insofar as clutch-size is a meristic character and a clutch of 2 is phenotypically different from one of 3 eggs. However, as shown by Perrins and Jones (1974), the underlying genetic basis for clutch size variation is presumably polygenic, similar to most continuous phenotypic variation, with no clear correlation of particular genotypes with particular clutch sizes. CLUTCH-SIZE variation is clearly quasi-discontinuous variation.

Investigations into polymorphism in birds have fallen into 3 major categories: genetic, evolutionary and taxonomic.

Genetic studies have been carried out in an attempt to elucidate the genetic basis for the phenotypic discontinuities of polymorphism, but on relatively few species. Genetic differences between red and grey morphs of the Screech Owl have been ascribed to a single pair of alleles with red dominant to grey. Red-footed Boobies *Sula sula* on the Galapagos Islands have been classified into 3 morphs: Brown, Intermediate and White. In this case two codominant alleles at one locus was the simplest genetic explanation for the polymorphism, the intermediate plumage birds being heterozygous. A similar explanation could account for the polymorphism in Arctic Skuas. Lemmetyinen *et al* (1974) postulated 2 independently assorting pairs of alleles at each of 2 loci to account for the polymorphism in Arctic tern *Sterna paradisaea* chicks.

Thorneycroft (1966) showed a chromosomal basis for the plumage polymorphism in the White-throated Sparrow *Zonotrichia albicollis* and other chromosomal polymorphisms have been detected in species showing no detectable phenotypic variation.

The genetic tools available to the ornithologist studying polymorphism in a wild population of birds are limited. Since controlled crosses are usually not possible, it is necessary to use data from samples collected in the field where sample size often limits reliability of interpretation. Unless long term studies are carried out with marked birds, it is possible to use family data only if the polymorphism is visible in adult and young birds. Interpretation is also difficult if the genes controlling polymorphism do not obey the HARDY-WEINBERG equilibrium. If, for example, mating between the morphs is not random, it becomes difficult to predict the distribution of the morphs in the offspring of different types of matings. A genetic analysis of families of the dimorphic Lesser Snow Goose *Anser caerulescens* which did not rely on Hardy-Weinberg equilibrium, led to the postulation of a 2-allele, single gene explanation for the difference between the blue and white morphs of the snow goose, with the allele for blue coloration incompletely dominant over the allele for white.

Evolutionary studies in polymorphism have been concerned mainly with the question of natural selection. R.A. Fisher stressed that the presence of a stable polymorphism implies a selective balance between the morphs, with one genotype favoured in some circumstances, another genotype favoured in others. Various explanations have been put forward to explain the maintenance of polymorphism. These include: (a) heterozygote advantage (heterosis) where organisms carrying both alleles (heterozygotes) in a 2-allele polymorphism have a higher reproductive fitness than the homozygotes; (b) negative assortative mating, i.e. the tendency of one morph to choose the other morph as a mate; (c) frequency dependent selection, where the fitness of a morph varies with its frequency in the population, such that a morph has higher fitness than its alternate when rare and vice versa; and (d) balance of advantages due to temporal or spatial heterogeneity in the environment.

Huxley, following Dobzhansky's work with *Drosophila*, believed that heterozygote advantage was the primary explanation for the maintenance of polymorphism in birds; this has not been shown in the avian literature.

Negative assortative mating is the rule in the White-throated Sparrow with tan morphs usually mating with white morphs. It has also been documented in some populations of Arctic Skuas, but is not necessarily the mechanism whereby the polymorphism is maintained. Dark birds could be favoured where early breeding is advantageous, whereas light birds are favoured where late breeding is preferable. Neither of these explanations has been effectively demonstrated.

Apostatic selection is selection for variation for its own sake and is thought to be maintained by FREQUENCY DEPENDENT SELECTION, in that a given phenotype is favoured in direct proportion to its rarity through frequency dependent predator pressure. No avian prey species has been demonstrated to be polymorphic due to apostatic selection, but the hypothesis has been extended to include parasitic birds such as cuckoos and predators such as hawks and skuas. It has been argued that the hosts of parasitic cuckoos would be less likely to recognize and respond to a rare morph, which would be to the advantage of that morph. Paulson (1973) has hypothesized that the rarer morphs of a predator would be less familiar to a potential prey individual and thus have a greater chance for successful capture. This advantage should lead to balanced polymorphism and could explain the high frequency of polymorphism in hawks and skuas.

In contrast to the classic studies in Lepidoptera where selective differences between the morphs have been amply demonstrated, there are far fewer avian examples. The reasons for this are simple. Fitness differences between morphs would be very small or non-existent and to detect fitness differences over a range of temporal or spatial environments would require extremely large sample sizes. Thus, although Lemmetyinen *et al* (1974) postulated that grey morphs of the Arctic tern were favoured in areas dominated by grey rocks and brown morphs where the rocks were reddish or the soil sandy, they could detect no differences in reproductive fitness between the morphs in either environment. A notable example is the Lesser Snow Goose. An early study showed the blue morph increasing in frequency at the expense of the white morph. This was accounted for by higher nest predation and hunter pressure on the white phase birds. However, a later study of a different population and with a sample of several thousand birds over 10 years found no differences in reproductive fitness between the 2 morphs. All other measures of reproductive fitness at different stages of the life cycle also showed no differences.

An interesting case where disruptive selection pressure has been suggested to account for the dimorphism is the European Cuckoo *Cuculus canorus* where Voipio (1953) suggested mimicry of 2 common European raptors, the Kestrel *Falco tinnunculus* and the Sparrowhawk *Accipiter nisus*, the red morph resembling the former, the grey morph the latter. Similarity to the models, it was postulated, enables the Cuckoo to intimidate the host species.

Evolutionary studies have also centred around the question of assortative mating and mate choice. Many species of birds choose mates randomly with respect to morph. There is no evidence of assortative mating in Red-footed Boobies, Screech Owls, some populations of Arctic Skuas, New Zealand Fantails *Rhipidura fuliginosa*, and Ferruginous Hawks *Buteo regalis*. In White-throated Sparrows there is strong negative assortative mating. In some populations of Arctic Skuas, and Western Grebes *Aechmophorus occidentalis*, there is positive assortative mating. In Snow Geese there are elements of both positive and negative assortative mating. Only in Snow Geese has it been shown that the assortative mating is a consequence of mate choice based on morph appearance (Cooke 1978). In this species, a bird from a monomorphic family will generally choose a mate of the same morph as that of its family. By manipulation it has been shown that the choice of a mate is a function of learned experience during the pre-pairing period of the bird's life. This is important because it shows that a learned response can influence the genetic structure of a population, and thus the degree of mixed matings within the population. Kalmus and Maynard-Smith (1966) showed that in theory such a mechanism could lead to speciation of former morphs but only if 100% efficient. In Snow Geese, only 85% of the birds from monomorphic families choose a mate of that family colour. Two other notable examples of evolutionary studies of polymorphic birds are of interest. The Ruff *Philomachus pugnax* is a polygamous shorebird with males showing a considerable variety of breeding plumage morphs. The darker morphs have greater success at acquiring territories and attracting mates than the white morphs. The genetics of plumage colour in this species are obscure and the reasons for the maintenance of the white morphs are puzzling. A possible genetically based behavioural polymorphism in the Common Eider *Somateria mollissima* is described by Milne and Robertson (1965). The population consists of migratory and non-migratory birds, the 2 groups having different gene frequencies at a number of gene loci where enzyme polymorphism occurs.

Enzyme polymorphisms have been much studied in the hope of discovering more about the genetic structure of bird populations, both inter- and intra-specifically. Enzyme polymorphism as detected by electrophoresis is less frequent among birds than amongst most other taxa studied. Reasons for this are unclear.

The third area of interest in polymorphism is taxonomic and systematic. It has been pointed out that visible polymorphism in birds is restricted to relatively few families—Procellariidae, Ardeidae, Accipitridae, Falconidae, Stercorariidae and Cuculidae. Elsewhere it is scattered among one or two species within a family, e.g. Phalacrocoracidae, Anatidae, Phasianidae, Haematopodidae, Scolopacidae, Alcidae, Strigidae, Corvidae, Turdidae, Muscicapidae, Laniidae, Thraupidae and Estrildidae.

A well known observation related to polymorphism is the phenomenon of 'ratio-clines', where the proportion of the morphs differs in different parts of the range. A classical example is the Guillemot *Uria aalge*, where the frequency of the bridled morph increased with latitude from below 0.5% to over 50%. Attempts to relate this and other ratio-clines to differing environment conditions along the clines have seldom been successful. The selective pressures affecting the relative fitness of the morphs are obviously complex and gene flow along the clines must be taken into account. In addition, genetic drift and historical factors play a role. The Lesser Snow Geese which winter on the Gulf Coast of USA consist predominantly of blue morphs at the eastern end of the distribution and white morphs at the west. There is some historical evidence that the 2 morphs were formerly allopatric with blue morphs wintering in the Mississippi delta and the white morphs in Texas. The mixing of the morphs may be recent as a result of historical modification by man of traditional feeding areas by such policies as burning of marshes, and the cline may reflect a stage in the equilibrium of the morphs. Rockwell and Cooke (1977) showed that localized changes in the ratios of the morphs in time and space could be explained largely by gene flow between populations. Why the original difference occurred in the wintering distribution of the morphs is not answered.

In the early development of ideas on speciation, major mutations such as those found in polymorphic species were thought to be the origin of new species. Mayr (1970) has summarized the reasons why speciation is now thought to be mainly due to selection acting on genes affecting continuously variable characters differentially in different isolated subpopulations of an originally inter-breeding population. While this is clearly true and generally accepted, there are some interesting species groups where polymorphism may have represented a stage of their evolutionary history. In many taxa there are dark species, light species and polymorphic species consisting of both light and dark morphs (*Buteo*, *Anser* (*Chen*), *Phalacrocorax*, *Haematopus*, Ardeidae, *Falco*, *Sula*). In *Sula* for instance, most species are white but the Brown Booby *Sula leucogaster* is brown and the Red-footed Booby is dimorphic. Most *Anser* geese have a grey plumage, but the Ross Goose *Anser rossii* is white and the Lesser Snow Goose dimorphic. Perhaps the Brown Booby and Ross Goose have had a dimorphic period in their evolutionary past. In fact the Ross Goose is polymorphic in its gosling stage.

Often polymorphism has not been recognized taxonomically as such. For example, the Brown Jay *Cyanocorax morio* and the Sooty-capped Bush Tanager *Chlorosphingus pileatus*, both of which are dimorphic, were formerly each separated into 2 species. Presumably there are many examples of polymorphism as yet undiscovered, particularly in the tropics and in cases where there is a strong ratio-cline. If there is strong positive assortative mating among the morphs, this will appear similar to the hybridization between closely related species. Only a careful genetic analysis will elucidate the true taxonomic status. F.C.

POLYPHYLETIC: of more than one evolutionary ancestry; applied to an assemblage of species, and contrasted with MONOPHYLETIC.

POLYTOPIC: found in different places—applied to a form that has widely separated populations.

POLYTYPIC: term applied to a taxon that has more than one unit in the immediately subordinate category, e.g. a genus comprising 2 or more species, or a species divisible into subspecies—contrasted with MONOTYPIC.

POMATORHININI: see BABBLER.

POORWILL: substantive name of *Phalaenoptilus nuttallii* and *Nyctiphrynus* spp. (see NIGHTJAR; also WHIP-POOR-WILL).

POPULATION DYNAMICS: see AGE; ECOLOGY.

POPULATION INDEX: a measure of population level related to a base figure, usually 100 (see CENSUS).

PORPHYRIN PIGMENTS: see COLOUR.

PORTAL: term applied, especially, to a system of veins draining the abdominal portion of the alimentary tract and associated organs to the liver, but also to some other systems similarly leading into glandular organs (see VASCULAR SYSTEM).

POSTURAL FACILITATION: see FACILITATION, POSTURAL.

POSTURE: see COMFORT BEHAVIOUR; SIZE; SLEEP.

POTOO: substantive name of the species of Nyctibiidae (Caprimulgiformes, suborder Caprimulgi); in the plural, general term (alternatively 'tree-nighthawk') for the family. 'Potoo' is the creole name for one of the species; it was apparently used for the first time in ornithology by Gosse in *Birds of Jamaica* (1847).

Characteristics. Potoos are 23–50 cm in length, rather long-winged and long-tailed birds, with soft cryptic coloration of grey, white, buffish-brown and almost black. The sexes are alike. The downy nestlings are white with narrow dark shafts (*Nyctibius griseus*) or white barred all over with brown (*N. grandis*). The bill is small and terminally decurved with a projecting 'tooth' on the maxillary tomium. There is a huge mouth of which the inside is flesh coloured. The legs are very short. The eyes are very large; *N. griseus* has a bright yellow iris, *N. grandis* a dark brown one, but both species reflect bright orange at night. Their flight is silent.

Habitat. *N. griseus* and *N. grandis* inhabit open woodland and also cultivated land, e.g. coffee and citrus plantations.

Distribution. The family is confined to tropical Middle and South America. The family consists of a single genus, with 5 species. The Great

Common Potoo *Nyctibius griseus*. (*C.E.T.K.*).

Potoo *Nyctibius grandis* is much the largest (weights from Surinam: 5 males 450–624, mean 533 g; 7 females 504–604, mean 557 g). It has been recorded locally in Central America (records from Guatemala, Nicaragua and Panama) and is widespread in South America, south to Peru and Brazil. The best known species, the Common Potoo *N. griseus*, is considerably smaller (weights from Surinam: 4 males 146–167, mean 156 g; 2 females 149, 155 g). It has the widest distribution, occurring from southern Mexico east through Central America and throughout South America south to Argentina, and also on the islands of Jamaica, Hispaniola, Gonave, Trinidad and Tobago. The 3 other species are rare and their ranges are probably not fully known. The Long-tailed Potoo *N. aethereus* is rufous and has a long, markedly graduated tail with the central feathers pointed. It is recorded from Guyana, southern Venezuela, western Colombia, eastern Peru, Paraguay and Brazil. The White-winged Potoo *N. leucopterus* is distinguishable by its white, black-tipped inner wing-coverts, forming a broad white band on the wing. It is recorded from Venezuela, northern Colombia and the coastal region of Brazil in Bahia. The Rufous Potoo *N. bracteatus* is the smallest, and is most rufous with the tail feathers barred black and tipped with white. It is recorded from Guyana, Colombia east of the Andes, eastern Ecuador and eastern Peru.

Food. The recorded food of *N. griseus* consists of insects of several orders (Hemiptera, Orthoptera, Coleoptera, Isoptera, Lepidoptera), that of *N. grandis* of various Coleoptera.

Behaviour. Potoos are strictly nocturnal, solitary and arboreal, spending the day sitting in an upright attitude on a branch of a tree or the top of a stump (cf. FROGMOUTH). Head scratching is done indirectly (over the wing). The roost is often used for a long time at a stretch. The birds become active in the evening, especially on bright moonlight nights, catching flying insects. This they do in flight from an elevated perch after the fashion of flycatchers (Muscicapidae), returning with their prey to the observation point.

Voice. *N. griseus* has a strophe of plaintive, very melodious notes in an exactly descending scale. *N. grandis* has a rich vocabulary, including a guttural *Oorrooroooo*, also a barking *wow* in which the head is thrown back with the bill pointed upwards.

Breeding. The single egg is laid in a small depression on a tree stump or branch, sometimes quite near the ground, but occasionally at a great height. The bird incubates by sitting in an upright position on the egg. When it feels unobserved and is at ease, it incubates with the head withdrawn and the bill pointed forwards, the plumage fluffed and relaxed; on becoming alarmed, the whole bird stiffens and lengthens slowly upwards, the bill pointing straight up and partly open, the eye partly opened into a slit. It can be closely approached and even handled, but then the bird threatens by opening its large eyes, fluffing out its plumage and spreading its tail, snapping its bill and opening wide its huge mouth.

The eggs of this species are oval and white without much gloss and are sparsely marked with small lilac and brown spots. Eggs from Trinidad measure 41.5 × 32.0 mm, from Surinam 35.9 × 26.1 mm and from Brazil 36.2 × 29 mm. The only known egg of *N. grandis*, from Brazil, was similar and measured 52.1 × 38.3 mm. Eggs of *N. griseus* have been found in Costa Rica in December, in Colombia in January, in Trinidad in March, April, July and August, in Surinam in April, and in Brazil in November and December. An egg of *N. grandis* was found in Brazil in July, and a nestling in Surinam in June. A probable egg of *N. aethereus* was found in Paraguay in December. Skutch (1970) studied the nesting habits of *N. griseus* in Costa Rica. He found that both parents incubated, covering the egg continuously except for an interval not exceeding 15 min at daybreak and a longer interval of 45–95 min at the beginning of the night. The long nocturnal session and the even longer diurnal session appeared to be continuous and by different parents. They apparently never turned or even touched the egg in its precarious position.

The incubation period was at least 33 days. The newly hatched nestling rested from the first facing the supporting branch just as the parents did when incubating and brooding. During the first 2 weeks a parent brooded the nestling, but ceased nocturnal brooding when it was 19 days old and diurnal brooding when it was 25 days old, after which it was always alone. When 10 days old it was fed 15 times by both parents on a moonlight night between nightfall and dawn, and when 35 days old it was fed 10 meals. When being fed, the nestling uttered a hoarse buzz. At the age of 26 days it was first seen to rest on a branch above the nest; at 35 days it was well feathered. Its first short flight was seen when it was 47 days old, and on its 51st day it finally flew from the tree and was not seen again. From the laying of the egg to its departure at least 84 days elapsed.

POTOYUNCO: a name for *Pelecanoides garnotii* (see PETREL).

POULT: a domestic chicken; sometimes applied to other species.

POULTRY: collective term for birds of domesticated species (as distinct from 'game') used for the table (see DOMESTICATION).

POWDER DOWN: feathers which produce a fine powder (see FEATHER; PLUMAGE).

PRAIRIE CHICKEN: substantive name of *Tympanuchus* spp. (see GROUSE).

PRATINCOLE: substantive name of the species of the subfamily Glareolinae (Charadriiformes, suborder Charadrii, family Glareolidae); in the plural, a general term for the subfamily. Pratincoles, like the closely related coursers (subfamily Cursoriinae; see COURSER), are an entirely Old World group found throughout Africa, southern Europe, Asia and Australasia.

Only 2 genera are currently recognized: *Glareola* with 7 species (*pratincola, nordmanni, maldivarum, ocularis, nuchalis, cinerea* and *lactea*) and *Stiltia* with one species (*isabella*). Australian Pratincole *Stiltia isabella* is structurally and behaviourally intermediate between the coursers and the pratincoles and, although it shows greater affinity with the pratincoles, it provides a clear evolutionary link between the 2 subfamilies.

Characteristics. Like most coursers, *Glareola* has a pectinated middle toe, but *Stiltia* does not. Members of the genus *Glareola* are characteristically short-legged and have short tails; *Stiltia* is long-legged, has a square tail and a dark belly-band, giving it the appearance of a courser. All the pratincoles have long wings (especially so in *Stiltia*), a black-and-white tail and rump pattern, plain brown or grey dorsal plumage, little or no sexual dimorphism, a black bill with a bright red or orange base, and a fairly well developed hind toe which is somewhat raised above ground level. Their front toes are much longer than those of the coursers. The long wings are an adaptation to catching flying insects on the wing, although pratincoles also feed on the ground. They measure 18–30 cm and weigh 80–100 g.

The Collared or Red-winged, Black-winged and Oriental Pratincoles (*Glareola pratincola, G. nordmanni* and *G. maldivarum*) have a narrow black collar bordering the yellowish throat; they are obviously closely related to each other and may be merely races of one species.

Habitat. All the *Glareola* species live near water, usually in the form of large rivers, but sometimes marshes or flooded rice paddies. *Stiltia* is less water-dependent and inhabits open semidesert or dry grasslands, although water is often available in the form of rivers, lakes or temporarily flooded hollows.

Distribution and movements. The Collared Pratincole has breeding populations from South Africa north to Europe and east to north-western India; all are migratory, but their movements have yet to be mapped out in detail. The Black-winged Pratincole breeds from south-eastern Europe to western Asia and migrates to Africa when not breeding. The Oriental Pratincole is an eastern Asian breeder, some populations of which migrate southward as far as Australia and rarely to New Zealand. The Madagascar Pratincole *G. ocularis* breeds on Madagascar and migrates in the non-breeding season (from about April to September) to East Africa.

The White-collared Pratincole *G. nuchalis* of tropical Africa, the Grey Pratincole *G. cinerea* of West Africa and the Little Pratincole *G. lactea* of India and southeastern Asia are all resident. They have less deeply forked tails, lack a black collar and are sometimes put in a separate genus, *Galachrysia*. The Australian Pratincole breeds in northern and central Australia (rarely as far south as Adelaide) and migrates in the southern winter northwards, part of the population remaining in northern Australia and the rest crossing the sea to Indonesia.

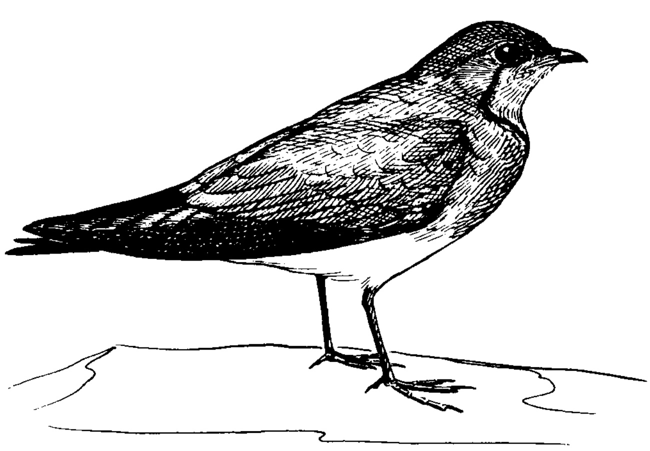
Food. All pratincoles feed entirely on insects caught on the wing or on the ground. The Australian Pratincole probably feeds mostly on the ground, chasing its prey with a swift run ending in a sudden turn with a wing outstretched, apparently to stop the prey from escaping further.

Behaviour. The pratincoles are all highly gregarious at all times, even when breeding. During migration they occur in flocks of several hundred birds. Like coursers, they are especially active in the evening when the flocks zig-zag to and fro with high-pitched calling. Flocks may wheel high in the air, and the riverine species often skim the surface of the water while feeding.

Voice. Pratincoles are particularly vocal in flight, although they also have contact calls given on the ground. The notes are high-pitched trilling or twittering in the genus *Glareola* and beautiful piping whistles in *Stiltia*. Alarm calls are somewhat harsher in tone. When inactive, pratincoles are mostly silent, often settling in a more or less close pack, all facing in the same direction and remaining motionless and inconspicuous.

Breeding. The *Glareola* species breed colonially near large rivers or marshes, sometimes on rocks in the middle of a river. Their nest is a mere scrape in the ground or a hollow on a rock. The eggs number 1–4 per clutch depending on the species (usually 2–3) and are well camouflaged with their bold irregular dark markings on a light yellowish background. Eggs of the Red-winged Pratincole in southern Africa are very dark—an adaptation to the birds' habit of often nesting on areas of burnt grassland. Their downy young are similarly blackish in colour.

The Australian Pratincole also nests in loose colonies, but on open stony semidesert in inland Australia. Like other pratincoles it nests near water, usually temporary pans flooded by recent rain, sometimes up to 2 km away. It makes no nest, laying its clutch of 2 eggs on a bare patch of soil among stones or gravel. The eggs resemble stones in colour and texture. The downy plumage of the chicks is pale buff with almost no markings, to match the light coloured clay substrate of the normal breeding habitat.



Collared or Red-winged Pratincole *Glareola pratincola*. (*C.E.T.K.*).

In all pratincoles both sexes incubate almost equally, with a nest-relief occurring every 1–2 hours. In very hot weather (when air temperatures exceed 35°C) the changeovers may be more frequent than this. Incubation is said to take 17–18 days in the Collared Pratincole and 21 days in the Australian Pratincole. The young leave the nest as soon as they are dry, and are led to the shelter of a shady shrub from which they emerge only to be fed by a parent arriving with an insect in its bill. The chicks obtain all their water from their food; like the adults they have a functional salt gland (see EXCRETION, EXTRARENAL) which removes excess sodium chloride and conserves water. The adults drink frequently. In very hot weather at least one species, the Little Pratincole, soaks its belly feathers at the nearest water and flies back to its nest to cool its eggs at each nest-relief which occurs about every half hour (see BELL-SOAKING).

Courtship in the pratincoles consists of elegant displays usually involving the wings and head-down body postures. Injury-feigning distraction displays are well developed in all species when they have eggs or young. G.L.M.

Maclean, G.L. 1976. A field study of the Australian Pratincole. Emu 76: 171–182.
Sterbetz, I. 1974. Die Brachschwalbe. Wittenberg.

PRE-ADAPTATION: see under ADAPTATION.

PRECOCIAL: active immediately after hatching (see YOUNG BIRD).

PRECOCIOUS FLIGHT: see FLIGHT, PRECOCIOUS.

PREDATION: the killing of members of one species by members of another species for food (see also FEEDING HABITS); the term is almost entirely confined to discussion of the effects of activities of predators upon the population of the prey species (see also ECOLOGY). A predation study demands a means of ascertaining the numbers in which a species is present in a given area, and the numbers killed within that locality by a known predator. The population may be measured directly or by a sampling method such as the LINCOLN INDEX; the second parameter demands that some visible and measurable traces of the slaughter remain: feathers, bones, skulls, elytra or wings of insects or even rifled dwelling places, as in the cases of the larvae of beetles of the genus *Pissodes* or of the moth *Ernarmonia conicolana*, whereof the ravaged and uninvaded wintering chambers can be distinguished.

In Holland, remnants at nests and plucking places were used to show that about half the deaths of all House Sparrows *Passer domesticus* in the area were due to the talons of Sparrowhawks *Accipiter nisus*. During a vole plague on the Scottish Border, pellets and stores at nesting sites showed that Short-eared Owls *Asio flammeus* were making inroads on the rodent population of not more than 0.05% per diem, and that the owls were, in fact, not in any way checking the plague. During an outbreak of *Archips fumiferana* in the spruce forests of Ontario, S.C. Kendeigh calculated that, at most, bird predation destroyed 5% of the larvae. There is one classic case of the effects of bird predation being immediately visible: during an outbreak of defoliating insects in Prussia in 1905, the woods of the Baron von Berlepsch, where the nesting of birds had been encouraged, were said to stand out 'among the surrounding woods like a green oasis' (see NEST SITES, MAN-MADE).

The incidence of bird predation may vary greatly from year to year in one locality, or within a single season between places very close together. In an area of rural Suffolk, England, 49 samples of marked *Helix aspersa* were released between the years 1956 and 1978. Of 1,009 snails released, 164 were recovered at the anvils of Song Thrushes *Turdus philomelos*, giving a minimal predation rate of 16%. In the 3 consecutive years 1956 to 1958 predation rates were 44%, 13% and 28%, while in 1963 (after a very severe winter) thrush predation was nil. At 2 sites within 200 m of one another predation rates in 1959 were 44% and 8%.

The effects of predation are not always adverse to the population level of the victim species. It has been demonstrated mathematically that if the principal cause of death in a species be the attacks of a pathogenic organism, and that if a predator tends to take weakly or sick specimens, the final result of the predation will be to increase the population of the prey species.

The effects of predation are not, of course, limited to alterations in the population levels of the prey species. Predation pressure is the effective agent in the evolution of cryptic adaptations of form and behaviour, as has been so clearly demonstrated in the relationship between Song Thrushes and the polymorphic snail *Cepea nemoralis*.

PREEN GLAND: see COMFORT BEHAVIOUR.

PREENING: see COMFORT BEHAVIOUR. See photos COMFORT BEHAVIOUR; FLIGHTLESSNESS.

PREFRONTAL: a paired bone of the SKULL.

PREMAXILLA: the main bone, on each side, of the upper jaw (see SKULL).

PREMIGRATORY RESTLESSNESS: marked behavioural changes in nocturnal migrants, particularly small passerines, which develop an additional activity rhythm during the hours of darkness, when they normally roost (see MIGRATION).

PRICKED: see WINGED.

PRICKLETAIL: *Siptornis striaticollis*, a South American furnariid (for family see OVENBIRD (1)).

PRIMARY: or 'primary feather', any one of the flight feathers borne on the manus (carpometacarpus and digital phalanges)—contrasted with the 'secondaries', borne on the forearm (see PLUMAGE; WING). The primaries are best numbered from the carpal joint outwards, but as the opposite practice is followed by some authors it is always desirable to say which is being used (cf. Ashmole *et al* 1961). In most non-passerine species there are—not counting a remicle, if present (see REMICLE)—10 primaries in normal individuals, but in grebes, except the flightless *Rollandia micropterum*, storks and flamingos, there are 11. In passerine birds, there are basically 10 primaries, but the 10th (outermost) is reduced to various extents in the different families, being vestigial in many and absent in the so-called nine-primaried Oscines (see PASSERIFORMES). (Stresemann 1963). See also MOULT; WING FORMULA.

Ashmole, N.P., Dorward, D.F. & Stonehouse, B. 1961. Numbering of primaries. Ibis 103a: 297–298.
Stresemann, E. 1963. Variations in the number of primaries. Condor 65: 449–459.

PRIMARY COVERTS: see TOPOGRAPHY.

PRIMITIVE: retaining characters (known or, often, presumed) of an ancestral form. Alternatively, and in general preferably, the term may be applied to characters that are similar to those of an ancestral form.

PRINIA: generic name commonly used as English substantive name of *Prinia* spp., alternatively 'long-tail' (see WARBLER (1) (Grass warblers)).

PRION: substantive name of *Pachyptila* spp. (see PETREL).

PRIONOPIDAE: a family of PASSERIFORMES suborder Oscines; HELMET-SHRIKE.

PRIORITY, LAW OF: see NOMENCLATURE.

PROAPOSEMATIC: see under APOSEMATIC.

PROCELLARIIDAE: see below.

PROCELLARIIFORMES: an order, alternatively 'Tubinares', comprising 4 families: Diomedeidae (Albatross), Procellariidae (Shearwater), Hydrobatidae (Petrel), Pelecanoididae (Diving Petrel). For general characteristics of the family see PETREL.

PROCRYPTIC: see under CRYPTIC.

PROEPISEMATIC: see under EPISEMATIC.

PROGESTERONE: see ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

PROKINESIS: the form of upper jaw mobility seen in the majority of birds (including all with holorhinal nostrils), in which rotation takes place about a region of flexible bone (zone elastica craniofacialis) at the junction of upper jaw and neurocranium. See SKULL.

PROLACTIN: see CROP, MILK; ENDOCRINOLOGY AND THE REPRODUCTIVE SYSTEM.

PROMEROPIDAE: a family of PASSERIFORMES, suborder Oscines; SUGARBIRD.

PROOTIC: a paired bone of the SKULL.

PROPATAGIUM: a membranous fold of skin along the anterior margin of the wing from shoulder to carpal joint (see MUSCULATURE; WING).

PROPRIOCEPTIVE: the senses involved when what is perceived is internal (sometimes termed 'interoceptive').

PROTECTION: see CONSERVATION.

PROTEIN METABOLISM: see ENERGETICS; METABOLISM; NUTRITION.

PROTOPTILE: term applied to the first of two nestling down plumages, in cases where there is such a sequence, the second then being called 'mesoptile' (see PLUMAGE).

PROTOZOA: see ENDOPARASITE.

PROVENTRICULUS: see ALIMENTARY SYSTEM; also, for stomach oil, under PETREL.

PROXIMAL: nearest to the centre of the body or to the point of attachment (e.g. of a limb); opposite of DISTAL.

PROXIMATE: applied to factors, in a system of causation, that immediately precede the effect; contrasted with ULTIMATE.

PRUNELLIDAE: a family of the PASSERIFORMES, suborder Oscines; ACCENTOR.

PSEUDAPOSEMATIC: see under APOSEMATIC.

PSEUDEPISEMATIC: see under EPISEMATIC.

PSEUDOCHELIDONINAE: see SWALLOW.

PSEUDONESTOR: alternative substantive name for the Maui Parrotbill *Pseudonestor xanthophrys*, one of the HAWAIIAN HONEYCREEPERS.

PSEUDOSCHIZORHINAL: see NARIS.

PSEUDOSUCHIA: see under FOSSIL BIRDS.

PSILOPAEDIC: with little or no down when hatched (see YOUNG BIRD).

PSITTACIDAE: see PSITTACIFORMES; PARROT.

PSITTACIFORMES: an order comprising only the family Psittacidae (see PARROT).

PSITTACOSIS: a virus disease, on occasion communicable to man, originally described as affecting parrots (Psittacidae) and allied birds but now known to affect widely different species (e.g. the Fulmar *Fulmarus glacialis*), as the result of infection by an identical or closely related virus, and therefore sometimes called 'ornithosis' (see DISEASE).

PSITTIROSTRINAE: see HAWAIIAN HONEYCREEPER.

PSITTRICHADINAE: see PARROT.

PSOPHIIDAE: see under GRUIFORMES; TRUMPETER.

PTARMIGAN: substantive name of *Lagopus* spp. other than *L. l. scoticus* and sometimes *L. lagopus*; used without qualification in Britain for *L. mutus*, elsewhere known as the Rock Ptarmigan; in the plural (sometimes unchanged), serves as a general term for the genus (see GROUSE).

PTEROCLETES; PTEROCLIDIDAE: see below.

PTEROCLIDIFORMES: an order, comprising the sole family Pteroclididae (see SANDGROUSE). In Wetmore's system treated as a suborder Pterocletes of the order Columbiformes, but other authors consider them more closely related to the Charadriiformes, particularly the COURSERS Glareolidae.

PTERODACTYL: see WINGS, COMPARATIVE ANATOMY OF.

PTERYGOID: a paired bone of the SKULL (see PALATE).

PTERYLA: (plural pterylae): an area of skin bearing contour feathers; a tract of contour feathers arranged in rows (see PTERYLOSIS).

PTERYLOGRAPHY: the study of feather tracts (see PTERYLOSIS).

PTERYLOSIS: the arrangement of contour feathers into orderly groupings (pterylae or feather tracts) on the skin; pterylae may also contain filoplumes, down, and/or powderdown among the contour feathers. The intervening spaces (apteria) are completely devoid of contour feathers, but may contain semiplumes, down, powderdown, or no feathers at all.

Except in a few species that have visible areas of bare skin (e.g. naked-headed vultures), the skin of birds appears to be fully and evenly covered by feathers. In reality, most birds have their feathers growing from relatively limited tracts. Land species usually have narrow pterylae, on about half of the skin area; the remainder of the body has essentially bare skin, overlain by the feathers that fan out from adjoining pterylae and cover the apteria. Waterbirds tend to have wider pterylae, and narrow apteria filled with down. Only in adult ratites, penguins Spheniscidae, and screamers Anhimidae are the contour feathers distributed uniformly over the body, but still arranged in discernible patterns (rows) and with at least a few small apteria in such areas as the ventral midline, the axillary region, or the head and neck; well-developed embryos of these birds show clearly defined pterylae and apteria. Pterylosis, therefore, is a basic feature of all birds—and is as uniquely avian as feathers themselves.

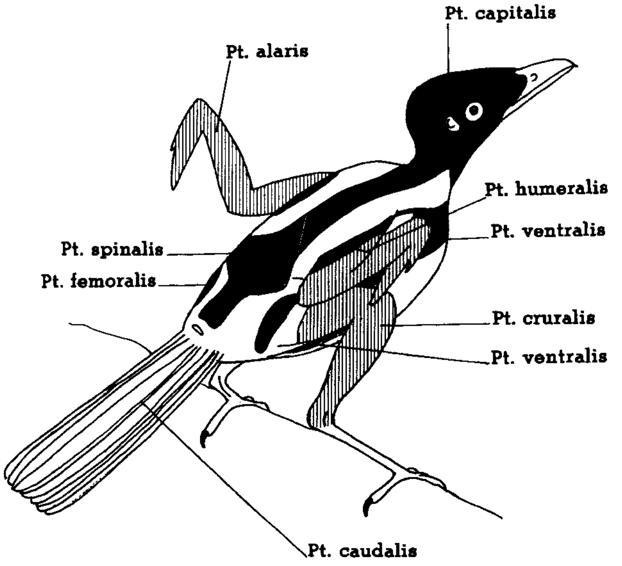

Fig. 1. A generalized passerine, showing the 8 major pterylae (feather tracts). (Redrawn by J. William Hardy from Ames, Heimerdinger & Warter 1968).

Use as a taxonomic character. The study of pterylosis (pterylography) has considerable potential for systematics studies. Although it is still in its infancy from the standpoint of the number of taxa studied, many different tract patterns are found to be indicative of relationships. The system seems to be evolutionarily conservative, and thus is most useful at the higher levels of classification (usually familial or above.) The only class-wide study of pterylography was made by its founder, C.L. Nitzsch (1867), in the early 19th century. His broad sampling of Aves, however, was just a beginning; since then morphologists have concentrated on describing the pterylae of additional species, studying them in finer detail, and applying their findings to systematics studies. The most significant differences of pterylae seem to lie in the number of feathers present and the internal patterns (arrangement of follicles into rows) in the major body tracts (spinal and ventral), and in the wings and tail.

Nomenclature. Most birds are feathered by discrete, easily visible, groupings of contour feathers. Whether each discernible patch is called a 'tract', or whether several related components should be classified together as a 'tract', is arguable. Following Nitzsch's concept of a bird's body being covered by a few large tracts, the 8 major pterylae may be termed:

1. *Pteryla capitalis*: the capital tract, that covers all surfaces of the head, often in many discrete subunits.
2. *Pteryla spinalis*: the spinal or dorsal tract, that extends, continuously or divided, narrow or broad, from the nape of the neck to the base of the tail and covers the dorsal neck, back, and rump. In passerines this tract typically is an uninterrupted band of feathering, narrow on the neck, broadly expanded over the back, and narrowing again on the rump.
3. *Pteryla ventralis*: the usually complex ventral tract, that covers the under surface from the neck to the cloaca. In passerines this takes the form of a substantial band of feathering on each side of the body from the upper breast to the flanks, then branching to a thin band that extends down either side of the abdomen to end at the cloaca. A broad median apterium, the site of the brood patch in many species, is enclosed by the 2 forks of this tract.
4. *Pteryla humeralis*: the humeral, scapular, or scapulohumeral tract, that covers the base of the wings and shoulders; commonly it is a relatively simple rectangular patch of feathers.
5. *Pteryla alaris*: the wing feathers (remiges) and their associated coverts.
6. *Pteryla femoralis*: the femoral tract, that covers the base of the legs, also usually with a simple rectangular grouping.
7. *Pteryla cruralis*: the often sparse crural tract, that covers the legs.
8. *Pteryla caudalis*: the tail (rectrices) and its coverts, and adjacent feathering of the uropygial gland and cloaca.

The tracts associated with appendages (humeral, alar, femoral, crural) are paired; the others are centred on the long axis of the body and have essentially perfect bilateral symmetry. In different species, genera, or families, the tracts may be well developed or merged, or subdivided to various degrees, leading to refinements of their terminologies. The apteria, being present only in the absence of, or between, pterylae, customarily are named by their location on the body or their relationship to adjacent pterylae.

Function. The adaptive significance of having feathers grouped into pterylae, with apteria in between, has never been satisfactorily explained. The answer probably involves many factors: the reduction of total feather weight; the reduced physiological drain by growing fewer feathers; the increased mobility of the limbs by having apteria under moving joints; and better thermoregulation through controlled heat exchange from bare skin. (See also FEATHER; FEATHERS NUMBER OF; PLUMAGE.) M.H.C.

PTILOGONATIDAE: a family of PASSERIFORMES, suborder Oscines; SILKY-FLYCATCHER.

PTILOGONYS: generic name often used as substantive name of *Ptilogonys* spp. (see SILKY-FLYCATCHER).

PTILONORHYNCHIDAE: a family of the PASSERIFORMES, suborder Oscines (see BOWERBIRD).

PTILOPAEDIC: clad in down when hatched (see YOUNG BIRD).

PTILOPODY: the condition of having feathers on the tarsus and toes.

PTILOSIS: synonym of PLUMAGE.

PUAIOHI: *Phaeornis palmeri* of the Hawaiian Islands (for subfamily see THRUSH).

PUBIS: a paired bone (plural 'pubes') of the pelvic girdle, partly fused with the other elements (see SKELETON, POST-CRANIAL).

PUFF-BACK: substantive name of *Dryoscopus* spp. (see SHRIKE). There are also 'puff-back flycatchers' *Batis* spp. (for family see FLYCATCHER (1)).

PUFFBIRD: substantive name of some species of Bucconidae (Piciformes, suborder Galbulae); in the plural, general term for the family. This consists of 10 genera and 33 species of small or medium-sized arboreal birds (14–29 cm long) confined to continental tropical America.

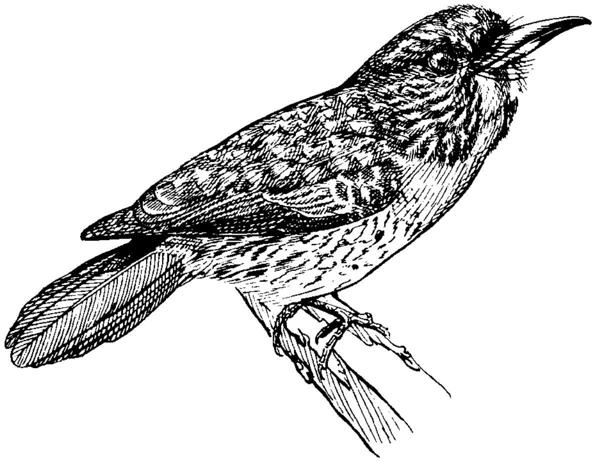
Characteristics, distribution and behaviour. The puffbirds are closely related to the jacamars (Galbulidae). Their large heads, abundant, lax, often dull-coloured plumage, and short tails make them appear stout and 'puffy', whence their name. The bill, of short or medium length, often notably stout, is decurved or hooked at the tip. The feet are zygodactylous, with two toes directed backward. The family is best represented in the Amazon Valley and Colombia, and is largely confined to warm lowlands. Its ancestors appear to have been much more widely distributed, and may have been the dominant small perching birds during the Eocene in North America, where at least 5 genera of the fossil family Primobucconidae have been found in deposits of this age in Wyoming.

One of the largest and most widespread extant members of the Bucconidae is the handsome, 25 cm long White-necked Puffbird *Notharchus macrorhynchus*, which ranges from southern Mexico to north-eastern Argentina. Both sexes are largely black on the dorsal surface. The forehead, nuchal collar, sides of the head, and under parts are white, with a broad black band across the breast. The thick, tapering bill is black.

Slightly smaller is the White-whiskered Puffbird, or Softwing, *Malacoptila panamensis*, which is found from southern Mexico to western Ecuador. The male is largely chestnut-brown and cinnamon, with the posterior under parts pale buff or whitish. Both above and below the female is more olive and greyish. Both sexes are liberally spotted and streaked with tawny and buff on the upper parts and streaked with brown and dusky on the breast and sides. Both sexes wear the long, slender, slightly curved, white malar tufts which are indicated by their name. Their large eyes are dull red.

Both the White-necked Puffbird and the White-whiskered Puffbird are found singly or in pairs, or sometimes in family groups of 3 or 4, but never in flocks. They rest motionless for long periods on a more or less exposed lookout perch at no great height, apparently lethargic but actually keeping a sharp watch for suitable food. By means of a surprisingly sudden dart, they snatch a caterpillar, winged insect, spider, or small lizard from a neighbouring bough, or sometimes they drop down to seize it amid low herbage. Then they carry it back to a perch and devour it at leisure.

A very different type of puffbird is the Swallow-wing *Chelidoptera tenebrosa*, widespread in tropical South America. This is a stout, large-headed bird about 15 cm in length. When folded, its long wings reach almost to the end of its short tail. Both sexes are largely blackish, with a patch of white on the lower back and rump. The abdomen is rufous-chestnut, which pales to white on the under tail coverts. The voyager along the Amazon and its great tributaries often sees these graceful birds perching in pairs on the topmost naked twigs of tall riverside trees, whence they make long, spectacular darts to snatch insects (including many winged ants) from the air, much in the fashion of some of the bigger American flycatchers (Tyrannidae).



White-whiskered Puffbird *Malacoptila panamensis*. (*C.E.T.K.*).

Because of their very plain attire, the 4 species of the genus *Monasa* are called 'nunbirds'. The Black-fronted Nunbird *M. nigrifrons* of the Amazon valley is about 29 cm long. In both sexes, the upper plumage, wings, and tail are dull black and the ventral surface is dark grey. The bill, which tapers from a broad base to a sharp point, is bright orange—whence the name 'pico de lacre' ('sealingwax bill') sometimes applied to birds of this genus. More gregarious than other puffbirds, nunbirds travel in small flocks, and at least one species breeds co-operatively.

The 6 small species of the genus *Nonnula* are known as 'nunlets'. Both sexes of the 14-cm-long Grey-cheeked Nunlet *N. frontalis* are plain brown above and ochraceous or tawny below. This species is found in the lowlands of Colombia and eastern Panama, and little is known of its habits.

Voice. Puffbirds show the same contrasts in voice as in plumage. The loudest utterance of the White-whiskered Puffbird is a high, thin whistle or 'peep'. The Swallow-wing has a weak, appealing whistle. The sociable nunbirds have a surprising range of utterances from soft, musical murmurs to far-carrying shouts. From 3 to 10 White-fronted Nunbirds *Monasa morphoeus*, often perching in a row on a high, horizontal branch or liana, join their almost soprano voices in a chorus that rings through the rain forest for 15–20 min. While calling, puffbirds often twitch their tails from side to side.

Breeding. The breeding habits of puffbirds are poorly known, but two main types of nests have been discovered: cavities which they carve in the hard, black, arboreal nests of termites, and burrows in the ground. Less frequent sites include hollow trees, holes made by woodpeckers, burrows made by small mammals, and oven-shaped nests of clay built by the Pale-legged Hornero *Furnarius leucopus*. Both sexes of the Black-breasted Puffbird *Notharchus pectoralis* take turns at digging with their bills into the side of a large, roughly globular termitary. Their narrow, horizontal tunnel expands at its inner end into a neatly rounded chamber, on the hard floor of which the eggs rest.

Burrows of the White-whiskered Puffbird have been found in the gently or at times steeply sloping, leaf-strewn ground in rain forest. From a round opening, the tunnel descends with a slight inclination for about 50 cm. At the lower end it widens into a chamber, which is lined on the bottom and sides with brown dead leaves. Around the opening of the burrow, which is flush with the ground, the birds arrange twigs, petioles, and the like to form a low collar, through which they enter and leave, and which makes the aperture less conspicuous. This feature is far more strongly developed in the Black Nunbird *Monasa atra* of northern South America, which above the entrance to its descending burrow in level ground raises a large pile of coarse dead sticks; the birds reach their burrow through a rounded tunnel that runs along the surface of the ground beneath the heap of sticks. Probably the chamber at the inner end is lined with dead leaves, like that of the White-fronted Nunbird, which, however, arranges only a low collar around the mouth of its 100–125 cm long burrow. The Swallow-wing, however, places no sticks or other material around the entrance to its burrow, which may be in a bank or in level ground. Like the tunnels of other puffbirds, those of the Swallow-wing are downwardly inclined and straight, but they are longer than those of other species, up to 200 cm in length. The eggs rest on a slight lining of dry grass.

Puffbirds lay 2 or 3, rarely 4, white, glossy eggs that resemble the eggs of woodpeckers. These are incubated by both parents, at least in the Black-breasted and the White-whiskered Puffbird. The latter incubates according to a simple but unusual schedule; the male sits continuously from early afternoon to the following dawn, then the female takes one long session of 5–8 h. The eggs are unattended for a half hour or more between these sessions. Black-breasted Puffbirds take shorter sessions, entering and leaving the nest a number of times in a day. The incubation period is unknown.

Newly hatched puffbirds are blind and perfectly naked, without natal down. The prominent callous pads on their heels are smooth, as in jacamars and motmots. The male White-whiskered Puffbird does all the brooding and his duller mate nearly all the feeding, an arrangement that may have some slight protective value. When only a day or two old, the blind nestlings move up the tunnel to take food from their mother at the burrow's mouth. This consists of large, badly mangled insects, with an occasional spider or small lizard, carried in the parent's bill, one item at a time. Waste is not removed from the burrow. After the father ceases to brood them by night, the nestlings, now with open eyes and becoming feathered, at nightfall somehow raise up the fragmented leaves from the bottom of the chamber to form a screen between themselves and the entrance tunnel. They leave the burrow at the age of 20–21 days, when they are well feathered and have 'whiskers' like their parents. Blind, naked nestlings of the White-fronted Nunbird toddle up to the mouth of their longer burrow to receive food from the 3 or 4 adults—parents plus helpers—who often attend them. After emerging at the age of about 30 days, juvenile nunbirds rise high into the trees. Soon they take their food in a spectacular manner, flying up from a distance to snatch it from an attendant's bill as they shoot past. This provides practice for nunbirds' habitual mode of foraging. PUFFIN: substantive name of *Fratercula* spp. (see AUK); used without qualification, in Britain, for the sole Atlantic species, *F. arctica*. See photo FLIGHT.

PUFFINOSIS: name given to a disease of the Manx Shearwater *Puffinus puffinus*, probably allied to psittacosis and sometimes causing heavy mortality among the young birds (see PSITTACOSIS).

PUFFLEG: substantive name of *Eriocnemis* spp. (for family see HUMMINGBIRD).

PUKEKO: native name for the Purple Gallinule *Porphyrio melanotus* of New Zealand, considered by some to be a race of *P. porphyrio* (for family see RAIL).

PULLET: an immature female domestic fowl (which may lay infertile eggs).

PULLUS: a nestling or chick prior to fledging. Most frequently used of ringed birds and of museum specimens, as an age-class term.

PULMONARY ARCH: see VASCULAR SYSTEM.

PUPIL: the opening in the iris of the eye (see VISION).

PURPLETUFT: substantive name of the 3 species of *Iodopleura*, a genus of small, somewhat swallow-like COTINGAS, the males of which have an erectile patch of bright violet feathers on either flank.

PYCNONOTIDAE: a family of the PASSERIFORMES, suborder Oscines; BULBUL.

PYGOPODES: formerly used as the name of an order which embraced the present Gaviiformes and Podicipediformes and originally also the Alcae.

PYGOSTYLE: the fused caudal portion of the vertebral column (see SKELETON, POST-CRANIAL).

PYLORIC ORIFICE: the exit of the gizzard into the duodenum (see ALIMENTARY SYSTEM).

PYRRHULOXIA: *Cardinalis sinuatus* (formerly *Pyrrhuloxia sinuatus*) (see CARDINAL-GROSBEAK).

PYRRHULOXIINAE: see CARDINAL-GROSBEAK.

PYTILIA: substantive name of the 3 species of *Pytilia*, an African genus of waxbills (see ESTRIDID FINCH).

Q

QUADRAT: a square of ground of any size used for sampling (see CENSUS).

QUADRATE: a paired bone of the SKULL.

QUADRATOJUGAL: a paired bone of the SKULL.

QUAIL: substantive name of species in two distinct groups of Phasianidae, the American quails of the subfamily Odontophorinae and the Old World quails *Coturnix* spp. etc. (the so-called 'bush-quails' of India are in fact dwarf partridges)—see PHEASANT. The arrival of migratory parties, still a familiar event in Mediterranean countries, is described in the Book of Numbers, 11, 31: 'And there went forth a wind from the Lord, and brought quails from the sea, and let them fall by the camp, as it were a day's journey on this side, and as it were a day's journey on the other side, round about the camp, and as it were two cubits high upon the face of the earth.'

QUAIL, BUSTARD- or BUTTON-: see BUTTONQUAIL.

QUAIL-DOVE: substantive name of *Geotrygon* spp. (see PIGEON).

QUAIL-FINCH: *Ortygospiza atricollis* (for family see ESTRILDID FINCH).

QUAIL-THRUSH: alternatively 'ground-thrush', substantive name of *Cinclosoma* spp. (see RAIL-BABBLER).

QUELEA: substantive name of the 4 species of *Quelea*, a genus of African weaverbirds one of which, the Red-billed Quelea *Q. quelea*, periodically becomes a serious agricultural pest (see QUELEA CONTROL; WEAVER).

QUELEA CONTROL: action taken against the Red-billed Quelea *Quelea quelea* (see WEAVER) to reduce the damage that this notorious pest causes to small-grain cereal crops in Africa.

The majority of small grain cereals in Africa, such as millet, sorghum and increasingly rice and wheat, are grown in the savanna regions. The savannas include extensive tracts of annual grasslands that produce vast quantities of seed, supporting very high densities of granivorous birds. Of these, Queleas are easily the most numerous, feeding in flocks numbering tens of thousands and whose roosts and breeding colonies frequently contain millions of individuals. Because of the similarity of their natural food of wild grass seeds to the grains of cultivated grasses grown by man, Queleas can cause extensive damage to cereal crops, though usually only when their preferred wild food is not readily available. Crop damage caused by this huge number of birds can be devastating, particularly to subsistence farmers who may regularly lose 30–50% of their crop and occasionally the whole crop. In many African countries either the national government or international agencies accept responsibility for trying to alleviate crop losses by maintaining Quelea control units. The effectiveness of the methods they use has been greatly improved by research into Quelea ecology and patterns of crop damage.

Quelea damage occurs at 3 main periods of the year:

1. From the middle to end of the rains as rain-fed cereals are ripening. Damage is usually caused by hordes of young birds newly fledged from local breeding colonies. Whereas adult Queleas may migrate elsewhere to rear another brood (see ITINERANT BREEDING) the young do not move far in the first few weeks of independence and often use the old colony as a roost so that any fields within foraging distance (10–15 km) will be subject to continuing depredations unless harvested.

2. In the dry season to irrigated crops. This time of year is one of increasing food shortage as the stock of dry grass seeds produced during the previous rains is gradually depleted. Quelea roosts and feeding flocks become even larger as the dry season progresses and food becomes increasingly patchily distributed. Irrigated crops ripening then are especially vulnerable.

3. To crops maturing in areas of early rainfall by Queleas on their 'early-rains' migration (see ITINERANT BREEDING).

Early control methods in all these situations centred around a strategy of permanent reduction of the Quelea population to a level where they would no longer be of economic importance. However, despite increasingly desperate attempts to eradicate the birds, using flame-throwers to destroy their nests, explosives placed in the roosts, and finally by aerial spraying of roosts and colonies with highly toxic organophosphorus contact poisons like parathion (in a single year an estimated 183 million Queleas were destroyed in South Africa alone), no long-term reduction of the population occurred. The long-distance migrations regularly undertaken by Queleas simply meant that other individuals invaded every year from outside the controlled area.

Destruction of birds on this scale does, however, result in a local population reduction, perhaps for long enough for a crop to be harvested without loss. Similarly, the destruction of nests removes the very real threat of damage to nearby fields by newly fledged young (though if the nesting bushes are simply chopped down the adults frequently continue feeding the young even at ground level). Such a strategy of 'immediate crop protection', which ignores birds not actually causing damage, is now carried out by aerial spraying from a helicopter or fixed-wing aircraft of fenthion, a more safely handled organophosphorus poison. The method is very hazardous, involving low-level flying often in the dark, may kill other species and poison livestock, and pollutes the environment (though fenthion degrades quickly). The chemical is applied at rates of 20–25 l/ha^{-1} of 20% active ingredient (4–5 kg/ha^{-1}) and often more. Lower dosages may inhibit the birds' feeding so that they die later of starvation but this is not attempted routinely.

Spraying is expensive, requires highly-skilled personnel and cannot be used over water or near villages and is often not worthwhile on small numbers of birds. In such situations traditional methods of bird scaring are often resorted to, such as banging gongs and throwing sticks. However, the net effect of this is to scare the birds from field to field, spreading the damage more evenly over all the plots (though a farmer unable to employ as many scarers as his neighbour is penalized), rather than reduce the overall damage. The point is that damage often occurs when the Queleas have no readily available alternative food source and birds that would otherwise starve are nearly impossible to keep off the crops. Likewise distasteful chemical repellents applied directly to the crop (e.g. methiocarb) may be effective enough when the neighbouring farmer cannot afford to use them, for the birds simply descend on his crop instead. However, their widespread use forces the starving birds to eat the contaminated grain. For the same reason acoustic scarers may be ineffective and the growing of 'bird-proof' varieties of cereal, e.g., 'goose-necked' sorghum or long-awned wheat, may only reduce crop losses where Queleas have an alternative choice of food, or can move elsewhere. Dissuasive methods may only work where damage is caused by birds already on migration; certainly large-scale killing has no long-term benefit in such a situation for the dead birds are immediately replaced by new arrivals.

The timing of Quelea migrations may be used to advantage in some regions, where the harvest may be gathered while the birds are elsewhere. In northern Botswana early crops (either early-planted or quick-maturing) may be harvested before Queleas returning on their 'breeding migration' produce young in local colonies. In Cameroun and Chad rice is grown in an area not normally inhabited by Queleas though they pass through on migration. There damage can be reduced if the vulnerable period of growth, when the grain is at the 'milky' or 'doughy' stage, can be timed to occur before the birds pass through on their southward 'early rains' migration. Normally, however, this dovetailing of the agricultural calendar with the Queleas' seasonal migration pattern cannot easily be done. In the near future Quelea control will continue to rely on large-scale destruction of birds, though it is to be hoped with a minimum of environmental pollution.

Ward, P. 1979. Rational strategies for the control of queleas and other migrant bird pests in Africa. Phil. Trans. R. Soc. Lond. B287: 289–300.

QUEO: *Rhodinocichla rosea* (for family see TANAGER).

QUETZAL: *Pharomachrus mocinno*, often called Resplendent Quetzal and sometimes Resplendent Trogon (see TROGON); also the substantive name of other *Pharomachrus* spp.

QUILL: the calamus of a feather, or the calamus and rachis together; more loosely used for the feather itself, especially a remex or rectrix (see FEATHER).

QUINTOCUBITALISM: or 'eutaxis' (see WING).

R

RACE: used synonymously with SUBSPECIES. The term 'race' is preferred by some, as indicating the geographical basis of subspecific differentiation and perhaps suggesting a more flexible concept. On the other hand, 'subspecies' is the official term in the International Code of Zoological Nomenclature (1984)—see NOMENCLATURE.

RACHIS: sometimes 'rhachis', the distal portion of the shaft of a feather, bearing the vane (see FEATHER).

RACING PIGEON: see HOMING PIGEON.

RACKET; RACQUET: a terminal broadening of the vane of a feather, characteristic of (especially) certain of the rectrices in some species; the subterminal portion of the rachis of such a feather may be devoid of barbs or carry a relatively narrow vane.

RACKETTAIL: substantive name of *Discosura longicauda* and *Ocreatus underwoodii* (for family see HUMMINGBIRD); and of *Tanysiptera* spp. (see KINGFISHER).

RADAR: makes possible the detection and mapping of simultaneous bird movements over wide areas, and of bird movements that cannot be detected visually—at night, at high altitudes, within and above clouds. Since its start in the late 1950s, radar ornithology has developed into several different branches and has greatly expanded knowledge of the timing and course of bird MIGRATION.

The principles of 'RADAR' (RAdio Detection And Ranging) involve transmission of pulses, usually 0.1–5 μs long, of radio waves, normally 3–25 cm wavelength, and reception of the reflected signal. Radio waves propagate with the speed of light, and the range to the target can be determined from the time taken for the echo to return. The azimuth and, for radars with a vertically narrow beam, elevation of the radar antenna give the direction to the target. The resolving power of the radar is dependent on pulse duration and beam width, while maximum detection range is determined by transmitting power, receiver sensitivity, gain of aerial and echoing area of the target. The inverse square spreading rule applies to both outgoing and reflected radio waves, with the result that maximum range is proportional to the fourth power root of echoing area. As a consequence, radar can detect small targets, like birds, bats and insects, at surprisingly long distances—maximum range of a target 1/10,000 the echoing area of another, is 1/10 the maximum range of the larger target. Echo information from radars with horizontally rotating beams normally are displayed on a plan position indicator (PPI), and with vertically nodding beams on a range height indicator (RHI).

Two principal types of radars have been used as tools in ornithology—fan-beam surveillance and pencil-beam search/tracking radars. The former is most suitable for obtaining a broad view of bird movements over large volumes of air space, while the latter provides height data, and, when operated in a tracking mode, gives detailed and continuous information for individual birds or bird flocks about flight speed, height and direction. Doppler radar has also been used for recording bird flight speeds.

The radar echoing area of a bird depends on the ratio of the size of the bird to the radar wavelength. When this ratio is high, optical scattering from the bird of radio waves occurs, and the echoing area is effectively that of a sphere of water equal to the mass of the bird, or about half the silhouette area of an equally-sized metal sphere. This applies to most bird species when registered by X-band (wavelength 3 cm) radars. For ratios smaller than one, Rayleigh-type scattering of the radar waves occurs, and the echoing area becomes disproportionately small. As a consequence, L-band (wavelength about 25 cm) radars are poor for detection of small birds. For bird sizes similar to the radar wavelength, echoing areas fluctuate, due to interference scattering, and may be as high as four times that of the water sphere or as small as one-quarter of the water sphere. These fluctuations occur when an S-band (wavelength 10 cm) radar is used to detect small and medium-sized birds. The echoing area of a bird is not constant but varies greatly with direction from which the bird is observed. Detailed analysis of modulations in the reflected radar signal, signature analysis, reveals the wing-beat pattern of flying birds, in terms of flapping frequency, duration of flapping and non-flapping periods. Characteristic echo signatures can be used for species identification.

The first extensive radar studies of bird migration, in the years just before and after 1960, were carried out by Ernst Sutter in Switzerland, David Lack in Great Britain, and William H. Drury, J.A. Keith and Ian C.T. Nisbet in the United States. Lack mapped migration across the North Sea at all times of the year, and initiated analysis of many of the behavioural and ecological problems in bird migration pursued in later radar studies. Extensive radar investigations of bird migration have since been carried out in further areas in and around Great Britain, e.g., Shetland, the Hebrides and the English Channel, in many regions of the United States, Canada and the West Indies, in Scandinavia, and in Switzerland, where migration over both the lowlands and the Alps has been studied by surveillance as well as tracking radars. Marine radars

have been used for monitoring bird migration across the Mediterranean Sea and the western North Atlantic Ocean. So far radar has only been used in one tropical country (Ghana) and not yet in the Southern Hemisphere.

Main ornithological research issues analysed in radar studies are the following:

(1) **Mapping** of geographical patterns of bird migration or bird roosting movements. High-power surveillance L-band radars permit effective mapping of routes of migrating birds up to 100–200 km from the radar station. Echo-type and speed can be used for distinguishing a few broad categories of birds. More detailed identification is not usually possible, except for a few distinctive behaviour patterns (e.g., Starling *Sturnus vulgaris* roosts, aerial roosting Swifts *Apus apus*) and diurnal bird movements if radar recording is combined with simultaneous field observations from a network of sites, or from an aircraft. Under such premises, radar studies may provide a detailed picture of the migratory pattern of a single species, as exemplified in Figure 1A for the spring migration of the Baltic Sea Eider *Somateria mollissima* population. Widening the perspective from the short-distance Eider migration to routes about 10 times as long, Figure 1B demonstrates a migratory pathway across the western North Atlantic Ocean, documented by observations from radars at places indicated in the figure, and from radars on board ships. This pathway is regularly used by passerines and shorebirds on autumn migration, flying non-stop for 60–100 hours over the open ocean, with median heights at Puerto Rico/Antigua often as high as 4,000–5,000 m, top heights close to 7,000 m.

(2) **Population monitoring.** Combined radar and field observations, providing data on numbers of echoes from migrating bird flocks and mean flock sizes, respectively, can be used for estimating population sizes. By way of example, the Baltic Sea Eider population is estimated in this way at 750,000 birds, an estimate later confirmed by aircraft censuses of breeding birds in the countries concerned.

(3) **Migratory intensity** in relation to weather. Radar has provided extensive evidence that following winds and absence of precipitation are key factors associated with dense broad-front migration. Radar investigations of points (1), (2) and (3) are often embodied in bird hazard to aircraft studies.

(4) **Flight strategies of birds.** Detailed tracking radar data on, e.g., flight speed, altitude and wing-beat pattern are used for testing theories about mechanics and aerodynamics of bird flight, including gliding and soaring theory. Figure 2A shows, as an example, a minute-by-minute radar record of height versus distance along the migratory direction of a flock of Cranes *Grus grus*. The Cranes use soaring migration, gaining height by circling in thermals and gliding between thermals towards their goal. Radar studies demonstrate that migrating birds select altitudes with favourable winds. The majority of migrants regularly fly below 1,000 m, while maximum heights have been noted from 6,000 to above 8,000 m.
